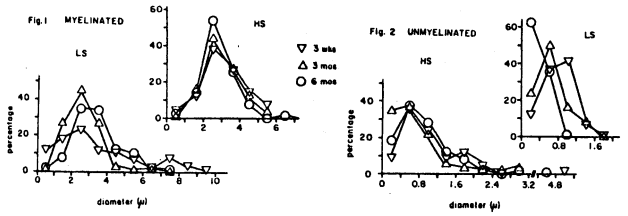
Rats with high autotomy scores (HS) had U:M ratios of about 6:1; those with low score (LS) had ratios of about 1:1. Comparing M axons in the two groups showed that LS rats have a wider range of axon diameters (Fig. 1). However, the M diameters in both groups were smaller than in normal sciatic nerves. The HS rats had a wider range of U axon diameters than the LS rats (Fig. 2). LS rats showed a reduction in U axon diameter with longer survival times. All HS rats had a group of unusually large U axons. These large axons were neither watery, nor swollen with organelles or fibrils; they were grouped with other U axons wrapped in Schwann cell cytoplasm.

The correlation of this unusual ultrastructure with autotomy over long survival times may elucidate some of the anatomical substrates involved in painful sensation or paresthesia from amputation neuromas. (Supported by USPHS Grant NS 16329)



77.2 AFFERENT FIBERS IN MERIDIAN POINTS AND THEIR ROLE IN ACUPUNCTURE ANALGESIA. G.W. Lu* (SPON: M. HOFFERT). Dept. of Neurophysiology, Beijing Second Medical College, Beijing, China.

We studied the relation of peripheral afferent fibers to meridian points and acupuncture analgesia on 308 rabbits, 15 cats, 71 normals and 845 patients. We found: a) compared to non-meridian points, points zusanli possess a special axon diameter spectrum characterized by more myelinated (myelinated/unmyelinated = 2.7), more large-sized ($A\alpha\beta\gamma/A\delta$ = 2.8), and more $A\beta\gamma$ ($A\beta\gamma/A\alpha\beta\gamma\delta$ = 52) fibers. b) The velocity spectrum of afferent fibers in points zusanli also showed a special pattern. The frequency of $A\alpha$, $A\beta\gamma$, and $A\delta$ was 7.9%, 67.8% and 24.3%, respectively. The ratio of $A\alpha\beta\gamma$ to $A\delta$ was 3.1. c) The analgesic effect induced by needling points zusanli was markedly reduced by blocking the activity of $A\beta\gamma$ and some $A\delta$ fibers. The same analgesic effect could be produced by direct stimulation of $A\beta\gamma$ fibers. d) The disappearance of the sensation produced by needling acupoints occurred between the loss of touch and pain sensations during limb compression, extradural and spinal anesthesia. Adequate needling sensation was accompanied by $A\beta\gamma$ and some $A\delta$ fiber activity. e) In n.VPL of the thalamus the unitary activity activated by peripheral C fiber stimulation was markedly inhibited by the conditioning activity of $A\beta\gamma$ fibers, decreasing the frequency and duration of its late discharges. Activity induced by peripheral $A\beta\gamma$ fiber stimulation, however, could not be modulated by the conditioning activity of both $A\beta\gamma$ and C fibers. f) The conditioning activity of $A\beta\gamma$ and some $A\delta$ fibers could significantly prolong the refractory period of cortical neuron populations and decrease the amplitude of the primary component of the evoked potential: P2>N1>P1. g) Analgesia was significantly increased in experimental and clinical surgery when meridian points were stimulated and electro-stimulation was applied to the surgical field through the surgical instruments. Using two tourniquets alternately on two places in the same extremity markedly reduced the tourniquet reaction and increased acupuncture analgesia. h) By injection of dilute anesthetic solution into acupoints the skin pain threshold and the efficacy of acupuncture analgesia were significantly raised. We believe that (1) the predominance of large afferent fibers (mainly $A\beta\gamma$ fibers) is one of the structural and functional characteristics of the meridian points; (2) needling impulses arising from meridian points are transmitted along the $A\beta\gamma$ and some $A\delta$ afferent fibers; (3) the inhibitory action exerted by large fiber activity on small fiber activity in the CNS is one of the mechanisms of acupuncture analgesia; (4) increased activation of large fibers and/or decreased activity of small fibers is one means of promoting acupuncture efficiency.

77.3 UNMYELINATED AXONS IN THE DORSAL WHITE COLUMNS OF HUMANS & RATS. Lauren A. Langford and Richard E. Coggeshall. Depts. of Anatomy & of Physiology and Biophysics & the Marine Biomedical Institute. The University of Texas Medical Branch, Galveston TX 77550

The dorsal white column of the mammalian spinal cord is said to consist of myelinated primary afferent fibers. Recently, however, unmyelinated fibers were seen to be more numerous in rats. Because of the role of this pathway in somatic sensation and because stimulation of this pathway is reported to influence pain, it is important to determine how many unmyelinated fibers are present in humans. The present study reports the results from two humans indicating that the unmyelinated fibers are predominant in this pathway in humans. If these preliminary data are confirmed, the presence of these fibers must be considered when stimulation of the dorsal white columns is done and a functional understanding of these fibers is of considerable interest.

To determine the function of the unmyelinated axons in the dorsal white columns, it is necessary to use experimental animals. Our first step is to determine where the fibers originate in rats. Dorsal rhizotomies remove primary afferent fibers, spinal transections remove ascending or descending fibers, and isolation of a spinal segment removes all fibers but propriospinal axons. Our preliminary results are shown in the following table:

	DORSAL COLUMN PROPER		CORTICOSPINAL TRACT		TOTAL	
	MY	UN	MY	UN	MY	UN
UNILATERAL DORSAL RHIZOTOMY L5, L6 and S1						
L6 NOR	14,442	15,238	12,752	14,721	27,194	29,959
OP	5,687	7,370	5,107	7,450	10,794	14,820
S2 NOR	4,229	5,787	2,882	3,536	7,111	9,323
OP	3,352	4,182	4,065	4,596	7,417	8,778
TRANSECTION C4						
S2	6,662	3,556	1,503	1,179	8,165	4,735

Note that there is a decrease in the unmyelinated fibers after each of the above surgical procedures. The greatest decrease occurs with the cervical transection. Our preliminary conclusions are that there are a significant number of primary afferent, long descending, and propriospinal unmyelinated axons in rat dorsal white columns. The largest group seems to be descending axons which originate above the mid-cervical level, but the presence of significant numbers of unmyelinated sensory fibers in the dorsal white columns is also of interest. Supported by grants NS 10161, NS 07377 and NS 11255 from NIH.

77.4 SYMPATHETIC ACTIVITY SHOWN TO HAVE NO SHORT-TERM EFFECT ON POLYMODAL NOCICEPTORS IN CATS. William J. Roberts and Amy U. Lindsay*, Neurololgical Sciences Inst., Good Samaritan Hospital and Med. Ctr., Portland, OR 97209.

The pain in causalgia is burning in character and is therefore likely to be mediated by C-polymodal nociceptors, the receptors thought to subserve burning, aching pain. Causalgic pain is triggered or exacerbated by sympathetic arousal and is relieved by sympathetic block. Such findings suggest that sympathetic efferents may have an excitatory effect on C-fiber terminals in the skin and, in this way, contribute to causalgic pain. The present study was designed to test for sympathetic effect on the responses of polymodal nociceptors to noxious heat.

The study was done in chloralose anesthetized cats in which both carotid arteries were ligated; a stimulating electrode was placed on one lumbar sympathetic trunk. Central arterial pressure was recorded from one carotid artery. The pressor response to noxious thermal stimulation of the skin on a hindleg site was used as a measure of activity in a population in polymodal efferents.

It was found that the pressor response was graded with stimulus temperature (50-60°C). The amplitude of the pressor response was found to be relatively stable during repeated, short-duration stimuli (30 sec. duration, 5 min. intervals).

Supramaximal sympathetic stimulation produced no significant change in the pressor response to noxious heat during either brief (3 min.) or prolonged (1 hr.) periods of sympathetic stimulation. The results therefore failed to support the hypothesis that sympathetic activity contributes to causalgic pain by acting upon polymodal nociceptors in the skin.

77.5 PAIN AND ITCH FROM C FIBER STIMULATION. H.E. Torebjörk* and J.L. Ochoa (SPON: J. Metzler). Dept. of Clinical Neurophysiology, University Hospital, Uppsala, 75014 Sweden and Dept. of Neurology, Dartmouth Medical School, Hanover, NH. 03755.

Introduction. Delayed pain and itch have some common neuroanatomical and neurophysiological substrates, and the question has repeatedly been asked as to whether itch can be induced by low frequency discharges in nociceptive fibers which mediate pain at higher frequencies.

Methods. Tungsten electrodes were used for microneurographic recordings of impulse activity in single afferent A and C units in the median or radial nerves in alert humans. Such electrodes were also used for intraneural microstimulation (INMS) of afferent fibers.

Results. INMS in cutaneous nerves at liminal intensity for sensation sometimes elicited itch, referred to a focal area in the skin, or pain, referred diffusely to a larger area. Such sensations were evoked only from certain points in the nerve fascicles, and could be induced even after selective A fiber block. Recordings from such points consistently revealed polymodal nociceptive units with C fibers close to the electrode tip and with receptive fields in the precise area of referral of pain or itch in the skin. No qualitative difference was recorded between receptive properties of C nociceptors identified by referral of itch sensation as compared to those identified by referral of pain. The C polymodal nociceptors could be activated by mechanical, thermal and chemical skin stimuli which elicited itch if the stimuli were focal, and pain if the stimuli were widespread or strong.

Pain and itch could be perceived simultaneously at the same frequency of INMS. Changes in frequency did not transform itch into pain or vice versa. Itch often persisted for many seconds after cessation of INMS, in contrast to pain. Scratching suppressed itch at a stage when only minor fatigue of C nociceptors was observed.

Conclusions: Delayed pain and itch are subserved by C afferent fibers. Itch cannot be explained by low frequency activation of nociceptive units. So far we have failed to demonstrate a specific itch receptor. If delayed pain and itch are induced by activity in a common receptor type, the C polymodal nociceptor, then spatial interactions as well as different central processing of the signals may be involved in the differentiation of pain from itch. Scratching seems to suppress itch by central inhibition rather than just by peripheral receptor fatigue.

77.6 EVIDENCE FOR TWO DISTINCT CLASSES OF UNMYELINATED NOCICEPTIVE AFFERENTS RESPONSIVE TO MECHANICAL AND THERMAL STIMULI IN THE MONKEY. J.N. Campbell[1], R.A. Meyer[1,2], and S.R. Jaffe[1,*], Department of Neurosurgery[1] and Applied Physics Laboratory[2], The Johns Hopkins University, Baltimore, Maryland 21205 USA

We determined that C-fiber nociceptive afferents responsive to both intense mechanical and heat stimuli (CMHs) may be subdivided into two classes based on their temporal response to heat stimuli. Other properties of the two groups of units were found also to differ. The thermal response properties of 40 CMHs innervating the hairy skin of monkey were studied using standard single fiber recording techniques. A laser thermal stimulator under radiometer feedback control provided step increases in skin temperature with rise times of less than 150ms. In response to 41°-49°C stimuli (3s duration), the CMHs displayed either a quickly adapting or a slowly adapting response. The quickly adapting units (QCs) displayed an initial burst of neural activity (spike frequencies as high as 115 impulses/sec) which decreased within 1s to a low steady discharge rate (< 8 impulses/s). The slowly adapting units (SCs) did not display this initial burst of activity but instead responded at a relatively uniform rate throughout the stimulus. Of the 40 CMHs, 20 were QCs and 20 were SCs. The mean Von Frey mechanical threshold, initial thermal threshold, and response to a 53°C, 30s burn of the QCs were significantly lower than that of the SCs, whereas the mean receptive field areas and conduction velocities were not significantly different. Another 31 CMHs innervating glabrous (26) and transitional (5) skin were also subdivided into QCs (14) and SCs (11). Six glabrous CMHs had characteristics of each class: a slowly adapting response to stimuli below 49°C but a quickly adapting response to 53°C stimuli. Could the QC receptor correspond to the elusive "first pain" receptor in monkey? (Supported by USPHS grants NS-14447 and NS-00519)

77.7 INHIBITION OF PRIMATE SPINOTHALAMIC TRACT NEURONS BY STIMULATION WITHIN IPSILATERAL OR CONTRALATERAL VENTROPOSTEROLATERAL (VPL) THALAMIC NUCLEI. K.D. Gerhart, R.P. Yezierski and W.D. Willis. Marine Biomedical Institute and Departments of Physiology & Biophysics and of Anatomy, University of Texas Medical Branch, Galveston, Texas 77550

Electrical stimulation within several medial brainstem areas, including the nucleus raphe magnus (NRM) and periaqueductal gray matter (PAG), has been shown to produce behavioral analgesia in rats, cats and monkeys, and also to inhibit responses of primate spinothalamic tract (STT) neurons to noxious and innocuous stimuli. The spinothalamic tract is thought to be the main somatosensory pathway in primates, including man, to carry information concerning painful stimulation of the body. Stimulation of ventrobasal thalamic areas, including the ventral posterior lateral (VPL) nucleus, has been shown to be clinically effective in reducing chronic pain in man. In order to examine further descending influences on primate STT cell responses, this project studies the effects of stimulation in the VPL nuclei of both ipsilateral and contralateral thalamus on STT cell background activity and on evoked responses.

Monkeys (M. fascicularis) were anesthetized with α-chloralose and pentobarbital, paralyzed, and artificially ventilated. Spinothalamic tract cells were antidromically activated from the contralateral VPL nucleus. A second thalamic stimulating electrode was positioned in the ipsilateral VPL nucleus. STT cells were classified as wide dynamic range or high threshold, and their excitatory and inhibitory cutaneous receptive fields were mapped. The effects of thalamic stimulation were examined using trains of 0.2-2 second duration at 333 Hz with currents of 25-400 μA (but not exceeding the antidromic activation threshold from contralateral thalamus).

Inhibition of spontaneous background STT cell activity, as well as of responses to innocuous or noxious cutaneous stimulation, was caused by stimulating the ipsilateral or contralateral VPL nuclei. Inhibition of responses to A- or C-fiber volleys in the ipsilateral sural nerve was also observed; the inhibition of responses to C fibers was more potent than inhibition of responses to A fibers.

77.8 A FURTHER EXAMINATION OF THE EFFECTS OF CORTICAL STIMULATION ON PRIMATE SPINOTHALAMIC TRACT CELLS. R.P. Yezierski, K.D. Gerhart and W.D. Willis. Marine Biomedical Institute and Department of Physiology and of Anatomy, University of Texas Medical Branch, Galveston, Texas 77550

Stimulation in the sensorimotor cortex with short trains of electrical pulses (four 0.2 millisecond pulses at 333 Hz) has been shown by our laboratory to inhibit activity of primate spinothalamic tract (STT) cells evoked by innocuous cutaneous stimulation. The failure of cortical stimulation to inhibit activity evoked by noxious stimulation is in contrast with our findings following stimulation in the nucleus raphe magnus and periaqueductal gray. Long trains of electrical pulses delivered to these brainstem sites has been shown to inhibit both noxious and non-noxious responses evoked in primate STT cells. The present study was therefore designed to examine the effects of cortical stimulation on STT cells using stimulus parameters comparable to those used for brainstem stimulation.

Monkeys (M. fascicularis) were anesthetized with α-chloralose and pentobarbital, paralyzed and artifically ventilated. Recordings were made from identified STT cells in the lumbosacral spinal cord using glass or stainless steel microelectrodes. The ipsilateral sural nerve was dissected free from connective tissue and prepared for electrical stimulation. A monopolar stimulating electrode was positioned in the sensorimotor cortex. Inhibition of STT cell activity was obtained using 0.2-2 second trains (333 Hz) delivered once every 2 or 10 seconds, respectively, at stimulus intensities of 200-300 μA.

The results of the present study confirm previous observations using short train stimulation of the sensorimotor cortex. In addition, we have now shown that activity of STT cells evoked by noxious and non-noxious natural stimuli or by C-fibers in the sural nerve can be inhibited by stimulation in sensorimotor cortex using long stimulus trains.

(Supported by grants NS 09743 and NS 11255, by postdoctoral fellowship NS 06193 to R.P.Y. from NIH and by a grant from the Moody Foundation.)

77.9 CHARACTERISTICS OF NEURONAL RESPONSES TO NOXIOUS STIMULI IN RAT SI SOMATIC SENSORY CORTEX. Y. Lamour, J.C. Willer* and G. Guilbaud* (SPON : M. Abdelmoumène). Unité de Recherches de Neurophysiologie Pharmacologique de l'INSERM, U. 161, 2 rue d'Alésia 75014 Paris, France.

Little is known about the physiological properties and laminar distribution of cerebral cortical neurons receiving noxious input. The present experiment was designed to study such neurons in rat's first somatic sensory cortex (SI) and to determine their laminar distribution. Male Sprague Dawley rats (250-350 gr) were anaesthetized with fluothane (0.5 % in a mixture of 66 % N_2O, 33 % O_2) paralyzed with gallamine triethiodide and artificially ventilated. Single unit activity was recorded in the different parts of SI corresponding to forelimb, hindlimb or tail representation, during penetrations perpendicular to the cortical surface, using glass microelectrodes filled with 2 % pontamine blue in 1 M NaCl. Each electrode penetration was reconstructed on a camera lucida drawing of 100 µm frozen sections using the dye deposit made at the last recording site. The receptive fields of the units were characterized using a variety of innocuous and noxious stimuli. Innocuous stimuli consisted of hair movement, light touch,pressure and joint movements ; noxious stimuli included intense mechanical stimulation and noxious heat (radiant heat or hot water bath from 48° to 60°C). To date 319 neurons have been recorded, and a peripheral receptive field characterized for 129 of them. 24 (16 excited, 8 inhibited) received convergent noxious and non-noxious (deep or superficial) inputs and 28 pure noxious inputs (25 excited, 3 inhibited). About 63 % of the neurons discharged tonically and 37 % phasically in both groups. Most of the "tonic type" neurons were observed to have large peripheral fields. 22 out of 27 neurons receiving mechanical noxious inputs were also responsive to noxious heat. Neurons responsive to noxious inputs increased their discharge rate with stimuli of increasing strength. The threshold of the responses to noxious heat was always above 46°C but usually below 50°C. Both types of neurons were rarely found in the superficial layers (I to IV). In a given penetration neurons receiving noxious inputs were intermingled with other neurons receiving pure cutaneous or joint inputs from the same area. The different types of neurons could be recorded successively in typical "columnar" penetrations.

77.10 NUCLEUS RAPHE MAGNUS AFFERENTS IN THE RAT: A RETROGRADE STUDY USING HORSERADISH PEROXIDASE GEL IMPLANTS AND TETRAMETHYLBENZIDINE NEUROHISTOCHEMISTRY. S.M. Carlton*, E.G. Young*, G.R. Leichnetz, D.J. Mayer (SPON: J.H. Johnson). Departments of Anatomy and Physiology, Medical College of Virginia, Virginia Commonwealth University, Richmond, Va 23298.

The nucleus raphe magnus (NRM) is known to play an important role in a descending antinociceptive system through its projections to the spinal cord dorsal horn and trigeminal subnucleus caudalis. Thus the study of its afferents is essential in determining other CNS cell groups which could influence analgesic mechanisms by virtue of their connections with NRM.

Accordingly, tiny fragments of HRP gel were stereotaxically implanted within NRM and in adjacent areas in 16 adult Sprague-Dawley rats. The gel was introduced through previously implanted stainless steel cannulae to prevent contamination of the tract, a factor which has compromised previous studies of this area. After survival periods of 48 hours, the brains were processed according to the TMB-HRP protocol of Mesulam (1978).

Retrogradely-labelled cells were consistently found in the thalamic parafascicular nucleus, zona incerta, dorsal periaqueductal gray, lateral periaqueductal gray, deep layers of the superior colliculus, nucleus cuneiformis and a cell group in the ventralmost periaqueductal gray which was ventral to, and continuous with, the nucleus of Darkschewitsch. Even though the technique accomplished extremely small placements, the presence of retrogradely-labelled cells in the deep superior colliculus made us consider that the inferior olivary nucleus could have been involved. However, since we never observed labelled cells in the red nucleus, which also projects to the inferior olive, this seems unlikely. Control HRP gel implants in the spinal cord retrogradely filled cells in the zona incerta, deep superior colliculus and nucleus of Darkschewitsch, and thus the possible involvement of axons of passage originating from these nuclei and passing through NRM must be considered. However, the heavy and consistent retrograde labelling of the parafascicular, dorsal periaqueductal gray, lateral periaqueductal gray, and nucleus cuneiformis indicates that these nuclei are important constituents of the NRM afferent system.

77.11 BRAINSTEM AREAS PROJECTING TO LAMINAE I AND II OF THE SPINAL CORD IN CAT. AN AUTORADIOGRAPHICAL STUDY. Gert Holstege, Department of Anatomy, Erasmus University Rotterdam, P.O.Box 1738, 3000 DR Rotterdam, The Netherlands.

Physiological studies indicated that neurons in Rexed's laminae I and II of the spinal cord are especially involved in painperception. Such studies also suggested an inhibitory influence on these neurons from supraspinal levels. In the framework of a study of brainstem-spinal pathways in cat three different brainstem areas were found that project to spinal laminae I and II.

^{3}H-leucine injections (± 0,5 µl containing 50 µCi) were made in mesencephalon, pons and medulla. The cats were allowed to survive the operations for six weeks after which they were sacrificed and perfused with saline followed by 10% formalin. Brainstem, all cervical and lumbosacral segments and 7 thoracic segments were cut in transverse frozen sections 25 µm thick. They were prepared for autoradiography with Ilford G5 emulsion, exposed for three months and then counterstained with cresyl violet.

Three brainstem areas were found to project to spinal laminae I and II:

1: The medial reticular formation at rostral medullary and caudal pontine levels, including the nucleus raphe magnus. Remarkably the nuclei raphe obscurus and pallidus did not project to spinal laminae I and II.
2: The lateral pontine reticular formation at levels rostral to the motor V nucleus. This area distributed labeled fibers to spinal laminae I and II and the lateral part of lamina V especially contralaterally.
3: The area of the nucleus subcoeruleus. This area distributed labeled fibers to all spinal laminae among which laminae I and II.

The first area, which partly contains serotonergic neurons, could be involved in a "pain level setting system". The second area receives many afferents from especially the spino-thalamic tract which is strongly involved in painperception. The neurons which axons constitute this spino-thalamic tract are especially located in the contralateral laminae I and II. The lateral pontine area, which contains virtually no serotonergic and no noradrenergic neurons, distributed labeled fibers to laminae I and II especially contralaterally. This suggests that this area could serve as a feedback system for the spino-thalamic tract and thus could modulate painperception. The third area, nucleus subcoeruleus, contains many noradrenergic neurons and distributes fibers to large parts of the central nervous system. For this reason the nucleus subcoeruleus does not seem to be a typical pain modulating area.

77.12 THE PROJECTION OF THE CINGULATE CORTEX TO THE PERIAQUEDUCTAL GRAY IN THE RAT. J. M. Wyss, Department of Anatomy, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

The mesencephalic periaqueductal gray matter (PAG) has attracted considerable interest because of its apparent role in the modulation of pain input. Behavioral evidence has suggested that several cortical areas including the cingulate gyrus may also be involved in the modulation of pain and therefore are in some fashion functionally connected into the same pathways. In a series of ongoing studies of the connections of the cingulate gyrus, the present paper reports that as Domesick (1969) (Brain Research 12, 296-320) suggested on the basis of degeneration techniques, the anterior portion of this cortex does project to the lateral dorsal portion of the PAG. In thirty-five rats, iontophoretic injections of a mixture of ^{3}H proline, ^{3}H leucine and ^{3}H lysine were placed into the various division of the cingulate cortex and adjacent cortex. Following injections into the anterior ventral cingulate cortex (area infraradiata [IR] a and b α) silver grains were consistently transported to the lateral portion of the dorsal PAG. Injections into slightly more dorsal areas (IR c α and the precentral agranular cortex) result in only slight labeling in this same area of the PAG. The cortex immediately caudal to IR a and b α, i.e. IR a and b β, also projects to the same region of PAG; however, these projections are somewhat more restricted toward the lateral margin. Since in both cases a limited projection passes on to the deeper layers of the superior colliculus, it is unclear whether the overlap that exists between the two projections is a true overlap of the terminal fields or simply fibers of passage from the anterior injections overlapping the terminal field of the IR β cortex. No projections to either the PAG or the superior colliculus arise from the more caudal portions of the IR β cortex or from any sector of the retrosplenial cortex. These results demonstrate that the ventral anterior portion of the cingulate cortex is directly connected to the area of PAG known from previous anatomical and behavioral studies to be involved in the modulation of pain.

78.1 |^{14}C|-2-DEOXYGLUCOSE MAPPING OF THE DORSAL COCHLEAR NUCLEUS OF THE KITTEN. R. J. Nudo* and R. B. Masterton. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

The distribution of metabolic activity in the dorsal cochlear nucleus (DCN) of the kitten during free-field auditory stimulation was examined by use of the |^{14}C|-2-DG method. The autoradiographs show that a continuous pure-tone stimulus results in an approximately horizontal band of labeled tissue through the DCN cortex. Increases in stimulus intensity widen the labeled band. Increases in stimulus frequency shift the band dorsally; decreases in frequency shift the band ventrally. A section through the active band anywhere along its length shows a compact column of labeled tissue normal to the nuclear surface, extending from the most superficial into the deepest layer, and demonstrating a columnar organization of DCN cortex. However, throughout the most superficial, or molecular layer of DCN, high metabolic activity is present regardless of stimulus parameters. This spontaneous activity is not lessened by ipsilateral nor bilateral destruction of the cochlea.
(Supported by NIH Grant NS 07726)

78.2 MEDIAL GENICULATE PROJECTIONS TO AUDITORY CORTICAL FIELDS A, AI AND P IN THE CAT. T.J. Imig and R.A. Reale*, Dept. of Physiology, K.U. Medical Center, Kansas City, KS 66103 and Dept. of Neurophysiology, University of Wisconsin School of Medicine, Madison, WI 53711.

Cat auditory cortex has been divided into a number of fields on the basis of tonotopic mapping experiments. We have studied the locations of medial geniculate neurons projecting to the anterior (A), primary (AI) and posterior (P) auditory fields using retrograde transport of horseradish peroxidase (HRP) and tritiated bovine serum albumin. Tonotopic maps were obtained in each experiment and used as guides for placement of injections. One tracer was injected into an identified portion of the tonotopic representation of one field, the other tracer was injected into the same portion of the frequency representation of another field. By combining HRP histochemistry and autoradiography in the same tissue section, it was possible to visualize distributions of neurons projecting to the same portions of the frequency representations in two different fields.

The caudal pole of the medial geniculate was devoid of neurons projecting to fields A, AI or P. Following injections of tracer into AI, a dense accumulation of labeled cells formed a band coursing through pars lateralis and pars ovoidea of the ventral divison of the medial geniculate (terminology of Morest). Injections of tracer into field P labeled neurons aggregating around the dorsal, ventral, caudal and rostral perimeter of the band of neurons labeled by AI injections. Few neurons projecting to field P were found within the band of AI projection neurons. On the other hand, neurons projecting to field A were scattered throughout the band of AI projection neurons in the ventral division, although neurons projecting to field A were fewer in number than neurons projecting to field AI in this region.

All three fields received projections from the medial and dorsal divisions of the medial geniculate. Field A received a much more dense projection from the lateral division of the posterior group than did fields AI or P. Although projections overlap in many areas within the geniculate, there is a clear spatial segregation of neurons projecting to these three fields.

In each of the geniculate subdivisions, neurons were found which were labeled with both tracers suggesting that they projected via axon collaterals to at least two cortical auditory fields. (Supported by BRSG SO7 RR05373, Biomedical Research Support Grant Program, NIH; NSF Grant BNS76-19893, NIH Program Project Grant NS12732, NIH Core Support Grant HD03352, and NIH Grant NS 17220).

78.3 AUDITORY THALAMOCORTICAL PROJECTIONS IN CATS. A. Jayaraman. Department of Neurology. LSU School of Medicine, New Orleans, La. 70112.

Several auditory cortical regions in the cat have been shown to have tonotopic organization. To evaluate the presence of a precise topographical projection pattern between the auditory cortical regions and the different subdivisions of the medial geniculate nucleus, small quantities of horseradish peroxidase (HRP) were injected into the auditory cortex of 42 adult cats. After a survival of 24 to 36 hours, the cats were sacrificed and the brains processed according to the method of Mesulam. Injections covering the entire rostrocaudal extent of area AI resulted in the transport of the label to neurons located within the ventral and magnocellular nuclei. The labelled cells within the ventral nucleus were organized mediolaterally and rostrocaudally. Injections in tonotopically different regions of the anterior auditory field resulted in retrograde labelling of neurons of the lateral division of the posterior thalamic nucleus, deep dorsal nucleus and the nucleus ovoidea. Several injections in the cochleotopically organized dorsal and ventral divisions of the posterior ectosylvian gyrus led to transport of HRP to the suprageniculate nucleus, the Poi division, the ventral and ventromedial regions of the ventrolateral nucleus and the magnocellular nucleus. HRP was transported from area AII regions to neurons of the deep dorsal nucleus, magnocellular and ventrolateral nucleii. After injections of the insular cortex the neurons within the suprageniculate nucleus and the ventrolateral subdivisions were labelled. In three cats HRP injections were made in the suprasylvian fringe region and this resulted in transport of the enzyme to neurons within the suprageniculate nucleus, but more towards the lateral parts bordering the intermediate division of the LP nucleus. Temporal injections led to labelling of cells within the caudal subdivisions of MGB primarily.

The present study confirms the previous observations from anatomical and physiological studies that the projection pattern between the ventral nucleus and area AI are tonotopically organized, but fails to confirm similar anatomical substrate for a tonotopical projection pattern between the other subdivisions of the medial geniculate nucleus and auditory cortical regions.

Supported by The Deafness Research Foundation.

78.4 THALAMIC CONNECTIONS TO AND FROM BINAURAL INTERACTION BANDS IN AI OF THE CAT. John C. Middlebrooks and John M. Zook. Coleman Laboratory, HSE 863, UCSF, San Francisco, CA 94143.

The primary auditory cortex (AI) of the cat contains "binaural interaction bands" oriented orthogonal to the lines of constant characteristic frequency. Bands of neurons that receive excitatory inputs from both ears (EE neurons) alternate with bands of neurons that are excited by contralateral stimulation and inhibited by ipsilateral stimulation (EI neurons). In previous anatomical tracing studies, loci in AI larger than the mediolateral width of a single binaural interaction band have been shown to interconnect reciprocally with continuous sheets of cells within the ventral nucleus of the medial geniculate body. With smaller tracer injections, discontinuous banded arrays of label were seen within the ventral nucleus. This discontinuous labelling might reflect a segregation within the ventral nucleus of neurons interconnected with different cortical binaural interaction bands. To test that hypothesis, the thalamocortical and corticothalamic connections of single binaural interaction bands were demonstrated using neuroanatomical tracing methods in conjunction with microelectrode cortical mapping. AI was mapped in fine grain using conventional multiunit recording methods and diotic sound stimulation. Small ($\ll$50nl) injections of retrograde or anterograde tracers then were introduced into given binaural bands. Different tracers, separately or together, were injected into binaural interaction bands of the same or of different classes. Following a short survival period, cats were perfused and the tissue was processed histochemically and autoradiographically. Injections of anterograde or retrograde tracer that apparently were restricted to a single binaural interaction band resulted in a banded pattern of label within at least part of the ventral nucleus. These patterns of label appeared in transverse section as interrupted contours, and could be reconstructed in three dimensions to reveal multiple rostro-caudally oriented slabs of label extending for a significant distance along that axis of the nucleus. These data enable a comparison of the anatomical connections of single EE and EI bands as well as a description of the relationship between thalamocortical and corticothalamic connections. These results support a model of the central auditory system in which: 1) input to EE and EI bands is distinguishable and anatomically distinct throughout several levels from the binaural nuclei of the pons to AI; 2) there are convergent and divergent interconnections among anatomical subunits within a single binaural interaction class; and 3) the ventral thalamus, like AI, apparently contains repeating layers or bands corresponding to a simple functional dichotomy.

78.5 RESPONSE PROPERTIES AND TOPOGRAPHIC MAPS OF CAT AI AND AII AUDITORY CORTEX. C. Schreiner* and M. Cynader. Coleman Laboratory, U.C.S.F., San Francisco, CA 94143.

A finegrain analysis of parts of cortical areas AI and AII was made by taking up to 200 penetrations within a 4x4 mm area near the AI/AII border.

Neurons within the middle layers of AI were characterized by sharp frequency tuning, low thresholds, predominantly phasic responses, short latencies and binaural interactions of the excitatory-excitatory (EE) or excitatory-inhibitory type (EI). In AII, we observed broader frequency tuning, higher thresholds and both EE and EI binaural interaction classes. In parts of AII, responses were more sustained and latencies could be much longer than those recorded in AI.

Area AI displayed clear isofrequency contours usually oriented across the medial to lateral dimension of the field. EE and EI cells clustered into aggregates which had a tendency to run orthogonal to the isofrequency contours. A prominent EI patch marked the border between ventralmost AI and dorsalmost AII. Whereas the response thresholds of AI cells tended to decrease as the border was approached, the AI/AII border itself was a zone of great variability in threshold. Here, cells with thresholds differing by more than 40 dB could be found in nearly contiguous locations.

Isofrequency contours established in AI sometimes continued uninterrupted into AII, with cells in AII displaying the same center tuning. In other cases, we noted abrupt shifts of best frequency preferences as the border was crossed. Nonetheless, the dorsal part of AII displayed a best frequency map similar to that of AI, with low frequency responses represented posterior to high frequency responding neurons. In more ventral parts of AII, frequency tuning broadened still more, with neurons responding well over more than one octave. The broad tuning blurred the topographic map in the ventral part of AII.

Aggregates of EE and EI cells were found in AII. In contrast with AI, the patches of EE and EI cells tended to be elongated in the dorsal to ventral rather than the anterior to posterior dimension. The properties of AII cells are consistent with a possible role for AII in a binaural localization process based on comparison of broadband spectral characteristics of inputs from the two ears.

78.6 AUDITORY RECEPTIVE FIELDS: THEIR ORIGIN IN THE BRAINSTEM NUCLEI. Andrew Moiseff and Masakazu Konishi, Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

Auditory neurons having small, discrete spatial receptive fields have been described in the midbrain auditory nucleus (MLD) of the barn owl (Tyto alba). We have been recording from single auditory neurons in the owl's brainstem auditory nuclei to determine at which stage in the auditory system neurons with spatial receptive fields emerge.

Anatomical studies have shown that with the exception of the primary cochlear nuclei (nucleus angularis and nucleus magnocelularis) and one of the lemniscal nuclei (lemniscus lateralis, pons ventralis) the brainstem auditory nuclei receive binaural input. We recorded from single auditory neurons within these binaural nuclei (nucleus laminaris, nucleus olivaris superior, and nuclei of lemniscus lateralis) with glass-insulated Platinum-Iridium microelectrodes and glass microelectrodes. Electrolytic lesions or injection of HRP enabled us to positively identify the recording site and, in some experiments, confirm the input and output pathways of the auditory nuclei.

Our preliminary results indicate that auditory neurons within the owl's lateral lemniscus are selective for specific binaural on-going time disparities. Selectivity to dichotically presented on-going time disparities corresponds to selectivity to specific azimuthal positions under free-field stimulus conditions. The auditory responses exhibited by these lemniscal neurons are indicative of complex neuronal interactions. When either ear is stimulated alone the neurons are excited; when both ears are stimulated simultaneously, under dichotic conditions, the magnitude of the excitation is dependent on the on-going time disparity presented. Unlike MLD neurons with small receptive fields, which are narrowly tuned to both on-going time disparities and interaural intensity differences, neurons in lateral lemniscus are sensitive to on-going time disparity over a broad range of intensity differences. In as much as interaural intensity differences provide the owl with a cue for determining the elevation of a sound source, these neurons would not have spatial receptive fields with well-defined elevational borders.

Our data suggest that neurons in the auditory brainstem nuclei respond to the binaural cues responsible for sound localization and can, through additional interactions, give rise to the small receptive field auditory neurons present in MLD. 78.7 TONOTOPIC ORGANIZATION AND BEST FREQUENCY DISTRIBUTION OF SINGLE UNITS IN THE INFERIOR COLLICULUS OF THE MUSTACHE BAT. R.D. Bodenhamer* and G.D. Pollak. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Echolocating bats identify objects around them by emitting ultrasonic biosonar signals and listening to the returning echoes. The biosonar signals of the mustache bat, Pteronotus parnellii, are characterized by a relatively long duration, constant frequency (CF) component having a fundamental frequency of 30 kHz with second and third harmonics. The dominant harmonic is the second, which lies between 60-63 kHz depending upon the individual animal. The mustache bat is sensitive to Doppler shifts of this "60 kHz" CF component, and if the echo CF returns at a frequency greater than the emitted CF, it lowers the frequency of subsequent signals. In this way, the bat stabilizes the echoes within a very narrow frequency band.

In this study, we monitored the activity of neurons in the mustache bat's inferior colliculus (IC), directing special attention toward the distribution of best frequencies (BFs) and the manner in which different BFs are organized within the nucleus. By sampling large areas of the IC, we encountered neurons tuned to frequencies ranging from 10-100 kHz. However, the population of cells we sampled was not uniformly distributed over this frequency range. On the contrary, each bat devoted approximately 50% of its neurons to a band of frequencies only 300-500 Hz wide. This overrepresented frequency band corresponds to the frequency of the echo CF and ranged from 61-63 kHz depending, again, upon the individual animal. Neurons having BFs in this frequency band were much more sharply tuned than neurons outside the overrepresented band, having an average Q10-dB value of over 120.

The different BFs were systematically arranged within the IC, and different frequency regions could be repeatedly located in a reliable fashion. The most striking feature of the tonotopic organization was that the population of sharply tuned neurons constituting the overrepresented frequency band was located in a specific, clearly demarcated region of the IC. This essentially isofrequency region occupies a significantly disproportionate percentage of IC volume. In short, the mustache bat devotes an extremely large amount of neural tissue to processing information contained in the stabilized echo CF component.

78.8 RESPONSE PROPERTIES OF THE FM-FM COMBINATION-SENSITIVE NEURONS IN THE AUDITORY CORTEX OF THE MUSTACHED BAT. I. Taniguchi,* H. Niwa* and N. Suga. Dept. of Biology, Washington University, St. Louis, MO. 63130.

The FM-FM area of the auditory cortex of the mustached bat processes target-range information, analyzing time interval between the emitted pulse and its echo (O'Neill and Suga, Science, 203: 69, 1979). Neurons in this area exhibit remarkable facilitation when they are stimulated by the first harmonic component (FM_1) of a pulse followed by one of the higher harmonic FM's (FM_n, n=2,3,4) of an echo. For facilitation, about 40% of the FM-FM neurons studied require the downward sweeping FM_n as seen in the natural pulse and echo. About 60% of the neurons, however, show good facilitation regardless of sweep direction. For the maximum facilitation of these neurons, an FM_n should be delivered with particular time delays (0.4-18 msec) from an FM_1 (Suga and O'Neill, Science, 206: 315, 1979). The mechanism for the facilitation however, has not yet been explored. Measurements of the latencies of responses to FM_1 and FM_n demonstrate that the response to FM_1 arrives at the FM-FM area with a latency longer than that of FM_n. Therefore, the integration of these inputs for maximal facilitation requires an FM_n delay from FM_1 which is comparable to the difference in latency between the FM_1 and FM_n responses. What kind of neural mechanism is responsible for the long latency of the FM_1 response? Two working hypotheses, the multiple-delay hypothesis and the inhibition hypothesis, are conceivable. The former predicts that the long latency of the FM_1 response is due to multiple synaptic delays en route to the FM-FM area from the periphery. The latter proposes that the long latency is due to inhibition evoked by the initial portion of FM_1. Our data show that in many FM-FM neurons, inhibition is evoked by the initial portion of FM_1 preceding its essential component for facilitation, but the removal of this initial portion, i.e., inhibition does not cause any significant change in the latency of FM_1 response and facilitation. Therefore the multiple-delay hypothesis is more likely than the inhibition hypothesis. The functional role of inhibition may be in increasing the contrast of temporal pattern of neural activity. 78.9 AUDITORY RESPONSES IN THE ZEBRA FINCH'S MOTOR SYSTEM FOR SONG. L. C. Katz* and M. E. Gurney (SPON: M. Konishi) Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

Vocal learning of the motor program for song by oscine birds depends upon the bird using auditory feedback; thus, auditory information must be accessible to the vocal control system. This system includes at least 3 telencephalic nuclei: the hyperstriatum ventrale, pars caudale (HVc), the nucleus robustus archistriatalis (RA), and Area X. Lesion of either HVc or RA produces a deficit in song (Nottebohm et al., J. Comp. Neurol. **165**:457, 1976). We have discovered neurons within HVc of the zebra finch (Poephilia guttata) which respond to auditory stimuli, as demonstrated by using intracellular recording and horseradish peroxidase (HRP) staining of single neurons.

HRP filled glass microelecrodes (resistance 150-200 MΩ) were used for recording and staining. Successfully penetrated cells were presented with noise or tone bursts through a closed sound delivery system. Cells were filled with HRP by passing depolarizing current pulses.

In 22 adult males, we tested 59 HVc neurons for auditory responses. 36 (61%) responded to noise bursts; 23 neurons (39%) did not. Most auditory neurons were excited or inhibited by the onset and/or the offset of the noise burst. Excitatory response latencies to stimulus onset were 25-40 msec; response latencies to stimulus offset were 35-50 msec.

HVc projects rostrally to Area X, and caudally to RA. Our results indicate that HVc auditory neurons project to Area X, and that RA-projecting HVc cells do not show auditory responses. Area X-projecting HVc neurons (nine filled) had dendritic arms heavily endowed with spines, somatal diameters of 10-15 μm and dendritic field diameters of 150-200 μm. Two classes of non-responding HVc neurons were seen: RA-projecting and Area X-projecting. The four RA projecting neurons had somatal diameters of 6-8 μm and a sparse dendritic arborization 80-120 μm in diameter. The morphologies of the non-responding Area X-projecting neurons (3 filled) closely resembled those of the auditory Area X-projecting cells. Two additional auditory neurons filled were within the neostriatum caudale (NC) immediately beneath HVc, which receives a projection from Field L in canaries (Kelley, D. B. and Nottebohm, F., J. Comp. Neurol. **183**:455, 1979). Axonal collaterals from these two cells arborized dorsally into HVc as well as ventrally into Field L. Their response patterns resembled that of many HVc neurons.

Interfaces between auditory and motor pathways for song define levels in the brain at which the motor output can be modified. The existence of auditory units in HVc presents the possibility that such an interface may exist in this nucleus. 78.10 SINGLE NEURON RESPONSES TO A NATURAL SEQUENCE OF SPECIES SPECIFIC VOCALIZATIONS IN THE AUDITORY CORTEX OF AWAKE SQUIRREL MONKEYS. I. Glass* and Z. Wollberg. Dept. of Zoology, Tel-Aviv Univ., Tel-Aviv, Israel.

The activity of 82 auditory cortex (AC) neurons was extracellularly recorded in the awake, unmedicated squirrel monkey. A sequence of 70 species-specific vocalizations (total duration = 82 sec) emitted by a colony of squirrel monkeys during feeding was presented consecutively 15 times to the experimental monkey, at 75 ± 10 dB SPL. The responses of each unit to 21 representative calls of the 70 comprising the sequence were analyzed in detail. The 21 calls consist mainly of two call types, a twitter (10 calls) and a long-peep (6 calls), which differ in their temporal and spectral structures. Eighty-five percent of the cells responded to at least one of the 21 calls with an average of 7.9 effective calls per neuron. This responsiveness was significantly lower than the responsiveness of AC neurons to isolated species-specific vocalizations (Glass, I. and Wollberg, Z., Exp. Brain Res., 34:489, 1979). The most common response pattern was a simple excitatory response. A particular response to a given stimulus was not necessarily correlated with a response to other stimuli. A significant difference was found in the number of neurons responding to each of the 21 stimuli. However, no apparent correlation was observed between the number of responding neurons and the order of the calls in the sequence, their intensity, or their spectral content. The potency of the 10 twitter calls to evoke responses differed significantly. That was also true for the 6 long-peep calls. The average number of responding units per twitter call was not significantly different from the corresponding value for a long-peep call. It appears that the responsiveness to natural calls of a certain type is variable even if these calls are produced in the same behavioral context, and thus presumably have the same communicative content. Moreover, the presentation of species-specific vocalizations in a consecutive sequence appears to result in a suppression or adaptation of the AC neurons in comparison to individual vocalizations presented in an isolated manner.

78.11 METABOLIC RESPONSE OF THE HUMAN BRAIN TO VERBAL AND NON-VERBAL AUDITORY STIMULATION. J.C. Mazziotta*, M.E. Phelps, R. Carson* (SPON: D.E. Kuhl). Dept. of Neurology and Div. of Biophysics, UCLA School of Medicine, Los Angeles, CA 90024.

Normal right-handed male volunteers receiving auditory stimulation were studied using fluorodeoxyglucose and positron computed tomography. Paired studies were always performed. Control states consisted of plugging the ears and covering them with sound-proof headsets with eyes either open or closed. The following day a manaural (equal numbers of left and right sided stimulations were performed for each sub-group) stimulation study was performed using material that was either verbal (Sherlock Holmes story, N=6), non-verbal (tone sequences, N=8; or chord pairs, N=4) or both. Subjects described in detail their strategy for stimulus identifications and were paid in proportion to their accuracy on a subsequent test that was given for each task.

Control studies demonstrated cerebral metabolic (left/right) symmetry with eyes open (previous studies with ears open, eyes closed or both open have been symmetric) but when both the eyes and ears were closed there was relative left sided hypermetabolism, particularly frontal ($p < 0.015$), perisylvian ($p < 0.001$) and associative visual ($p < .04$) cortex. All auditory stimulations resulted in symmetric (L/R: $p < .05$) bilateral activation of the posterior transverse temporal surfaces, with the left-sided activation being more posteriorly placed and more extensive in terms of the surface area activated. This pattern corresponds to previous reported human morphological asymmetries of this region. Verbal stimulation caused bilateral posterior temporal (l>R, $p<.01$), left inferior frontal ($p < .01$) and left associative visual ($p < .001$) cortical activations. Stimulation with chords resulted in bilateral inferior panetol ($p < .01$) and right posterior temporal ($p < .01$) and frontal ($p < .001$) cortical activations. The results of the tone sequence task depended on the subjects, task strategy and musical sophistication. Subjects who used non-analytical methods and were musically naive (N=5) had right sided activations particularly of the posterior temporal ($p < .001$), and frontal ($p < .001$) cortex. Analytical or musically sophisticated subjects (N=3) had left sided activations of the posterior temporal ($p < .01$) and inferior frontal ($p < .001$) cortex. These results will be discussed in terms of functional neuroanatomy and cerebral dominance.

79.1 DISRUPTION OF THE SLEEP-WAKING CYCLE AFTER PONTINE TEGMENTAL LESIONS AS REVEALED BY COMPUTER GRAPHICS ANALYSIS. Lee Friedman*, and Barbara E. Jones. Lab. of Neuroanatomy, Montreal Neurological Inst., Dept., Neurology and Neurosurgery, McGill Univ., Montreal, Quebec, Canada H3A 2B4.

Previous research has shown that large lesions involving the pontine gigantocellular tegmental field (FTG) and the lateral tegmental field (FTL) eliminate the state of paradoxical sleep (Jones, Neurosci. Lett., 13:285-293, 1979). The aims of the present research were to quantify and analyze more accurately this effect on the sleep-waking electrographic variables and cycle organization and to delimit the effective lesion site.

The electrographic variables were recorded from chronically implanted cats on a Grass Model 78D Polygraph. For quantification the respective filtered amplitudes of EEG, EMG, EOG and olfactory bulb spindles (OBS) were integrated and digitized and PGO spikes were automatically detected and counted on a Buxco Electronics Data Logger for successive one minute epochs over 24 hours. One day's data were collected and transferred to a PDP 11/60 computer for analysis. Bivariate frequency histograms based on amplitude (EEG, EMG, EOG, OBS) or number (PGO spikes) of electrographic variables per minute epoch were displayed for baseline and post-lesion days on a color Lexidata System 3400 Image Processor.

In 24 hour baseline records, bivariate histograms reliably manifested three major clusters which corresponded to waking, high amplitude sleep and paradoxical sleep. One to three weeks after radiofrequency lesions of the pontine FTG and FTL, the histograms showed a complete alteration of the association among parameters and revealed a transformation of the cluster configuration. Graphics analysis of state clusters demonstrated that paradoxical sleep was absent for the three week post-lesion survival period. In examination of individual variables, it was obvious that relative to baseline amounts, there was a downward shift in EEG amplitude, an upward shift in EMG amplitude, and a loss of epochs with a high rate of PGO spiking. The sequential display of data points on the bivariate histograms showed underlying truncation of the sleep-waking cycle after the lesion, such that only the initial segment between waking and moderate EEG amplitude sleep was evident. Smaller lesions restricted to either the FTG or the FTL of the pontine tegmentum were not associated with the same longterm cycle disruption. In conclusion this analysis demonstrates that the pontine tegmentum, including both gigantocellular and lateral tegmental fields, is essential not only for the state of PS but moreover for the full coordination and concatenation of electrographic parameters that underlie the sleep-waking cycle.

(Supported by Canadian Medical Research Council Grant no. 6464).

79.2 BEHAVIORAL STATES AFTER BRAINSTEM TRANSECTION AT THE MEDULLARY LEVEL

J.M. Siegel, R. Nienhuis*, K. Tomaszewski* and R. Wheeler*
Veterans Administration Medical Center, Sepulveda, California and Dept. of Psychiatry, UCLA School of Medicine, Los Angeles, California

We have attempted a) to determine which elements of REM sleep survive in cats which have had their brainstem transected just rostral to the level of the 6th nerve nucleus and b) to characterize the physiological periodicities and behavioral states in each half of the preparation. Unit activity on both sides of the cut as well as standard EEG, EKG, PGO, and respiration measures were recorded. Surgical section of the 3rd and 4th nerves on one side and the 6th nerve on the other side allowed the separate observation of eye movements controlled by the forebrain and brainstem. Cats were maintained in stable physiological condition for as long as 30 days.

Forebrain States: Three distinct states were seen. 1) a state with desynchronized EEG and no PGO spikes. 2) A state with intermittent synchronized EEG and no PGO spikes. 3) A state with continuous synchronized EEG and isolated, high amplitude PGO spikes. This latter state resembled the state of transitional SWS seen in the intact cat. No state with PGO spikes and desynchronized EEG was seen. Neuronal activation resembling that of REM sleep was not observed. Synchronized EEG periods were accompanied by lower but more irregular rates of midbrain unit activity than desynchronized periods.

Medulla States: In the isolated medulla, three states could be recognized. 1) A quiescent state. At this time, heart rate and unit activity were slow and regular and muscle tone was very low, although not completely absent. 2) Strong stimulation could produce a second state that can be described as tonic activation. In this state, EMG amplitude, heart rate, and brainstem unit activity were all high. Respiration was rapid and gross body movements often occurred. A brief stimulus could precipitate a tonic activation period which lasted several hours, terminating with a gradual return to the quiescent state. 3) The third state, can be described as phasic activation. It occurred periodically in the undisturbed cat and consisted of a brief, one to three minute activation of EKG, EMG and respiration.

79.3 PGO WAVE ACTIVITY AND CORTICAL EEG IN THE RESERPINIZED, ANESTHETIZED CAT. P. J. Morgane, J. D. Bronzino and M. M. Kennard*. Worcester Foundation for Expt. Biology, Shrewsbury, MA 01545.

In order to study PGO spike waves in relation to cortical EEG activity we have quantitatively studied PGO spike rhythms and the relation of PGO spikes to degrees of cortical EEG synchrony in the reserpinized, anesthetized cat. In waking cats it has been repeatedly shown that numerous drugs which act upon brain monoamines can dissociate the appearance of PGO waves from REM sleep. In the reserpinized, anesthetized cat we still see a recurring PGO rhythm and a clear relation of PGO waves to specific patterns of EEG activity in the cerebral cortex. It has been reported that in unanesthetized cats there is a desynchronizing tendency of the PGO wave mechanism. Under reserpine PGO waves occur with a periodic character having a basic rhythm of approximately 30-35 minutes within the range of a sleep EEG cycle (24-30 minutes) in the cat though longer than the normal REM cycle (18-22 minutes) in this species. After peaking in each cycle PGO activity rates either dropped to zero or fell to very low values. Cortical EEG activity, particularly in the frontal cortex, was clearly related to the density of PGO waves. In periods of dense PGO waves the frontal cortex was highly synchronized and the degree of synchrony diminished as the PGO wave rate fell. During periods of EEG desynchronization no PGO waves were present. Coherence values between frontal and occipital cortices were greatest during high PGO spike activity. It is noteworthy that the changes in PGO wave discharge always preceded the EEG changes whether proceeding toward synchrony or desynchrony (PGO waves becoming more or less dense, respectively). We found routinely that when there were more PGO waves there was more power in the lower frequency ranges of the EEG. In these preparations we also found that the most dramatic EEG changes from synchrony to desynchrony and the reverse were seen in the frontal cortex while the occipital cortex exhibited far less fluctuations in this regard. Even when there was extreme synchrony in the frontal cortex with dense PGO wave activity there appeared in most instances fewer changes in the occipital cortex. On some occasions when we saw the most extreme density of PGO waves we found hypersynchrony in both the frontal and occipital cortex. These studies indicate that PGO waves in the reserpinized, anesthetized cat are under control of a periodic generator and bear an unvarying relation to cortical EEG activity. Thus, in this preparation we have shown that there is not a desynchronizing tendency of PGO waves. Reserpine does not block cortical EEG synchronization but does eliminate any mutual exclusivity of PGO waves and cortical synchronization such as appears in normal sleep. (Supported by NSF grant 79-22507).

79.4 THE EFFECTS OF SLEEP ON THE STRENGTH OF NEURAL ENTRAINMENT IN DIFFERENT LAYERS OF THE SOMATOSENSORY CORTEX. G. Gücer. Department of Neurosurgery and Physiology, Johns Hopkins University, Balto.MD 21205

Somatosensory neurons show a decrease in the strength of entrainment during different stages of sleep. The transition from waking to slow wave sleep is accompanied by a decrease in the amplitude of the post stimulus histograms (PSH) while entrainment to the peripheral vibratory stimulus is unchanged. During desynchronized sleep with REM'S the amplitude of the PSH is further reduced to 9 ± .98% of waking. However some neurons do not show a loss in the strength of entrainment during slow wave sleep but show a loss during desynchronized sleep with rapid eye movements (Gücer, G., Exp. Brain Res., 34:287, 1979).

The purpose of this study was to determine how the effects of sleep as seen by a change in the strength of entrainment are distributed across the six layers of the somatosensory cortex. Twelve macaque monkeys were trained to fall asleep in a primate chair while the head was restrained. A gentle vibratory stimulus was delivered to the glabrous skin of the hand; it did not alter the normal sleep cycle of the macaque. Single unit studies of the post central gyrus neurons was performed with extracellular recording. One hundred and twenty three neurons could be entrained to peripheral sinusoidal mechanical stimuli and studied through a sleep cycle. Thirty nine neurons were studied through a sleep cycle which included a desynchronized sleep epochs with rapid eye movements.

The strength of entrainment of neurons located in the supragranular layers of the cortex was decreased during slow wave sleep as well as during desynchronized sleep. The strength of entrainment of neurons located in Layer 4 was unaffected by slow wave sleep however a decrease in the strength of entrainment during desynchronized sleep to 35% ±1.5was observed. This was even further reduced during rapid eye movement epochs of desynchronized sleep to 9% ±.98.

Neurons in the input layers of the somatosensory cortex are strongly linked to sensory drive and not affected by slow wave sleep. However, as information transmission to the cortex is decreased by brainstem inhibition of relay nuclei during rapid eye movements of desynchronized sleep, even neurons in the input layer show a decrease in strength of entrainment but not in the fidelity of entrainment.

79.5 HYPNOGENIC-CENTER THEORY OF SLEEP: NO SUPPORT FROM 2-DEOXYGLUCOSE STUDIES IN MONKEYS. R.K. Nakamura, C. Kennedy, J.C. Gillin, S. Suda*, M. Ito*, F. Storch*, W. Mendelson, M. Mishkin, L. Sokoloff
National Institute of Mental Health, Bethesda, MD 20205.

The hypnogenic-center theory postulates that sleep is initiated and maintained by an active process in some cerebral structure (cf Bremer, Ann. Neurol., 2:1-6, 1977). We examined this theory by applying the 2-deoxyglucose (2DG) technique in monkeys that were either awake (n=4) or in slow wave sleep (n=4). All animals were adapted to sleeping in a restraint chair within a dark booth with 70 db of masking white noise. EEG, EOG, and EMG were monitored throughout, and behavior was observed via an infrared TV camera. The experimental animals were allowed to enter slow wave sleep (SWS), whereas the control animals were awakened (and kept awake) by light taps on, and movements of, the booth. Then 2DG was given, and 30 minutes later the animals were killed. In all cases, the electrographic and behavioral evidence confirmed that the desired states were maintained for a minimum of 27 minutes.

After autoradiographic development of the brain sections, calculations were made in each monkey of rates of local cerebral glucose utilization (LCGU) for 74 structures, including more than a dozen that have been suggested as possible hypnogenic centers. In none of the 74 structures was the mean value for LCGU higher in SWS than in waking. In fact, in 43 structures, LCGU was significantly lower in SWS. Overall there was a 30% reduction. Besides the structures analyzed quantitatively, others scanned visually likewise yielded no suggestion of a significant increase in SWS.

Since the control animals were awakened and had to be regularly disturbed in order to be kept awake, a hypnogenic center may have been active in these monkeys despite their awake state. We therefore made further comparisons with six monkeys that had been studied earlier with the 2DG technique while they were fully alert. Out of the 74 structures examined only two, the cochlear nucleus and inferior colliculus, had significantly higher metabolic activity in either the sleeping or control animals than in the fully alert animals, a finding that was presumably due to the use of the masking noise in the present study. Thus, the comparison of the sleeping monkeys with either the control or the fully alert monkeys gives no support to the notion of a hypnogenic center that actively maintains sleep. In addition, the absence of a metabolic hot spot in drowsy as compared with alert animals weakens the possibility of a center that triggers sleep.

A hypnogenic center could have been missed if its mechanism involves: a) a small or brief increase in activity, b) a change in the temporal pattern of activity, or c) a closely intermixed set of reciprocally related cells. At present, however, the 2DG evidence appears to favor a deactivation theory of sleep.

79.6 SEQUENCING OF SLEEP STATES IS ALTERED IN INFANTS AT RISK FOR THE SUDDEN INFANT DEATH SYNDROME. R. M. Harper, B. Leake*, T. Hoppenbrouwers*, M. Sterman and J. Hodgman*. Dept. of Anatomy and the Brain Research Institute, UCLA, Los Angeles, CA 90024, and LAC-USC Med Center, Los Angeles, CA 90033.

Infants normally exhibit a sequence of active and quiet sleep states which is interrupted by episodes of waking during a night recording. A periodicity appears in the temporal organization of states such that epochs of quiet sleep and active sleep follow each other at hourly intervals; this periodicity requires 3 to 4 months to stabilize and provides a valuable neurological indicator of development. The development of state sequencing is disturbed in infants at risk for the Sudden Infant Death Syndrome (SIDS), and this disturbance persists until at least the sixth month of life.

25 control infants and 25 age and socio-economically matched siblings of SIDS victims, who are at 5-fold higher risk for the syndrome, were recorded at 1 week and at 1, 2, 3, 4 and 6 months of age. 12 hr all-night sleep recordings were obtained using EEG, EKG, eye movement, EMG activity, somatic movement and respiratory signals to indicate sleep state. Each successive minute of the all-night recording was classified as quiet sleep (QS), active sleep (AS) or waking (AW) and transformed into a binary series of 0 (representing presence of a particular state) or 1 (representing absence of that state). These binary sequences were then smoothed with a digital filter and subjected to spectral analysis to examine the temporal sequence. ANOVA procedures were used to provide statistical assessment of trends.

As described earlier (Harper, R.M. et al., Science, In Press), the organization of sleep states is disturbed even by the first week of life. This larger group of infants additionally demonstrates that risk infants show a decreased 1 cycle/hr activity in AS and AW at 3 months and in AS at 6 months.

These changes in periodicity of state organization were reflected in binary plots of state epochs as a combination of fewer short-term wakings, sustained inter-awake intervals as well as long inter-AS intervals. Infants at risk for SIDS appear to have difficulty in establishing the normal waking patterns that occur, often momentarily, during a night's sleep. Sudden Infant Death may reflect a "failure to arouse" to events which might compromise an infant during sleep.

80.1 THE AMNESIC PATIENT H.M.: CLINICAL OBSERVATIONS AND TEST PERFORMANCE 28 YEARS AFTER OPERATION. Suzanne Corkin, Edith V. Sullivan, Thomas E. Twitchell*, and Elizabeth Grove*. Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139.

In 1953, at the age of 27, H.M. underwent an experimental operation for intractable epilepsy in which the uncus, amygdala, and anterior portions of the hippocampus and parahippocampal gyrus were removed bilaterally. The severe and lasting global amnesia that followed was described initially by Scoville and Milner (1957), and a 14-year follow-up study of H.M. was conducted by Milner, Corkin, and Teuber (1968). We now document H.M.'s condition at the age of 55, 28 years after operation.

The most striking finding with H.M. is the stability of his symptoms over the 28 years. He still exhibits a profound anterograde amnesia, and does not know where he lives, who cares for him, or what he ate at his last meal. His guesses as to the current year range from 1958 to 1993, and, when he does not stop to calculate it, he estimates his age to be 10 to 26 years less than it is. Nevertheless, he has islands of remembering, such as knowing that an astronaut is someone who travels in outer space, that a public figure named Kennedy was assassinated, and that rock music is "that new kind of music we have." He can still draw an accurate floor plan of the house in which he had lived from 1960 to 1974; moreover, he believes that he still lives there. A typical day's activities include doing crossword puzzles and watching television.

Neurological examination of H.M. reveals ataxia of gait, polyneuropathy, and a left ulnar neuropathy. These signs are identical to those found in 1966, except for progression of the polyneuropathy since 1970 and the appearance of the ulnar neuropathy in 1977. H.M.'s CT scan shows postsurgical changes in both anterior temporal lobes, a slight increase in Sylvian fissure size, and significant cerebellar atrophy.

Formal neuropsychological testing showed a drop on several measures between 1977 and 1980 (Wechsler Intelligence Scale, verbal fluency, expressive and receptive language capacities, recency discrimination). Over the same time, however, there was no change on many other tests (Wechsler Memory Scale, Hidden Figures Test, Porteus Maze Test, nonverbal fleuncy, copy of the Rey figure, speed of tapping, short-term retention, continuous recognition of verbal and nonverbal material). In addition, H.M. failed to show the depth-of-processing effect when given 30 words at a time but did show it when given 6. Our findings reflect the interaction of mnemonic processes, other cognitive mechanisms, and age-related changes in the brain.

80.2 THE AMNESIC PATIENT H.M.: LEARNING AND RETENTION OF A COGNITIVE SKILL. Neal J. Cohen and Suzanne Corkin. Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139.

The patient H.M. has exhibited a profound amnesia since sustaining a bilateral removal in the medial temporal-lobe region for relief of chronic epilepsy in 1953. His disorder of learning and memory affects both verbal and nonverbal stimulus material irrespective of the modality of stimulus presentation. Nonetheless, H.M. has been able to learn and retain certain perceptual-motor skills (Milner, Physiologie de l'Hippocampe, 1962, p. 257; Corkin, Neuropsychologia, 1968, 6, 255), although he could not recall his experience with the task. More recently, other amnesic patients exhibited normal learning and 3-month retention of a mirror-reading skill, despite markedly impaired memory for the words that had been read and for the training experience itself (Cohen and Squire, Science, 1980, 210, 207). This work suggested a dissociation among memory systems, such that the learning of skills involving procedural, rule-based knowledge is spared in amnesia, whereas learning and memory of declarative, data-based knowledge (comprised of specific episodes and facts about the world) is markedly impaired.

New work with H.M. provides further support for this view: H.M. was tested on the Tower of Hanoi puzzle, a well-studied problem domain involving a number of pegs and a number of blocks of differing sizes. To begin the problem, all of the blocks are arranged on the "source" peg in size order, with the smallest on top and the largest on the bottom. The task of the subject is to move the blocks, one at a time, onto the "goal" peg, reestablishing the size order while never placing a block onto one smaller than itself. Normal control subjects require a decreasing number of moves for solution across trials. H.M. was tested four times per day on four consecutive days and, one week later, on another four consecutive days. Despite his inability to remember particular moves and whether they advance or retard solution, H.M.'s performance improved systematically across days, from a mean of 46.3 moves per solution on the first day of testing to a mean of 32 moves per solution on the eighth day of testing (minimum number of moves=31). By the seventh and eighth days of training, despite near-perfect performance, his commentary during each trial always sounded as if he were solving the puzzle for the first time. In short, H.M. was able to learn the procedures or operations necessary for the successful performance of this cognitive skill, despite markedly impaired declarative memory for the task. This finding is corroborated by our results for patients with amnesias of other etiologies.

Supported by grants MH 24433, MH 08280, and RR 00088.

80.3 THE AMNESIC PATIENT H.M.: LEARNING AND RETENTION OF PERCEPTUAL SKILLS. Mary Jo. Nissen*, Neal J. Cohen, and Suzanne Corkin (SPON: Edith V. Sullivan). Dept. of Psychol., Mass. Inst. Tech., Cambridge, MA 02139.

Following a bilateral resection in the medial temporal region, H.M. has demonstrated a severe amnesia for new declarative information, including both verbal and nonverbal material. He nevertheless is able to learn and retain new perceptual and perceptual-motor skills. We have now replicated an earlier demonstration (Milner, Corkin, and Teuber, Neuropsychologia, 1968, 6, 215) that H.M.'s ability to identify fragmented pictures is facilitated by prior experience with the stimulus set. In addition, we have extended the analysis of his perceptual-learning capacity by testing the effect of experience on the identification of words presented briefly. The present paradigm allowed us to determine whether his perceptual learning is limited to the specific stimulus material presented previously or whether it generalizes to new material.

Words were presented in blocks of 40, of which half were common to each block of the experiment (repeated words), and half were unique (non-repeated words). H.M. identified more of the repeated words than the non-repeated words. In addition, he showed a more general perceptual learning: He identified an increasing number of non-repeated words over the course of the experiment. Both of these effects persisted after delays of 1 hour and 1 day, the same delays over which facilitation was observed in the fragmented pictures test. Despite his perceptual learning in both of these tasks, H.M. did not remember having performed the task, a finding consistent with observations made in previous reports of impressive learning by amnesic patients. Moreover, H.M.'s recognition-memory performance after the experiment for the words that had been presented during the experiment was at chance.

The present results corroborate the findings of intact learning and long-term retention of certain skills in amnesic patients, despite impaired memory for the details of the experimental sessions and for the specific stimuli that had been presented (Milner, Physiologie de l'Hippocampe, 1962, p. 257; Corkin, Neuropsychologia, 1968, 6, 255; Cohen and Squire, Science, 1980, 210, 207). These findings provide further support for a dissociation among memory systems. In particular, they support the distinction between acquisition of procedural and declarative knowledge.

80.4 THE AMNESIC PATIENT H.M.: DIMINISHED ABILITY TO INTERPRET AND REPORT INTERNAL STATES. Nancy Hebben, Karen J. Shedlack*, Howard B. Eichenbaum, and Suzanne Corkin. Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139, and Dept. Biol., Wellesley Coll., Wellesley, MA 02181.

H.M. became amnesic after a bilateral resection in the medial temporal region for epilepsy. Since then it has been noted that he rarely comments on such internal states as hunger, thirst, pain, and fatigue. In order to document these clinical observations, we examined his thermal pain perception in relation to his other somatosensory capacities, and his reports of hunger before and after meals of normal and twice normal quantity.

H.M.'s thermal pain perception was evaluated using a Hardy-Wolff-Goodell dolorimeter. On three occasions, the radiant-heat stimuli were self-administered to the volar surface of both forearms. Subsequently, the same stimuli were self-administered to the chest, in case the results for the forearms had been affected by his known peripheral neuropathy. During each test session, 144 stimuli, 24 at each of 6 intensities (0, 90, 180, 270, 320, and 370 mcal), were presented pseudorandomly with respect to intensity. H.M. was instructed to assign each sensory experience to one of 11 categories ranging from "absolutely nothing" to "very painful" and "withdrawal." The data were analyzed using the methods of sensory decision theory, providing both an index of discriminability, P(A), and of report criterion, B. At all three stimulus sites, H.M. had significantly poorer discriminability scores for all intensity levels than did a group of normal control subjects. He also had higher criterion scores than did normal subjects, particularly at the three highest stimulus intensities. In fact, H.M. never gave reports of pain for the most intense stimulus applied either to his forearms or chest, and, in contrast to most other subjects, he did not withdraw the stimulus before the end of the 3 sec. stimulus duration.

A similar neglect of internal states is seen in H.M.'s reports of hunger. On a scale of 0 to 100, where 0 is "famished" and 100 is "too full to eat another bite," he consistently reported 50, whether he was about to eat or had just eaten. On one occasion we attempted to influence his report of satiety by supplying him with as much food as he could eat at one sitting. After he consumed one full dinner, his empty tray was removed, and without explanation another full dinner was provided. He did not behave as if anything unusual had happened, and only after having eaten the second dinner, except for the salad, did he report simply that he was "finished." At the time, he rated his satiation at 75. We conclude that medial temporal structures participate in the monitoring of pain and hunger.

80.5 THE AMNESIC PATIENT H.M.: SEVERE, SELECTIVE OLFACTORY-DISCRIMINATION DEFICIT FOLLOWING BILATERAL MEDIAL TEMPORAL LOBECTOMY. Howard B. Eichenbaum, Harry Potter*, and Suzanne Corkin. Dept. Biol., Wellesley Coll., Wellesley, MA 02181, and Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139.

Following bilateral resection in the medial temporal region, the patient H.M. has suffered from global anterograde amnesia. This man has been studied extensively because of the purity of his amnesia, a near-total inability to learn, in the absence of other serious cognitive, perceptual, or emotional impairments. Despite the well-known intimacy of olfactory and limbic brain structures, however, H.M.'s olfactory capacities have not been measured formally until now.

A series of measures, including threshold adaptation, intensity and quality discrimination, and odor identification, were used to compare the olfactory capacities of H.M., age-matched control subjects, patients with Korsakoff's disease, and patients with unilateral frontal-cortex lesions. H.M.'s thresholds for almond, ethanol, lemon, and acetone, using a forced-choice descending-staircase procedure, were comparable to controls'. In a standard signal-detection paradigm, H.M.'s detection of n-butanol and phenethyl alcohol was at least as good as controls', and, in the same paradigm, he demonstrated normal adaptation and cross-adaptation.

H.M. also performed normally on an intensity-discrimination task, where subjects were forced to choose the stronger of two odor intensities. The most intense of each of four odors was paired with each of nine others of less intensity. On this task, H.M.'s performance was superior to the mean scores of control subjects.

In striking contrast to his ability to detect and discriminate odor intensities, H.M. demonstrated virtually no ability to discriminate odors by quality, nor could he identify common odors: H.M.'s d' on a same-different signal-detection task was near-zero, even on a discrimination that normal subjects found easy. In a matching-to-sample task on which the performance of normal subjects is nearly perfect, H.M.'s score was at chance (except perfect detection of a blank stimulus), and he could not name any of the common odors correctly. H.M.'s perceptual difficulties seem to be restricted to the olfactory mode, since he performs well on a color-discrimination signal-detection task, and he can identify by vision or touch the same common foods he cannot name by smell. After naming a lemon by vision, he remarked, "Funny, it doesn't smell like a lemon."

80.6 RECOGNITION IMPAIRMENT AFTER MEDIAL THALAMIC LESIONS IN MONKEYS. J.P.Aggleton* and M.Mishkin (SPON: L. Ungerleider). Lab of Neuropsychology, NIMH, Bethesda, MD 20205.

Although it has been known for nearly a century that some amnesic syndromes are associated with damage to the diencephalon, the locus of the critical lesion has remained uncertain. One region, however, that has been implicated by neuropathological evidence, both from amnesic patients with Korsakoff's psychosis and from those with third ventricle tumors, is the medial thalamus. In this experiment we tested whether or not surgical lesions of the medial thalamus in monkeys would impair memory.

Six cynomolgus monkeys (Macaca fascicularis) were trained preoperatively on a one-trial visual recognition task in which they were required to distinguish a sample object, presented 10 sec previously, from one that was completely novel (delayed nonmatching-to-sample). After reaching a criterion of 90% correct responses, three of the monkeys received thalamic lesions and three were kept as unoperated controls. The thalamus was approached from its dorsal aspect through a slit in the corpus callosum, after which the entire extent of the interthalamic connection, or massa intermedia, was transected along the midline. A sagittal strip of tissue extending 1-2 mm lateral to the midline was then removed from the massa intermedia on either side of the transection. The thalamic structures within the area of removal include the medial portion of n. medialis dorsalis, n. parataenialis, n. anterior medialis, n. reuniens and all of the midline nuclei.

This surgery had a profound effect on performance of the recognition task. Whereas the control animals reattained the preoperative criterion within a maximum of 80 trials, the best operated monkey needed 640 trials. The other two operated monkeys required over 1,000 trials and then could reach criterion only when the sample object was presented twice prior to the recognition test. Imposition of gradually increasing delays, from 10 to 120 sec, between sample and test, reinstated this deficit: whereas the normal monkeys' performance at the 120 sec delay remained high (range, 89-92%), that of the operated animals fell sharply (range, 67-71%). Subsequently, when the same monkeys were tested for visual discrimination learning, no evidence of impairment was found on either of two pattern discrimination. These preliminary results indicate that medial thalamic lesions in monkeys may impair memory selectively, and thus may provide an animal model of diencephalic amnesia.

80.7 THE ANATOMY OF AMNESIA: AMYGDALA-HIPPOCAMPUS VS. TEMPORAL STEM. Stuart Zola-Morgan* Larry R. Squire and Mortimer Mishkin, Veterans Administration Medical Center, San Diego, CA, Dept. of Psychiatry, UCSD School of Medicine, and NIMH, Bethesda, MD.

There has for some time been a lack of correspondence between the brain regions presumed critical to human amnesia and the findings in experimental animals with lesions in those same brain regions. Results from new studies have suggested that the specific brain structures most often linked to human amnesia and consequently most frequently investigated in animal experiments may have been misidentified, at least in part. Thus, Horel has suggested that damage to the temporal stem (TS) and not damage to the hippocampus itself is responsible for the deficit in human amnesia. TS contains afferents and efferents of temporal neocortex and more medial brain structures. Alternatively, Mishkin has demonstrated that conjoint damage to amygdala (A) and hippocampus (H), but not separate lesions of A or H, mimic some of the critical features of human amnesia. We have addressed these two views of amnesia by comparing the effects of TS damage with the effects of conjoint damage to A and H.

Monkeys with A+H lesions, those with lesions of TS, and a group of normal control monkeys were given two tasks: 1) the trial-unique delayed non-matching to sample task. This task can be easily mastered by monkeys who have had no previous test experience, and tests memory in much the same way that forced-choice recognition does in humans. We used intervals of 5 sec to 10 min between the acquisition and retention trials, permitting measurement of forgetting over relatively long delays. Impairment in delayed recall or recognition is a hallmark of human amnesia; 2) two-dimensional pattern discrimination. This task is known to be sensitive to temporal neocortical damage.

A double dissociation was found: animals with A+H lesions were severely impaired on the non-matching task and the severity of their impairment correlated with the length of delay. They were only mildly impaired on the pattern discrimination task. By contrast, monkeys with TS lesions were severely impaired on the pattern discrimination task, but were not different from normal monkeys on the non-matching to sample task.

The results will be discussed in terms of their implications for the neuropsychology of memory.

80.8 DIFFERENCES BETWEEN LIMBIC AND NONLIMBIC RETENTION PROCESSES. B. L. Malamut* and M. Mishkin. LN, NIMH, Bethesda, MD 20205.

Monkeys with combined amygdalo-hippocampal ablations cannot recognize objects they have seen only a minute or two before; yet they readily learn to select the baited object of a pair even when successive trials with that pair are separated by 24-hour intervals (Malamut et al., Neurosci. Abstr., 6:191, 1980). This successful learning in the face of rapid forgetting indicates the existence of a powerful mechanism for retention of information that is independent of the limbic system. New experiments characterize further the essential difference in function between the limbic and nonlimbic retention mechanisms.

Rhesus monkeys with amygdalo-hippocampal lesions (Group A+H) and their unoperated controls (Group N) were tested on Gaffan's object-reward association task involving the principle of win-stay, lose-shift (Learn. & Motiv., 10:419, 1979). In Experiment I, a list of 20 objects, half baited and half unbaited, were presented one at a time for acquisition. The baited and unbaited objects were then paired in a series of ten test trials. This series was repeated up to 4 times each day until the animals reached 90% performance on it twice. On ten such lists, each with different objects, Group A+H required an average of 6 trials to reach criterion, significantly longer than Group N, which averaged only 2.5 trials. On the first test trial of each list, however, the two groups did not differ significantly, Group A+H averaging 62%, and Group N, 71%. In Experiment II, the animals were tested on 50 new lists of 20 objects each, but the test trials for each list were given only once. Again, there was little difference in trial-one performance, Group A+H averaging 63%, and Group N, 68%. Finally, in Experiment III, the number of objects in each list was reduced from 20 to 2, with only one test trial per pair as before. In this experiment, Group A+H still averaged 63%, showing no evidence of improvement over the course of 1000 trials. Group N, by contrast, achieved 90% performance after an average of 460 trials.

Thus, an intact limbic system yielded no advantage on trial-one performance of the first two experiments, a small advantage when the object pairs were repeated within sessions in Experiment I, and a decisive advantage on trial-one performance in the third experiment. Apparently, the limbic system is critical for high levels of retention of object-reward associations after a single acquisition trial with short lists, or after two or three repetitions with long lists but short intertrial delays. With greater repetition, however, retention of object-reward associations can be mediated by a nonlimbic mechanism (Experiment I), and this retention appears to be independent of both list length and delay (Malamut et al., op cit).

80.9 ROLE OF THE AMYGDALA AND HIPPOCAMPUS IN TACTUAL MEMORY. Elisabeth A. Murray and M. Mishkin. Lab. of Neuropsychology, N.I.M.H., Bethesda, MD 20205

A severe deficit in the visual recognition memory of monkeys follows combined bilateral removal of the amygdala and hippocampus (Mishkin, Nature, 273: 279, 1978). To determine whether the memory impairment following this ablation is restricted to vision, possibly as a result of inadvertent damage to the visually related white matter and cortex of the temporal lobe, we examined the effects of combined lesions of the amygdala and hippocampus on monkeys' tactual memory.

One rhesus and three cynomolgus monkeys were trained preoperatively on a delayed nonmatching-to-sample task in the dark. In this paradigm the monkey is presented with a baited sample object and, subsequently, is rewarded for choosing the one of two simultaneously presented objects that does not match the sample. The animals were tested for 20 trials per day with a fixed set of 40 tactually distinctive objects that were randomly re-paired daily. The objects were mounted on corks which fit snugly into the wells of the testing board so that the monkeys had to grasp and lift the objects in order to obtain the reward. After achieving the criterion of 90% correct responses in 100 trials with 10 sec delays between sample presentation and choice, the animals' performance was measured in blocks of 100 trials each with delays of 30, 60, and 120 sec. The monkeys then underwent bilateral removal either of the amygdaloid complex, the hippocampal formation, or both. Following reattainment of criterion at 10 sec delays, the animals' performance was again measured at the longer delays.

Preoperatively, the monkeys averaged greater than 90% correct responses at all delays. Postoperatively, two monkeys (one rhesus and one cynomolgus) with the combined amygdalectomy and hippocampectomy eventually reattained an average of 87% correct responses at 10 sec delays but then were severely impaired at the longer delays, averaging 60% at 60 sec and 56% at 120 sec. A hippocampectomized monkey performed at better than 90% accuracy across all delays, while an amygdalectomized monkey's performance dropped to approximately 80% at 120 sec delays.

These preliminary results suggest that the amygdala and hippocampus are necessary for memory of tactual as well as visual and, perhaps, other stimuli and support the view that only the combined removal of these structures produces a severe memory impairment.

80.10 HIPPOCAMPAL ABLATION CAUSES SPATIAL REFERENCE MEMORY DEFICIT IN THE RAT. R.G.M.Morris*,P.Garrud* and J.N.P.Rawlins* (SPON: W.J.Heitler). Psychology Laboratory,University of St.Andrews, Scotland and Dept.Exptl.Psychology,Univ.Oxford,England.

The purpose of this behavioural study was to test Olton et al's(Behav.Brain.Sci.,1979) claim that spatial reference memory is unimpaired by hippocampal damage. Rats with total lesions of the hippocampus, superficial cortical lesions or sham control surgery (Ns=13,11,8 respectively) were allowed to escape from opaque water (26-1°C) onto a small platform (8.7 cm diameter) hidden (1 cm below water surface) at a fixed position in a large (132 cm diameter) pool (See Morris, Learn & Motiv,1981, for behav.procedure). Spatial room cues were readily available but no local cues marked the position of the platform. Hippocampally lesioned rats only were impaired throughout training ($p<0.001$) measured in terms of both escape-latency and path-length. On a subsequent "probe" trial during which the hidden platform was removed from the apparatus, control and cortical rats searched persistently in the previous vicinity of the platform; hippocampals did not. When a visible platform (1 cm above water surface) was then used for escape, again in a fixed place, the hippocampals soon showed rapid directional escape behaviour onto the platform indicating that their deficit was not due to any motor, motivational or reinforcement aspects of the task. A second identical "probe" test was conducted and the hippocampals again, unlike the controls and corticals, did not show directional search, so calling into question Moore's (Physiol.Psych.,1980) claim that damage to this brain area may result in greater attention to redundant cues. Finally, transfer of the rats back onto the "pure" spatial task resulted in the hippocampal deficit reappearing ($p<0.001$) so demonstrating that the original learning difficulties were not caused by interference from inflexible motor strategies. This pattern of results calls into question Olton et al's (1979) hypothesis. The effective performance of the control and cortically lesioned rats may be based on their learning a "spatial map" (O'Keefe and Nadel,1978) of the environment and encoding the position of the hidden platform. The poor performance of the hippocampally lesioned rats is caused either by the outright lack of such a map, an inability to use it, or by a severe impairment in spatial "acuity". A short film will be presented.

80.11 DISRUPTION OF SINGLE ALTERNATION LEARNING IN RABBITS BY HIPPOCAMPAL LESIONS. W. R. Salafia, K. M. Cardosi*, D. Marini*, J. M. Hogan*, D. R. Olson* and E. J. Pollack*. Dept. of Psychology, Fairfield Univ., Fairfield, CT 06430.

O'Keefe and Nadel (Behav. Brain Sci., 2:487-533, 1979) have argued that the hippocampus is responsible exclusively for the processing of spatial information. Hippocampal lesions are thought to disrupt the construction, storage and/or use of spatial maps. The purpose of the present experiments was to evaluate the effects of hippocampal lesions on a Pavlovian conditioning task, which required for performance, the processing of fundamentally temporal information. The task chosen was single-alternation (SA) pattern learning in which each SA trial consisted of presentation of a CS-US or reinforced (R) trial followed after 3 sec by a CS-alone or non-reinforced (N) trial. This sequence was repeated each 30 sec for a total of 50 SA trials per session.

Initially, rabbits were conditioned, at interstimulus intervals (ISIs) of either 250 or 1000 msec, to make nictitating membrane CRs. At each ISI, there were 3 groups, viz., dorsal hippocampal lesion (H), cortical lesion (C) and unoperated (U). After conditioning, animals were shifted to the SA pattern. At the 250-msec ISI, all animals appeared to learn the SA task, i.e., to respond more on R trials than on N trials, but the level of proficiency was low. At 1000-msec ISI, however, the C and U groups performed very well (90% CRs on R trials vs 15% CRs on N trials) while considerably poorer performance was in evidence for Group H.

A second phase was run to determine if some of the apparent SA-pattern learning may have been generated solely by the reinforcement schedule which was 50% by definition. In this phase normal (unoperated) animals were conditioned, then shifted to a quasi-alternation (QA) task which consisted of the same pattern of trials as previously i.e. one trial (A) followed after a 3-sec interval by another (B), followed by a 30-sec interval, etc. However, for the QA task, the CS was paired with a US on a 50% schedule randomly distributed across A and B trials. An overall tendency was seen at both ISI values, for there to be fewer CRs on B trials than on A trials, an effect which was particularly pronounced at the 1000-msec ISI. This indicated that in the previous SA phase, most of the learning displayed by Group H at 1000-msec ISI was not SA-pattern learning and therefore, that the disruption of this type of learning by hippocampal lesions was virtually complete. These data are incongruent with the spatial information processing hypothesis of hippocampal functioning.

80.12 MEMORY FOR LISTS OF ITEMS IN RATS: ROLE OF THE HIPPOCAMPUS. Raymond P. Kesner and Jeanne M. Novak*. Dept. of Psychol. Univ. of Utah, Salt Lake City, UT. 84112.

The present study was designed to examine whether similar to humans rats (a) can remember a list of 8 items, (b) can display a serial position curve, (c) do not show the "recency" component of a serial position curve when tests are delayed, (d) do not show the "primacy" component of a serial position curve after the hippocampus is ablated.

Rats were trained on an eight arm radial maze for Froot Loop reinforcement. After extensive training each animal was allowed on each trial (one per day) to visit all eight arms in an order that was randomly selected for that trial. The sequencing of the eight arms was accomplished by sequentially opening of Plexiglas doors (one at a time) located at the entrance of each arm. Thirty seconds after the animal had received reinforcement from the last of the eight arms, the test phase began. Only one test was given for each trial and consisted of opening two doors simultaneously. On a random basis either the first and second, fourth and fifth, or seventh and eighth doors that occurred in the sequence were selected for the test. The rule to be learned leading to an additional reinforcement was to choose the arm that occurred earlier in the sequence. Based on 36 tests per animal all rats displayed a serial position curve, e.g., excellent retention (better than chance performance) for 1-2 and 7-8 positions, but no retention (chance performance) for 4-5 position. Delaying the test phase by 10 min eliminated retention of the "recency" (7-8) component of the serial position curve without markedly altering the "primacy" (1-2) component. Dorsal hippocampal lesions impaired retention of the "primacy" (1-2) component of the serial position curve without markedly altering the "recency" (7-8) component. These data are remarkably similar to memory performance seen with normal humans and humans with presumed hippocampal damage. It is concluded that the hippocampus of both rats and humans plays an important role in encoding of mnemonic information in episodic long-term but not short-term memory.

80.13 EFFECTS OF FRONTAL- AND TEMPORAL-LOBE LESIONS ON PERFORMANCE OF SELF-ORDERING TASKS. M. Petrides* and B. Milner. Dept. of Psychology and the Montreal Neurological Institute, McGill Univ., Montreal, Quebec, Canada, H3A 2BA.

Patients with excisions of the left frontal (LF) or right frontal (RF) lobe, left (LTh) or right (RTh) temporal lobe involving little or no damage to the hippocampal region, and left (LTH) or right (RTH) temporal lobe with extensive damage to this region were tested on four self-ordering tasks. In these tasks, the subject had to organize and carry out a sequence of responses rather than merely reproduce a sequence imposed by the experimenter. On any given trial, the subject was required to touch a set of stimuli, one at a time and in any order he liked but without touching any stimulus more than once. The four self-ordering tasks differed only in the type of stimulus-material: abstract designs (AD), representational drawings (RD), high-imagery (HI) or low-imagery (LI) words.

The LF group was impaired on all four tasks, whilst the RF group was impaired only on the two nonverbal tasks. The deficits appeared to be due both to poor organizational strategies and poor monitoring of responses. In addition, a deficit was observed in the LTH group on the more difficult verbal task (LI) and in the RTH group on the two nonverbal tasks (AD and RD). The LTh and RTh groups showed no impairment on any of these tasks. The material-specific deficits of the temporal-lobe groups with extensive involvement of the hippocampal region can be ascribed to the memory-demands of the tasks. These results as a whole point to an interaction between the frontal neocortex and the hippocampal region in self-ordering behavior.

81.1 READINESS-POTENTIALS (RP's) CORRELATED WITH MENTAL "PLANNING" VS. "SPONTANEITY", WHEN PERFORMING SELF-PACED MOTOR ACTS. B. Libet, E.W. Wright, Jr.*, and C.A. Gleason*, Dept. Neurosci.-Neurol.Inst., Mt. Zion Hospital, and Dept. Physiol., University of California, San Francisco, CA. 94143.

The slow negative RP's that precede self-paced, quick flexions of fingers can exhibit durations from 0.3 to > 1.4 sec, as recorded at the vertex and averaged for 40 trials. These formed two groups: I) durations clustered close to 0.5 sec (0.4-0.6); II) durations usually considerably longer than 0.6 sec. A given subject (S) may exhibit both types.

(a) After a type-II RP, questioning S almost invariably revealed S was aware of a plan or intent to act some variable time up to 1 sec or more before at least some of the acts in the 40-trial series. (b) When S was instructed to "try to let the urge to act come on its own, no matter how long it may take, without concentrating on and/or pre-planning the act" - (i) a type-II RP in a preceding uninstructed trial series could "switch" to a type-I RP in the next series; (ii) RP's of all series with such instructions were predominantly type-I. (c) Conversely, if a condition for pre-planning was introduced deliberately, the potentials appearing before the acts (averaged for 40) resembled type-II RP's, though they were generally larger and longer. In this condition, S's were instructed to act at a predetermined "clock-time" whose impending arrival was displayed to S. Such "planning potentials" did not appear when S expected to receive (and subsequently report) a sensory stimulus to the hand rather than being required to act, at similarly predetermined times; these potentials are therefore a function of neural preparation for a motor act, not one of anticipation of the occurrence of any event.

We conclude (1) that duration and amplitude of RP's may be altered in variable but potentially large amounts by a factor related to pre-planning to act; and (2) that substantial RP's of more uniform durations (~0.5 sec) appear when the immediate urge, felt by S to perform the self-paced act, arises suddenly and "spontaneously".

81.2 DYNAMIC BRAIN POTENTIAL PATTERNS OF HUMAN HIGHER COGNITIVE FUNCTIONS. Alan S. Gevins, Joseph C. Doyle*, Brian A. Cutillo*, Robert E. Schaffer*, Robert S. Tannehill*, EEG SYSTEMS LABORATORY, Univ. California Sch. of Med., SAN FRANCISCO, CA 94143.

A new technique has been developed to identify dynamic spatiotemporal electrical patterns of the human brain during purposive behaviors. In this method single-trial time-series correlations between brain macropotentials recorded from different scalp sites are analyzed by distribution-independent mathematical pattern recognition. Dynamic patterns of correlation clearly distinguished two brief visuomotor tasks differing only in type of mental judgment required (spatial or numeric). These complex patterns shifted in the anterior-posterior and left-right axes between successive 175 msec intervals, indicating that many areas in both cerebral hemispheres were involved even in these simple judgments. These patterns were not obtainable by conventional analysis of averaged evoked potentials or by linear analysis of correlations, suggesting that this method will advance the study of human brain activity related to cognition and goal-directed behaviors.

81.3 FUNCTIONAL 2-DEOXYGLUCOSE MAPPING IN ASSOCIATION CORTEX: PREFRONTAL ACTIVATION IN MONKEYS PERFORMING A COGNITIVE TASK. N.M. Bugbee and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale Univ. School of Medicine, New Haven, CT 06510.

Surveys of local cerebral metabolism using 2-deoxyglucose have been successful in identifying central correlates of sensory and motor stimulation in behaving animals. We now demonstrate that this method also reveals metabolic changes associated with the performance of a cognitive task.

Ten rhesus monkeys, ranging in age from 3-48 months, served as subjects. Six animals were trained on a delayed response (DR) task, a behavioral paradigm known to be dependent upon prefrontal association cortex. In this task, the monkey was required to remember the location of a target over a 12 second delay period. Correct responses were rewarded with food. Four control (CON) animals were tested under identical circumstances, with the same number of trials and reinforcements, except that no delay was interposed; these subjects were allowed to respond as soon as the target was presented. To insure that motor activity and auditory input were similar for both groups, all subjects were restrained in primate chairs and exposed to amplified white noise. At the beginning of its final testing session, each monkey received an i.v. pulse of ^{14}C 2DG (100 μCi/kg) via a femoral catheter; arterial samples were collected throughout the session. Subjects worked steadily over the 45 minute period of 2DG administration, with DR animals performing at 90% correct.

Local cerebral glucose utilization (LCGU) quantified according to the procedures described by Sokoloff et al (J. Neurochem., 28, 897, 1977), was measured in eight cortical regions: prefrontal, motor, auditory, striate, extrastriate, entorhinal, and superior and inferior temporal gyrus. To compensate for individual variations in absolute LCGU, data for each animal was expressed as ratios. LCGU of each of the above cortical regions was compared to that of primary auditory cortex, a region in which sensory input was constant for all subjects. Statistical comparisons demonstrated that only the prefrontal ratio differed for the DR and CON groups ($p < .05$, t test, two-tailed). None of the other cortical areas examined could be differentiated according to behavioral task.

These findings based on metabolic mapping add to a large body of behavioral and electrophysiological evidence demonstrating the involvement of prefrontal cortex in DR performance. Whether these prefrontal metabolic changes are specific to the spatial-mnemonic aspects of the task, or whether they reflect the more general attentional demands of any task, the results indicate that the 2DG method can be used to study neural systems associated with cognitive processes. 81.4 ONLINE CLASSIFICATION OF INDIVIDUAL VISUAL EVOKED POTENTIALS. H. Galin*, D.R. Crapper McLachlan. (SPON: J.T. Murphy). Dept. of Physiology, Univ. of Toronto, Toronto, Ontario. M5S 1A8 (Canada).

Human visual evoked potentials were recorded in response to nine different randomly presented stimuli generated by an 8x8 matrix of yellow light emmitting diodes. Stimuli, subtending about 4^{o}, were presented for 5 msec. at an intensity of 8 to 14 cd/m^2. Stimulus presentation, data collection and the subsequent processing of the evoked potential were controlled by a program running on a PDP 11/35 computer and interacting with a CAMAC crate. Data sampled at 1 kHz, consisted of a 50 msec. pre-stimulus period and a 462 msec. post-stimulus period. The post-stimulus period was divided into nine segments and the slope and the logarithm of the residual sum of squares was calculated for each segment. These eighteen parameters were stored for each presentation until a sufficient number of repetitions for each stimulus had been accumulated to allow the calculation of a co-variance matrix and its inverse. A discriminant analysis was then performed in order to generate a set of classification criteria for the stimulus sub-types. These classification criteria were then applied to the previously collected response vectors and the set of posterior probabilities calculated. Based on the error rate of this criterion check either these criteria were utilized to process subsequent novel presentations or these criteria were rejected and additional stimuli were accumulated.

In eight experimental sessions involving three subjects, over 90% of the approximately 2000 presented stimuli have been successfully predicted based on the calculated posterior probabilities.

81.5 METABOLIC AND STRUCTURAL COMPARISONS TO LANGUAGE FUNCTION IN APHASIA, E. J. Metter*, W.Riege, W.Hanson*, L. Camerus*, M. Phelps , D. Kuhl (SPON: N. P. Rosenthal). Dept. of Nuclear Medicine, UCLA Med. Ctr., Los Angeles 90024.

Tomographic images of brain metabolism in post-stroke aphasics using ^{18}fluorodeoxyglucose positron emission computed tomography (FDG PECT) showed areas of metabolic depression extending beyond the zones of infarction determined by x-ray CT. To evaluate the relationship between language abnormalities and anatomic or metabolic lesions, eleven right handed aphasic patients had FDG PECT, x-ray CT, and the Boston Diagnostic Aphasia Examination (BDAE). Local cerebral metabolic rates for glucose (LCMRglc) were determined for thirteen brain areas in the damaged hemisphere and were compared to the opposite hemisphere. Corresponding areas on x-ray CT scans were graded by a neuroradiologist on a five point scale for severity of damage. The BDAE subtests were reduced to eleven mean scores, and were compared to either metabolic or CT data using correlational analysis. At $p<0.01$, the LCMRglc of the posterior middle-inferior temporal ($r\sim0.80$) and the parietal regions ($r\sim0.82$) were significantly correlated with auditory comprehension, naming, oral reading, and repetition. X-ray CT did not show these correlations but showed correlation of left frontal damage with writing ($r=0.74$), left parietal damage with repetiton ($r=0.70$), damage of Wernicke's area with oral reading and repetition ($r\sim0.77$), and posterior middle-inferior temporal area damage with automatic speech ($r=0.87$) and repetition ($r=0.69$). These findings suggest that language correlations with structural damage may be deceptive by ignoring abnormal function in remaining cerebrum. The correlations from metabolic rates, suggest that areas posterior, inferior, and superior to the traditional Wernicke's area may be important in the abnormal language of these aphasics.

81.6 MONKEY VOCALIZATION: EFFECTS OF SUPPLEMENTARY MOTOR DAMAGE. D. Sutton, R.E. Trachy* and R.C. Lindeman*. Virginia Mason Research Center, Seattle, WA 98101.

Two rhesus monkeys were trained to produce a vocal call (coo) or a lever press to distinctive visual cues. Measures of latency, discrimination index and efficiency were obtained for each response. In addition, acoustic properties of the coo were analyzed. Bilateral lesions of the supplementary motor area (SMA) were imposed after the animals had achieved a stable performance level reflected by high discrimination and short-latency responding. Following a one-week recovery period, retesting was carried out daily for one month.

SMA lesions failed to disturb lever press measures. By contrast, vocalization performance underwent sustained increases in latency on the part of both monkeys. There was little influence of lesions upon other vocal performance measures.

Histologic study of brain tissue from the two animals revealed damage confined largely to superior frontal gyrus (areas 6 & 8), superior to the cingulate sulcus.

The results suggest that supplementary motor area participates in the process of initiating voluntary phonation.

81.7 PROLONGED VISUAL RECOGNITION MEMORY IN SQUIRREL MONKEYS. William H. Overman, Jr. University of North Carolina at Wilmington, N.C. 28401

Memory capabilities of non-human primates are often assessed by the procedure of delayed-match-to-sample in which a sample object is presented, removed, and after a delay, presented again together with a second object. The animal's task is to respond to (match) the object previously seen. When the same pair of objects is used repeatedly, one or the other serving as the sample, macaques have difficulty making the match after a few seconds; however, when a new pair of objects is used for each trial, macaques can make reliable matches after delays of hours or days (Overman and Doty, Neuroscience 5: 1825, 1980). Moreover, when tested by the trial-unique procedure, macaques can accurately remember lists of ten items (ten consecutive samples) after delays of several minutes (Gaffan, J. Comp. Physiol. Psychol. 86: 1100, 1974). Recently, the serial position curves of errors on lists of ten items have been shown to be quite similar for man and macaques (Sands and Wright, Science 209:938, 1980).

In the present study the trial-unique procedure of matching was extended to a species of new world primates (Saimiri sciureus) It was found that squirrel monkeys, like old world monkeys (Mishkin and Delacour, J. exp. Psychol.:An. Beh. Proc. 1:326, 1975) tend to respond preferentially to novel objects. Thus, one group (N=5) learned a trail-unique, non-match-to-sample task with an average of 216 errors while another group (N=5) learned a trial-unique match-to-sample task with an average of 587 errors. Once either the match or non-match group learned, however, the animals could reliable remember lists of 3, 5,or 10 items significantly better than chance.

The non-match group was given 40 days training on lists of 20 items. When the groups errors were computed for each of the 20 serial positions, there were strong recency and primacy effects. A quadratic curve fitted to these data was highly significant.

Thus, it is concluded that visual recognition memory operates by similar mechanisms in a variety of primates including man, old world monkeys and according to the present data, a species of readily available new world primates, squirrel monkeys.

81.8 RANDOM DOT KINEMATOGRAMS: DISPLACEMENT LIMIT DEPENDS ON STIMULUS AREA. Curtis L. Baker, Jr. and Oliver J. Braddick*, Departments of Physiology and Experimental Psychology, Cambridge University, Cambridge, U.K.

The sensation of a smoothly moving textured surface elicited by 'random dot kinematograms', in which a contiguous patch of dots is uniformly displaced from one frame to the next, illustrates a 'correspondence problem' for motion similar to that which is recognised for random dot stereograms. Braddick (1974) showed that the perceptual segregation of a displaced patch in such patterns depended on a 'short-range' motion process which could detect displacements of less than 15 min.arc, regardless of the number of element positions this entailed.

We have now shown that this displacement limit increases with the area of the displaced patch (measured in retinal angle). (This would be analogous to the maximum disparity for stereopsis increasing with the area of a random dot stereogram.) Changing patch area over a range of 0.25-12.0 deg^2 results in displacement limit variation ca 4-15 min.arc. The limit for directional discrimination shows a similar area dependence to that for segregation. Experiments varying dot density show that the number of dots in the patch is not a confounding variable, and in fact has surprisingly little effect over a large range. The displacement limit also increases slightly with eccentricity, but not enough to account for the observed effects. The result is not an artifact of changes in surround size.

Displacement limit dependence on patch area, but not on dot density, is consistent with a motion analog of the cooperative stereopsis model of Marr and Poggio (1976).

Psychophysics experiments on random dot kinematograms delineate a low level motion-detecting process with well-defined dependence on displacement and other stimulus variables. We therefore believe that they provide a promising correlate for potential neurophysiological investigations, which may lead to better understanding of the neural basis of motion detection, the solution of correspondence problems, and figure-ground segregation.

81.9 ELECTROPHYSIOLOGIC ASYMMETRY AND BRAIN CHANGE IN PRIMARY DEGENRATIVE DEMENTIA. B. Reisberg,* S.H. Ferris, H. Ahn and E.R. John. Dept. of Psychiatry, N.Y.U. Med. Ctr., New York, N.Y. 10016.

We studied progressive EEG and auditory evoked potential (AEP) changes accompanying cognitive decrement in 12 outpatients 60 to 85 years of age with Primary Degenerative Dementia (PDD).

Electrophysiologic data were gathered using an automated digital electrophysiological data acquisition and analysis system which gathered data simultaneously from all 19 electrodes of the international 10/20 system, monopolar, referenced to linked earlobes. Bipolar derivations were constructed by computation. An automatic artifact rejection algorithm rejected data contaminated by eye movements. Spectral computations for the one minute eyes-closed EEG condition were performed by numerical filtering. These analyses yielded relative power in each of 4 frequency bands: delta (1.5-3.5Hz), theta (3.5-7.5Hz), alpha (7.5-12.5Hz) and beta (12.5-25Hz). Power asymmetry in the fronto-temporal and temporal brain regions for delta, theta and alpha wavebands increased significantly ($p<.05$) with cognitive decrement assessed on a global deterioration scale (GDS). Some of these relationships were particularly strong. Most notably, theta asymmetry in the fronto-temporal region correlated with global assessments of deterioration ($r=.81$, $p<.001$).

AEP measures for regularly produced auditory stimuli were examined for the anterior temporal regions (T3 and T4). The stimuli consisted of clicks with a duration of .1 msec, presented 8 feet from the patient with an intensity of 60 db at a rate of 1/sec over a 1-minute period. Fifty evoked potentials were averaged to produce the AEP waveform which we studied. We measured the latency of successive negative and positive peaks whick deviated more than 0.5 μv from the baseline. These peaks were labeled in an ordinal fashion, successively being designated N_1, P_1, etc. We constructed ratios of the longer of the two hemispheric latency measures to the shorter of the two hemispheric latency measures. Increased asymmetry of N1 and N3 correlated significantly with GDS assessments of deterioration ($r=.67$ and .60 respectively, p's<.05).

We conclude that although PDD is customarily thought of as a symmetric degenerative process, occurring to approximately the same extent in both brain hemispheres, it is logical to postulate that subtle asymmetric neurophysiologic changes do indeed occur. The electrophysiologic manifestations of these asymmetries appear to relate strongly to the severity of the disorder. These results also suggest that electrophysiologic asymmetries may be related to general impairments of cognitive processing accompanying PDD.

81.10 A CORRELATIONAL INVESTIGATION BETWEEN POWER SPECTRAL BANDS FROM MULTI-CHANNEL EEGs IN THE CAT. J. H. Stramler. Department of Biology, Texas A&M University, College Station, TX 77843.

The coherence measure represents, in the frequency domain, the degree of linear relationship at a given frequency between two channels of time series data. It has been observed that for EEG data the coherence measure is rather varient over time, and values are generally low, indicating the lack of such a relationship. However, this technique is not capable of comparing relationships between different frequencies. To explore a possible means of determining whether one frequency in one channel may correlate with another frequency in a second channel, data were used from an experiment which recorded multi-channel EEG activity from cats in both normal and drugged (physostigmine, scopolamine, amphetamine) states. The usual power, phase and coherence spectra were computed, but additionally correlation matrices were constructed from normalized power spectral intensities divided into a number of bands over the range of frequencies from 0-50 Hz. The resulting matrices were presented for visual examination using a Fortran subroutine PRTCM (Stramler, J. H. and Lewis, J. L., Behav. Res. Meth. Instr., 12: 471-2, 1980). In general, the linear correlations obtained with this technique were low, as are most coherence values, but a greater number of bands show significant correlations than would be expected by chance at the .01 level. The pattern of these correlations changes with state.

81.11 EEG CORRELATES OF INTELLIGENCE IN CHILDREN. Robert W. Thatcher, Mike L. Lester, Rebecca McAlaster and Richard Horst. Applied Neuroscience Inst., University of Maryland Eastern Shore, Princess Anne, MD 21853.

Two minutes of eyes closed EEG was obtained from 19 scalp locations (O1, O2, P3, P4, T5, T6, T3, T4, C3, C4, F3, F4, F7, F8, Fp1, Fp2, Fz, Cz, Pz) and a eye monitor channel in 196 children age 5 to 16. Power spectral analyses were performed on artifact free EEG samples yielding measures of absolute power, relative power; interhemispheric amplitude symmetry, and interhemispheric coherence in the frequency bands of delta (1.5 to 3.5 hz), theta (3.5 to 7.0 hz), alpha (7.0 to 13 hz) and beta (17 to 22 Hz). Psychometric tests were administered to each child which included the WISC-R, WRAT, Purdue Pegboard, The Stott, Moyers and Henderson test for Motor Impairment and measures of handedness. The psychometric statistics for the sample were full scale I.Q. (mean = 110.449, range 66 to 150), WRAT reading (mean = 112.659, range = 58 to 156), WRAT spelling (mean = 107.116, range 56 to 151), and WRAT arithmetic (mean = 98.572, range 63 to 149).

Hierarchical regression analyses in which age was regressed out yielded significant relations between WISC and WRAT scores and measures of interhemispheric coherence. A quadratic function (inverted "U") significantly fit the relation between interhemispheric coherence and I.Q. in the delta ($P < .01$) and theta ($P < .01$) frequency bands. A linear function was significantly related to I.Q. and interhemispheric coherence in the alpha ($P < .0002$) and beta ($P < .01$) bands. The former relationship was found in widespread regions of the scalp while the latter occurred strongest in frontal derivations. To test the strength of these relations "effect size" was calculated and split-half replications (BMDP P9R) were performed. The effect size power was .9995 and the split half replications were also significant.

81.12 AUDITORY BRAINSTEM EVOKED RESPONSES IN ATTENTION DEFICIT DISORDER WITH HYPERACTIVITY. Janet A. Camp* and Bertrand G. Winsberg* (SPON: Henri Begleiter). Long Island Research Institute, State University of New York at Stony Brook, Stony Brook NY 11794.

Although a variety of data provide circumstantial evidence that children with Attention Deficit Disorder with Hyperactivity (ADD/HA) are stigmatized by central nervous system (CNS) dysfunction, there is little direct data to support this notion. The present study addressed the question of CNS integrity in this population by asking whether 1) ADD/HA children differ from normal controls with respect to auditory brainstem evoked responses (BER), 2) the BER correlates with psychological/behavioral parameters used in diagnosing ADD/HA, and 3) methylphenidate (Ritalin) normalizes the BER.

Subjects were boys aged 67-154 months with IQ ≥86. The clinical sample (N=20) had been diagnosed as ADD/HA according to DSM-III criteria, and in addition all had received scores >1σ above the standardized mean on both the Attention and Hyperactivity factors of the Conners' Teacher Rating Scale; normal controls (N=20) all had received factor scores below this mean. A similar dichotomization was used with parental ratings of the child's behavior. Monaural BERs to left and right ear 60 dB clicks were recorded between the vertex and the ipsilateral mastoid, with the contralateral mastoid as ground. Data were recorded on tape, and tapes were edited to eliminate movement artefacts. All children were tested without sedation and were free of all other medications at the time of testing.

ADD/HA children showed significantly longer latencies for BER Wave I and Wave V, while brainstem conduction times did not differentiate the two groups. Since IQs for the control sample were significantly higher, a subsample of 10 children per group were matched for age and IQ; identical group differences were obtained from this subsample. Regarding behavioral parameters, no aspect of the BER correlated with any psychological or rating scale data obtained from the ADD/HA children. Finally, when half the ADD/HA children were reexamined under methylphenidate, both Wave I and Wave V latencies were significantly decreased.

Since the putative generators of both Wave I and Wave V of the BER receive efferent inhibitory inputs from more central CNS structures, it may be that the longer BER latencies in the ADD/HA children represent a peripheral reflection of a dysfunctional CNS inhibitory process. The fact that methylphenidate appears to correct this electrophysiological problem suggests that the drug may be acting on those structures involved in providing this inhibition.

82.1 PRINCIPLES OF USE OF FREEZE-SUBSTITUTION FOR FINE-RESOLUTION (2-DEOXY-D-GLUCOSE) GLUCOGRAPHY OF BRAIN. S.J. Schein and F.M. de Monasterio*. Clinical Branch, National Eye Institute, Bethesda, MD 20205.

Fine-resolution glucography, employing 2-deoxy-D-glucose (2-DG) to map rates of glucose utilization, promises discrimination of small structures and high signal-to-background ratios. The accumulated intracellular label, 2-deoxy-D-glucose-6-phosphate (2-DG-6-P), is water soluble, imposing severe constraints on how the tissue may be processed. The large size of most central nervous system material, from a rat brain (∿1.5 ml) to a cynomolgus monkey brain (∿60 ml) imposes an additional difficulty. Freeze-substitution has been used to retain localization of water-soluble molecules in thin material. We show here that freeze-substitution may also be used with large structures.

First, we discuss the physical principles of freeze substitution. The rates of withdrawal of water from a rat hemisphere or a gelatin block fall exponentially with time and are proportional to the surface area. The surface-normalized initial rate of withdrawal of water (R) is the same for a rat hemisphere as for a block of gelatin. These findings implicate diffusion as the mechanism of water withdrawal. For a given solvent, R declines as the temperature declines. The temperature dependence is not fit by a single line on an Arrhenius plot. Instead, the effect of lower temperature is to lower the solubility of water in solvent, and R falls proportionately. The nature of the solvent also plays a role: In tetrahydrofuran R is 0.016 gm/day·cm^2 for each percent water solubility. In pyridine, acetone and dimethylformamide, R is less by the factors 0.94, 0.38 and 0.26, respectively. These additional findings permit us to present a detailed description of the physical process of freeze-substitution, including the factors which affect it. Given these data, appropriate conditions of solvent, temperature and time may be determined for freeze-substitution of tissue of any size, even tissue as large as a monkey brain.

Second, using both ^{14}C- and ^{3}H-2-DG, we will demonstrate that preservation of strict localization of 2-DG-6-P may be obtained with freeze-substitution of brain.

82.2 THE INTERACTION OF BLOOD-BRAIN BARRIER TRANSPORT AND BRAIN PHOSPHORYLATION OF GLUCOSE AND 2-DEOXYGLUCOSE: A REEVALUATION OF THE LUMPED CONSTANT. W.M.Pardridge, P.D.Crane* and W.H. Oldendorf. UCLA School of Medicine, Los Angeles, CA 90024

The quantitation of regional brain glycolysis with the 2-deoxyglucose (2-DG) technique requires the use of a correction factor, the lumped constant (LC), which expresses the relative rates of phosphorylation of the two hexoses. Since LC is a function of λ (the relative brain volumes of distribution of the two sugars), it is to be expected that LC will not be constant, but will vary with the given physiological condition. For example, when brain phosphorylation rates are slow relative to blood-brain barrier (BBB) transport rates (e.g., the conscious or anesthetized states), the LC will approximate 0.4 (Sokoloff, 1977) and this reflects the greater affinity of hexokinase for glucose relative to 2-DG. However, when brain phosphorylation is limited by BBB transport (e.g., hypoglycemia or states of accelerated demand such as ischemia) then LC will equal or exceed values of 1.0 (Crane et al, J. Neurochem. 36:1601, 1981) and this reflects the greater rate of 2-DG transport through the BBB relative to glucose (Oldendorf, 1971). Although LC is not constant, this parameter can be reduced to absolute constants. Given these absolute constants, then LC can be predicted from data on only plasma (Ca) and brain (C_B) glucose. The absolute constants needed to predict LC from Ca and C_B are (i) the K_m, V_{max}, K_D of BBB transport of glucose and 2-DG and (ii) the k_3^*/k_3 ratio which is the ratio of fractional rate constants of hexokinase phosphorylation of 2-DG (k_3^*) and glucose (k_3). Therefore, in the present studies we determined for seven regions of the barbiturate-anesthetized rat brain the K_m, V_{max}, K_D of hexose transport and the k_3^*/k_3 ratio of hexose phosphorylation. Parameters for two regions are:

Hexose	Parameter	Hippocampus	Hemisphere
Glucose	K_m (mM)	5.5 ± 1.6	11.2 ± 2.7
	V_{max} (μmol/min.g)	0.47 ± 0.18	1.14 ± 0.37
2-DG	K_m (mM)	10.1 ± 3.8	7.7 ± 0.4
	V_{max} (μmol/min.g)	1.45 ± 0.76	1.15 ± 0.13
	k_3^*/k_3	0.26 ± 0.06	0.38 ± 0.16

Given known values for Ca and C_B, the calculated λ is 1.65 and 1.39, and the calculated LC is 0.43 and 0.53, for the hippocampus and hemisphere, respectively. However, under conditions of hypoglycemia, e.g., hypothetical values of Ca = 1.0 mM and C_B = 0.1 μmol g^{-1}, then the calculated values for λ and LC are 2.70 and 1.03 respectively, for the hemisphere. In conclusion, the lumped constant varies with changing plasma and/or brain glucose and the magnitude of LC can be predicted from known constants of BBB hexose transport and brain phosphorylation.

82.3 A COMPARISON OF THE BLOOD-BRAIN BARRIER TRANSPORT AND HEXOKINASE KINETICS OF 2-FLUORO-2-DEOXY-D-GLUCOSE AND 2-DEOXY-D-GLUCOSE. P.D.Crane*, W.M.Pardridge, L.D.Braun*, and W.H.Oldendorf (SPON:M.Philippart). Depts. of Neurology and Medicine, UCLA Sch. of Med.,and Brentwood VA Med. Ctr., L.A., CA 90073

The kinetics of transport across the blood-brain barrier (BBB) and metabolism in brain (hemisphere) of ^{14}C 2-fluoro-2-deoxy-D-glucose (FDG) were compared with that of ^{3}H 2-deoxy-D-glucose (DG) and D-glucose in the adult pentobarbital anesthetized rat. Saturation kinetics of transport across the BBB, measured with the brain uptake index (BUI) method (Oldendorf,W.H., Brain Res. 24:372, 1970) indicated a BUI of 56 ± 2 with a Km = 9.1 ± 1.5 mM, Vm = 2.6 ± 0.5 umol/min/g and the Ki of glucose inhibition of FDG transport was 10.7 ±4.4 mM. The kinetic constants of influx (k_1), efflux (k_2), and metabolism (k_3) for FDG were calculated from the Km, Vm, and plasma and hemisphere glucose concentrations, 2.51 umol/g and 9.7 mM, respectively. The lumped constant (LC) was obtained with the equation of Sokoloff et al. (J.Neurochem. 28:897, 1977), $LC = (k_1^*/k_1)(k_3^*/k_3)[(k_2+k_3)/(k_2^*+k_3^*)]$. The calculated LC for DG = 0.47 and for FDG = 0.71. We have predicted (Crane et al., J. Neurochem. 36:1601, 1981) that the LC will rise under conditions of transport limitation (hypoglycemia) or elevated glycolysis (ischemia, seizures) to a maximum = k_1^*/k_1 (1.2 for DG, 1.79 for FDG) and drop to a minimum = k_3^*/k_3 (0.34 for DG and 0.47 for FDG) during phosphorylation limitation in extreme hyperglycemia. Conclusion: The fluctuation of the LC can be predicted on the basis of the known Km and Vm of FDG and glucose transport across the BBB. Knowledge of this fluctuation in the LC is crucial in interpreting data obtained from ^{18}FDG analysis of regional glucose utilization in human brain in pathological states. (This study was funded by the American Diabetes Association, St. Louis Chapter, by NIAAA-AA03513, and by the Veterans Administration.)

82.4 RAPID TRANSIENT DROP IN BRAIN FREE GLUCOSE AFTER INTRAVENOUS PHLORETIN. W.H. Oldendorf, P.D.Crane*,and L.D.Braun*. Research Service, Brentwood VA Medical Center, Los Angeles, CA 90073 and Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Phloretin, the aglycone of the glycoside phlorizin, was injected into the tail vein of awake adult Wistar rats to assess its effect on brain free glucose (BFG). Dosage range was 30-90 mg/kg in 0.5 ml propylene glycol. Injection of the vehicle alone as a control had no measurable effect on plasma or brain glucose. Phloretin is an inhibitor of many transport systems and other enzymes but has an especially high affinity for non-sodium dependent glucose transport. When present in blood, it competes for blood-brain barrier (BBB) transport of glucose, diminishing influx of glucose into brain and BFG falls. At intervals up to 20 minutes after injection, the rat brain was brought rapidly (2 sec) to 90-100C by exposure to high intensity microwaves (12.4 cm mavelength, Gerling-Moore "Metabostat"). After cooling, the cerebral cortex was dissected free and its BFG determined enzymatically. Control rat BFG was 2.2 umol/g. By one minute after injection of 90 mg/kg, BFG was 0.8 umol/g, falling by 4 minutes to a minimum of 0.65 umol/g. After a single injection of phloretin, the BFG had returned to control levels by 15 minutes. One rat receiving 200 mg/kg died within 3 minutes, BFG not done. Although plasma glucose remained within normal limits, the animals exhibited behavior compatible with hypoglycemia (shivering, piloerection) during the periods when BFG was depressed. This approach provides a means of rapidly and transiently dropping BFG and may find application in experimental brain ischemia studies in which the influence of a lowered BFG might be of interest. These studies also suggest that the traditional symptoms and signs of hypoglycemia are related to lowered BFG and not to systemic hypoglycemia. (This study was funded by the Veterans Administration, the American Diabetes Association, St. Louis Chapter, and by NIAAA-AA03513.)

82.5 [^{3}H]2-DEOXYGLUCOSE TRANSPORT BY BRAIN SLICES: APPARENT ENERGY DEPENDENCE. Jayne T. Kyle and Barry I. Gold. Dept. of Pharmacol. Uniformed Services Univ., Sch. of Med., Bethesda, MD 20014.

Glucose transport by brain is thought to proceed by facilitated diffusion. Several investigators have, however, reported high affinity uptake of the glucose analogue 2-deoxyglucose (2DG) by synaptosomes. This process is sensitive to inhibition by the mitochondrial uncoupler 2,4-dinitrophenol (DNP). We have begun to study the uptake of [^{3}H]2DG by brain slices to explore the nature and apparent energy dependence of the glucose transport system in brain.

Rats were decapitated and the brains rapidly removed to a 0.9% saline-moistened filter paper atop an ice-filled petri dish. Cerebral cortex was dissected free of basal ganglia and brain stem and was cut into pieces (~50 mg). Brain slices were prepared with a Sorvall tissue chopper to an indicated thickness of 225 μ. Slices were transferred to vials containing a modified Krebs-Ringer-bicarbonate medium which was bubbled with O_2/CO_2 (95:5) immediately before the addition of slices. After a 5 min equilibration, [^{3}H]2DG or L-[^{3}H]glucose (both 0.1 μCi/μmole) was added to a final concentration of 0.5 mM. Transport was terminated 5 min later by rapid filtration over GF/B filters. The slices were rinsed, tissue was digested in Protosol, and radioactivity was estimated by liquid scintillation spectrometry.

Net transport, defined as the difference between [^{3}H]2DG uptake and the uptake of L-[^{3}H]glucose (the diffusion component) in parallel samples, was linear for at least 3 min and exhibited half-maximal saturation at 2.0 mM 2DG. Singular deletion of Na^+, K^+, Ca^{2+}, Mg^{2+}, or Cl^- from the incubation medium had no effect on net [^{3}H]2DG transport. Incubation of the slices in the presence of 4.0 μM A23187 or 5.0 μM tetrodotoxin did not alter net transport; preincubation in 1.0 mM ouabain was also without effect. DNP at 1.0 mM significantly inhibited net [^{3}H]2DG uptake whereas the glucose transport inhibitors phlorizin and phloretin in concentrations up to 0.1 mM did not affect net [^{3}H]2DG transport. The temperature coefficient (Q_{10}) of the transport system between 4° and 25° was estimated graphically to be 2.1. Preliminary results demonstrated decreased net [^{3}H]2DG uptake as a function of preincubation time in the absence of an energy source; this decrease was more pronounced in the presence of DNP.

These results are consistent with the hypothesis that glucose transport by brain slices proceeds, in part, by an energy-dependent mechanism different from glucose transport in other tissues.

82.6 PATTERNS OF ^{14}C DEOXYGLUCOSE UPTAKE IN THE BRAIN OF THE HIBERNATING GROUND SQUIRREL. T.S. Kilduff, F.R. Sharp and H.C. Heller*. Dept. of Biological Sciences, Stanford University, Stanford, CA and Dept. of Neurosciences, UCSD Medical Center, San Diego, CA.

The autoradiographic ^{14}C 2-deoxyglucose (2DG) method of labelling tissues as a function of their glucose utilization offers a global perspective on brain function by providing a pictorial representation of simultaneous metabolic activity. We have utilized this technique to describe changes in the metabolic activity of neural structures between euthermia and the different phases of hibernation. Golden-mantled ground squirrels (Citellus lateralis) were implanted with chronic jugular catheters and subcutaneous thermocouple re-entrant tubes. After injecting ^{14}C 2DG via the catheter (150uCi/kg body weight) and allowing an appropriate incubation time, the brain and spinal cord were removed, frozen, sectioned in a cryostat and exposed to X-ray film for 7 days. On the resultant autoradiographs, we measured the optical densities (OD) of the images of 85 neural structures. The relative 2-deoxyglucose uptake (R2DGU) of each structure was calculated as the ratio of the OD of the structure to the OD of the optic tract. The autoradiographs of brains of hibernators were remarkably homogeneous in comparison to euthermic animals; hence, the R2DGU decreased in almost all structures. Two categories of structures were identified as functionally important during hibernation: (1) structures which had the highest R2DGU during hibernation and (2) structures that underwent the smallest reduction in R2DGU when compared to the euthermic group. The former category includes several sensory nuclei which receive primary afferent projections (cochlear nuclei and superior colliculus), which may reflect the sensitivity of the hibernator to environmental changes, and structures implicated in sleep and circadian organization (locus coeruleus, dorsal tegmental nucleus and the suprachiasmatic nucleus (SCN)). Structures undergoing the smallest reduction in R2DGU between euthermia and hibernation include the SCN, pontine nuclei and a limbic structure, the lateral septal nucleus. The only structure of the brain to undergo a significant increase in R2DGU during hibernation is the paratrigeminal n., a poorly studied cell group of the medulla. The zone of activity in the autoradiographs is continuous between the paratrigeminal n. and the marginal zone of the spinal trigeminal nucleus. Because of the known thermosensitive function of the latter, a similar function is suggested for the paratrigeminal n.

An important general principle that has emerged is that the % reduction in R2DGU of a structure between euthermia and hibernation is directly proportional to the euthermic R2DGU of that structure. However, some structures undergo less of a reduction than would be predicted from this relationship and, hence, may have significant roles in hibernation. These include the paratrigeminal n., suprachiasmatic n. and cochlear nuclei. (Supported by NIH NS10367 to H.C.H. and Danforth and National Science Foundation Graduate Fellowships to T.S.K.)

82.7 REGIONAL BRAIN GLUCOSE UTILIZATION IS LOWER IN UNSTRESSED RATS. R. M. Bryan, R. A. Hawkins, A. M. Mans*, and R. B. Page*. Depts. of Surgery, Anesthesia, and Physiology, M.S. Hershey Medical Center of The Pennsylvania State University, Hershey, PA 17033.

The rate of cerebral glucose utilization (CMRglu) was measured in awake, freely moving, unstressed rats using (2-^{14}C)glucose autoradiography. CMRglu decreased as much as 40% and showed a different distribution between brain regions from that previously reported for conscious (paralyzed or restrained) rats, using either (2-^{14}C) glucose or ^{14}C-deoxyglucose. The jugular and epigastric veins were chronically catheterized and each rat was placed in a specially designed box for 7 days to recover from surgery. The rat could be viewed through a one way mirror. The catheters were accessible to the investigators by passing them through the top of the box. After recovery, plasma glucose was normal (7.5 mM), plasma ketones were low (0.13 mM), and body weight was maintained. Plasma catecholamines were lower than those ever reported for conscious rats; epinephrine (31 pg/ml) was approximately 1/100th of the level in restrained rats. Injections and blood withdrawals through the catheters did not produce changes in heart rate, blood pressure, plasma catecholamines, or blood metabolites. Visual observations demonstrated that the rats were unaware of (2-^{14}C)glucose injections and the subsequent blood sampling. This model thus provides a method for physiological studies in unstressed rats and has enabled the measurement, for the first time, of regional glucose utilization under basal conditions.

82.8 A NEW HIGH RESOLUTION POSITRON COMPUTED TOMOGRAPH (PCT) FOR MAPPING CEREBRAL GLUCOSE METABOLISM: STUDIES IN NORMAL AND SENSORY STIMULATED SUBJECTS. M.E. Phelps, E.J. Hoffman*, J.C. Mazziotta*, Div. of Biophysics and Dept. of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

A new neurological tomograph (NeuroECAT) consisting of 3 octagonal rings of 88 BGO detectors providing 5 simultaneous tomographic images has been developed. The high resolution mode provides an intrinsic resolution of 7.4 ± 0.5mm and a gantry tilt of ± 25° allows flexible image plane selection. This resolution is about a factor of two improvement over our previous tomograph. Images are reconstructed with an array processor in about 5 seconds per image plane and tomographic sections throughout the whole brain are rapidly viewed in a cinegraphic format (variable speed; gray scale or color) in transverse, coronal or saggital planes for convenient and rapid tracking of structures and extraction of local metabolic rates.

Studies of resting cerebral glucose metabolism with (F-18) fluorodeoxyglucose show the highest resolution brain studies performed to date. Images show clear delineation of the convolutions of the entire cortical ribbon, internal and external capsule, thalamus, basal ganglia separated by the anterior and posterior limbs of the internal capsule, separation between the putamen and insular cortex, brainstem, hippocampus and deep cerebellar substructures including the vermis and dentate.

The improved resolution of the NeuroECAT is also seen in the measured gray to white matter metabolic rate of 4 which is about a factor of two higher than with our previous tomograph (ave of 1.9) and is in agreement with the values found in monkeys and rats with autoradiography.

Auditory stimulation showed clear delineation of the known morphological asymmetries of Heschel's gyri and planum temporale (i.e., left larger and more posterior; right narrow, anteriorly angled and positioned). Requirements of memorizing the auditory input (evaluated by subsequent test) produced activation of the hippocampus. Metabolic patterns of visual and auditory stimulations of varying content will be presented to illustrate the potential of this technique.

We have also developed another approach for PCT: the signal amplification technique (SAT). Theoretical, computer simulation and an experimental study with a prototype tomograph illustrate that SAT provides a factor of two resolution improvement over the NeuroECAT. Examples of simulated brain sections with SAT will be shown.

PCT and physiologically active compounds labeled with positron emitting isotopes of F-18, C-11, N-13 and O-15 are setting a new standard for studying cerebral function in man.

82.9 POTENTIAL USE OF DIMETHYL SULFOXIDE TO OPEN THE BLOOD-BRAIN BARRIER. R. D. Broadwell, R. Kaplan* and M. Salcman. Laboratory of Experimental Neuropathology, Division of Neuropathology, Dept. of Pathol., Univ. of Maryland Sch. of Med., Baltimore, MD

In mammals the blood-brain barrier (BBB) prevents many blood-borne, non-fat soluble substances from gaining access to brain parenchyma. Ascertaining a non-injurious approach to reversibly opening the BBB would have important clinical implications in the polychemotherapeutic treatment of individuals harboring primary and metastatic brain tumors as well as in the delivery of psychotherapeutic drugs, antibiotics, and antidotes. One substance which offers clinical potential for temporarily opening the BBB is the membrane solvent dimethyl sulfoxide (DMSO). Forty-six mice were injected into the tail vein with 0.25-0.5 cc of 2-30% DMSO in combination with the enzymatic tracer horseradish peroxidase (HRP) (1 mg/gm body wt.). Within 2 hrs. HRP filled the extracellular clefts throughout the brain. HRP penetration was best with DMSO concentrations of 10% and above. Similar results were achieved in mice receiving 1 cc of 10-30% DMSO intraperitoneally and 0.25 cc of HRP intravenously. In the absence of DMSO, HRP failed to enter brain parenchyma except through the normally leaky circumventricular organs. The normal BBB is not absolute, however, for pericytes lying on the surfaces of cerebral microvasculature become labeled with HRP. Cerebral capillaries, arterioles, and pericytes associated with these vessels readily pinocytose HRP into vesicles which are channeled primarily to lysosomes, as identified by acid hydrolase cytochemistry. Pericytes perhaps serve as the first line of defense once the formal BBB has been breached. Pinocytosis of HRP and the lysosomal concentration in cerebral microvasculature appear to be increased with exposure to DMSO. Possible actions of DMSO in opening the BBB include stimulating vesicular transport through microvasculature, opening the tight junctions between contiguous endothelial cells, inducing the formation of transcellular endothelial channels, or rupturing the endothelial cell membrane. The latter possibility seems unlikely, since DMSO does not appear to adversely affect the ultrastructural morphology of brain parenchyma and vasculature. Whether or not vesicular transport occurs normally in cerebral microvasculature and is significantly increased by DMSO treatment require further investigation. Opening of the BBB with DMSO is transient. HRP entry into brains from mice intravenously injected with the protein 12 hrs. after DMSO treatment is similar to that seen in control mice. The search for a safe and effective means of reversibly opening the BBB may depend on an increased understanding of the mechanisms of barrier function as demonstrated in normal and DMSO-treated animals.

82.10 IN VIVO RELATIONSHIP OF INTRACELLULAR OXYGEN AVAILABILITY AND UTILIZATION DURING ANOXIA. K.Kariman*, F.F.Jöbsis, and S.R. Burns*. (SPON: P. Kaufmann), Departments of Medicine and Physiology, Duke University Medical Center, Durham, NC 27710.

To evaluate the relationship of oxygen availability and utilization within the cerebral cortex, we have examined, *in vivo*, the tissue PO_2 (P_tO_2) and the reduction-oxidation state of cytochrome *c* oxidase (*cyt a,a*$_3$) during anoxia. Thirteen cats were anesthetized, ventilated mechanically with room air, submitted to a limited craniotomy and then injected with 25 mg/kg of pyrene butyric acid (PBA) intravenously. One hour later P_tO_2, the redox state of *cyt a,a*$_3$ and the brain EcoG were measured simultaneously before, during, and after a one minute exposure to 100% nitrogen. These measurements were used to determine the range of responses from normoxia to values approximating anoxia (P_aO_2 ± 5 mmHg; no brain activity). Tissue PO_2 was measured from PBA generated fluorescence, emitted by monitored cerebral cortical cells. The *cyt a,a*$_3$ redox state was measured from differential absorption of monochromatic light at 605 vs 590 nm reflected from the same cortical cells. The following results were obtained: 1) in response to nitrogen ventilation, reduction of *cyt a,a*$_3$ occurred earlier and at a faster rate than decline in P_tO_2. At 50% of maximal reduction of *cyt a,a*$_3$ the tissue PO_2 decreased only 33 ± 4% (M ± SE) of total; when *cyt a,a*$_3$ reached its 100% reduction there was 78.9 ± 4% of total decline in P_tO_2. 2) In returning to the baseline, when animals were ventilated with room air, a similar lag between the increase in P_tO_2 and *cyt a,a*$_3$ reoxidation was observed. When *cyt a,a*$_3$ returned to 50% of baseline the P_tO_2 had returned only 20 ± 5% to the baseline P_tO_2. When *cyt a,a*$_3$ reached its baseline the P_tO_2 had returned only 66 ± 4% to its baseline. These observations indicate that hysteresis exists in the relation between P_tO_2 and *cyt a,a*$_3$ reduction level. This may be the result of the situation that 1) Low tissue oxygen concentration is partially compensated *in vivo* by accumulation of reduced *cyt a,a*$_3$. 2) Following brief periods of tissue anoxia the affinity of *cyt a,a*$_3$ to oxygen is increased.

Supported by a grant from the American Lung Association.

82.11 **DIFFERENTIAL RESISTANCE OF PERIPHERAL NERVE FIBERS TO ANOXIA.** B.R. Fink and A.M. Cairns*. Dept. of Anesthesiology, Univ. of Washington, School of Medicine, Seattle, Washington 98195

Ischemia involving peripheral nerve preponderantly tends to destroy myelinated fibers. We sought to evaluate whether these fibers are particularly susceptible to oxygen lack.

Desheathed cervical vagus nerve of rabbit was incubated at 37.5°C, pH 7.35 in Ringer solution containing (mM) $NaHCO_3$ 24 and glucose 5 or 20, bubbled with hypoxic or anoxic gas mixtures containing 5% CO_2 and N_2. Control nerves were treated with 5% CO_2 - 95% O_2. Stimuli supramaximal for A or for C fibers were applied once every 5-10 min. Compound action potentials were recorded on digital storage oscilloscope and magnetic disc. In other experiments NaCN 10 mM was present in the Ringer (pH 7.30), and the gas phase consisted of 10% CO_2 - 90% N_2. Solution P_{O_2}, pH and P_{CO_2} were monitored.

In controls the amplitude of the Aβ, Aδ and C components declined at average rates of 4 ± 6, 4 ± 3, and 2 ± 3 %/hr for 3 hrs, (n = 7). With 5.8% O_2 (n = 7) the decline rates were not statistically different from control. With 3.7-1.6% O_2 (n = 7) the decline of Aβ and Aδ averaged 13 ± 5 %/hr ($p < 0.02$) and 17 ± 3 %/hr ($p < 0.001$); the decline of C was the same as control.

In cyanide-Ringer with 5 mM glucose (n = 4) Aβ and Aδ were extinguished in 30 min; with 20 mM glucose Aδ survived at 50% of pre-cyanide amplitude in 2 of 4 nerves for over two hours. The C component was not extinguished by NaCN; with 5 mM glucose it declined by 50-70% and then partially recovered; with 20 mM glucose (n = 4) the total 3 hr decline averaged 23 ± 14%. Repetitive stimulation at 10/sec for 100 sec depressed C both before and during incubation with cyanide, and in both conditions was followed by recovery to the pre-stimulation amplitude within 15 min.

The results show that Aβ fibers are wholly dependent on oxidative phosphorylation for energy, the Aδ fibers somewhat less so. C fibers, in contrast, can maintain excitability under conditions of total anoxia, provided that enough ambient glucose is available to supply glycolytic energy. This result is surprising since C fibers have a smaller volume to surface ratio than A fibers, and on that basis should have a relatively lesser cytoplasmic capacity for glycolysis.

The observations extend existing data (Lundberg, Acta Physiol Scand 52:156, 1952) and suggest that unmyelinated fibers can survive functionally with little or no oxygen, but that myelinated fibers generally cannot. This may partly explain greater vulnerability of myelinated fibers in ischemic peripheral neuropathies.

(Supported by NIH Grant GM 27678-01)

82.12 HIGH-ACCURACY MEASUREMENT OF CNS ZINC AND LEAD BY STABLE ISOTOPE DILUTION MASS SPECTROMETRY. C.J. Frederickson, M.A. Mallory*, M.H. Frederickson, G.A. Howell, and W.I. Manton*. Laboratory for Geochronology, Univ. of Texas at Dallas, Richardson, Tx.

Recent work has suggested that the hippocampus contains large amounts of lead and zinc, but has left unresolved the absolute amounts of those metals. For the rat, Danscher et al. (Brain Res., 1976, 112: 442) suggest a hippocampal zinc content of 500 Parts Per Million (PPM) (dry weight), and a lead content of 18 PPM, Kemp and Danscher (Histochem., 1979, 59: 167) report 120 PPM for zinc, and 3 PPM for lead, and data in Fjerdingstad et al. (Brain Res., 1974, 79: 338) indicate that hippocampal zinc varies from 46 to 585 PPM among rats.

In search of an accurate assay for zinc and lead in the hippocampus, we turned to the geochemists' technique of stable isotope dilution. Samples were removed fresh, trimmed, lyophilized, and weighed, and then a known amount of stable isotope "spike" (enriched ZN-64 and/or PB-206) was added to the sample. Next, the sample was decomposed, allowing the atoms of endogenous metal to mix freely with the atoms of the spike, and the metal (endogenous and spike alike) was separated from the matrix by ion exchange. All tissue processing was done in a clean room in which personnel wore lint-free overgarments, room air was filtered, and work stations were washed by laminar-flow air showers. Finally, the isotope ratio of the mixture (ZN-66/ZN-64 or PB-208/PB-206) was measured on an isotope-ratio mass spectrometer, and the amount of metal originally present in the sample was computed. For Bovine Liver (National Bureau of Standards Material #1577), our procedure yielded zinc and lead concentrations within 2% of the Bureau's values.

We used adult, Wistar albino rats and found that lead in a single hippocampus or cord was below the limit (2 ng) of accurate measurement; pooled tissue from two sets of five rats gave the following lead concentrations: hippocampus, .053 and .054 PPM, cord, .017 and .019 PPM. For zinc, the values for the same tissue were: hippocampus, 73.1 and 72.2 PPM, cord, 26.8 and 25.4 PPM. Hippocampal zinc concentrations for 10 individual rats ranged from 59 to 79 PPM, with left and right hippocampi differing by an average of 4 PPM within animals; cord zinc ranged from 19 to 34 PPM, with left and right halves differing an average of 3 PPM.

The results indicate: (1) The absolute amounts of zinc and lead in cord and hippocampus are from 2- to 100-fold lower than recently published estimates; (2) The amount of zinc in both tissues varies relatively little among rats.

83.1 THE TIMING OF PROTEIN SYNTHESIS NECESSARY FOR THE ACQUISITION OF THE Na^+ ACTION POTENTIAL DURING DEVELOPMENT. L. Blair. Dept. of Biology, UCSD, La Jolla, CA 92093

The development of electrical excitability has been characterized in vivo for a population of developing spinal neurons, the Rohon-Beard cells of the clawed frog Xenopus laevis. When these cells first become excitable, their action potentials depend on an influx of Ca^{++}. They later acquire a Na^+ component to their action potentials and gradually lose the voltage-dependent Ca^{++} current (Baccaglini & Spitzer, 1977). Embryonic neurons in dissociated cell culture follow the same timetable (Spitzer & Lamborghini, 1976, Willard, 1980). Thus these cultures are a useful model system for studying the timing of the molecular events which underlie the development of the excitable membrane properties.

Protein synthesis inhibitors (cycloheximide, puromycin) have been used to find the time periods during which the proteins required for expression of these phenotypes are synthesized. Cultures of spinal neurons were made from neural plate stage embryos and plated in modified Steinberg's medium; no exogenous growth factors or other proteins were included. I have found that continuous exposure to inhibitors of protein synthesis, if started prior to 4.5-5 hr in culture (equivalent to early neural tube stage) prevents the appearance of morphologically differentiated neurons. Later addition of the inhibitor does not affect the normal outgrowth of neurites which occurs at 6-7 hr after plating.

These cultured neurons are normally capable of producing Ca^{++} action potentials as neurites are extended. A Na^+ component of the impulse is first detected at 10-15 hr after plating. Addition of inhibitor at 5 hr after plating did not affect the normal appearance of the Ca^{++} action potential, but blocked the acquisition of the Na^+ component. Later addition of the inhibitor, at about the time when the Na^+ current actually appears, did not affect the normal expression of this property. These results suggest that the protein synthetic events underlying the appearance of the Ca^{++} action potential occur very early in the development of these neurons. Thus, the period of RNA synthesis (D. K. O'Dowd, this volume) terminates shortly before the end of the period of protein synthesis required for the expression of the Na^+ component of the neuronal action potential.

83.2 THE TIMING OF RNA SYNTHESIS NECESSARY FOR THE DEVELOPMENT OF THE Na^+-DEPENDENT ACTION POTENTIAL IN CULTURED NEURONS. Diane K. O'Dowd. Department of Biology, UCSD, La Jolla, CA 92093.

The ionic dependence of the overshooting action potential (AP) changes during early amphibian development, both in Rohon-Beard neurons in vivo and in a more diverse population of spinal neurons in vitro (Baccaglini and Spitzer,'77;Spitzer and Lamborghini,'76). At the time of onset of electrical excitability the voltage-dependent inward current is carried largely by Ca^{++}. The AP at slightly later stages acquires a Na^+ component, and the ionic dependence of the AP shifts gradually until Na^+ is the major charge carrier. Such a developmental sequence presumably involves changes in the metabolism of RNA or protein, or both. In this study, RNA synthesis of cultured spinal neurons was inhibited at different stages of development, to elucidate the timing of some of the molecular events underlying the observed phenotypic changes. Effects of protein synthesis inhibition in this system have also been examined (Blair, L., this volume).

Cultures were made from dissociated neural plates of Xenopus embryos, grown in minimal medium with no exogenous proteins, and exposed to an RNA synthesis inhibitor (actinomycin-D) at various times after plating. The concentration required to block 95% of RNA synthesis in the cultured neurons was determined by autoradiographic analysis of ^3H-uridine incorporation. Cultures plated directly into medium containing inhibitor and examined after 24 hrs. do not contain differentiated cells with neurites. However, when the inhibitor is added 3 or more hrs. after plating (when sibling embryos are at early neural tube stage), neurons with identifiable neurites appear at 6-7 hrs. and can be maintained up to 3 days, as in control cultures. This result suggests that RNA synthetic events during the first few hours of culture are necessary for the production of neurites.

Neurons from cultures inhibited at 3-4½ hrs. are morphologically similar to controls and have normal resting potentials and input resistances. The AP's of these cells depend on Ca^{++} when they first appear; however, the ionic dependence of these impulses does not change even after 2½ days in culture. In contrast, the ionic dependence of the AP in control neurons changes from Ca^{++} to Na^+ during this period. Application of the inhibitor after the appearance of the inward Na^+ current (10-15 hrs. in vitro) doesn't affect the normal developmental progression to a chiefly Na^+- dependent AP. These data suggest that the inhibitor prevents the appearance of the Na^+ component of the AP by blocking RNA synthesis, rather than by causing nonspecific cellular damage. Presentation of the inhibitor at different times in early development has revealed a temporal window during which the Na^+ component of the AP is sensitive to inhibition of RNA synthesis. One possibility is that the RNA coding for the voltage-dependent Na^+ channel is synthesized during this period. (NSF predoctoral fellowship, NIH(NS15918), ONR(N00014-79C-0798)).

83.3 APPEARANCE AND DEVELOPMENT OF CHEMOSENSITIVITY IN EMBRYONIC AMPHIBIAN SPINAL NEURONS IN VIVO. John L. Bixby* and Nicholas C. Spitzer, Dept. Biol., Univ. Calif. San Diego, La Jolla, CA 92093

The development of several neuronal membrane properties has been studied in Rohon-Beard neurons of the embryonic Xenopus spinal cord, with intracellular microelectrode recordings. Previous work has shown that these cells develop the capability to make Ca^{++} action potentials at the neural tube stage, and that the ionic dependence of these action potentials gradually shifts to Na^+ over a period of 3-4 days. These cells are electrically coupled, in a voltage-dependent manner, prior to the time of appearance of the Ca^{++} spike, but become permanently uncoupled around the time of first appearance of the Na^+ component of the impulse. At late stages of development, these neurons are sensitive to GABA, and insensitive to a variety of other neurotransmitter candidates. Here we report the time of onset and subsequent development of this membrane property.

In mature cells (tadpoles 5-9 days old), bath application of 50μm GABA produces a conductance increase and depolarization recorded in the cell body. Iontophoretic application of GABA to the soma yielded dose-response curves with slopes as high as 330 mV/nC. The reversal potential of the iontophoretic response was determined by injecting current to adjust the membrane potential to different levels. Voltage-dependent conductances were largely blocked pharmacologically, and measurements were made in the linear portion of the cells' I-V relation. Although the depolarizing response could be inverted, determinations of the reversal potential were routinely obtained by extrapolation. The reversal potential has a value of -30.2 ±1.6 mV (n=11). Ion substitution experiments indicate that GABA causes increases in Na^+ and K^+ conductance. The responses are blocked by 50 μM curare or picrotoxin.

Rohon-Beard neurons become sensitive to bath application of GABA at the early tail bud stage of the embryo (30 hrs old), about the time when the cells acquire the Na^+ component of their action potential and become electrically uncoupled from each other. The acquisition of GABA sensitivity is tightly correlated with the presence of detectable inward Na^+ current, but neither of these membrane properties is well correlated with the loss of electrical coupling. The sensitivity of cells with Na^+/Ca^{++} spikes to iontophoretically applied GABA was comparable to that obtained from mature cells. The reversal potential at this stage has a value of -28.5±2.9 mV (n=8); this value is indistinguishable from that obtained for mature cells. Thus, as previously found for vertebrate skeletal muscle and invertebrate nerve cells, the ionic basis of the response to a neurotransmitter appears to be constant during the development of these vertebrate neurons.

83.4 ^3H-SAXITOXIN BINDING AND SCORPION TOXIN-STIMULATED $^{22}Na^+$ FLUXES SHOW DIFFERENT DEVELOPMENTAL KINETICS. Jesse Baumgold, J. Brian Parent* and Ilan Spector*. Lab. of Neurobiology, NIMH, Bethesda, Md 20205. Howard University Cancer Center, Washington, D.C., 20059 and Lab of Biochemical Genetics, NIH, Bethesda, Md 20205.

The kinetics of development of ^3H-Saxitoxin-binding and of scorpion-toxin-stimulated $^{22}Na^+$ fluxes were studied in chick skeletal muscle cultures. Myoblasts from 12 day old chick embryos were plated under tissue culture conditions which induced a very synchronous burst of fusion (myotube formation) 36-48 hours after plating. ^3H-Saxitoxin (^3H-STX) binding sites were not found in the unfused electrically inexcitable myoblasts. These binding sites were first observed around day 3 and were found to increase gradually until day 8, after which they remained constant at 6-7 fmole per mg protein. The dissociation constant for this binding was found to remain constant throughout this developmental process (Kd=1.6nM).

The developmental kinetics of the appearance of ^3H-saxitoxin binding sites correlates well with the previously published kinetics of the appearance of excitability (as measured by inward currents) in these same cells (Spector and Prives, P.N.A.S., 74: 5166, 1977).

The scorpion-toxin stimulated incorporation of $^{22}Na^+$ into cells in the presence of veratridine has recently been used in many labs as an assay for sodium channels. This toxin-stimulated incorporation of $^{22}Na^+$ can be inhibited in a dose-dependent manner, by the addition of tetrodotoxin (TTX). As an additional measure of the development of TTX-(or STX-) binding sites, we studied the dose-dependency of the TTX inhibition of the $^{22}Na^+$ flux into developing muscle cells. We found that, in contrast to the binding of ^3H-saxitoxin, the dissociation constant (half maximal effect) of the TTX inhibition of the $^{22}Na^+$ flux shifted considerably, during development, from 30-40 nM on day 3 to 3-6 nM on day 9. This finding indicated that the binding of ^3H-STX and the inhibition by TTX of the $^{22}Na^+$ flux measure different functional components of the "sodium channel" and that these components develop differently.

83.5 DEVELOPMENTAL CHANGES IN THE MEMBRANE PROPERTIES OF IDENTIFIED MOLLUSCAN NEURONS. Peter A. Pawson and Ronald Chase . Dept. Biol. McGill University, Montréal, Québec, H3A 1B1.

We have been studying the development of several identified neurons in the snail, Achatina fulica, from the last 1/3 of embryonic life to adulthood. In the course of an analysis of transmission at a developing synapse (Soc.Neurosci.Abstr.,Vol.6,p.677, 1980), we observed developmental changes in the waveforms of the spontaneous post-synaptic potentials (PSPs). Embryonic PSPs are slower rising and have much greater decay times than those recorded in the first month post-hatching; when the PSPs are more frequent, have faster rise-times and much faster decay times. In subsequent months; PSPs become less frequent, smaller in amplitude, have slower rise-times and are longer in duration.

To account for these observations, we examined some of the membrane properties of these neurons. The RMPs are similar during the period, as are the spike threshold values. The I-V curves are linear within ±15 mV of the RMP. Input resistances drop progressively from 97.42 ± 35.26 Mohms in embryos to 4.54 ± 1.73 Mohms in adults. There is however a striking change in the shape of the voltage transient in response to an intrasomatic current step. The time constant (Tm) of the neurons drops from 177.7 ± 51.54 msec. in embryos to 100.7 ± 53.83 msec. in 20-30 day-old animals. The Tm values then rise to an adult average of 312.54 ± 77.66 msec. The larger Tm found in embryos is not due to electrical coupling with other neurons, as a plot of ln (Vt/Vmax) vs. time is linear. Assuming a constant specific membrane capacitance during development, these changes in Tm values reflect changes in the neurons' specific membrane resistances. The apparent leakiness of the cell's membrane was also seen in that a cell with a short Tm also had a substantially higher value for rheobase current, although it possessed a normal threshold voltage value.

At the stage when the Tm values are the shortest, there is a large amount (both in terms of number of events and individual amplitudes) of spontaneous synaptic activity. It seemed possible that the large number of synaptic events might lead to a tonically higher resting membrane conductance, producing smaller Tm values. Using a 0 Ca/2xMg Ringer, we blocked all synaptic conductances and found that this had no effect on Tm values (103 ± 25%, N=10).

In conclusion, during the period of development when these neurons are presumably undergoing rapid morphological growth and increasing their number of synaptic inputs, their membranes exhibit a higher resting conductance level, unrelated to synaptic conductances. The aforementioned changes in PSP waveforms are therefore reflective of developmental variations in the resting conductances of the post-synaptic membrane.

83.6 ROLE OF CALCIUM CONDUCTANCE IN NEONATAL MOTONEURONS OF ISOLATED RAT SPINAL CORD. K.D.Walton and B.P.Fulton . Dept. of Biophysics, University College London, Gower Street, London, U.K.

We have previously reported the presence of Ca^{++} electroresponsiveness in spinal motoneurons (Mns) of neonatal rat (J.Physiol. 1981, in press). During this work it was noticed that spikes recorded from Mns of the youngest animals (3-6 d) differed from those recorded from older rats (to 11 d). This observation was investigated further in the light of the proposed role for Ca^{++} in neuronal growth (Llinas & Sugimori, Prog. Brain Res. 51: 323, 1979; Spitzer, Ann.Rev.Neurosci. 2: 363, 1979). The electrical properties of 3-6 d Mns are remarkable in three respects: 1. The antidromic spike is broad and has a prolonged afterdepolarization (ADP). 2. Spikes elicited by direct stimulation have a marked delayed depolarization (DD) and afterhyperpolarization (AHP). 3. The DD amplitude is increased by broad, small 'spikes', often accompanied by an increase in AHP amplitude.

In experiments where Mn^{++} or Mg^{++} replaced Ca^{++} in the saline, a Ca^{++} conductance was shown to be responsible for the increased width of the antidromic spike, and the DD and small 'spike' following the direct spike. Under these conditions the antidromic spike became narrower, its ADP was smaller and the direct spike was not followed by a DD or its 'spike'. Also, the AHP was absent suggesting that a Ca-dependent g_K underlies this potential. The input resistance was not significantly changed. Consistent with the interpretation that a Ca^{++} conductance underlies these phenomena is the finding that when g_K was progressively blocked by intracellular injection of Cs^+ the DD increased in amplitude and developed into a regenerative TTX-resistant spike.

The contribution of Ca^{++} entry to determining the repetitive firing of developing Mns (3-11 d) was studied. Firing during long current pulses (1.5 s) was examined in normal saline and saline in which Mg^{++}, Mn^{++} or Cd^{++} replaced Ca^{++}. Plots of firing frequency vs current in Mg^{++}, Mn^{++} and Cd^{++} salines were displaced upwards and had an increased gain with respect to controls. These results suggest that an increased intracellular Ca^{++} concentration, by activating a Ca-dependent g_K, limits the Mn firing rate for a given current level.

The presence of a marked Ca-dependent electroresponsiveness in spinal Mns during the first few postnatal days and its decrease with maturation is consistent with the suggestion that this early g_{Ca} is related to cell growth. In addition, the present results provide evidence that modulation of this Ca^{++} conductance serves to regulate Mn repetitive firing during development.

84.1 CORTICO-DCN PROJECTIONS FROM FUNCTIONAL SUBFIELDS OF SENSORI-MOTOR CORTEX IN THE CAT: AN ANTEROGRADE HRP STUDY. S.S. CHEEMA, A. RUSTIONI, B.L. WHITSEL. Depts. of Anatomy and Physiology, Univ. of North Carolina, Chapel Hill, N.C. 27514.

The organization of corticofugal projections upon the dorsal column nuclei (DCN) of adult cats were investigated by the use of anterograde transport of HRP. HRP injections were placed in various body representations involving areas 4,3a,3b,1 and 2. The availability of a detailed, "flattened" map indicating the somatotopic and functional arrangement in S_I of the cat (McKenna et al., 1981) allowed the injection of selected parts of this region without the need for electrophysiological monitoring. The terminal pattern of cortico-DCN fibers was reconstructed from 40µm thick, serial sections incubated in TMB. The results from different experiments were superimposed on a standardized,stereotaxic map of the DCN derived from serial series of Nissl stained sections, spaced one millimeter apart and normalized with reference to the obex. In our hands, the HRP-TMB method for anterograde tracing of pathways had greater sensitivity than the method of anterograde transport of tritiated aminoacids.

HRP injections that infiltrated the entire sensorimotor cortex labelled cortico-DCN fibers whose terminations were present at all levels of the DCN extending from 9 mm below to 4 mm above the obex. The terminal fields of the cortico-DCN fibers labelled by such large injections included the clusters region of both gracile and cuneate nuclei as well as the non-cluster regions. In both nuclei the maximal density of fibers labelled by large injections occupied terminal sites located ventral to the clusters region. When the enzyme injection was restricted to area 4, corticofugal afferents to the DCN were also distributed throughout the longitudinal extent of these nuclei but the clusters region was spared. On the other hand, after injections restricted to the hand representation of areas 3a and 3b, terminal labelling was negligible at the base of the cuneate nucleus, while patches of terminals were present in the clusters region.

Attempts are presently being made to combine TMB histochemistry with electron microscopy to identify the type of synapses established by corticofugal fibers reaching the clusters region of the DCN. Besides demonstrating a precise pattern of cortico-DCN connections which appear relatable to S-I topographic organization, the present results provide a map of DCN connectivity which shall be related to the nuclear terminations accessed by peripheral nerves as visualized by transganglionic transport of HRP and to maps of the body representation in the DCN obtained by the method of single unit analysis. (Supported by USPHS grants NS 16264).

84.2 VESTIBULAR INPUT TO MOTONEURONS OF THE CAT LATERAL FACIAL NUCLEUS. M. Shaw* and R. Baker (SPON: J. Gruner). Dept. Physiol. and Biophys., New York Univ. Med. Ctr., New York, N.Y. 10016

Previous studies have revealed that second order vestibular neurons which project to extraocular motor nuclei may also send axon collaterals to the lateral portion of the facial nucleus. To determine the synaptic effects following vestibular stimulation, intracellular recordings were obtained from antidromically identified facial motoneurons in the lateral subgroups.

Stimulating electrodes were placed on the superior buccal, zygomatic and nasal branches of the facial nerve to identify motoneurons innervating, respectively, the upper lip, orbicularis oculis (eyelid closure) and quadratus labii superioris muscles (whisker erection). Electrodes were also placed on both vestibular nerves and the facial nerve near the geniculate ganglion. Retrograde HRP injections and antidromic activation indicated that the motoneurons of orbicularis oculis and quadratus labii superioris lie intermingled in the dorso-lateral subgroup of the facial nucleus. Neither population received synaptic input from contralateral vestibular stimulation. Both populations contained some cells which received disynaptic input from ipsilateral vestibular stimulation, either an EPSP (latencies 1.1-2.2 msec) or an IPSP (1.1-2.2 msec). Stimulation of trigeminal fibers often induced EPSPs with latencies of 1.5-3.0 msec. Motoneurons activated antidromically by superior buccal nerve stimulation, located in the ventro-lateral subgroup, never displayed synaptic responses to vestibular stimulation. Another subgroup of motoneurons, on the medial edge of the dorso-lateral subgroup, could only be antidromically activated by stimulation of the whole facial nerve. Based on their location, these neurons probably project to the corrugator supercilii muscle, which pulls the ear forward. They received no ipsilateral vestibular input, but always had a disynaptic EPSP response to contralateral vestibular stimulation with latencies of 1.1-2.0 msec. These neurons also received longer latency EPSPs from trigeminal pathways.

We have demonstrated, with electrophysiological techniques, excitatory and inhibitory monosynaptic projections from second order vestibular neurons upon facial motoneurons. The input is segregated by nuclear subgroup. Since the activity of second order vestibular neurons projecting to both the extraocular motor nuclei and the facial nucleus relates to eye movement, the vestibular projection to the lateral facial nucleus must, in part, aid in the coordination of eyelid, whisker, ear and ocular movements. Supported by NIH #EY0504, Fight-For-Sight, NYC #F-346 and USPHS #NS13742.

84.3 SIMPLE REACTION TIME IS UNCHANGED BY COOLING MONKEYS' VENTRAL LATERAL THALAMUS[1]. A. D. Miller and V. B. Brooks. Department of Physiology, The University of Western Ontario, London, Ontario N6A 5C1, Canada.

The pathway through ventral lateral (VL) thalamus from cerebellum to motor cortex was tested for participation in movement initiation. Three Cebus monkeys performed a simple reaction time (RT) task involving prompt elbow flexion or extension in response to an audiovisual GO! signal. Mean RTs were on the order of 300 ms as detected by a velocity threshold. RTs were not changed by reversible cooling of the VL arm area (which includes rostral VPL) contralateral to the operant arm (20 trials). The caudal-lateral portion of n. centralis lateralis (CL) was also included in the region cooled in one of these monkeys. In contrast, cooling the ipsilateral cerebellar dentate nucleus prolonged RTs by about 75 ms, as tested in 2 of the same monkeys (18 trials). These delays of movement onset were not due to lower initial velocities during cooling. The results confirm cerebellar participation in prompt generation of well-learned intended arm movements (J. Neurophysiol. 1977, 40: 1038-1050), but they also indicate that the route through the VL arm area to motor cortex is not essential for initiation of the same movements. The supposition is made that at least 3 sets of parallel pathways normally sustain each other: cerebello-thalamic to motor cortex and cerebello-thalamic to association cortex, e.g. supplementary motor area (SMA), and hence to motor cortex. In addition, spinal projections from motor cortex can converge with cerebello-reticulospinal projections.

84.4 COORDINATION BETWEEN GRIP FORCE AND VERTICAL LIFTING FORCE WHEN LIFTING OBJECTS BETWEEN INDEX AND THUMB. R. S. Johansson* and G. Westling* (SPON: R. H. LaMotte). Dept. of Physiology, Univ. of Umea, S-901 87, Umea, Sweden.

Precision manipulation of a small object requires a refined coordination of the forces exerted on the object by the tips of the fingers and thumb. The present paper deals quantitatively with this coordination.

A small object, standing on a table, was gripped between the index and thumb, lifted and held stationary about an inch above the table. The weight and the surface structure of the object could be changed between consecutive liftings without changing its visual appearance. Three sets of surface structures were used (sandpaper, suede, silk), all of which had different coefficients of static friction in relation to the skin.

The grip force (GF) and the vertical lifting force (LF) acting on the object were measured, as well as the vertical position of the object. When the object was gripped, there was a small, short lasting increase in GF. Thereafter, the GF and LF increased in parallel until the LF overcame the force of gravity acting on the object and the object began to move. In contrast to the rate of LF increase, the rate of GF increase was dependent on the surface structure of the object. The lower the friction between the skin and the object, the higher the GF/LF ratio.

After a transitional phase in which the object was elevated, the GF reached a static value and the LF counterbalanced the force of gravity acting on the stationary object. The static GF force was greater, by a small safety margin, than the minimal grip force required to prevent slippage. This minimal force, in turn, was dependent on the friction and the weight of the object. The safety margin varied between subjects and could be influenced, to some degree, by the surface structure of the object in the previous trial. Local anaesthesia of the fingers abolished the appropriate adjustments of the GF with changes in friction.

We conclude that when a small object is lifted, the friction between the gripped object and the skin of the finger tips profoundly influences the coordination between the muscle units accounting for the GF and the LF. This was the case during the dynamic as well as the static phases of the liftings. The findings probably apply to fine manipulation in general in the sense that friction unconsciously influences the relationship between the GF and the forces applied to overcome forces counteracting intended manipulation. The CNS most likely obtains information about friction via cutaneous mechanoreceptive afferents.

84.5 ACTIVATION MECHANISMS AND RECOVERY OF FUNCTION AFTER UNILATERAL DORSAL RHIZOTOMY IN THE MONKEY. A.J. Berman, D.E. Teodoru, T.A. Tran.* Dept. of Neurosurgery, V.A. Hospital, Bronx, N.Y. 10468.

The sequence of recovery of function in monkeys after both unilateral and bilateral dorsal rhizotomy (DR) of the forelimbs is such that movements which bring the deafferented limb into contact with intact body parts occur long before movements which extend the limb into extrapersonal space. This can be attributed to substitution of sensation from intact body regions for sensory feedback from the responding limb. To examine the relationship between sensory substitution and disuse of a DR limb, five monkeys with unilateral DR, two of which had undergone bilateral dorsal column nuclei (DCN) lesion six months previously, were tested. A grape was brought into contact with intact body areas (face, torso, or arm) or was placed into the non-DR hand which was restrained. In all cases, the animals used their DR limb to reach smoothly and accurately, grasp and bring the grape to the mouth. Blindfolding did not degrade the movement with the exception that, if the grape was placed in the restrained non-DR hand, the deafferented hand of the three DR monkeys failed to grasp when the non-DR hand opened to transfer the grape. This was true even though thumb-finger apposition on the DR side was occuring regularly in other situations. Testing was continued for a total of over 500 trials, but the grape was always dropped. On the other hand, the two with DCN lesion as well as DR were able to transfer the grape from the DCN to the DCN-DR hand when blindfolded.

The inability of animals to make simultaneous movements of their non-DR and DR limbs in response to a sensory cue from the non-DR side may be based on a biasing of lateralized attentional mechanisms. Sensory input is believed to activate subcortical attentional mechanisms which control cortical responsiveness to ascending input (Wright, et.al. 1978). Sensory guidance of movements, on the other hand, functions by means of cortical circuits (Evarts, 1973). When sensory input from the non-DR side of the body is used to guide ipsilateral movements, subcortical attentional mechanisms may block interhemispheric transmission of the information to the contralateral side.

Since monkeys with bilateral DCN lesion and unilateral DR are capable of using residual input from the non-deafferented limb to guide both limbs, it can be inferred that they can transmit sensory information transcortically. Thus, DCN must be a part of the lateralized attentional mechanisms as proposed by Wall (1970).

84.6 DYNAMIC ROLE OF RUBRAL NEURONS IN CONTACT PLACING IN CATS. Deirdre Batson*, Vahe Amassian and Larry Eberle*. Dept. of Physiology, SUNY Downstate Medical Center, Brooklyn, New York, 11203.

Destruction of the feline red N abolishes contact placing (CP) in the contralateral forelimb (Amassian in: Integration in the Nervous System, 279-304 pp, ed: H. Asanuma and V. J. Wilson, Igaku-Shoin,1979). To test for a possible dynamic role of red N in CP, we recorded from individual rubral neurons with our standard techniques. Parameters of placing movements were monitored with photoelectric or force transducers supplemented by TV-Computer measurements at 60 Hz of shoulder, elbow and wrist joint angles. After being brought into contact at various positions on the placer, the forepaw (unguided by vision) had to ascend different distances before reaching the top of the apparatus.

Antidromic invasion following stimulation of contralateral caudal medulla was demonstrated in 52% of the 84 neurons recorded ; antidromic latencies ranged from 0.5-2.5 msec. In 54 neurons responding during the first phase of CP (lifting-withdrawal), the firing rate initially increased in 93%. The variable interval between contact and the onset of movement aided the differentiation of four types of response: 1) locked to initial contact regardless of whether CP subsequently occurred; 2) locked to initial contact, but markedly reduced or even reversed if CP subsequently failed to occur; 3) locked to and preceding movement by eg. 40-180 msec; 4) locked to, but starting either with or during , the movement. In types 1) and 2), the contact locked activity had a short latency eg, 20-40 msec and usually persisted during the contactual ascent. In all types, the increased discharge rate usually fell (sometimes transiently) when the forepaw broke contact at the top of the placer. Rarely, neurons began responding at this transition. A precontact response (presumably vestibular related) was identified in some neurons if the animal was rapidly moved towards the placer.

Types 2) and 3) rubral neurons increase in discharge rate in time to contribute to activation of the flexors that cause the lifting-withdrawal phase of CP. However, contactual ascent results in further cutaneous stimulation, presumably accounting in part for the maintained discharge of some rubral neurons, which in turn may contribute to continued contactual ascent of the forepaw. Such a positive feedback arrangement presumably involves a coordinated contraction of agonists acting at several joints, but not the muscle directly related to the cutaneous area stimulated, extensor digitorum communis being strongly inhibited following contact with the dorsum of the forepaw.

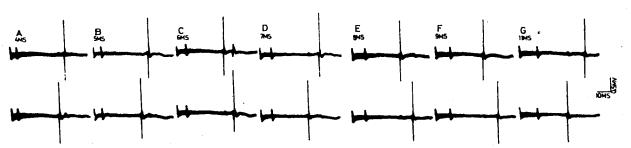
84.7 H-REFLEX RECOVERY STUDIES WITH SINGLE FIBER EMG. M.A. Sabbahi and E.M. Sedgwick*, Liberty Mutual Research Center, Hopkinton, MA., U.S.A., and Wessex Neurological Center, Southampton, U.K.

The primary facilitation and inhibition periods of the H-reflex recovery curve with paired stimuli are not well understood. Peripheral as well as central factors are involved in these recovery periods.

In this study a total of 30 motor units (MU) were studied by single fiber EMG while recording the H-reflex. The H-reflex was elicited by stimulating the posterior tibial nerve unifocally at threshold strength. The soleus muscle action potential was recorded using unipolar single fiber needle as well as surface electrodes. Single muscle fiber recording followed previously reported criteria (Sabbahi, 1976). Identical paired 1 msec pulses with varying interstimulus intervals or a conditioning train of 17 pulses for 30 msec followed by a test pulse at intervals were used.

Results show that with paired stimuli at threshold level the MU fired at H_1 only while with subthreshold stimuli it fired at H_2. It never fired simultaneously at H_1 and H_2. This dual firing occurred at 2-12 msec interstimulus interval with maximum firing occurrence at H_2 at 5-6 msec. H_2 was never recorded between 12-80 msec. When the subthreshold pulse train preceded the test stimulus with 1-10 msec they summated to fire the MU at H_2. From 10-15 msec, firing occurrence decreased with firing failure between 15-50 msec. Recovery was noticed after 50 msec interval when threshold testing pulses were used.

These results indicate no primary facilitation period in the recovery curve. The H_2 reflex during early periods is possibly due to temporal summation. Primary inhibition period lasted up to 50 msec due to strong inhibition mechanisms.



The motoneuron fired during either H_1 or H_2 but never during both.

84.8 THE HOFFMANN REFLEX IS ENHANCED BY SENSORY STIMULI. A. P. Rudell. Dept. of Physiol., Downstate Medical Center, SUNY, Brooklyn, N. Y. 11203.

A sudden sensory stimulus, such as a tone pip or a light flash produces a general arousal reaction. In cats it has been demonstrated that such stimuli enhance electrically evoked responses recorded from the visual cortex and from skeletal muscles.[1] A similar effect has now also been demonstrated in human subjects, using the Hoffmann reflex (H-reflex) as the response indicator.

The H-reflex is elicited by electrical stimulation of the tibial nerve, the response being recorded from gastrocnemius and soleus muscles. It is the electrical analog of the stretch reflex that is usually elicited by tapping the Achilles tendon. The response is monosynaptic. Fluctuations in the amplitude of the H-reflex may be due in part to fluctuations in the excitability of the alpha motoneurons.

Preliminary results indicate that a portion of the auditory visual, or somatosensory afferent signal is transmitted to the spinal cord, where it increases the excitability of the gastrocnemius alpha motoneurons.

A question of primary importance is the time course of the change in excitability following a sensory stimulus. An estimate of the time course was made by varying the interval between the onset of the sensory stimulus and the presentation of the electrical stimulus to the tibial nerve. For tone pips the minimum interval for enhancement of the response was 30 to 60 msec. Greatest enhancement occurred at about 150 msec, at which interval the H-reflex could be as much as ten times greater than the control level. A period of suppression below control level was observed at about 200 msec. The effects of light flashes and tone pips were similar, but the minimum time interval and the interval for greatest enhancement were about 30 msec longer for light flashes than for tone pips. Vibratory stimuli showed an intermediate time course.

The short minimum latency required for enhancement, taking into account the substantial conduction time from the sensory afferents to the spinal cord, indicates that a relatively direct connection exists between sensory afferents and alpha motoneurons.

84.9 EFFECT OF COOLING ON STRETCH REFLEXES. P. Bawa and I. Mekjavic* Kinesiology Dept., Simon Fraser University, Burnaby, B.C., V5A 1S6.

Torque motor imposed angular displacements of upper limb joints result in two main reflex components in the EMG recorded from stretched muscles. Similar two components have been observed in wrist flexors during tendon taps. These two components are distinguished primarily by their latencies. Experiments were conducted on cooled human subjects to test whether there were differential effects on the latencies of the two components. Also, whether the observed impaired motor control during hypothermia is reflected in abnormal reflexes.

The subject was immersed in 10°C or 15°C cold water monitoring their heart rate, esophageal, rectal and tympanic temperatures. He was taken out after an hour or when his esophageal temperature dropped to 35°C. He sat in a sleeping bag for rewarming while his reflex data were collected every ten minutes. EMG was recorded from wrist extensors and flexors. Reflexes were elicited both with a torque motor and with tendon taps of the wrist flexors. Rectified and unrectified records were averaged on a PDP8 computer.

No differential effect of temperature was apparent on the shorter or longer latency (SL or LL) components when the stretches were imposed by torque motor. However, when the tendons were tapped there was an additional delay of 4-5 msec in the SL component and 7-8 msec delay in the LL component at the lowest temperature as compared to the precooling values. This would suggest that the two reflex pathways for the SL and LL components are separate. The additional delay in the LL component above that of the SL component is perhaps due to slowing down of the synaptic transmission and/or slowing down in the conduction velocity in the 'long-loop' pathway. The lack of any apparent effect with torque motors is attributed to the slower rates of stretches and lesser degree of synchronization of afferent volleys resulting in broad overlapping reflex peaks.

The impaired motor performance during hypothermia is not related to large abnormalities in reflexes. It may perhaps be localised to the muscle itself.

This work was supported by BCHCRF and NSERC. The authors are thankful to Prof. R.B. Stein for the use of his computer.

84.10 REGULATION OF HUMAN TRICEPS SURAE MUSCLE STIFFNESS BY SHORT LATENCY REFLEXES. K.-H. Mauritz*, J.H.J. Allum and H. Vögele*. Brain Research Institute, University of Zurich, CH-8029 Zürich, Switzerland and Dept. of Neurology, University of Freiburg, D-78 Freiburg, Germany.

The incremental stiffness of human triceps surae (TS) muscles was tested by rotating the foot about the ankle joint. Subjects were asked to maintain a constant force prior to each rotation by contracting TS. For the force range used, 6 to 20 Nm plantar flexion, the antagonist tibialis anterior (TA) muscles were inactive. The rotations, 1 to 8 degrees amplitude, were applied by a servo-controlled torque motor which otherwise held the foot isometrically. To observe separately the two mechanims contributing to incremental stiffness (the intrinsic visco-elastic stiffness of active muscle and the force recruited via the stretch reflex) the duration of foot rotations was limited to 60 msec.

Muscle force in response to rotations stretching TS exhibited a step increase followed by rapid yielding as stretch velocity decreased. At 55 ms TS reflex action reversed this yielding. Force then continued to increase and then levelled off just prior to medium latency TS activity at 120 ms. The incremental force just prior to yielding (a measure of intrinsic visco-elasticity) increased with the prior level of tonic TS contraction, whereas the total force increment at 120 ms remained roughly constant. Muscle force in response to release of TS showed only a slow yielding once release terminated. Weak reflex activity at 70 ms in TA and TS arrested this yielding.

Our results indicate that short latency reflexes compensate for muscle non-linearities and regulate muscle stiffness. Similar results have been reported for cat soleus muscle (Nichols, T.R. and Houk, J.C., J. Neurophysiol. 39: 119, 1976; Hoffer, J.A. and Andreassen. S., J. Neurophysiol. 45: 267, 1981).

84.11 ADAPTIVE PLASTICITY OF PRIMATE M1 RESPONSE. J. R. Wolpaw, V. A. Kieffer*, D. J. Braitman and M. G. Sanders*. Div Labs Res, NYS Dpt Hlth, Albany NY 12201; AF Radbiol Res Inst, Bethesda MD 20014.

To learn if the earliest, largely monosynaptic, M1 component of the muscle stretch reflex can adapt, we trained rhesus monkeys to maintain elbow angle at 90°(±1.5°) against steady extension force. If correct angle was held for a randomly selected 1-2s period, and if the average absolute value of biceps EMG (from chronic i.m. electrodes) for the final 0.5s was 1.0-1.5 X a preset value, a 20ms pulse of extra extension force occurred. This stimulus (stim) extended the elbow 3-4°. M1 amplitude (amp) was measured as the average absolute value of biceps EMG 12.5-21.5ms after stim onset minus pre-stim EMG amp. Under the Control condition, reward was given 70ms after stim onset. Under the M1↑ or M1↓ condition, reward was given only if M1 was greater (M1↑) or less (M1↓) than a criterion value. Control and M1↑ or M1↓ data were obtained from each of 6 monkeys over 2-5 mos. Each usually completed 2500-6000 trials daily. Electrodes, pre-stim EMG, steady extension force, stim amp, and stim-induced movement were stable throughout.

Under the impetus of the M1↑ or M1↓ condition, 5 of the 6 monkeys markedly and appropriately changed M1 amp (Fig), while one showed no change. Changes became evident in 3-5 days, could continue to develop for at least 4 wks, and did not regress during the 2-4 day rest periods (Fig.). M1↑ could increase M1 to nearly twice control M1, while M1↓ could decrease it to less than 1/3 control.

Monkeys can markedly change M1 amplitude over days, without change in alpha motorneuron tone as measured by pre-stim EMG amp. Possible mechanisms include change in gamma motorneuron tone, in alpha motorneuron recruitment, or in Ia synaptic function.

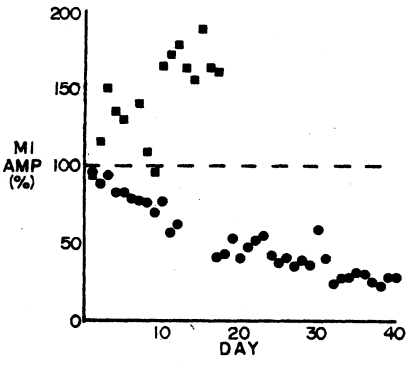

Fig. Squares are daily M1 amplitudes of one monkey after onset of M1↑ training; circles are daily M1 amplitudes of another monkey after onset of M1↓ training. M1 amplitudes are given as % of the monkey's average control M1 amplitude for the preceding 6 days. Each point represents 2500-6000 trials. Breaks in data are rest periods.

84.12 LONG LATENCY REFLEXES IN PATIENTS WITH COMPLETE SPINAL CORD TRANSECTION. K.C. Hayes*, K.L. Robinson* and J.D. Spencer* (SPON: J.D. Cooke) Fac. of Med., Univ. of Western Ontario, London, Ontario N6A 5C1.

The current interest in long latency stretch reflexes in spinal animals prompted our investigation designed to test whether similar long latency autogenic facilitation could be found in spinal man. H-reflex recovery curves were recorded from four patients with verified complete transection of the spinal cord. The recovery curves were obtained following conditioning with subthreshold and suprathreshold H-reflex stimuli. The mean subthreshold conditioned recovery curve exhibited periods of pronounced facilitation at interpulse intervals of 10 msec, 50-75 msec and 150-175 msec that were superimposed upon a long lasting (>1000 msec) depression of alpha motoneuron excitability. The time course of these periods of facilitation and inhibition showed a close correspondence to H-reflex recovery curves recorded from normal subjects. Differences were noted, however, in the amplitude and duration of the various phases of facilitation. The early phase, which peaked at 10 msec, and corresponded to EPSPs, was extended in one patient who had been a spastic quadriplegic for 12 years. This observation may reflect compensatory axonal sprouting of Ia afferent fibres. Facilitation at IPI= 50-75 msec occurred slightly earlier in all four patients than in normal subjects. Although supressed by a profound inhibition, the same three periods of facilitation were identifiable in the recovery curves following suprathreshold conditioning stimuli. These results indicate the presence of mechanisms intrinsic to the spinal cord in humans that are capable of yielding rhythmic autogenic facilitatory effects in response to a unitary discharge from Ia and cutaneous afferents. Identification of this spinal mechanism in humans appears to provide further insight into the pathophysiology of myoclonus and the mechanisms of load compensation.

85.1 SENSORY TRANSDUCTION IN THE COCKROACH FEMORAL TACTILE SPINE. Andrew S. French and Janice E. Kuster*. Department of Physiology, University of Alberta, Canada.

The femoral tactile spine of the cockroach has been used in a number of previous quantitative studies of sensory transduction because of the relative ease with which it can be stimulated and recorded from. Recent work in this laboratory has shown that the transduction mechanism may be characterised as a linear dynamic system with memory followed by a nonlinear system without memory. The linear component behaves as a fractional differentiator over the frequency range which has been studied.

Although the receptor has been used in a number of functional studies, we have only recently described its ultrastructure. The morphological findings place the receptor in the group of cuticular arthropod mechanoreceptors, characterised by a dense dendritic sheath and well defined tubular body, which is typical of trichoid sensilla, campaniform sensilla and chordotonal organs. However, the mechanical linkage between movement of the tactile spine and deformation of the sensory ending is not directly comparable with any of these three groups.

There are currently few theories to explain the dynamic properties of transduction in cuticular sensilla in terms of their known morphological components. The partial differentiator behaviour which has now been described in several of these receptors is difficult to relate to simple mechanical components or to membrane electrochemistry. The present work is aimed at discovering ways in which the morphological components of the sensilla could give rise to such behaviour and is particularly concentrated on possible roles of the visco-elastic behaviour of the tubular body in transduction.

The experiments consist of stimulating receptors with pseudo-random band-limited modulation of position of the spine within the socket. The resultant sensory action potentials and the position information are both fed to a digital computer and are analysed by both linear and nonlinear systems analysis techniques in the frequency domain. By redesigning the stimulating apparatus, we have now managed to extend the description of the receptor behaviour over a much wider bandwidth than has previously been possible and we have also measured the system parameters as a function of the strength of the stimulating position signal. Both of these additional sets of results support the description of the behaviour as a fractional differentiator and have reinforced our suggestions that the fractional power is very close to one half, which is relevant to discriminating between a number of possible models of mechanotransduction.

85.2 MORPHOLOGY AND PHYSIOLOGY OF CHEMORECEPTORS IN THE WALKING LEGS OF THE LOBSTER HOMARUS AMERICANUS. Charles D. Derby. Boston Univ. Marine Program, Marine Biological Lab., Woods Hole, MA 02543.

The chemoreceptor neurons in the legs of lobsters, which function in localization and handling of food, innervate several different types of sensilla: simple and squamous setae, located in rows and tufts on all five pairs of pereiopods; serrate setae, found on the last two pairs of walking legs; and squat sensilla, situated along the inner cutting edges of the chelate walking legs and on apposable cuticular regions of the last two segments of the non-chelate fourth pair of walking legs.

Multi-unit neurophysiological recordings, used to describe the response properties of the population of chemoreceptors as a whole, reveal that certain amino acids and amines are highly excitatory stimuli, some peptides and proteins are moderately excitatory, whereas carbohydrates, alcohols, nucleosides, and nucleotides are in general only slightly excitatory. Single-unit extracellular recording techniques were then employed to describe the specificity and threshold of single chemoreceptive cells.

Several different types of narrow-spectrum chemoreceptors were found, each type responding with maximal sensitivity to only one of the following compounds: L-glutamate, L-glutamine, L-arginine, taurine, betaine, and ammonium chloride. The most extensively studied type of receptor - the L-glutamate sensitive cell group - responded with less than 8% of the L-glutamate response to 25 other compounds at equimolar concentrations. The mean threshold of the population of L-glutamate sensitive cells was near 10^{-8} M; the lowest threshold recorded for any L-glutamate cell was 3.5×10^{-9} M. Ammonium chloride sensitive cells are also highly specific and have low thresholds: one ammonium chloride sensitive cell had a threshold of 3.5×10^{-14} M, while several had thresholds near 10^{-9} or 10^{-10} M. The other groups of narrow-spectrum cells - L-arginine, L-glutamine, taurine, and betaine sensitive chemoreceptors - showed equally strong specificity as well as thresholds of 3.5×10^{-8} to 3.5×10^{-9} M. There is also evidence for a protein-best cell: this cell responded to hemoglobin but not to its enzymatically-digested components. There was one cell that did not fit the narrow-specificity response pattern: it responded to at least 7 of 15 compounds tested at 3.5×10^{-4} M, 4 of 15 at 3.5×10^{-5} M, and 3 of 15 at 3.5×10^{-6} M. These results indicate that the peripheral coding system in the legs of lobsters is based largely but perhaps not exclusively on narrow-spectrum chemoreceptors.

85.3 THE FINE STRUCTURE OF LEECH SENSILLA. C. E. Phillips and W. O. Friesen. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

The leech Hirudo medicinalis responds to the water movements associated with surface waves by initiating crawling or swimming movements which are directed with a high probability towards the wave source (Young, Dedwylder & Friesen, J. Comp. Physiol., in press). Stimulation of a body wall flap in a dissected preparation with water waves evokes afferent impulses in peripheral segmental nerves. Transduction of this type of stimulation occurs only at the sensilla, specialized sensory structures found on the middle annulus of each body segment (Friesen, J. Exp. Biol., in press). The sensilla are papillar structures 100-200 μm in diameter which may protrude up to 50 μm out from the body wall. SEM studies of the Hirudo body wall have revealed that two types of filiform projections occur at the sensilla: single, 3-10 μm long processes and grouped, 1-2 μm long processes (DeRosa & Friesen, Biol. Bull., in press). One of these projections evidently is responsible for the detection of water movements.

We describe here the ultrastructure of Hirudo sensilla. Three types of ciliated sensory cells were observed at the sensilla. Two types, uniciliated and multiciliated sensory cells, with elongated cilia projecting through the body wall cuticle, correspond, respectively, to the single and grouped filiform processes observed in the SEM. The third cell type is multiciliated as well, but the cilia do not penetrate the cuticle, rather they lie between it and the epithelial cell layer. This receptor type was not detectable with the SEM. The single cilia have the characteristic 9 x 2 + 2 microtubular structure, but the arrangement in the multiciliated cells is somewhat variable. All the cilia arise from cup-like depressions in the apical surface of the sensory cells. In the uniciliated receptors, the cilium is surrounded by 10 pyriform stereocilia which are interconnected by a fine tubular feltwork of electron dense material extending to the level of the basal body. The sensory cells are narrow (1-2 μm) and very elongated, extending 40-50 μm below the cuticle. A U-shaped nucleus lies at the base of the cell body. In this region, bundles of microtubules are usually present and the cytoplasm undergoes a transition, taking on the appearance of axoplasm. These ciliated cells appear, therefore, to be primary sensory neurons. The uniciliated cells appear to be the sensory neurons transducing low amplitude water movements. Supported by NIH grant #NS 14965 to W.O.F.

85.4 INTACT AND REGENERATED SNAIL TENTACLES STUDIED WITH HRP STAINING AND OLFACTOMETRY. Ronald Chase and Rifa'at Kamil*. Department of Biology, McGill University, Montreal, Quebec, H3A 1B1.

The posterior tentacles of pulmonate molluscs possess a specialized epithelial pad that is sensitive to stimulation by wind and odors (Chase & Croll, J. Comp. Physiol., 1981; Chase, Comp. Biochem. Physiol., 1981). The sensory pad is innervated by the digitate extensions of a large peripheral ganglion. In the terrestrial snail Achatina fulica these structures regenerate following excision of the tentacular tip.

Backfills of the tentacular nerve with horseradish peroxidase (HRP) reveal that the intact tentacle contains at least five cell types with axons projecting to the CNS: 1) Small multipolar neurons (mean diameter, 7 μm) with cell bodies and dendritic processes limited to the ganglion; 2) Monopolar neurons (15 μm) arrayed along the digitate extensions; 3) Bipolar neurons (20 μm) with cell bodies and dendrites limited to the digits; 4) Bipolar neurons (20 μm) with cell bodies scattered between the digits, and dendrites extending to the cuticular surface; 5) Large multipolar neurons ("collar cells"; 35 μm) clustered in the digits near to the ganglion.

Each of the enumerated cell types is also seen in regenerated tentacles. The largest neurons reappear first, the smallest last. In intact tentacles the fiber pathways are neatly bundled to form sterotyped patterns. In regenerated tentacles the fibers are initially chaotic, but by six months their organization approaches that of intact tentacles. The regenerated fibers are thicker than the intact fibers.

Chemical sensitivity was quantitatively evaluated using a two-chambered tentacular olfactometer. The measure of sensitivity was the number of ipsilateral turns elicited by unilateral presentations of the diluted vapor of amyl acetate. Ten weeks after the lesion the regenerated tentacle shows definite olfactory sensitivity, but the threshold is higher than for the intact tentacle in the same animal. HRP backfills at this time demonstrate a complete absence of ganglion cells (Type 1). By seven months after the lesion, the regenerated tentacle is hypersensitive compared to the intact tentacle. The anatomy of regenerated tentacles at this time reveals the presence of superfluous, misplaced ganglion cells, as well as the repeated branching of processes directed toward the cuticular surface. Either or both of these features could account for the hypersensitivity of regenerated tentacles.

85.5 PRESYNAPTIC INHIBITION TO AFFERENTS OF THE CRAYFISH BRAIN. R.M. Glantz, Dept. of Biology, Rice University, Houston, Tx. 77001 Multimodal, descending sensory interneurons in crayfish brain exhibit EPSPs in response to shocks of up to eight afferent sensory roots and/or central nerve tracts. If pairs of afferent pathways are stimulated simultaneously the resultant compound excitatory synaptic potential is an approximately linear sum of the individually evoked synaptic events. If stimulation of one of the input pathways (CS-conditioning stimulus) precedes stimulation of a second pathway (test stimulus) by 20 to 40ms the monosynaptic response to the test stimulus is depressed by 64% $\pm$ 3.4% (S.E.). The following results suggest that the depression is due to presynaptic inhibition: a) The postsynaptic action of the conditioning stimulus is an EPSP capable of eliciting postsynaptic action potentials and with a reversal potential at least 30 mV more depolarized than the peak of the test EPSP; b) If CS are presented in pairs separated by intervals of 20 to 40 ms the homosynaptic depression of the CS pathway is generally substantially smaller (15.7$\pm$10.3%, S.E.) than the heterosynaptic depression. This result indicates that it is unlikely that CS elicits a remote IPSP. A notable feature of the heterosynaptic interaction is its selectivity. Although a given cell may receive monosynaptic input from up to eight afferent pathways, only a single pair will exhibit a heterosynaptic interaction and the interaction occurs only in one direction. Furthermore, if the same pair of inputs are examined in a different postsynaptic cell they may show no presynaptic interaction or possibly interact in the opposite direction. The presynaptic interaction cannot be initiated by the electrical activity of the postsynaptic cell as is the case for the lateral giant interneuron (Krasne and Bryan Science 182:590-592, 1973). The phenomena may be related to the findings of Kennedy et al (Science 186:451-454, 1974) which document primary afferent depolarizations contingent upon sensory activation of interneurons in crayfish abdominal ganglia. In agreement with the findings of Kennedy et al terminals entering the crayfish brain are subject to synaptic input with reversal potentials near the membrane resting potential. The reversal potential can be shifted to more positive levels by the injection of chloride ions into the afferent neuron terminal. The terminal synaptic potentials are elicited polysynaptically from selected afferent pathways and their latency and time course are strikingly similar to the latency and time course of the heterosynaptic interactions described above. The results imply that afferents entering the brain excite interneurons which presynaptically modulate the output of a select group of other afferent pathways.

85.6 LATERAL INHIBITION IN THE CRAYFISH VISUAL SYSTEM. B.Waldrop, M.D.Kirk and R.M.Glantz. Biology Department, Rice University, Houston, TX 77001

Sustaining fibers (SF), tonic light-ON cells in the crayfish optic tract, have well defined excitatory corneal receptive fields and whole-eye inhibitory surrounds. Lateral inhibition is postulated to be the basis of stimulus-dependent oscillations of SF output. (Glantz and Nudelman, J.Neurophysiol.39:1257-1271 (1976))

We have impaled SF's near their dendrites in the medulla externa. Large, light-evoked, depolarizing compound synaptic potentials can be seen giving rise to spikes. Extrinsicly injected current can affect both the size of these potentials and the SF firing rate. Small light spots placed in the inhibitory surround lead to a decrease of the depolarization and firing rate evoked by excitatory light stimuli, but do not cause hyperpolarizations when given alone, nor do they decrease the firing rate of a cell depolarized with extrinsic current.

Inhibitory light pulses can, depending on their position, give rise to oscillations in SF membrane potential and firing rate when added to steady state light-evoked depolarization. This begins with a decrease in depolarization which never brings the potential lower than rest level in the dark. Extrinsic current alone produces only tonic firing. No evidence for direct SF-SF synaptic interactions has been seen.

We conclude from these observations that only excitation, and not inhibition, is synaptically expressed on the SF's by visual input, and that the inhibitory interactions are contained entirely in cells interposed between photoreceptors and SF's.

85.7 Morphological Representation of Crayfish Sustaining Fiber Visual Receptive Fields. M. D. Kirk and R. M. Glantz, Dept. of Biology, Rice University, Houston, Texas 77001.

Crayfish (Pacifastacus leniusculus) sustaining fibers (SF) were impaled near their dendritic arborizations in the medulla externa using a semiintact eye-cup preparation. Subsequent to a careful mapping of the corneal receptive field with a fibre optic light guide the individual cells were filled with the dye lucifer yellow.

Each SF possesses an expanded region of axon at the proximal edge of the medulla externa which gives rise to a major transverse process within the neuropil (Waldrop and Glantz, 1980, Neurosci. Abstr. 6:221). Secondary dendrites arise from this process to form a uniplanar sheet of branches parallel to the proximal and distal faces of the externa. The SFs all have an efferent process within the medulla terminalis as well as a major termination within the brain.

Most importantly each SF's dendritic tertiary arborization is restricted to an area of the externa corresponding to its corneal receptive field (assuming a precise retinotopic projection through the first optic neuropile and chiasmata). Therefore, it is proposed that every SF has a well defined anatomical representation of its visual receptive field within the medulla externa.

Presently, experiments are being conducted to determine the variability in the weighting of SF receptive fields and whether they are accompanied by corresponding differences within the secondary or tertiary dendritic branching patterns.

85.8 THE CERCUS-TO-GIANT INTERNEURON SYSTEM OF THE PRAYING MANTIS, ARCHIMANTIS BRUNNERIANA. E.E. Ball, G.S. Boyan*, R.C. Stone*. Dept. of Neurobiology, Research School of Biological Sciences, Australian National Univ., Canberra City, ACT 2601, Australia.

Wind and sound-sensitive giant interneurons, which are driven by the cercal sensilla, have been studied intensively in crickets and cockroaches and the input-output relations of some of them are now understood in considerable detail. Mantids are phylogenetically related to crickets and cockroaches but have a very different mode of life. We therefore wondered whether they would have giant interneurons driven by cercal receptors, and, if so, how similar these would be to those of crickets and cockroaches.

The major receptor types on the cerci of mantids are filiform and trichoid sensilla. Filiform sensilla are thinner, frequently longer than the trichoid sensilla surrounding them, and are innervated by a single neuron. Trichoid sensilla show variable patterns of innervation with three to five neurons per sensillum. Neither external nor internal features, however, allow us to divide these sensilla into distinct classes. Both number of cercal segments and total number of cercal sensilla vary considerably between animals. Cobalt backfills of the cercal nerve show a projection that is mainly ipsilateral and near the midline, with some fibers extending forward into the connectives. Groups of fibers extend to or across the midline particularly at the anterior end of the ganglion, but three areas without such fibers reflect the ontogenetically fused nature of the terminal ganglion. On entering the terminal ganglion some cercal fibers run first ventral and then dorsal to surround two glomeruli. Intracellular recordings from unidentified wind-sensitive cercal receptors have been obtained from the terminal ganglion and their projections have been filled with Lucifer Yellow.

Lucifer Yellow or cobalt-filled electrodes have been used to record from and fill wind-sensitive interneurons in the terminal ganglion. On the basis of cell body position, pattern of dendritic branching and physiological responses at least eight classes of wind-sensitive cells are present. The responses of these interneurons to pulses of wind of different velocities and durations have been examined. Bilateral cercal inputs to the wind-sensitive cells were found in some cases. In terms of cell body position and neurite shape there are morphological similarities between some of the wind-sensitive mantid interneurons and the giant interneurons of cockroach and, to a lesser extent, cricket. However, detailed patterns of dendritic branching are quite different in mantid, with greater bilateral dendritic development. There are approximately nine "giant" neurons in each ventral cord.

85.9 CENTRAL MODULATION OF REFLEX EFFECTS OF THE LOCUST METATHORACIC FEMORAL CHORDOTONAL ORGAN. Sasha N. Zill* (SPON: G. Hoyle). Dept. of Biol., Univ. of Oregon, Eugene, OR 97403.

In many animals, functional connections between proprioceptive sense organs and motoneurons can be modulated by the central nervous system. The neuronal mechanisms underlying changes in gain of reflex effects of an insect leg mechanoreceptor, the locust metathoracic femoral chordotonal organ, are examined in this study.

The chordotonal organ consists of groups of bipolar neurons whose dendrites insert into ligaments that are coupled to the tibial segment of the leg. Extracellular recordings from the nerve of the chordotonal organ show that it monitors the angle of the femoro-tibial joint. Intracellular recordings from individual sensory neurons show that the organ exhibits range fractionation.

Reflex effects of the chordotonal organ were studied by mechanically pulling or releasing the main ligament of the organ, mimicking flexion or extension of the femoro-tibial joint. Abrupt displacements of the ligament elicit resistance reflex discharges in slow excitatory motoneurons of the extensor or flexor tibiae muscles. Intracellular recordings from motoneurons show that resistance discharges occur as 1) a constant phasic excitatory post-synaptic response and 2) a subsequent sustained excitatory response that is variable both in magnitude and duration and is subject to central modulation.

Intracellular recordings from non-spiking interneurons in the metathoracic ganglion have shown that: 1) some interneurons exhibit maintained shifts in membrane potential of an amplitude proportional to the magnitude of ligament displacement; 2) others show only a phasic response; 3) some interneurons receive tonic excitatory input from the chordotonal organ and also excite appropriate leg motoneurons upon depolarization and thus could mediate the resistance reflex; 4) depolarization or hyperpolarization of other interneurons can modulate the resistance reflex.

It is concluded that non-spiking interneurons are able to set the gain of reflex effects of proprioceptive sense organs.

85.10 NEURAL BASIS OF THE DIRECTIONAL SELECTIVITY OF WIND-RECEPTIVE FIELDS OF COCKROACH GIANT INTERNEURONS. Darryl L. Daley and Jeffrey M. Camhi. Sect. Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14850.

The giant interneurons (GI's) of the cockroach (Periplaneta americana) show different directional selectivity in response to controlled puffs of wind. While the wind-receptive fields of some GI's are quite restricted, others are much broader and some are even omnidirectional. The wind-sensitive receptors, filiform hairs located on the ventral surface of each of the two cerci (peg-like abdominal appendages), also show directional selectivity. The hairs are arranged on the cerci in longitudinal columns. All hairs of a particular column have the same best excitatory direction. When a single column of sensory hairs is left intact (usually 6 hairs), controlled puffs of wind elicit synaptic potentials and often action potentials over approximately 180° of wind angle (Daley and Camhi, Neurosci. Abst., 1980). We report here on the pattern of connectivity (presence or absence of connection, sign, and relative strength) between identified columns of sensory hairs and GI's 1, 2, and 3.

GI 1, a somewhat directionally selective interneuron receives excitatory synaptic input from all hair columns of the ipsilateral cercus. GI 2, an omnidirectional cell, also receives excitatory synaptic input from ipsilateral hair columns. The difference in directional selectivity of GI's 1 and 2 appears to be due to differences in the strength of connection of two of the nine hair columns. The strength of connection, for both hair columns, is greater to GI 2 than to GI 1. Contralateral inputs to these two GI's are weaker than ipsilateral inputs and do not show the large difference in connection strength.

The sharply restricted wind-receptive field of GI 3 appears to result from both selectivity of afferent connection and inhibition. GI 3 receives strong excitatory input from ipsilateral hair columns whose best excitatory directions fall well within the receptive field of the cell. Hair columns with best excitatory directions near the edges of the receptive field of GI 3 provide no detectable input, while those hair columns with best excitatory directions outside the wind-receptive field provide inhibition. Contralateral inputs to GI 3 are similar to ipsilateral inputs though weaker.

85.11 ANTERIOR-MOST PROJECTIONS OF GIANT INTERNEURONS IN ACHETA DOMESTICUS TERMINATE IN MECHANO-RECEPTOR NEUROPILE OF THE BRAIN.
John S. Edwards and Les Williams. Max-Planck-Institut fuer Verhaltensphysiologie, D-8131 Seewiesen, Federal Republic of Germany.

Anterior projections of the lateral and median giant interneurons of Acheta were determined from intensified cobalt fills of the ventral nerve cord. Anterograde fills prepared by cutting the connectives in an anterior abdominal segment filled large numbers of axons. Prolonged filling of the cercal sensory nerve (up to 4 days at 4-9°C) led to selective transneuronal filling of giant interneurons. We assume that cobalt is taken up from an extracellular pool delivered to the cercal glomerulus in which a large number of cercal afferents terminate. Comparison of the two filling techniques allows detailed reconstruction of distant projections.

Aborization in each of the abdominal ganglia appear to be similar in form and reflect metameric organisation. This is also evident in the two abdominal neuromeres of the condensed metathoracic ganglion. The more extensive lateral aborizations in each of the thoracic ganglia reflects the greater lateral extension of neuropile in these segments, and also show serial homology.

It is possible that median projections from each of the paired giant interneurons communicate by mutual synapses within each segment.

The anterior terminations lie within the brain in a specific region of the lateral protocerebrum which is known also to contain other ascending mechanoreceptive inputs such as high and low frequency acoustic units. In common with these mechanoreceptor units the median and lateral giant interneurons traverse the ventral nerve cord in the ventral intermediate tract.

85.12 SENSORY CHARACTERISTICS OF LOCAL NEURONS IN THE LAST ABDOMINAL GANGLION OF THE CRAYFISH. Heinrich Reichert, Mark R. Plummer, Grace Hagiwara*, Richard L. Roth* and Jeffrey J. Wine. Dept. of Psychology, Stanford Univ., Stanford, CA 94305.

We have begun a systematic description of the properties of local circuit neurons (LCNs) in the sixth abdominal ganglion of the crayfish, Procambarus clarkii. Estimates of the number of LCNs reveals that as many as one-half of the cells in the ganglion may be LCNs. This was determined by repeatedly backfilling with cobalt the thirteen roots and two connectives that leave the ganglion, and comparing the resulting soma counts with the total soma counts obtained from Azure B stained 7 µm cross sections. The largest count for backfills was 322 somata. The total number of somata in the ganglion was 620. Thus approximately 300 neurons in the ganglion were not stained by cobalt backfills and hence may not have axons which leave the ganglion.

To determine the sensory properties of such LCNs we have been recording intracellularly with Lucifer-filled electrodes from the neuropilar processes of these cells in semi-intact, viable animals while presenting various forms of natural stimuli. We find sixth ganglion LCN cell types with sensory characteristics which correspond to those of each major class of sixth ganglion projecting interneuron. LCN cell types which respond to either 'headward' or 'tailward' water movements (directionally selective cells) as well as cell types which respond to tactile stimulation, to pinch or to movement of uropods have been identified. One modality we have not seen represented is photosensitivity. Although represented in the population of projecting neurons, it is rare and therefore sampling considerations do not preclude there being photosensitive LCNs.

We have also begun to examine the functional role of sensory LCNs within the ganglion. For example, experiments of Wiese, Wollnik and Schultz (pers. commun.) indicate that directionally sensitive projecting neurons of similar directional preference inhibit their contralateral counterparts. We have preliminary evidence that large, non-spiking LCNs with bilateral processes mediate this type of lateral inhibition, since these cells respond to sinusoidal water movements with directionally selective depolarizations and injection of depolarizing current into these cells causes inhibition of specific projecting sensory interneurons of the same directional preference.

86.1 AN INSECT CARDIOACTIVE PEPTIDE MODULATES HEART RATE DURING DEVELOPMENT. N. Tublitz and J.W. Truman. Department of Zoology, University of Washington, Seattle, WA 98195.

Cardioactive factors have been isolated from the CNS of many invertebrates. In the insects, these factors have been pharmacologically identified in many orders, however, none to date have been implicated in any cardioregulatory function. We report on the identification, isolation, and partial characterization of a cardioactive peptide(CAP) from the tobacco hawkmoth, Manduca sexta, which is released into the haemolymph to cause a significant increase in heart rate.

To quantify the activity of various cardioactive factors, we have developed a highly sensitive(threshold=0.1 picomole serotonin) in vitro Manduca heart bioassay. Crude extracts from the ventral nerve cords of pharate adults cause a dose dependent increase in heart rate when applied to the isolated heart. This cardioactive factor is pronase sensitive, resistant to boiling, and has an apparent molecular weight of less than 1000 daltons, suggesting that this factor is a peptide. CAP has been primarily localized to the abdominal transverse nerves, an unpaired segmental nerve that is a classical neurohaemal site. CAP appears not to be proctolin, an insect neuropeptide that is pharmacologically cardioactive in some insects. Proctolin is ineffective on the isolated Manduca heart at concentrations up to 10^{-4} M, and does not coelute with CAP on gel filtration columns.

To investigate a possible physiological role for CAP, heart rate was recorded in vivo during adult eclosion and wing spreading behaviors, a 75 minute developmental period during which the animal sheds its pupal cuticle and inflates its wings to their proper adult length. A significant rise(50%) in heart rate is seen immediately following eclosion and remains elevated throughout wing spreading. This increase returns to pre-eclosion levels only after the wings are fully inflated. We next measured blood CAP titers to ascertain whether CAP was responsible for the increase in heart rate. Significant levels of CAP were detected in the blood immediately after eclosion and remained elevated throughout wing spreading with the peak CAP concentration at 5 minutes after the initiation of eclosion. Furthermore, an 80% decrease in the amount of CAP stored in the ventral nerve cord was measured during this period. These data suggest that CAP, released from the abdominal transverse nerves, acts as a neurohormone to increase heart rate during eclosion and wing spreading behaviors in Manduca sexta.

86.2 PEPTIDERGIC NEURONS: A BIOCHEMICAL, ANATOMICAL, IMMUNOLOGICAL AND PHYSIOLOGICAL ANALYSIS. M. O'Shea, C.A. Bishop and M. Adams*. Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637 and Abt. Huber, M.P.I.V., Seewiesen, W. Germany.

We are interested in the neurobiology of individually characterized peptidergic neurons. In the central nervous systems of invertebrates, uniquely identifiable neurons may provide model systems to study peptide action on the cellular level. A prerequisite for such a study is the individual identification of neurons containing a sequenced bioactive peptide. Proctolin (H-Arg-Tyr-Leu-Pro-Thr-OH) is among the few sequenced bioactive invertebrate peptides. It was first extracted from cockroaches. We have therefore developed techniques which combine intracellular electrophysiological, intracellular dye injection, immunocytochemical and biochemical techniques in an attempt to identify individual proctolin-containing neurons in cockroaches and other animals.

We have produced a proctolin antiserum which can be employed in the immunocytochemical visualization of neuronal cell bodies in whole, unsectioned central ganglia. Immunoreactive neurons include bilaterally paired cell bodies in cerebral, thoracic and abdominal ganglia. Bilateral symmetry at the single cell level suggests the neurons are individually identifiable and this has now been confirmed for some of the larger immunoreactive neurons by combining intracellular Lucifer yellow injection with immunocytochemistry. Anti-proctolin sera may crossreact with peptides other than proctolin and immunocytochemistry cannot therefore identify proctolin in immunoreactive neurons. Reverse phase high performance liquid chromatography (HPLC) applied to single identified neurons provides more direct evidence and we are currently studying individual proctolinergic neurons which were biochemically characterized in this way. These studies focus on biochemical and physiological aspects of identified neurons. For example, we are attempting to describe the biosynthesis of proctolin and to identify the bioactive compounds other than proctolin in proctolin-containing neurons. Our functional studies are concerned with the physiological action of proctolin neurons on identified targets. Recent anatomical evidence on the projections of immunoreactive neurons and pharmacological experiments suggest identified octopaminergic neurons may be postsynaptic to proctolinergic neurons.

86.3 EFFECT OF PROCTOLIN ON THE LOBSTER CARDIAC GANGLION. R. E. Sullivan, K. Tazaki*, and M. W. Miller*. Bekesy Laboratory of Neurobiology, University of Hawaii, Honolulu, HI 96822.

We have examined the actions of proctolin (PROC) on the isolated cardiac ganglion of Homarus americanus. PROC has concentration-dependent excitatory effects on this 9-cell motor pattern generator. Intra- and extracellular recording reveals that bath applied PROC (10^{-8} - 10^{-5} M) produces distinct changes in motor output. These include: 1) increase in burst duration, 2) increase in burst frequency, 3) increase in the number of impulses per burst, 4) alteration of intraburst impulse patterning. In addition, PROC effects a long-lasting depolarization of the anterior motor neurons. The PROC-induced, ganglionic excitation is mediated by both small (pacemaker) and large (motoneuron) cell effects. The predominant effect on small cells, as recorded extracellularly from the trunk, is an immediate (<10 sec) increase in the duration of small cell bursting and the number of spikes per burst. This effect reverses within 5 minutes of washout. In contrast, selective application of PROC to the anterior large cell region effects a depolarization (up to 10 mV) of the somatic membrane and enhances interburst pacemaker potentials. Anterior cell effects are maximal within 60-80 seconds and require 20-30 minutes of washout for complete reversal. Prolonged application of PROC to either anterior or posterior regions results in increases in duration and frequency of bursting. The distinctive time courses for each effect give rise to a "characteristic" temporal sequence of altered motor output when whole ganglia are exposed to PROC. The motor output of ganglia exposed to a pulse of ($5X10^{-7}$ - $5X10^{-6}$ M) PROC frequently exhibit a "doublet" burst pattern within 30 sec of exposure which is associated with the prolonged small cell burst. Shortly thereafter (1 min), the ganglion returns to a singlet burst mode of high frequency, and prolonged duration characteristic of large cell effects. These effects were not observed with crab ganglia (J. Benson, pers. comm.). In ganglia silenced with TTX ($3X10^{-7}$ M), application of a low concentration (<$5X10^{-7}$ M) of proctolin produces a long-lasting depolarization which is accompanied by an increase in the large cell apparent input resistance. Higher concentrations also elicit trains of driver potentials (DP), i.e. slow (200-300 msec), regenerative, Ca^{++}-dependent potentials which have been postulated to participate in burst formation. Preliminary voltage clamp experiments on TTX-treated, ligatured, large cells suggests that PROC (10^{-6} M) may delay a voltage-dependent K^{+}-conductance which underlies DP repolarization. Proctolin induced, repetitive DP have also been observed in ligatured anterior large cells in normal saline. Although out of synchrony with the remaining network, the frequency of these repetitive DP is comparable to the burst frequency of the PROC-treated ganglion. These results suggest that neurohormones may direct temporal sequences of patterned motor output from simple networks through differential interactions with pacemaker and motor elements. Supported by NIH grant NS06191 to RES, NIH NS11808 to I. M. Cooke, and the University of Hawaii Foundation.

86.4 PROCTOLIN-LIKE IMMUNOREACTIVITY IN THE NERVOUS SYSTEM OF THE LOBSTER HOMARUS AMERICANUS. T. L. Schwarz*, G. Lee* and E. A. Kravitz. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The ability of proctolin (Arg-Tyr-Leu-Pro-Thr) to cause a contracture of the dactyl opener muscle of the lobster walking leg (Schwarz et al., J.Neurobiol., 11:623, 1980) has motivated us to seek endogenous proctolin-like substances in this organism and to study their distribution. To this end a radioimmunoassay has been developed for the peptide.

To obtain a rabbit antibody to proctolin, several immunization protocols were tried. An antiserum suitable for use in an RIA was obtained from a rabbit that had been immunized with a carbodiimide cross-linked proctolin-BSA complex. At a 1:1000 dilution this antiserum can detect 10fmoles of proctolin. (70 fmoles gives a 50% displacement of the maximum binding of iodinated tracer). The specificity of this serum was checked with 0.5-20 nmoles of 11 other peptides. No cross-reactivity was detected.

Lobster tissues were extracted and examined with this RIA. Proctolin-like immunoreactivity was found in nearly every portion of the nervous system. Substantial amounts were detected in each of the thoracic ganglia (2-5pmoles), the abdominal ganglia (1-2.5pmoles), the subesophageal (8pmoles) and circumesophageal (1pmole) ganglia, brain (5 pmoles) and the optic nerve and eyestalk (5pmoles). In contrast, no proctolin-like material was detected in exoskeletal muscles.

The highest amounts of proctolin-like immunoreactivity (up to 20pmoles) were found in the pericardial organs (PCO's) of the thoracic segments. The concentration per mg protein in these structures is 400 times that in a larger organ such as the brain. Another region that is greatly enriched in proctolin-like material is the proximal region of each of the second thoracic roots. Both the PCO's and the proximal regions of the roots are known to synthesize and release two amine hormones (serotonin and octopamine) into the haemolymph. The highest concentrations of proctolin-like material are thus associated with neurosecretory structures. A proctolin-like peptide in crustacean PCO's has also been reported by Sullivan (J.Exp.Zool. 210:543).

In a preliminary experiment, haemolymph from a lobster was found to contain $4x10^{-10}$ m/l of a proctolin-like material. This is 4 times the threshold for the action of the peptide on the opener muscle. These results and earlier studies of amine levels in the haemolymph raise the possibility that basal levels of tension in lobster muscles are continuously adjusted by circulating hormones.

86.5 LIMULUS CARDIOACTIVE PEPTIDES. W. Watson, K. Neill*, E. Tillinghast*, Zoology Dept., U.N.H., Durham, N.H. 03824 R. M. Dores*, U. of Colorado Med. Center, Dept. Physiol., Denver, CO, G. Augustine, Biol. Dept., UCLA, Los Angeles, CA. T. O'Donohue*, NIH, Bethesda, MD.

The nervous system of Limulus contains two peptides which modulate the activity of the isolated neurogenic heart. One appears to be a proctolin-like peptide which increases the strength of heart contractions without influencing the heart rate. The other is similar in its biochemical properties to Limulus chromatophorotropic factor (LCF, Dores and Herman, CBP 67:459, 1980), and it has a potent inhibitory effect on the rate and strength of heart contractions.

The initial separation of both peptides was achieved via gel filtration chromatography using a modification of a procedure described previously by Pezalla et al. (Biol. Bull. 154: 148, 1978). This protocol resulted in two peaks with biological activity when assayed on the Limulus heart. Both peaks fell between standards with mol. wts. of 400 and 1400, and both were insensitive to trypsin.

Both peptides were assayed further to determine whether they were acting on the cardiac ganglion neurons or the myocardium. Simultaneous intracellular recordings from cardiac ganglion follower neurons and tension recordings from the cardiac muscle revealed that the inotropic peptide, like synthetic proctolin, was acting directly on the myocardium, while the inhibitory peptide hyperpolarized follower cells and abolished antidromic spikes. A small fraction (0.4%) of one Limulus brain yielded enough proctolin-like material to increase the strength of heart contractions by 100%. A 50% reduction in heart rate was observed following addition of 10% of the inhibitory factor present in 1 brain.

In order to test whether the inhibitory peptide was equivalent to LCF we performed chromatophorotropic assays on Uca pugilator. LCF activity was present in brain extracts but peak LCF activity did not correspond exactly with peak inhibition. Further purification of extracts with HPLC demonstrated that the peptides were indeed distinct.

Further studies are presently underway to purify both peptides, map their distribution in the CNS, and determine their mechanism of action.

86.6 PROCTOLIN INDUCES MYOGENICITY IN THE DEGANGLIONATED LIMULUS HEART. T. Hoshi* and W. Watson (SPON: E. Hagstrom). Zoology Dept., Univ. of New Hampshire, Durham, NH 03824.

Proctolin is a pentapeptide (Arg-Tyr-Leu-Pro-Thr) originally isolated from the viscera of the cockroach (Starratt, A. N., Brown, B. E., Life Sci. 17: 1253, 1975). This peptide or its analogue is present in a variety of insects, several crustaceans, and Limulus (Brown, B. E., J. Insect Physiol., 23: 861, 1977; Sullivan, R. E., J. Exp. Zool., 210: 543, 1979; Benson et al., Brain Res., in press). Its primary physiological role appears to be modulation of muscle fiber contraction/contracture. In Limulus bath application of 10^{-8} M proctolin results in a 200% increase in the amplitude of heart contractions. This inotropic effect is the result of proctolin acting directly on the muscle fibers, rather than on the neurons which comprise the cardiac ganglion (Benson et al., Brain Res., in press; Watson et al., in prep.).

At high concentrations (> 10^{-7} M) proctolin induced slight contracture and strong rhythmic (but not synchronous) contractions of the deganglionated Limulus heart. The frequency and amplitude of the proctolin-induced contractions in the deganglionated heart were equivalent to normal heart contractions with the cardiac ganglion intact. At a concentration of 10^{-6} M proctolin the myogenicity usually required 2 - 10 minutes to develop and 1 hour to reverse following perfusion with normal saline solution.

The proctolin-induced myogenicity persisted in Na^{+}-free choline Cl, and TTX + normal saline solutions, which were sufficient to block all the cardiac ganglion activity and muscle EJP's. However, Mn^{++} (15 mM) and Co^{++} (25 mM) blocked the myogenicity. One cAMP analogue, caffeine (10 mM), and procaine (25 mM) had no effect.

Proctolin could induce myogenic contractions in the neurogenic deganglionated Limulus heart by either affecting the electrical properties of the muscle membrane or internal contractile mechanisms. Preliminary intracellular recordings from cardiac muscle fibers indicate that no significant potential or resistance changes are associated with the proctolin-induced contractions. However, the obvious hypothesis that high concentrations of proctolin induce Ca^{++}-dependent spikes cannot be rejected without more rigorous experiments.

87.1 INTRACELLULAR RESPONSES OF IDENTIFIED HRP-FILLED DORSAL RAPHE NEURONS TO VMT STIMULATION. M.R. Park, H.Imai* and S.T. Kitai. Dept. of Anatomy, Michigan State University, E. Lansing, MI. 48824.

Intracellular recordings were made from neurons of the dorsal raphe nucleus of the rat. In order to localize the nucleus, the overlying cerebellum was removed exposing the floor of the fourth ventricle. Recordings were made with beveled microelectrodes filled with 4% horseradish peroxidase (HRP) in 0.1 M tris buffer, pH 7.6 and 0.5 M potassium methylsulphate. Bipolar stimulating electrodes were placed in midline ventral tegmentum (VMT) just dorsal to the interpeduncular nucleus. The two types of responses to VMT stimulation observed were correlated with axonal trajectory. Intracellularly labeled cells with dorsally or laterally directed axons showed only an inhibitory postsynaptic potential (IPSP). In addition to IPSPs, antidromic action potentials were observed in neurons with axons projecting from the nucleus in a ventral and rostral direction. Increasing stimulus strength produced a reduction in the latency of the IPSP but not the action potential. The onset of the IPSP could preceed the antidromic action potential. There was also a latency shift in the IPSP of neurons not antidromically activated. This decrease in latency with increasing stimulus strength is in itself a failure to demonstrate monosynaptic inhibition. Two possible explanations are as follows: 1) Multiple inhibitory inputs to dorsal raphe are being activated, any one of which could be monosynaptic, but with the faster conducting system having higher threshold. 2) The inhibition is not monosynaptic and therefore involves an interneuron interposed between antidromically activated dorsal raphe axons and the somata of dorsal raphe neurons being recorded from. IPSPs were seen to be reduced in amplitude with the injection of hyperpolarizing current. They are therefore due to an increase in membrane conductance. Examination of action potentials (>65mV amplitude and with 15 mV overshoot) shows a repolarization which declines exponentially toward an asymptote, the equilibrium potential for outward current (E_{I_o}),and which is roughly equal to the resting membrane potential. The IPSP following the action potential reaches a potential 13 mV more hyperpolarized than E_{I_o}. If repolarization is principally dependent on potassium then E_{I_o} represents the potassium equilibrium potential (E_K). The IPSP passes below E_K and therefore cannot be K^+ mediated. By elimination it must be due to a conductance increase to Cl^- ions. Action potentials show a clear inflection in their rising phase, suggestive of separate initial segment (IS) and soma-dendritic (SD) components. Hyperpolarization caused failure of the SD spike. (Supported by USPHS Grant 14866 to S.T.K. and NIH BRSG Grant RR 05772-04 to M.R.P.).

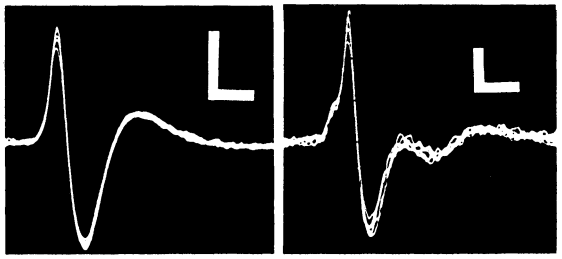
87.2 ONE TYPE OF SEROTONERGIC UNIT IN THE NUCLEUS RAPHE MAGNUS (NRM) HAS A DISTINCTIVE SPIKE SHAPE. E.G. Anderson and M.W. Wessendorf. Dept. of Pharmacology, Univ. of Ill. Med. Ctr., Chicago, IL 60680.

We have reported that, in the NRM, 2 groups of neurons conducting between 0.5 and 1.1 m/sec and between 2.5 and 6.0 m/sec are destroyed by 5,7-dihydroxytryptamine and can be identified as serotonergic. We now report that some 5-HT units also exhibit a characteristic spike shape. Using single barrel glass microelectrodes pulled to a tip diameter of about 0.75 µm for extracellular recording, 5-HT neurons in the NRM were observed for their spike shape and their responsiveness to i.v. LSD. NRM units were also observed for their responsiveness to 5-HT using a 7-barrel iontophoretic electrode glued to the recording electrode.

5-HT units conducting at less than 1.1 m/sec consistently exhibited a unique spike shape characterized by a negative inflection on the afterpotential (right frame). In contrast, the 5-HT units conducting between 2.5 and 6.0 m/sec never showed this inflection (left frame). Their spike shapes were indistinguishable from faster-conducting, non-5-HT units.

Some quantitative, but no qualitative differences were observed in the responses of the cell groups to LSD or 5-HT. The response to 5-HT was predominantly inhibitory in both groups of 5-HT cells. (Some excitatory responses to 5-HT were observed in non-5-HT units). LSD produced both inhibitory and excitatory effects on 5-HT neurons.

We conclude that the spike shape of the 0.5-1.1 m/sec 5-HT units is an identifying characteristic. However, pharmacological responsiveness to LSD is not uniform within either group of 5-HT units.



Left: Spike shape of unit conducting at 4.5 m/sec. Positivity is upwards. Right: Spike shape of unit conducting at 0.8 m/sec. Note the negative inflection superimposed on the after potential. Scale: 0.5 mV, 0.5 msec.

87.3 NEURONAL INTERACTIONS IN THE DORSAL RAPHE NUCLEUS. R.Y. Wang and G.K. Aghajanian, Dept. Pharmacol., St. Louis Univ., Sch. Med., St. Louis, MO 63104 and Depts. Pharmacol. and Psychiat., Yale Univ., Sch. Med., New Haven, CT 06508.

In previous studies (Brain Res. 132:186-193, 1977; Neuropharmacol. 17:819-825, 1978), we have shown that in the rat dorsal raphe nucleus (DRN) there is a powerful serotonin (5-hydroxytryptamine; 5-HT) autoregulatory system, which exerts its action onto 5-HT cells presumably via 5-HT axon collaterals and/or dendrodendritic junctions. The aim of the present study was to further elucidate the nature of 5-HT autoinhibition and to analyze local interactions of cells in the DRN by use of autocorrelation and crosscorrelation histograms.

Chloral hydrate anesthetized rats were used. 5-HT cells in the DRN were tentatively identified by their wave form and by their slow, regular and rhythmic firing pattern (0.5-3Hz). This firing pattern has been demonstrated previously by use of combined single cell recording and fluorescence histochemical methods and by antidromic stimulation of the ascending 5-HT pathway and collision tests to be characteristic for 5-HT-containing neurons but not for non-5-HT cells in the DRN.

The autocorrelation histograms of 5-HT cells showed an initial prolonged quiescent period followed by periodic fluctuation with equally spaced peaks; the periodic density peaks slowly flattened out. This silhouette of 5-HT neuron's autocorrelogram bears a striking resemblance to the shape of autocorrelograms generated from computer-simulated pacemaker cells with inhibitory synaptic input. Crosscorrelograms revealed that all adjacent 5-HT neuronal pairs (N=21) recorded simultaneously by a single-barreled micropipette displayed complicated patterns of interactions. The interactions could be grouped into the following categories: 1) synchronization, 2) synchronization and direct inhibition and 3) synchronization and mutual inhibition. In contrast, only 1 out of 9 non-adjacent 5-HT neuronal pairs (recorded by double-barreled micropipettes with 100 µm tip separation) showed positive functional interaction; no interaction was found between 5-HT and non-5-HT cells. The synchronous firing among adjacent 5-HT neurons could be the result of direct activation from one cell to another or the result of sharing a direct activation from a third neuron. However, based upon available evidence, it is most likely that the synchronous firing was due to simultaneous disinhibition from a shared inhibitory input from a common source. These results support our previous finding that in the DRN 5-HT neurons contain a powerful auto and mutual regulatory system. (Supported by USPHS Grants MH-34424 to R.Y.W., MH-17871 and MH-14459 to G.K.A. and by the State of Connecticut.)

87.4 SEROTONIN-INDUCED DEPOLARIZATION IN RAT FACIAL MOTONEURONS: EVIDENCE FOR DECREASED POTASSIUM CONDUCTANCE. C.P. VanderMaelen and G.K. Aghajanian, Depts. Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Previous work has shown that microiontophoretic application of serotonin onto rat facial motoneurons causes a depolarization of the membrane, accompanied by an increase in neuronal excitability, and an increase in input resistance (i.e., a decrease in net membrane conductance; Nature, 1980, 287, 346-347). The present experiments were undertaken to investigate the ionic conductance changes which occur during these serotonin-induced responses. Intracellular recordings were made in vivo from facial motoneurons of rats anesthetized with chloral hydrate. Intracellular recording electrodes were filled with K-acetate, K-citrate, or KCl, and glued to 5-barrel micropipettes used for microiontophoresis, with tip separations of 40-60 µm. Responses to iontophoretically applied serotonin were compared to those of other putative neurotransmitters and their analogues.

The serotonin-induced depolarization could conceivably be caused by a decrease in resting potassium conductance (g_K) or resting chloride conductance (g_{Cl}). The latter was ruled out because estimates of reversal potentials for responses to GABA, glycine, or the GABA analog, muscimol, which presumably are chloride mediated, were always more positive than for the serotonin response. When intracellular chloride concentrations were increased by recording with KCl electrodes, GABA, glycine, or muscimol caused large (20 mV) depolarizations along with profound decreases in membrane resistance, clearly indicating that E_{Cl} was displaced in the depolarizing direction. On these same neurons serotonin still produced its typical depolarizing response with increased resistance. Thus, serotonin does not produce depolarization by decreasing g_{Cl}, nor does it do so presynaptically by disinhibition of a tonic GABA or glycine input to these neurons.

Subthreshold depolarization by current injection causes an increase in input resistance (anomolous rectification) in these neurons. Perhaps because of this, depolarizations produced by glutamate or its analog DL-homocysteic acid (which presumably increases g_{Na}) were also accompanied by increased input resistance. However, the glutamate response was shown to be different from that of serotonin since hyperpolarization of the membrane by current injection to approximately E_K greatly attenuated or slightly reversed the serotonin response, but not the glutamate or DL-homocysteic acid responses.

These experiments suggest that decreased g_K accounts for the serotonin-induced depolarization and is not secondary to a sodium-driven depolarization. Supported by USPHS Grants MH-17871 and MH-14459 and the State of Connecticut.

87.5 A COMPARISON OF CORTICAL NEURONE RESPONSES TO IONTOPHORETICALLY APPLIED TRYPTAMINE (T) AND 5-HYDROXYTRYPTAMINE (5HT). R.S.G. Jones* (SPON: A.A. Boulton) Psychiatric Research Div.; Univ. Hosp; Saskatoon, Sask. Canada S7N 0X0

Previous iontophoresis studies in various brain regions have shown that T evokes similar neuronal responses to 5HT and it has been assumed that T acts simply as an agonist at 5HT receptors. The present experiments have made a detailed comparison of the actions of T and 5HT on single spontaneously active neurones in the somatosensory cortex of urethane anaesthetized rats. In addition, the release of ^{14}C-labelled T and 5HT has been determined *in vitro* and used to calculate the ionic transport number of the indoleamines in four microelectrodes.

For the *in vivo* experiments, recording and extracellular drug application techniques were entirely conventional. When a suitable neurone was located its spontaneous firing rate was recorded and responses to identical applications of T and 5HT determined. Of 123 neurones tested 115 were depressed by iontophoretically applied T, 4 excited and 4 unaffected. Sixty-four of the neurones depressed by T were also depressed by 5HT but on 46 cells 5HT was excitatory and on 5 had no effect. In addition two of the 4 cells excited by tryptamine were depressed by 5HT. Thus on 42% of the neurones responsive to both amines opposite effects were observed. A comparison of depressant responses to the two amines on individual cells was made with reference to the 5HT responses. This revealed that the T responses had a mean (± SEM) duration of 185±15% of the 5HT response. The maximum decrease of firing from baseline was 115±6% compared to 5HT and the time taken to reach the maximum was 80±8%. Thus the tryptamine responses were quicker in onset and had a much greater duration than 5HT. The mean transport numbers for the two amines were 0.303±0.04 for 5HT and 0.283±0.04 for T indicating that the differences in responses were genuinely biological. Neurones in animals which had received prior (10 days) lesions in ascending 5HT pathways showed similar differences in depressant responses indicating that the difference is probably postsynaptic in origin. Finally, the effects of the putative 5HT antagonist metergoline (0-25nA) on T and 5HT depressant responses of 10 neurones was tested. On five cells, responses to T were antagonized by metergoline in the absence of any effect on the 5HT responses. This occurred with the weak ejecting currents 0-5nA). At higher currents responses to both indoleamines were blocked. On 5 other cells no differential antagonism was noted. These results may suggest that T has postsynaptic neuronal effects independent of 5HT. It is possible that specific tryptaminergic receptors may exist in the cortex. Supported by Sask. Health and M.R.C.

88.1 COLUMNAR ORGANIZATION OF PRIMATE PREFRONTAL CORTEX: ARRANGEMENT OF CALLOSAL AND ASSOCIATIONAL TERMINAL FIELDS. P.S. Goldman-Rakic and M.L. Schwartz, Sect. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT. 06510.

Recent studies using autoradiographic tracing methods have revealed that callosal fibers in the prefrontal association cortex of rhesus monkey are distributed in the form of well-defined columns alternating with roughly equal sized areas that remain free of callosal input (Goldman and Nauta, Brain Res.,122: 393, 1977). In order to determine the source and pattern of distribution of axons that terminate in the acallosal spaces, we employed two distinctive anterograde tracers to label converging cortico-cortical systems in the same animal. Acrylamide-bis gel HRP pellets were implanted in the intraparietal sulcus (Brodmann's area 7) of the parietal lobe in one hemisphere; at the same time, a mixture of ^{3}H-proline and ^{3}H-leucine was injected into the dorsal bank of the principal sulcus (Brodmann's area 9) in the frontal lobe of the other hemisphere. Serial sections were alternately processed for HRP activity and autoradiography. The distribution of terminal labeling was analyzed in the dorsal bank of the principal sulcus that was ipsilateral to the implant in parietal cortex and contralateral to the injected principal sulcus.

In harmony with earlier studies, both the associational and callosal projections to the prefrontal cortex were distributed in a spatially periodic pattern in which bands of labeled axons alternated with irregular spaces lacking label. In general, both HRP and radioactively labeled columns extended across the full thickness of the cortex. The major new findings exposed by serial reconstruction of adjacent autoradiograms and HRP-reacted sections was that in areas of convergence, the two sets of cortico-cortical afferents tended to occupy mutually exclusive columnar territories with some variable amount of overlap along the borders of adjoining columns. This evidence suggests homotopic callosal fiber columns in prefrontal cortex interdigitate with associational fibers from the same side to provide a unique set of ipsilateral-contralateral hypercolumns that could provide a modular basis of interhemispheric integration. Whether this relationship of callosal and associational fiber systems represents a general principle of organization for callosally recipient cortex or is restricted to an area of frontal association cortex remains to be demonstrated.

88.2 CARBONIC ANHYDRASE HISTOCHEMISTRY REVEALS SUBPOPULATIONS OF MYELINATED AXONS IN THE DORSAL AND VENTRAL ROOTS OF RAT SPINAL NERVES. D.A. Riley, S. Ellis* and J. Bain*. Dept. of Anatomy, UCSF, San Francisco, CA 94143.

Carbonic anhydrase (CA) functions in acid-base balance, secretory processes and transport of water and ions across membranes. It occurs both as soluble and membrane bound forms in central and peripheral nervous tissues, localized predominantly in neuroglia and Schwann cells. Neurons of the dorsal root and celiac ganglia are the only nerve cells demonstrated histochemically to contain CA activity. The cell bodies of the dorsal root neurons were reactive, but their axons exhibited no activity.

While characterizing the distribution of anhydrase activity histochemically in rat skeletal muscles, we noted that some myelinated axons within the intramuscular nerve bundles possessed intense axoplasmic staining. The present study sought to identify the nerve type of the reactive axons. Rats were anesthetized and perfused with 2.5% glutaraldehyde. Perfusion proved essential for retaining enzymatic activity. Tissues were frozen and cryostat sections were reacted for CA activity using Hanson's medium either with or without 10^{-6}M acetazolamide, a specific inhibitor of neural CA.

The common peroneal, tibial and sural cutaneous branches of the sciatic nerves all contained mixtures of reactive and nonreactive axons. Within lumbar dorsal roots, about 49% of the myelinated axons of all sizes (1.5 - 16μm in diameter) were stained. A subpopulation of dorsal root ganglion cells and their axons exhibited dark cytoplasmic staining. In contrast, none of the large axons in the companion ventral roots were reactive. However, axons ranging in size from 3 to 8μm were stained and they constituted approximately 24% of the myelinated axons. Cross sections of lumbar spinal cord contained many darkly stained axons in the dorsal columns. Nerve cell bodies were not stained in the ventral horn. In all cases, histochemical staining was inhibited by acetazolamide.

The present findings indicate that a subpopulation of sensory neurons contains cytoplasmic carbonic anhydrase in their axons and cell bodies. The reactive axons in the ventral roots appear not to originate from ventral motoneurons because motoneurons are nonreactive. Some of the ventral root axons may be sensory fibers entering the spinal cord by an aberrant pathway. Supported by NASA Ames grant NAC2-OR665-903.

88.3 COMMISSURAL CONNECTIONS OF THE HIPPOCAMPAL FORMATION IN THE RHESUS MONKEY. D.L. Rosene and G.W. Van Hoesen, Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA, and Depts. of Anatomy and Neurology, Univ. of Iowa Coll. of Med., Iowa City, IA.

The hippocampal formation and entorhinal area in the rat have an extensive set of commissural connections. In the rhesus monkey we can now report both anatomical and physiological data indicating the surprising absence and or topographic restriction of these commissural connections.

The commissural system in the monkey that is most consistent with the organization observed in rats is the crossed projection from the presubiculum to the contralateral entorhinal cortex. In the monkey, both injections of 3H-labeled amino acids (HAA) into the presubiculum and horseradish peroxidase (HRP) injections into the entorhinal area demonstrate this pathway from all levels of the presubiculum to layer III of the entorhinal area. In contrast, two crossed projections originating from the entorhinal cortex in the rat, the homotopic connection to the opposite entorhinal area and the crossed projection to the opposite hippocampus, were, respectively, exceedingly weak and totally absent when assessed with injections of HAA and HRP into the monkey entorhinal area or hippocampus.

Two other commissural systems that are prominent in rats are the crossed Schaffer collateral system and the crossed dentate gyrus commissural system. In the monkey, both HAA and HRP injections located anywhere in the rostrocaudal extent of the main body of the hippocampus fail to demonstrate either of these commissural systems. To confirm this anatomical data evoked potential experiments were conducted. Electrical stimulation of the body of the hippocampus produced only weak and long latency (> 50 msec) contralateral evoked responses suggesting multisynaptic conduction (e.g. through the septum). However, when the stimulating and recording electrodes were placed homotopically in the uncal hippocampus, a strong response was evoked at a 20 msec latency. This response was used to guide HAA and HRP injections into the uncal hippocampus. In the contralateral uncus anterograde termination was observed in the inner third of the dentate gyrus molecular layer and the stratum radiatum of CA3 and CA1 as well as retrograde labeling of CA3 and hilar (CA4) neurons. These data indicate that in the monkey only the uncal hippocampus retains hippocampal commissural connections while the body of the hippocampus lacks these connections and the entire hippocampus lacks commissural input from the entorhinal area. These data suggest that the functional lateralization of the primate cerebral cortex and related restriction of commissural connections demonstrated in motor and sensory systems may also occur in the hippocampal formation.
(Supported by NSF grant BNS-7924099 and NIH grant NS 14944).

88.4 QUANTITATIVE AND QUALITATIVE DIFFERENCES IN UPTAKE OF PEROXIDASE (HRP) AND PEROXIDASE-LECTIN (HRP-WGA) CONJUGATE. W.W. Pugh* and M. Kalia. Laboratories of Anatomy, School of Vet. Med., Inst. of Neurological Sciences, Univ. of PA., Phila., PA., 19104 and Dept. of Physiology, Hahnemann Med. Col., Phila., PA., 19102.

The affinity of lectins (WGA in this case) for neuronal surface membranes has been shown to be mediated through specific binding to the n-acetyl glucosamine receptor at cell surfaces of perikaria and terminals of neurons as well as glia and vasculature. Due to this affinity, there is a disproportionate distribution of applied WGA or HRP coupled to WGA in the extracellular space of the injection site as lectins accumulate around the surface membranes. The resultant uptake of HRP-WGA occuring during endocytosis will be much greater compared to the uptake of free HRP distributed randomly in the extracellular space. HRP-WGA was prepared according to the method of Gonatas et al. with the following modifications: after initial conjugation, all procedures were carried out at 4^{0}C; separation of HRP-WGA from free HRP and free WGA was accomplished by several passes through a Sephadex G-150 column.

The nodose ganglion in the cat, containing cell bodies of sensory vagal afferents and passing efferent fibers of vagal motor neurons, was injected unilaterally with 3-30 uL of either HRP or HRP-WGA and subsequently examined at 24-48 hrs. using TMB histochemistry. Injections of 33% HRP labeled sensory afferent fibers in tractus solitarius and terminal fields in nucleus solitarius (anterograde) as well as vagal motor neurons (passing retrograde) in the brainstem (Kalia and Mesulam). Injections of 0.167% (200:1 dilution) HRP-WGA intensely labeled the sensory projections but did not retrogradely label any passing fiber motor neurons. Similar injections of 0.167% HRP failed to label any sensory terminals but did label motor neurons. A third injection of 0.167% HRP-WGA mixed with 100X excess free WGA (16.7%) did not label either sensory terminals or motor neurons, demonstrating a competitive inhibition of HRP-WGA uptake in the presence of excess free WGA.

In conclusion: 1) high concentrations of HRP result in uptake by perikaria and passing fibers; 2) low concentrations of HRP showed uptake by passing fibers with no uptake by cell bodies or consequent anterograde transport; 3) HRP-WGA in low concentrations intensely labeled anterograde projections but did not significantly label passing fibers; 4) selective uptake by cell bodies and not passing fibers of HRP-WGA can be inhibited by excess WGA demonstrating a surface membrane affinity and resultant great increase in uptake by endocytosis in the presence of WGA either free or coupled to HRP.

88.5 PATHWAYS RESOLVED BY TRANSNEURONAL UPTAKE OF HORSERADISH PEROXIDASE IN C.N.S. OF FLIES. D.R. Nässel*. European Molecular Biology Laboratory, D-6900 Heidelberg, W. Germany. (SPON: B. Mulloney).

It was recently shown that horseradish peroxidase (HRP) in addition to labeling injured neurons passes transneuronally into contiguous nerve cells (Nässel, D.R., Brain Res., 206: 431, 1981). This transneuronal uptake of the enzyme resulted in detailed secondary, tertiary and quarternary labeling. This technique has now been used to resolve neuronal pathways connecting the optic lobes (lamina, medulla, lobula and lobula plate) with thoracic ganglia in the flies Calliphora, Musca and Drosophila.

After HRP uptake through severed thoracic ganglia four consecutive sets of neurons could be resolved in the brain and optic lobes. The tertiary and quarternary labeling was achieved after long uptake (18 hrs) or with the addition of 3% lysolecithin to the enzyme solution. One pathway consisted of (from periphery to center): columnar small field centripetal neurons of the lamina, columnar neurons of the medulla, columnar lobula neurons and a cluster of large descending neurons connecting the brain to the thoracic ganglia. Among these descending neurons is the giant descending neuron which is known to be part of an important giant pathway to tergotrochanter muscles and dorsal longitudinal flight muscles (King, D.G., Wyman, R.J., J. Neurocyt., 9: 753, 1980). A second pathway includes large horizontal and vertical motion sensitive neurons of the lobula plate (Hausen,K., Z. Naturforsch., 31c: 629, 1976) and descending neurons with more posterior dendrites.

The first pathway is especially interesting since it includes several identified neurons whose inputs are known and/or electrophysiologically studied (all but the lobula units have been recorded from). The three giant components of this pathway are under study in several laboratories and future work hopefully will further characterize the remaining units of the entire polyneural chain from the retina to muscles.

88.6 A BASAL AMYGDALOID PROJECTION TO THE CENTRAL AMYGDALOID AREA IN THE MONKEY. K.C. Kosel, G.W. Van Hoesen and D.L. Rosene Dept. of Anat. and Neurol. Univ. of Iowa, Iowa City, IA. 52242 and Dept. of Anat., Boston Univ., Boston, MA. 02118.

In axon stains like the Cajal or Vogt methods numerous pathways can be discerned coursing in the amygdala. In primates, these are sizeable, and course between nuclear groupings in the amygdala. In the monkey, the ventral amygdalofugal system, a prominent pathway, exits the posterior amygdala as a dorsal continuation of intrinsic amygdaloid white matter. However, we have observed that before leaving the amygdala a sizable contingent of axons that arise from the basal complex terminate within the amygdala, and in particular, in the central amygdaloid area.

In 5 monkeys ablations were made in the piriform lobe that damaged the entorhinal cortex and the dorsally adjacent basal amygdaloid complex (basomedial and basolateral amygdaloid nuclei). The brains were processed with the Fink and Heimer method. An additional 7 monkeys received labeled amino acid injections in the entorhinal cortex or in one or more of the basal amygdaloid nuclei (basomedial, basolateral and accessory basal). An additional 2 monkeys had injections in the medial and the lateral nuclei.

The results reveal that injections of the medial and lateral entorhinal cortex or the medial and lateral amygdaloid nuclei do not give rise to projections to the central amygdaloid area. However, all ablation cases and all autoradiographic cases involving the basal nuclei give rise to either terminal degeneration in, or terminal labeling over, the central amygdaloid area throughout its rostrocaudal extent, and these projections are sizable. Ventrally, they sweep through the basolateral nucleus. Dorsally, they course between the medial edge of the lateral nucleus and the lateral edge of the basolateral nucleus. Terminal degeneration and terminal labeling is most intense over the lateral part of the central amygdaloid area.

These findings are of interest as recent reports have shown that the central amygdaloid area projects to visceral and autonomic centers in the hypothalamus and brainstem. In view of the fact that the basal complex receives afferents from temporal cortical areas, cingulate gyrus and the subiculum, this intrinsic amygdaloid pathway may play a role in mediating telencephalic influences on visceral and autonomic reactions (Supported by grants NS 14944 to G.W.VH and NSF BNS 7924099 to D.L.R.).

88.7 SOME CORTICAL CONNECTIONS OF THE FRONTO-CINGULATE CORTEX IN THE RAT. S.L. Wertheim*. (SPON: W.J.H. Nauta). Dept. of Psychology, Mass. Institute of Technology, Cambridge, MA 02139.

In the rat, the cingulate and prefrontal cortices overlap on the medial wall of the hemisphere. This area has at least four cytoarchitectonic subdivisions. HRP has been used to trace the afferents and efferents of two of these zones: the anterior cingulate area and the precentral medial field (PrCm) of Krettek and Price (J. Comp. Neurol., 171:157, 1977). The enzyme was placed either iontophoretically or as pellets of HRP contained in a matrix of polyacrylamide gel.

HRP deposits that encompass both fields show two main types of ipsilateral cortical connections; connections with limbic cortex that include orbital, retrosplenial, presubicular, perirhinal and entorhinal cortices and connections with sensory cortex that include areas 17, 18a and 18b. Labeled cells in the orbital cortex are found primarily in the ventral orbital area. There is terminal labeling in layer I of the ventral and medial orbital areas. Both granular and agranular retrosplenial cortex contain many labeled cells in layer V. Layer II-III in agranular retrosplenial cortex contains an occasional labeled cell. Terminal labeling appears in layers V and I. There is a projection to layers I and III of the presubiculum. Labeled cells in the entorhinal area are in layer IV. There are many heavily labeled cells in areas 18a and 18b mainly in layer V. Area 17 contains fewer, more lightly labeled neurons, also mainly in layer V. The fronto-cingulate projection to these areas is to all layers of area 18b, to layers I, V, and VI of area 18a and to layer I of area 17.

Small pieces of HRP-gel placed in PrCm result in distinctive labeling of the thalamus and midbrain but show essentially the same pattern of cortical connections as deposits encompassing both fields. However, far fewer labeled cells are seen in granular retrosplenial cortex in these cases.

The pattern of distribution of visual cortical terminals in the fronto-cingulate cortex remains to be determined. In one animal, placement of HRP-gel in the region of area 18a resulted in cell and terminal labeling predominantly in PrCm. This relationship between visual cortex and PrCm is especially interesting because of cytoarchitectonic (Caviness, J. Comp. Neurol., 164: 247, 1975) and electrophysiological (Hall and Lindholm, Brain Res., 66:23, 1974) evidence that it is homologous to area 8 of the primate. There are some labeled cells in the sensory cortex outside the visual areas in these animals. Serial section reconstructions are being undertaken to determine whether what appear as isolated cells in transverse sections form an overall pattern.

89.1 REGENERATION FOLLOWING SELECTIVE AXOTOMY OF AN IDENTIFIED VERTEBRATE CENTRAL NEURON. S.J. Zottoli. Dept. of Biology, Williams College, Williamstown, MA 01267.

Axonal regeneration is known to occur across the site of spinal cord lesions in adult goldfish and this growth may result in return of function (i.e., swimming). However, the apparent failure of the Mauthner cell (M-cell) to regenerate its axon may indicate an intrinsic inability of this cell to sustain regrowth (Kiernan, Biol. Rev. 54, 1979). In order to investigate the M-cell response to axotomy, the M-axon has been lesioned exclusive of all other axons.

Goldfish, 9-12cm in body length were anesthetized and the skull overlying the caudal portion of the brain was removed. On separation of the vagal lobes both M-axons were usually visible and easily penetrated with glass microelectrodes filled with 2.7 M KCl (3-5 M Ω). Selective axotomy resulted when the electrode was vibrated by gently tapping the manipulator until the resting potential was reduced to at least 1/3 its initial value (i.e., 28mV) and held at or below this level for ten minutes. After removal of the electrode, the brain was covered with a vaseline-paraffin oil mixture and the hole sealed with epoxy. At post-operative intervals ranging from 5 to 79 days, four goldfish were anesthetized and the medulla was exposed as described above in order to fill their M-axons with Lucifer Yellow. After fixation, the brains were prepared for wholemount observation utilizing fluorescent microscopy. Then the brains were sectioned at 15μm, observed again with fluorescence and subsequently stained with Cresyl Violet. The brains of eleven other fish were prepared for histological examination exclusively.

An axon reaction characterized by partial chromatolysis and/or a perinuclear ring of basophilic material was visible as early as 9 days after axotomy 2mm caudal to the M-cell soma. This reaction persisted for at least 79 days. A total of 6 M-axons were filled with Lucifer Yellow. Retraction bulbs were apparent at 7 days after axotomy but no growth was seen. At 21 days sprouts were seen emanating at or slightly rostral to the tip. Finally, at 79 days the M-axon had undergone extensive regrowth, one process projecting rostrally and the other in a caudal direction well past the lesion site. These results clearly indicate the ability of the adult M-cell to regenerate its axon and the possible correlation of this regeneration to morphological changes in the cell soma. Furthermore, long-term changes in membrane excitability of the M-cell which parallel this cell's axon reaction (Faber and Zottoli, in press) emphasize its potential as a model for further studies on neuronal regeneration. (supported in part by NSF Grant No. BNS-7924655; special thanks is extended to W. Stewart for supplying the Lucifer Yellow.)

89.2 GLUCOSE UTILIZATION BY THE AXOTOMIZED RED NUCLEUS OF RAT. L.R. Rodichok, K.D. Barron and A.J. Popp. Depts. of Neurology and Neurosurgery, Albany Medical College, Albany, NY 12208.

The earliest biochemical responses required for successful regeneration after axon injury are essentially unknown. Increases in ^{14}C-2-deoxyglucose (^{14}C-2-DG) utilization have been demonstrated in rat facial and hypoglossal nuclei within 24 hours of neurotomy and persist for 14-28 days (Agranoff, Smith and Sokoloff, 1980; Kreutzberg and Emmert, 1980; Singer and Mehler, 1980). The facial and hypoglossal nuclei are aggregations of extrinsic neurons. We have examined ^{14}C-2-DG uptake after axotomy in the intrinsic neuronal population represented by the rat red nucleus. The right rubrospinal tract was knife sectioned at high cervical (C3) and mid-thoracic (T6) levels. The tract is completely decussated. Two lesioned and a control animal were sacrificed after 3, 6 and 9 days. ^{14}C-2-DG utilization was measured by the method of Sokoloff et al (1977). Under methoxyflurane anesthesia, male Sprague-Dawley rats weighing 300-400 gm were injected intravenously with ^{14}C-2-DG, 50-60 uCi/kg and sacrificed after 45 minutes by pentobarbital overdose. 20 um frozen sections of whole brain were cut serially at -22°C and mounted on coverslips. One series, comprising every 3rd section, was applied to Kodak SB5 X-ray film for two weeks. Another series was stained with 0.1% cresylviolet, pH 3.5. The third set of sections was held in reserve. Densitometric measurements were made with a Zeiss microspectrophotometer using a .07 mm aperture and monochromatic 585 mu light. The spinal cord was fixed in formalin and serially sectioned through the lesion.

Despite clear chromatolytic changes in the left red nucleus and the absence of detectable cytological alterations in the right red nucleus, there were no differences between the optical densities of the two red nuclei as measured on autoradiographs 3, 6 and 9 days postoperatively. This was true for both cervical and thoracic lesions. Animals surviving 1, 14, 30, 60 and 100 days are in preparation or under examination. Our data indicate an absence of an early increase in ^{14}C-2-deoxyglucose utilization by an axotomized central neuronal population. This negative finding seems to strengthen the proposition that the responses of mammalian central (intrinsic) and peripheral (extrinsic) neurons to axotomy can be fundamentally different. This difference may well be relevant to the failure of regeneration in mammalian CNS.

89.3 INTERACTIONS BETWEEN ASTROCYTES AND THE SCHWANN CELLS THAT INVADE AND SUBSEQUENTLY MYELINATE SPINAL CORD AXONS. T. J. Sims and S. A. Gilmore, Departments of Pathology and Anatomy, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205.

Myelination of spinal cord axons by Schwann cells has been shown to occur following irradiation of the lumbosacral spinal cord in 3-day-old rats (Gilmore and Duncan, '68, Sims and Gilmore '81). In the present study, further light and electron microscopic observations were conducted on rats 5 to 25 days after irradiation (4000R at 3 days of age), for the purpose of determining what factors were responsible for the invasion and free intermingling of Schwann cells in CNS tissue. On post-irradiation days 5 and 10 the dorsal funiculi (DF) were composed of naked axons and were strikingly acellular as compared to controls. At these times, astrocyte processes forming the glia limitans showed a variety of changes due to the irradiation. In some cases the foot-like, subpial processes showed signs of retraction, whereas in others these processes formed large, variegated protrusions extending beyond the surface of the cord. The basal lamina was intact, covering the entire surface of the irradiated cord, although taking a rather tortuous course over the astrocyte processes. By post-irradiation day 25 Schwann cells invaded and myelinated large-caliber axons in the superficial regions of the DF. The deeper regions of the DF remained unmeylinated and acellular as Schwall cells had not yet invaded to this depth. Subpial astrocyte processes were present but did not form a continuous glia limitans as they did in control subjects. The large variegated protrusions seen at earlier times were no longer present. In subpial regions where Schwann cells had invaded the DF, the basal lamina was interrupted by Schwann cells or their cytoplasmic extensions. From these observations it is our view that the initial disruption of the glia limitans and the substantial reduction in the astrocyte population following irradiation are the factors that allow Schwann cells to invade the spinal cord. We observed no evidence that Schwann cells have a toxic or inhibitory effect on astrocytes as has been suggested by other investigators. Furthermore, the basal lamina in itself is not a barrier to migrating Schwann cells.

89.4 RESTORATION OF SYNAPTIC AND BEHAVIORAL FUNCTION WITH EMBRYONIC TRANSPLANTS OF CHOLINERGIC NEURONS. Walter C. Low, Steven B. Dunnett, S. Terri Bunch, Steven R. Thomas, Peter R. Lewis, Susan D. Iversen, Anders Bjorklund and Ulf Stenevi, Physiological Laboratory and Experimental Psychology, Univ. of Cambridge, Cambridge, U.K. and Dept. of Histology, Univ. of Lund, Lund, Sweden.

Recent anatomical studies of embryonic transplants containing cholinergic neurons have demonstrated a reinnervation of the hippocampal formation in adult host SD rats. The pattern or reinnervation into the hippocampal formation is quite specific and appears to be restricted to laminae which are normally innervated by cholinergic fibers. We now provide electrophysiological evidence that embryonic transplants of cholinergic neurons form functional excitatory synaptic connections. Furthermore, these newly formed synapses enhance the spatial memory performance of rats in comparison to those without transplants.

Three groups of SD rats received either sham operations, bilateral lesions of the fimbria-fornix to eliminate the cholinergic innervation of the hippocampal formation, or bilateral lesions of the fimbria-fornix followed by bilateral transplants of cholinergic septal nuclei from 16-17 day old rat embryos. Five months after surgery the spatial memory performance of each animal was tested using an 8-arm radial maze task. Sham operated animals and animals with transplants exhibited a gradual improvement in maze performance with time ($p<0.001$ and $p<0.05$ respectively) whereas animals with bilateral lesions exhibited no improvement with repeated trials. The overall performance of the transplant group, however, did not significantly differ from the bilaterally lesioned animals. After 30 days of testing, animals were then tested for an additional 8 days in which they were alternately injected (i.p.) with 0.05 mg/kg of physostigmine, an AChE inhibitor, or with saline. Both sham operated animals and animals with cholinergic transplants exhibited enhanced maze performance ($p< 0.05$ and $p<0.001$ respectively) with physostigmine while bilaterally lesioned animals exhibited no change.

After behavioral testing, animals with transplants were used for electrophysiological analysis of synaptic function. Electrical stimulation of the transplants evoked field potentials in the hippocampus and dentate gyrus, reflecting functional synaptic connections. Furthermore, it was found that dentate field potentials evoked by the electrical stimulation of intact perforant path fibers could be potentiated when preceded by the electrical stimulation of the transplant. These results indicate that neural transplants from embryonic septal nuclei are capable of forming viable homosynaptic and heterosynaptic connections with the hippocampal formation of adult hosts. These functional synapses in turn have the apparent capacity to partially restore cognitive behavioral function.

89.5 REGENERATION OF CATECHOLAMINE FIBERS INTO A COLLAGEN BIOIMPLANT AFTER CORTICAL ABLATION. J. C. de la Torre. Univ. of Miami School of Medicine, Miami, FL 33101

A bioimplant composed of cell-free solubilized bovine collagen which polymerizes (hardens) at body temperature was used to study the regenerative capacity of central catecholamine axons and blood vessels in rat brain. Two groups of male Long-Evans hooded rats were anesthetized with sodium pentobarbital-ketamine and a boneflap was removed from the right side of the skull using a drill. The craniectomy extended 5 mm posteriorly from the bregma and 3 mm laterally from the midline. The dura was retracted and using a soft suction catheter, the cortex and an area 2 mm subcortically was ablated by aspiration. The ablated area measured 3.5 mm in the antero-posterior plane and 5 mm deep. After hemostasis, the bioimplant was inserted to fill the lesion. Control rats underwent the same surgery but gelfoam was inserted into the lesion. The boneflap was returned and held in place by suturing the periosteum over it. All rats were given 500 mg/kg nialamide i.p. 2 hours before sacrifice to enhance aminergic fluorescence. Rats were sacrificed 10, 21, and 31 days postoperatively (dpo). Brains were removed at each time point and processed for the SPG histofluorescence method. All rats showed a denser distribution of catecholamine-containing varicosities (CCV) in the caudal and medial aspect of the lesion with less CCV in rostral or lateral brain regions. These "reactive" CCV were larger and more intensely fluorescent than contralateral intact CCV. At 10 dpo, moderate CCV density were seen around the lesion in rats with the bioimplant. At this time, CCV were also seen entering the bioimplant at its interface with the brain tissue. A moderate number of blood vessels were noted within the bioimplant. At 21 and 31 days dpo, CCV within the bioimplant were seen rostrally with greater frequency than at 10 dpo. In control rats, CCV density was light to moderate near the necrotic tissue zone and a few blood vessels were seen at the scar:brain tissue interface. By contrast, these control rats showed no CCV or blood vessels within the scar tissue at any time point. Despite a necrotic zone of autofluorescing cellular debris around the lesion, reactive CCV were often seen traversing this zone in both groups of rats as early as 10 dpo. These preliminary findings indicate that the experimental bioimplant is capable of sustaining a blood supply as well as CCV that enter it, presumably from central regenerating catecholaminergic processes. No CCV or blood vessels were seen within the scar tissue in control rats. It is further suggested that following a cerebral lesion of this type, the scar tissue but not the necrotic tissue zone, poses a greater barrier to regenerating catecholaminergic processes.

89.6 SUBSTANCE P HAS A SPARING EFFECT ON LESIONED NORADRENALINE NEURONS IN THE RAT BRAIN DURING ONTOGENY. G. Jonsson* and H. Hallman* (SPON: G. Grant). Dept. of Histology, Karolinska Institutet, S-10401 Stockholm, Sweden

Systemic administration of the catecholamine neurotoxin 6-hydroxydopamine (6-OH-DA) in the neonatal stage causes a marked alteration of the postnatal development of the central noradrenaline (NA) neurons, in particular of the locus coeruleus NA system. The 6-OH-DA treatment results in pronounced and permanent denervations of distant NA nerve terminal projections (e.g. in the cerebral cortex and the spinal cord), whereas the cell-body near projections are increased leading to a hyperinnervation (e.g. in the cerebellum and the pons-medulla). The consequences following the 6-OH-DA treatment are mainly related to a 'pruning effect'. The purpose of the present study was to investigate whether or not substance P (SP) can modify the postnatal development of the central NA neuron and their alteration induced by 6-OH-DA, as monitored by chemical NA assay, ^{3}H-NA uptake in vitro and fluorescence histochemistry. Intracisternal injection of SP (2x50 µg in 10 µl; 20 hr interval) 4-6 hr (the first dose) after the administration of 6-OH-DA (100 mg/kg, s.c.) to newborn rats was found to cause a clear-cut counteraction of the 6-OH-DA induced NA denervation (analysis in the adult stage). The counteracting action of SP was significant in all regions of the cerebral cortex and the spinal cord, being most pronounced in the frontal cortex. When testing the effect of various doses of SP on the reduced NA levels produced by 6-OH-DA in the frontal cortex a clear dose-response was observed. SP was also found to counteract the 6-OH-DA induced hyperinnervation, both in the cerebellum and the pons-medulla. Neonatal treatment with SP alone had no effect on the NA neurons in most regions analysed. The present study has shown that SP can counteract the alterations of the postnatal development of central NA neurons produced by 6-OH-DA. Both the NA denervations and hyperinnervations are counteracted, the latter probably of consequence of the sparing effect SP has on distant NA nerve terminal projections. It is unlikely that this effect of SP is related to an interference with the degenerative actions of 6-OH-DA, since SP was administered at a time when the neurotoxic actions of 6-OH-DA are largely completed. The exact mode of action of the observed effect SP is at present unknown. It is suggested that it may be related to a growth stimulatory effect of SP associated with the known excitatory effect SP has on locus coeruleus neurons.

89.7 ACCURATE AXON AND SYNAPSE REGENERATION IN THE ABSENCE OF GLIA. Ellen J. Elliott and Kenneth J. Muller. Carnegie Institution of Washington, Baltimore, MD. 21210.

Glia are thought to play several different roles, some constructive and some obstructive, in nerve regeneration. In the leech Hirudo medicinalis, two large glial cells ensheath all the axons in the three connectives linking adjacent ganglia. To investigate the role of glia in nerve regeneration, individual connective glial cells were destroyed by intracellular injection of protease. A week later, the axons in the connectives were severed by cutting or crushing, and the regeneration of particular axons, those of the S interneuron and mechano-sensory neurons, was followed by physiological and morphological means.

Each sensory neuron studied sends its axon down one of the two paired lateral connectives, each of which is ensheathed by a single large glial cell. In lateral connectives in which the glial cell had been killed, sensory cell axons were able to regenerate to form chemical synapses in the next ganglion with normal motor neuron targets. The success rate of regeneration was similar to that of regeneration in the presence of the glial cell, i.e.,~20% in preparations examined from 3 to 16 weeks after injury. About 60% of those sensory cells that did not regenerate, whether glial-ensheathed or not, did grow across the crush toward the next ganglion. Desheathed axons, while able to make correct synaptic connections, generally sprouted more profusely than glial-ensheathed axons.

The axon of the S interneuron lies in the medial connective, which is ensheathed by one or both connective glial cells. The axon makes an electrical synapse at its tip with the next S cell midway between ganglia in the connective. After glial destruction, the injured axon regenerated as normally to synapse with the tip of the adjacent S axon, which did not grow. By 4 or more weeks after axons were severed, they reconnected selectively with their normal targets in all but 2 of 14 preparations. One difference in the course of regeneration without glia was that some distal stumps of severed S axons, which survive for months in the presence of glia, degenerated during the first month. Thus the glial cell may help the distal stump survive.

These experiments show that glia may influence the growth of axons in the leech, since sensory axons sprout more profusely in the absence of glia, and that glia may contribute to axon stump survival, as seen for S cell stumps. However, successful regeneration of sensory axons and S cell axons can occur in the absence of the connective glial cell.

90.1 PHENCYCLIDINE DISRUPTS SHORT-TERM SPATIAL MEMORY BY RATS IN A T-MAZE. Lynn S. Arenella* (SPON: G.J. Thomas), Center for Brain Research, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Phencyclidine (PCP) has different behavioral effects in different species. In rats, i.p. doses above 3 mg/kg produce increased motor activity, while doses between 5 and 10 mg/kg produce stereotyped behaviors and ataxia. The neurochemical bases for PCP's effects have been attributed to cholinergic, dopaminergic, serotonergic, and opiate neurons and to "PCP receptors". Glick et al. (Eur. J. Pharmacol. 59:103, 1979) concluded that PCP's impairment of spatial alternation had an anticholinergic basis because of various classes of drugs tested, only the muscarinic anticholinergics caused a similar impairment and only the concurrent administration of muscarinic agonists was able, partially, to block the effects of PCP. Because the task, lever pressing, used in the latter study involved an operant conditioning paradigm where many unknown performance factors could confound the results, the specificity of PCP's action in rats was tested on a more "truly" spatial task: contingently reinforced spatial alternation in a T-maze.

Young adult male Long-Evans rats were used as subjects. The T-maze and the behavioral procedures used in adaptation and acquisition trials were similar to those of Thomas (J. Comp. Physiol. Psych. 92:1128, 1978). All drug and saline control solutions were administered i.p. and the rats were tested in the T-maze 20 min later. In the first experiment, PCP was administered alone at the following doses: 0.25, 0.5, 1.0, 2.5, and 5.0 mg/kg. In the second experiment, PCP (5.0 mg/kg) and oxotremorine (0.2 mg/kg) were administered concurrently.

PCP administered alone disrupted contingently reinforced spatial alternation in the T-maze in a dose-dependent manner. At doses greater than 1.0 mg/kg, PCP caused a decrease in the median percent alternation. AT 5.0 mg/kg, PCP resulted in all rats (save one) performing at chance levels. Following concurrent administration of PCP and oxotremorine, the rats were not protected from the deleterious effects of PCP. For all drug sessions, the median response times were not significantly different from controls.

While this experiment does not disprove the proposed anticholinergic mechanism of action of PCP, it does show that the effects of PCP are task specific. Most experiments on the effects of PCP have used stereotyped responses. This is the first report of PCP's effect on the rat's ability to perform a complex task which presumably utilizes "higher cognitive abilities". While other explanations are possible, the results are consistent with the interpretation that the failure to perform a previously learned spatial alternation task is due to PCP's disruption of short-term spatial memory.

90.2 PHENCYCLIDINE INCREASES THE INTENSITY AND SPONTANEITY OF FIGHTING IN ISOLATED MICE. Carole Boyko-Wilmot*and Christina Vander Wende, Dept. Pharmacology, Rutgers Univ., College of Pharmacy, Piscataway, N.J. 08854.

There are numerous clinical references to a psychotic, often violent, state associated with acute and more frequently chronic phencyclidine (PCP) abuse, with a limited understanding of the neurochemical basis of this behavior. Whether the direct neurochemical effects of PCP increase the predisposition to violent behavior or indirectly release from inhibitions an inherent predisposition has not been established.

Using a pathological model of aggression, isolation-induced fighting in mice, we have examined the manner in which PCP alters the development and expression of fighting behavior. Male CF-1 mice were housed individually for 10,20, or 30 days, after which they were assigned to 4 treatment groups: no treatment, vehicle, PCP 1.25, or PCP 2.5 mg./kg.,i.p. Each mouse was tested individually for fighting with a standard stimulus mouse (olfactory bulbectomized), which does not initiate a fight or fight in return, but is an effective eliciter of aggression. Each mouse was tested only once to avoid the effects of repeated experience. The latency (LAT) in sec. to the first attack and the total fighting time (TFT) in sec. in a 10-min. interval were recorded. An acute treatment of PCP-1.25 did not alter the mean LAT in the 10-d. isolates, but did lower the mean LAT in the 20-d. and 30-d. isolates, and also significantly increased the TFT compared to the control groups. The effects of PCP-2.5 were more variable and attributed to ataxic effects impairing fighting performance. This is consistent with the increased neural sensitivity of isolates to central stimulants.

The quality of fighting under the influence of PCP showed a greater spontaneity; 33% and 50% of the fighters in the 20-d. and 30-d. isolation groups attacked the stimulus mouse in less than 10 sec., whereas only 5-10% of the control groups showed highly spontaneous fighting.

The aggression-eliciting effects of PCP were also compared between 2 groups of mice of different ages at the onset of a 30-35 d. isolation period, young sexually immature mice 35-40 d. old, and sexually mature mice 70 d. old. Again PCP-1.25 decreased the LAT and increased the TFT in both age groups compared to their respective controls. The younger isolates showed a higher spontaneity with a significantly lower LAT than the older isolates.

These results indicate that an acute PCP treatment appears to affect the spontaneity and intensity of fighting when a fighting predisposition is present.

90.3 BEHAVIORAL PHARMACOLOGY OF PHENCYCLIDINE. B.D. Greenberg* and D.S. Segal. Psychiatry Dept., UCSD School of Medicine, La Jolla, CA 92093.

The behavioral effects of phencyclidine (PCP) in rats were investigated in a series of studies. Rats were habituated individually to activity chambers for 3 days prior to s.c. administration of PCP (0.25 - 5.0 mg/kg). Food and water were available ad libitum, and injections were given during the light phase of the 12-hr light/dark cycle. A relatively complete behavioral inventory was obtained, which included continuous computer-monitored measures of locomotion (crossovers and rearings) and of duration of contact with the food grid and sipper tube. In addition, individual components of the response spectrum, including stereotyped behaviors were rated at regular intervals throughout the acute response. Phencyclidine (0.25 - 5.0 mg/kg) produced a dose-related increase in crossovers, rearings (at 5.0 mg/kg), sniffing, repetitive head and mouth movements, shuffling, ataxia, and in latency to onset and duration of eating and drinking. Phencyclidine caused dose-related decreases in crossovers and rearings during the dark phase following its acute administration. A low dose of PCP (0.25 mg/kg) given to rats not habituated to the activity chambers produced an initial decrease in behavioral measures (e.g., sniffing), followed by an increase relative to control values. Chronic administration of PCP (1.0 - 10.0 mg/kg) for 4 days caused differential changes in the response as a function of dose (e.g., crossovers progressively increased at 1.0 and 5.0 mg/kg, whereas repetitive head movements decreased at 10.0 mg/kg). The hypothesis that PCP exerts some of its effects through opioid mechanisms was examined by co-administration of PCP (1.0 and 2.5 mg/kg) and naloxone (0.5 and 10.0 mg/kg). An interaction between PCP and naloxone was found with respect to some components of the response (e.g., a delay in onset of PCP-induced eating).

This research was supported by USPHS DA-01994-03; B.D.G. is the recipient of a NSF predoctoral fellowship.

90.4 COCAINE/FIGHTING INTERACTIONS IN MICE. M. G. Hadfield, D. E. W. Mott* and E. A. Nugent*. Neuropathology Section, Dept. of Pathology, Med. Coll. Va./Va. Commonwealth U., Richmond, Va. 23298.

Last year, we reported that cocaine escalates fighting behavior in isolated male ICR mice (SN 110.8, 1980). Fight duration was increased by over 50% at 10 mg./kg. and was more than doubled at 35 mg./kg.

This year, we wish to report on follow-up studies concerned with cocaine/fighting interactions in the following situations: (i) group-housed male mice; (ii) isolated female mice; (iii) short-term or incompletely isolated male mice; (iv) Full-term isolated male mice fighting one-on-one instead of in groups of four as in last year's study; (v) A lower dose regimen in full-term isolated male mice and (vi) a high dose temporal course in full-term isolated male mice to correlate injection time with peak fighting effect. These extensive controls were instituted to help define the specificity of our drug effect on isolation-induced fighting behavior.

Drug-free group-housed males and isolated females did not fight. Moreover, cocaine did not produce fighting in these animals. It produced equivocal increases in fight duration in animals isolated for only two weeks. In fully isolated male mice fight duration was increased using just two animals as shown before with multiple animals. At doses of 5 mg./kg. or less, cocaine did not significantly alter fighting behavior in fully isolated male mice. Its peak effect after injection is noted at 1/2 hour in the latter animals.

The results indicate that cocaine enhancement of isolation-induced fighting is a specific one which occurs only at higher doses. This effect is important because most drugs inhibit fighting in this model, often by non-specific means such as sedation, etc. However, cocaine may enhance fighting by increasing general activity levels. Once fighting is precipitated, hyperactivity, coupled with cocaine's anti-fatigue properties may accelerate and sustain the fight. On the other hand, cocaine may specifically stimulate agonistic neurotransmitter systems already aroused by isolation.

Since (i) the catecholamines (CA's), in particular, have been implicated in aggressive behavior, since (ii) CA activity is increased in the brains of isolated animals and since (iii) we have demonstrated for the first time that in vivo cocaine competitively inhibits the uptake of the major central CA, norepinephrine, in cortical nerve endings (Biochem. Pharmacol. 29: 1861-1863, 1980), cocaine may increase fighting behavior in isolated animals by prolonging CA activity at the synapse.

90.5 SOME EFFECTS OF PHENOBARBITAL ON PREGNANT AND NONPREGNANT MICE. L.D. Middaugh, W.O. Boggan, T.N. Thomas and J.W. Zemp. Med. Univ. of So. Car., Charleston, SC 29425.

Perinatal exposure to phenobarbital appears to be deterimental to development. Offspring of mice and rats injected with the drug during pregnancy reportedly have neurochemical, hormonal and behavioral abnormalities. We are interested in the particular factors contributing to these abnormalities and in the present study have determined effects of phenobarbital on pregnant mice, in some cases using nonpregnant females as a control. C57BL/6J mice were used and phenobarbital was injected at doses and stages of pregnancy previously determined to be detrimental to offspring. Peak plasma concentrations produced by initial injections of 20 mg and 80 mg/kg doses 12 days after detection of a vaginal sperm plug were 4.6 µg/ml and 14.5 µg/ml, values 16% and 29% lower than for nonpregnant females. In spite of having lower plasma concentrations of phenobarbital, mice 12 days pregnant had greater drug-induced reductions in locomotor activity than noted for non-pregnant controls; and did not have the elevated activity exhibited by nonpregnant females at low drug doses. Pregnant mice also differed from nonpregnant females by having a greater increase in plasma concentration of corticosterone at one hour following the stress of saline injections. Phenobarbital prevented the stress induced increase of the steroid in nonpregnant but not pregnant mice; however, the drug did not extensively alter the normal increase of corticosterone observed during pregnancy in this species. Continued daily injections of phenobarbital (20 mg, 40 mg, 80 mg/kg) during pregnancy did not alter weight gain of dams, litter size or birth weight of pups. The results of the present study reduce the probability that growth retardation during gestation contributes extensively to the effect of maternal phenobarbital on offspring; and indicate that the reaction to stress and to phenobarbital is increased in pregnant mice, presumably due to accompanying hormonal changes. Grants DA0041 & AA03532.

90.6 PENTOBARBITAL INDUCES A NALOXONE-REVERSIBLE DECREASE IN MESOLIMBIC SELF-STIMULATION THRESHOLDS. Jules M. Nazzaro, Eliot L. Gardner, Wagner H. Bridger, Kristin R. Carlson, and Thomas F. Seeger*. Depts. of Psychiatry and Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. and Dept. of Pharmacology, University of Massachusetts Medical School, Worcester, Mass.

Site-specific increases in response rate for intracranial self-stimulation (ICSS) or decreases in the current level required to sustain ICSS have been demonstrated in rats for a variety of commonly abused drugs, including opiates, stimulants, chlordiazepoxide, alcohol, and phencyclidine. We now report the effects of sodium pentobarbital, another agent of common abuse potential, on ICSS thresholds in rats with electrodes aimed at the ventral tegmentum (A-10 DA cell body area). The testing paradigm was a two-lever rate independent threshold titration system, used in order to partially control for non-selective alterations in motor activity, arousal level, or coordination.

A low dose of pentobarbital (5 mg/kg i.p., 15 min. prior to test) did not significantly change ICSS thresholds, while a high dose (20 mg/kg) rendered the subjects too ataxic to respond reliably in the operant task. However, with a separate group of rats (N=17), a medium dose level (10 mg/kg) induced a highly significant decrease in thresholds in 16 of the subjects (average 17% below baseline saline levels, $p<0.001$), without apparent deterioration in their response capability. The concurrent administration of naloxone (2 mg/kg i.p.) with this dose of pentobarbital reversed the current decrease back towards baseline in 13 rats.

Histological examination of 16 electrode placements showed that the majority were within or just anterior to the target nucleus. Those rats which did not show naloxone-reversibility of their threshold changes demonstrated more lateral placements, primarily in the substantia nigra, pars compacta. We have previously demonstrated a similar relationship for the effects of naloxone on morphine-induced changes in ventral tegmental and substantia nigra ICSS (Pharmacology, Biochemistry and Behavior, 14:325, 1981).

The present results suggest that barbituates, in common with other drugs of abuse, induce a dose-dependent enhancement of brain reinforcement sensitivity and that these effects are mediated, in part, by endogenous opiate peptide systems.

90.7 DRUGS OF ABUSE AND BRAIN STIMULATION REWARD: EFFECT OF NUCLEUS ACCUMBENS LESIONS. C. Muñoz* and S. Lorens, Dept. Pharmacology, Loyola University Medical Center, Maywood, IL 60153

Several compounds with abuse liability enhance responding for lateral hypothalamic (LH) self-stimulation (SS). This suggests that brain stimulation reward (BSR) can be used as a model to study the neural substrate mediating the positively reinforcing effects of abused substances. Recently, Roberts et al (Pharm. Biochem. Behav., 12: 781, 1980) reported that 6-hydroxydopamine (6-DA) lesions of the nucleus accumbens (NAS) blocks intravenous cocaine self-administration in rats. Our work was directed at determining whether 6-DA lesions of the NAS would block the enhancing effect of amphetamine (AMP) as well as morphine (MOR) and chlordiazepoxide (CDP) on responding for BSR.

Responding for LH SS was stabilized according to published procedures (Lorens, Psychopharm., 48: 217, 1976) then surgery performed. Experimental animals (n=8) received bilateral injections of 6-DA (8µg base in 2µl vehicle) into the NAS, whereas control rats (n=12) received either vehicle injections or sham operations. Beginning 6 days post-op, the animals were tested daily in 10 min sessions. D-amphetamine sulfate was administered once every 3-4 days between post-op days 14 and 29 in doses of 0, 0.125, 0.25, 0.5, 1.0 and 2.0 mg/kg, i.p. as the base. CDP (0,4 and 8 mg/kg) was administered similarly between post-op days 32 and 38. On drug days, the rats received a 10 min predrug control session then were tested 10 min at 30 min post-injection. Finally the rats received saline then daily injections of morphine sulfate (5mg/kg, s.c. as the base) and their rates of responding 1, 3 and 5 h post-injection compared to predrug control. The animals were sacrificed 48-50 days post-op.

The 6-DA lesions significantly reduced (64%) dopamine and DOPAC concentrations in the NAS and olfactory tubercle. Responding for BSR post-op did not differ between the lesion and control group. The dose-response curve for AMP was significantly attenuated in the lesion animals. However, the enhanced responding produced by CDP and MOR was unaffected.

These data suggest that the mesolimbic dopaminergic projections to the NAS and surrounding structures may mediate the rewarding property of amphetamine, but not the rewarding properties of CDP and MOR.

90.8 SELF-INJECTION OF NICOTINE IN RATS. W. T. Nelson,Jr. and Brian Cox. Addiction Research Foundation, Palo Alto, CA 94304.

Female Wistar rats (250-300 g) with jugular cannulae were tested 23 hours a day in a paradigm of one week pre-drug saline, two weeks nicotine, and two weeks post-drug saline. Two response bars were available. Each press on the active bar delivered either saline or nicotine (3, 10, or 30 ug/kg) in an infusion of 100 ul/kg. Bar-presses on the control bar had no consequence and served as a control for nicotine's locomotor stimulant effects at these doses. In the 30 ug/kg group of seven rats, response rates on both bars were elevated in the nicotine tests and returned to pre-drug saline levels in the post-drug saline tests. A dim cue light over the drug bar failed to improve the rats' discrimination between the bars. Rats tested in operant chambers twice the standard size also showed no better discrimination than those tested in the standard size chambers.

Three of seven rats self-administered the 10 ug/kg dose above saline levels. Two of these rats selectively responded at higher rates on the drug bar, with unchanged rates on the dummy bar. Preliminary data on three rats indicate that 3 ug/kg has no effect on baseline responding in drug-naive animals. A group of six rats tested for five continuous weeks on saline showed no changes in response rates over time.

Another group of seven rats was tested in a paradigm of one week pre-drug saline, one or two weeks nicotine (30 ug/kg), one week nicotine (10 ug/kg), and two weeks post-drug saline. When the dose of nicotine was lowered, response rates increased on the drug bar and decreased on the dummy bar, but neither rate change was statistically significant compared to the prior week of nicotine 30 ug/kg. Experiments are now in progress in which the dose of nicotine is lowered from 30 to 3 ug/kg in the same paradigm as above. Preliminary data in three rats indicate that when the dose of nicotine was lowered, response rates significantly increased on the drug bar, with no change in rates on the dummy bar.

These studies demonstrate that rats will self-administer nicotine in the absence of any other coupled appetitive drive, such as hunger induced by food deprivation. The results also emphasize the importance of controlling for motor activity effects of the drug in studies of nicotine self-administration.

90.9 OPIATE AND STIMULANT INTRAVENOUS SELF-ADMINISTRATION IN RATS: MEDIATION BY SEPARATE NEURAL SYSTEMS. A. Ettenberg, G.F. Koob, H.O. Pettit*, and F.E. Bloom. Arthur Vining Davis Center for Behavioral Neurobiology, The Salk Institute, San Diego, California, 92138.

Recent reports have suggested that the reward produced during self administration of different psychoactive drugs might be mediated by a single common pathway, such as a dopamine or an endogenous opioid peptide system. The present study was devised to examine these possibilities by observing the effects of both the dopamine receptor antagonist drug alpha-flupenthixol and the opiate antagonist drug naltrexone on the self administration of either cocaine or heroin in rats.

Male albino rats implanted with jugular catheters were permitted to lever press for either cocaine (0.75 mg/kg/infusion) or heroin (60 ug/kg/infusion) during daily 3h sessions. On test days, animals were pretreated with i.p. injections of either naltrexone (0.01, 0.05, 0.1, 0.2, 1.0, or 10.0 mg/kg), alpha-flupenthixol (0.01, 0.5, 0.1, 0.2 or 0.4 mg/kg) or saline. For some animals the effects of these treatments were subsequently observed during drug reinforced responding while others were tested during a single extinction (i.e. no reinforcement) session. The dopamine antagonist (at doses below 0.2 mg/kg) produced dose-dependent increases in lever-press rates for cocaine but had no effect on the response rates (or pattern) of animals self administering heroin. Similarly, opiate receptor antagonism produced dose-dependent increases in responding for heroin without affecting responding for cocaine (even at the highest dose). The high doses of alpha-flupenthixol (0.2 and 0.4 mg/kg) either markedly reduced or completely eliminated all responding in both the cocaine and heroin conditions. There was, however, no evidence that the pattern of response disruption at these doses produced behaviors resembling the pattern of behavior observed during extinction. In addition, alpha-flupenthixol but not naltrexone, markedly attenuated the response rates of animals that were tested under conditions of extinction where the drug-reinforcement was withheld.

These data suggest that separate neural systems mediate the rewarding consequences of cocaine and heroin self administration. Dopamine receptors appear to be involved in cocaine but not opiate reinforcement with the opposite being the case for opiate receptors. These data also support the contention that high doses of neuroleptics, in addition to their effects on reward, may also produce a generalized or nonspecific disruption of response performance.

91.1 HORSERADISH PEROXIDASE DEMONSTRATION OF THE AFFERENT AND EFFERENT CONNECTIONS OF THE SUBFORNICAL ORGAN. D.A. Wheeler* and J.B. Simpson (SPON: R.H. Lovely). Department of Psychology, University of Washington, Seattle, WA 98195.

The subfornical organ (SFO), located on the rostral wall of the third ventricle at the level of the intraventricular foramen, has been shown to be involved in the central control of body fluid homeostasis. Knowledge of the connections of the SFO is a prerequisite to understanding its involvement in body fluid regulation. However, the neural connections of the SFO are still incompletely known (Miselis et al., Sci. 205: 1022, 1979).

Retrograde and anterograde transport of horseradish peroxidase (HRP) was used to locate the afferent and efferent connections of the SFO. Injections of 40-60 nl of 200 μg/μl HRP (Sigma Type VI) were made through a 31 ga cannula stereotaxically placed in or adjacent to the SFO. Injections often included portions of the ventricle fornical commissure adjacent to the SFO. The animals were sacrificed at times ranging from 19 h to 42 h post-injection. The perfusion procedure of Rosene and Mesulam (J. Histochem. Cytochem. 26: 28, 1978) and the tetramethyl benzidine procedure of Mesulam (J. Histochem. Cytochem. 28: 1255, 1980) were used to visualize the transport of the HRP.

Afferents to the SFO from the preoptic area were shown from: the organum vasculosum of the laminae terminalis; nucleus medianus; and the lateral, medial, and paraventricular preoptic nuclei. Afferents to the SFO from the septum were shown from: the medial, lateral, fimbrial, and triangular septal nuclei; the nucleus of the diagonal band; and the bed nucleus of the stria terminalis. Hypothalamic afferents to the SFO were shown from: the periventricular, paraventricular, anterior, and lateral hypothalamic nuclei. The anterior dorsal, anterior ventral, anterior medial, medial, ventral, lateral, and reticular thalamic nuclei were shown to have afferent connections to the SFO. Additionally, the anterior continuation of the hippocampus and the indusium gresium had afferents to the SFO.

Efferent connections from the SFO were shown to: the organum vasculosum of the laminae terminalis; nucleus medianus; the medial, lateral, fimbrial, and triangular septal nuclei; the periventricular and supraoptic hypothalamic nuclei; and the anterior dorsal thalamic nucleus.

The demonstrated connections may be parts of the neural substrate for the control of body fluid homeostasis subserved by the SFO and the other nuclei connected with it.

91.2 HYPERTONIC SALINE- AND ANGIOTENSIN-INDUCED DRINKING IS BLOCKED BY DESTRUCTION OF DORSAL NUCLEUS MEDIANUS. M.L. Mangiapane, T. Gardiner* and J.B. Simpson. Dept. of Physiol., U.C. San Francisco, CA 94143.

Several structures bordering the third ventricle have been implicated in the regulation of drinking, including the organum vasculosum (OVLT), subfornical organ (SFO), and anteroventral third ventricle (AV3V). Also in this region is the nucleus medianus (NM), a midline structure wrapped vise-like about the anterior commissure (AC), roughly equidistant from OVLT and SFO. NM receives input from SFO, and is one of several structures included in the AV3V lesion. In view of its central location in a region so strongly implicated in the control of fluid balance, we made lesions of the NM and assessed their effect on hypertonic saline- and angiotensin II (AII)- induced drinking. With 127μ tungsten electrodes, small electrolytic lesions were made in male Long-Evans rats. Using 7 millicoulombs x 3 penetrations, we destroyed only that portion of NM dorsal and anterior to AC. Ventral nucleus medianus and periventricular AV3V tissue (including OVLT) were undamaged. Control lesions were placed in lateral septum and diagonal band. One week later, animals were tested for drinking to s.c. injections of hypertonic saline or AII. The hypertonic saline dose (3.33 ml/kg, 2M) raised plasma osmolality by 3%; the AII dose (1.5 mg/kg) was chosen to replicate studies by others on the AV3V lesion syndrome of adipsia and deficits in drinking to AII.

Destruction of the dorsal-anterior NM (DNM) almost totally blocked drinking to hypertonic saline (1.2 ± 0.6 ml vs. 5.6 ± 0.7 ml for control-lesion rats, $p < .001$). Drinking to AII was significantly reduced (2.6 ± 1.7 ml vs. 7.8 ± 1.2 ml for control-lesion animals, $p < .05$). In addition, latencies to drinking were significantly longer in DNM-ablated rats ($p < .05$) given either dipsogen. With ad-lib drinking intact, the observed blockade of drinking to AII and hypertonic saline in DNM-ablated rats distinguishes them from SFO-ablated animals (no drinking to AII) and from AV3V-ablated animals (adipsia + deficits to both dipsogens). While the DNM region appears necessary for drinking induced by these two dipsogens, fibers of passage from the actual receptors involved may have been destroyed in this lesion. These are clearly not mutually exclusive explanations for the results.

(Supported by USPHS Grant AM06704 and an NIH postdoctoral fellowship).

91.3 DIPSOGENIC ADDITIVITY IN RODENT SPECIES WITH DIFFERING CENTRAL ANGIOTENSIN II BINDING CAPACITY. J. W. Wright, S. L. Morseth* and J. W. Harding. Departments of Psychology and Veterinary Comparative Anatomy, Physiology and Pharmacology, Washington State University, Pullman, WA 99164.

Cellular dehydration and hypovolemia are currently believed to activate separate receptor mechanisms responsible for the control of drinking. This dual detection hypothesis predicts that elevated effective osmotic pressure of body fluids and decreased intravascular volume, which stimulates renin release which in turn converts angiotensinogen into angiotensin in the circulation, exert additive effects upon water consumption. In the present series of experiments Sprague-Dawley rats, Mongolian gerbils, Golden Syrian hamsters and the South American rodent Octodon degus were initially tested with two treatments known to facilitate the release of renin in rats, viz. polyethylene glycol (PG) and isoproterenol (ISOP), plus the osmotic stimulus, hypertonic saline (NaCl). All species were responsive to NaCl. Rats were dipsogenically responsive to PG and ISOP treatments while degus and hamsters were maximally responsive to PG. Gerbils were unresponsive to PG but did drink following ISOP injection.

On the bases of these results either ISOP or PG, which ever was maximally effective, was paired with NaCl in a test of dipsogenic additivity in additional members of each of the four species. Rats revealed additivity when PG and NaCl were paired and also when ISOP and NaCl were paired. Gerbils failed to show additivity with ISOP + NaCl. Hamsters also failed to demonstrate additivity with the pairing of PG and NaCl. Degus did show additivity with PG + NaCl.

These results were not predicted on the bases of central angiotensin II (AII) receptor binding. The gerbil revealed binding only in the olfactory bulb while the degu indicated no binding anywhere in the brain. The rat and hamster indicated high levels of binding throughout many brain structures (Harding, J. W., Stone, L. P. and Wright, J. W. Brain Research, 205:265, 1981). In order to explain these results we hypothesized that gerbils and degus may possess angiotensin III (AIII) brain receptors. If this is the case these species would be expected to respond to the intracerebroventricular infusion of AIII. Gerbils prepared with chronic cannulas were found to drink vigorously in response to 5 and 50 ng AIII. We are presently extending this evaluation to the other three species.

91.4 LACK OF PENETRATION OF ANGIOTENSIN II INTO THE CEREBROSPINAL FLUID FOLLOWING INTRAVENOUS INFUSION. S.P. Frankmann*, I.A. Reid, and J.B. Simpson. (SPON: J.S. Lockard). Dept. Psychol., Univ. Washington, Seattle, WA 98195 & Dept. Physiol., UCSF, San Francisco, CA 94143.

Angiotensin II (AII) in the circulation is normally excluded from the cerebrospinal fluid (CSF) by the blood-CSF barrier (BCB). A question then arrises: do intraventricular injections of AII, which provoke various effects, mimic the central effects of circulating AII? Acute hypertension causes a transient disruption of the BCB, possibly allowing passage of normally excluded molecules from the blood into the CSF. Under certain pathophysiological states, such a systemic administration of large quantities of AII or renal hypertension, AII may cross the BCB. We measured quantities of AII reaching the CSF during acute hypertension induced by high circulating levels of AII.

Saline vehicle or AII doses of 1, 10, 100, or 1,000 ng/min were infused via jugular vein in anesthetized 300 gm rats. CSF from the cisterna magna and blood from the descending aorta were collected after a 30 min infusion (which continued during collection). The collection procedures took 8 min or less. Plasma and CSF AII concentration was measured by radioimmunoassay. Mean arterial pressure was monitored.

Blood pressure exhibited a dose-dependent increase up to the asymptotic AII dose of 100 ng/min. Out of 36 animals infused with AII, including 20 cases with plasma values greater than 1200 pg/ml, only 5 had values greater than the limit of detection of the assay of 100 pg/ml. In no case was the CSF value greater than 140 pg/ml. In contrast, a 10 ng injection of AII into the lateral ventricle (n=10) produced cisternal CSF concentrations of 2,652 pg/ml, 2 to 10 min later.

Thus, in some instances small quantities of AII may cross the BCB and appear in the CSF. These data suggest, however, that circulating AII does not normally enter the CSF in appreciable quantities, and question the physiological significance of intraventricular injections of AII.

Supported by HL 21800 and AM 06704.

91.5 ALTERATION OF DRINKING BEHAVIOR BY TRANSPLANTATION OF KIDNEY CORTEX TO THE RAT BRAIN. J.M. Morihisa,* H.E. Cannon-Spoor,* R.J. Wyatt, and W.J. Freed (SPON: A.P. Oliver). Adult Psychiatry Branch, National Institute of Mental Health, Washington, D.C. 20032.

Because of its special immunological characteristics, grafts placed in the brain are unlikely to be rejected. These favorable properties of the brain as a site for transplantation have recently been employed to produce grafts which retain some of their original function. In the present experiment we investigated the possibility that drinking behavior could be altered by increasing the production of the proteolytic enzyme renin, through transplantation of kidney cortex to the rat brain. Intracranial injections of renin stimulate drinking in the rat (Epstein, A.N., et al., J. Physiol. 210:457, 1970) and the cat (Brophy, P.D. and Levitt, R.A., Pharmacol. Biochem. Behav. 2:509, 1974). Thus, if grafts of kidney cortex survive and continue to produce renin, they would be expected to cause increases in drinking behavior.

Forty-four Sprague-Dawley male rats were housed individually in wire-mesh cages with free access to food and water. Some of these animals received grafts of pieces of kidney cortex from one-month old donors into both lateral ventricles. Control animals received bilateral injections of lactated Ringer's or no operation. Water intake was then recorded for a period of one to two months.

The rats with grafts of kidney cortex showed a transient two-fold increase in drinking, which was apparent immediately after grafting but returned to control levels within two weeks after the operation. Histological studies revealed surviving grafts in all of the animals, with cells and structures similar to those of typical kidney cortex.

Intracerebral grafts of renin-producing tissue cause elevated drinking behavior as do intracerebral injections of renin and angiotensin. Thus, cortical kidney grafts survive in the brain and transiently retain some of their functional characteristics. We are now attempting to determine whether the return to baseline drinking levels is due to adaptation of the brain to continuously elevated renin levels or to a loss of ability of the grafts to produce renin. The possibility of using the brain as a site for enzyme producing homografts to effect physiological changes is partially supported by these data.

91.6 STUDIES OF ANGIOTENSIN IN PRIMATES. E.P. Petersen*, J.W. Wright, and J.W. Harding. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, and Psychology, Washington State University, Pullman, WA 99164.

Angiotensin II (AII) is an octapeptide that has a major role in maintaining body water hemeostasis and insuring adequate tissue perfusion in times of vascular volume loss. The mechanisms by which AII accomplishes its function include both peripheral and central nervous system mediated events. Present concepts concerning the action of AII in primates have been extrapolated primarily from rodent studies. Recent studies in our laboratory have highlighted many interspecies differences in AII systems and mechanisms of body water maintenance. This has stimulated a more rigorous direct examination of primates. African green monkeys were found to respond to peripherally injected AII or AII-dependent stimuli by increasing water intake. In addition to this central effect, the peripheral release of aldosterone from the adrenal cortex was also noted. These results support the notion that AII in primates exerts both central and peripheral effects. Classically it is possible to envision these effects as being mediated through the interaction of AII and cell surface receptors. Because of the diverse actions initiated by AII, biochemical examination of AII receptors at different sites seemed warranted. Such a study, which measured ^{125}I-II binding, indicated the presence of different receptor types in brain, uterus, and adrenals. These receptors exhibited differences in metal ion requirements as well as differences in ligand specificity. In contrast to previous studies on rats, it was of particular interest to note the superior binding potency of angiotensin III (AIII), a naturally occurring AII derivative. This finding provides the initial suggestion that AIII, not AII, is the active peptide in primates. A second important finding that casts doubt on the use of rodents to predict AII characteristics in primates was a difference in brain region distribution of AII binding in the monkey as compared to rat.

92.1 EFFECTS OF CHRONIC AMPHETAMINE ON BLOOD, BRAIN AND ADRENAL CONCENTRATIONS OF TRYPTAMINE AND TETRAHYDRO-β-CARBOLINE: BEHAVIORAL IMPLICATIONS. R.E. Harrison, S.T. Christian, P. Hyde and G.V. Pegram, Neurosciences Program, Univ. of Alabama in Birmingham, Birmingham, Al. 35294.

Recent investigations from this laboratory have indicated that psychological stress will alter tryptamine (TA), N-methylated indole, and tetrahydro-β-carboline (THBC) content in rat brain and adrenal glands. Continuous administration of amphetamine is known to alter brain indole metabolism and gives rise to a behavioral syndrome similar to that produced by hallucinogens. Stress or amphetamine will cause a progressive enhancement (sensitization) of a similar behavioral syndrome. These phenomena might suggest that stress- and amphetamine-associated behaviors act through a common mechanism involving TA and its metabolites. To examine this question further, rats were subjected to a regimen of either saline or 3 mg/kg q.i.d. d-amphetamine x 8 days. Animals from both the control and amphetamine groups were sacrificed every two days. The blood, brain and adrenal TA, dimethyltryptamine (DMT), 5-methoxydimethyltryptamine (5-MeOT), 6-methoxytetrahydro-β-carboline (6-MeOTHBC) and THBC levels from these animals were measured with isotope-dilution gas chromatography/mass fragmentography. Additional assessments were made of heart rate, blood pressure, stereotypy and open-field behavior. In these experiments it was shown that 1) d-amphetamine caused increases in blood, brain and adrenal TA and THBC, but the increase in blood and adrenal TA and THBC concentration was greater than in the brain; 2) the increases in TA and THBC content of any tissue in rats given amphetamine were not dosage dependent; 3) the blood pressure was indirectly proportional ($r=-.911$) to the concentration of THBC in blood, but only in animals treated with d-amphetamine; 4) multiple injections of d-amphetamine produce sensitization phenomena during the initial portion of the amphetamine response. It is proposed that TA and THBC are involved in behavioral and physiological modifications resulting from amphetamine administration.

92.2 SHIFT FROM AMPHETAMINE-INDUCED INHIBITION TO EXCITATION IN THE NEOSTRIATUM, BUT NOT IN THE NUCLEUS ACCUMBENS, FOLLOWING LONG-TERM TREATMENT. Kevin D. Alloway and George V. Rebec. Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Acute administration of amphetamine produces a dose-dependent shift in neuronal activity in the neostriatum, but not in the nucleus accumbens. Whereas low doses inhibit the firing rate of neurons in both brain regions, high doses of amphetamine inhibit the nucleus accumbens but excite neostriatal activity. This shift in the firing rate of neostriatal neurons appears to parallel the amphetamine-induced dose-dependent transition from forward locomotion to focused stereotypy (Rebec and Zimmerman, Brain Res., 1980, 201: 485). Since the time-course and intensity of the amphetamine behavioral response are significantly altered with long-term treatment (eg., Rebec and Segal, Pharmac. Biochem. Behav., 1980, 13: 793), we extended our electrophysiological analysis to include the effects of repeated amphetamine injections on neuronal activity in these sites.

Adult, male rats received intraperitoneal (ip) injections of saline, 1.0 or 5.0 mg/kg d-amphetamine twice daily for six consecutive days. The animals were immobilized and locally anesthetized on the following day and single unit activity was recorded simultaneously from the neostriatum and nucleus accumbens. Challenge doses of amphetamine were injected via an in-dwelling ip catheter.

In saline pretreated rats, amphetamine produced a dose-dependent biphasic effect on neurons in the neostriatum. Thus, whereas the predominant response to 1.0 mg/kg d-amphetamine was an inhibition of firing rate, neurons responded to 5.0 mg/kg with either an inhibition or an excitation. Following chronic amphetamine treatment, both doses produced a significant increase in neostriatal activity compared to saline pretreated controls. Neurons in the nucleus accumbens, however, were mainly inhibited by 1.0 or 5.0 mg/kg d-amphetamine in both saline and amphetamine pretreated animals. In fact, no differences were apparent in either the duration or intensity of this response following chronic amphetamine administration. These results suggest that the neostriatum, rather than the nucleus accumbens, is responsible, at least in part, for the behavioral alterations that accompany long-term amphetamine treatment.

This research was supported by USPHS Grant DA-02451-03 from the National Institute on Drug Abuse.

92.3 EFFECTS OF SYSTEMIC TRYPTOPHAN LOADING ON CENTRAL SEROTONIN METABOLISM IN RATS FOLLOWING CHRONIC METHAMPHETAMINE ADMINISTRATION. Violet M. Trulson* and Michael E. Trulson (SPON: R. Stillman). Dept. Psychol., Univ. of Texas at Dallas, P.O. Box 688, Richardson, TX, 75080.

The various behavioral and physiological effects of amphetamine are thought to be mediated primarily through an action on brain catecholamines. Several recent studies, however, have focused on the serotonergic effects of amphetamine. Acute administration of amphetamine increases the release and turnover of serotonin (5HT), while chronic drug administration produces a decrease in central 5HT metabolism (Trulson and Jacobs, J. Pharm. Exp. Ther. 211: 375-384, 1979). This latter effect appears to be mediated, at least in part, by a decrease in the activity of tryptophan hydroxylase (TPH), the rate limiting enzyme in 5HT biosynthesis (Trulson and Jacobs, Life Sci. 26: 329-335, 1980). To more fully explore the serotonergic effects of amphetamine treatment, in the present study we investigated the effects of chronic administration of methamphetamine (METH) on the kinetics of TPH and examined the effects of tryptophan (TP) loading on 5HT metabolism following chronic METH treatment. Adult male rats were injected with either METH HCl (20 mg/kg, i.p.) or saline (SAL, 1.0 ml) every 12 hr for 6 consecutive days, and were killed for TPH assays (using the method of Gal and Patterson, Anal. Biochem. 52: 625-629, 1973) 12 hr after the final injection. Additional groups of rats received a single injection of either METH (20 mg/kg) or SAL and were assayed 12 hr later. Chronic METH treatment produced a significant decrease (-32%) in the V_{max} of brain TPH, while a single injection of the drug had no significant effect. Neither acute nor chronic METH administration produced any significant changes in the K_m of TPH for either TP or tetrahydrobiopterin. Chronic METH treatment also produced significant decreases in brain 5HT (-33%) and 5HIAA (-27%), while brain TP levels were not significantly changed. TP loading (50 mg/kg, i.p.) resulted in similar % increases in 5HT (31 & 34%) and 5HIAA (42 & 47%) levels in SAL and METH pretreated groups. Thus, 5HT and 5HIAA returned to normal levels following TP loading in the METH pretreated group, and were elevated above normal levels in the SAL group. Chronic METH administration decreased brain dopamine (-45%) and norepinephrine (-42%), and the catecholamines were not significantly changed by TP loading. The fact that only the V_{max} of TPH is changed by chronic METH administration, with no change in the affinity for either substrate or cofactor, suggests that there are either fewer enzyme molecules present or fewer active sites per enzyme molecule. The remaining 5HT biosynthetic machinery, however, appears to respond normally to TP administration. Therefore, it may be possible to restore central 5HT function to normal following chronic METH administration by systemic TP loading.

92.4 **WITHDRAWAL FROM CONTINUOUS APOMORPHINE: A NOVEL HALLUCINOGEN.** **R. E. Davis, W. W. Sant and G. Ellison. Department of Psychology, University of California, Los Angeles, CA. 90024**

Chronic, continuous amphetamine (D-AMP) administration induces a behavioral syndrome consisting of limb flicks, wet dog shakes and other abnormal behaviors. These behaviors are seen after acute administration of hallucinogens and are not seen following the acute administration of catecholamine agonists in rats. The appearance of these behaviors is correlated primarily with alterations in the metabolism and receptor sensitivity in the dopaminergic systems of the neostriatum (NS) and nucleus accumbens (NA). To further clarify the role of dopaminergic mechanisms in the appearance of these "hallucinogen-like" behaviors, we developed techniques for chronic, continuous administration of the selective dopamine (DA) agonist, apomorphine (APO).

Twenty-four male, albino rats were implanted subcutaneously either with a silicone pellet containing 25 mg of APO base (N=16) in PEG or one containing PEG (N=8). This pellet produces a mean dosage of 1.0 mg/kg/hr in 400 g animals. Since APO oxidizes rapidly, a new pellet was implanted 24 hrs after the first implantation. Forty-two hrs after the first implant, all animals were removed from their home cages and were placed in observation cages. One-half of the animals receiving APO had their pellets removed 4hrs prior to placement in the observation cages. The frequency and duration of 18 behavior classes were scored continuously for the next 30 mins. These behavior classes can be divided into 3 subcategories: 1) normal behaviors (e.g. grooming); 2) "hallucinogen-like" behaviors (e.g. limb flicks); and 3) motor dyskinesias (e.g rapid jaw movements). Parallel groups of animals given identical treatment as above were prepared for simultaneous analysis of DA, DOPAC, HVA, 5-HT and 5-HIAA in 3 DA rich regions (NS, NA and ventral tegmentum, VT) using HPLC with electrochemical detection.

Animals so treated did not exhibit stereotyped behavior at any time nor did they demonstrate "hallucinogen-like" behavior in their home cages. When these animals were removed from their home cages and were placed in novel environments, they initially exhibited a burst of "hallucinogen-like" behaviors. These behaviors gradually subsided during the observation session being replaced in later parts of the session by intense motor dyskinesias (rapid jaw movements and respitory tics). These behavioral changes were accompanied by increases in the levels of DA and HVA in the NS but not the NA or VT. In contrast, 5-HT levels were elevated in the NA and VT but not in the NS while 5-HIAA levels were elevated in all 3 areas.

92.5 EFFECTS OF CONTINUOUS LOW-LEVEL d-AMPHETAMINE ADMINISTRATION ON VOLUNTARY ALCOHOL CONSUMPTION. Allen D. Potthoff* and Gaylord D. Ellison (SPON: J. T. Cannon). Department of Psychology, U.C.L.A., Los Angeles, CA 90024.

Rats given subcutaneous implants of pellets which released 33 mg of d-amphetamine (d-AMP) continuously over a 30 day period increased voluntary intake of 10% v/v ethanol (EtOH), from a baseline mean of 15 cc/rat/day to a mean of 24 cc/rat/day during d-AMP treatment. Choice of 10% v/v EtOH solution increased from a pre-treatment group mean of 42 % of total fluid intake to 69% of total fluid intake during d-AMP treatment. Neither rats drinking anise-water or a solution isocaloric to 10% v/v EtOH given continuous d-AMP pellets, nor rats drinking 10% v/v EtOH and given daily injections of the same amount of d-AMP showed increases in flavored fluid intake comparable to the original group. Rats withdrawn from drinking 10% v/v EtOH for six days also exhibited less of an increase in EtOH intake than the original group. Behaviorally, rats treated with d-AMP pellets showed enhanced motor activity. Daily i.p. injections of 0.25 g/kg EtOH were increasingly effective in reducing the enhanced motor activity. It is hypothesized that the continuous low-level administration of d-AMP models the type of metabolic imbalance present in cases of chronic stress and that ethanol antagonizes the effects of the continuous d-AMP. Therefore, the d-AMP pellet treated rats increased ethanol intake as a means of self-medication. (Supported by AA02969)

92.6 HALLUCINOGEN-LIKE EFFECT OF CONTINUOUS AMPHETAMINES ON STARTLE. W. W. Sant*, R. Davis, and G. Ellison (SPON: D. Glanzman). Dept. Psychol., UCLA, Los Angeles 90024

Nielsen et al. (Psychopharm., 68) reported that an acute injection of d-amphetamine (d-Amp) decreased the frequency of behaviors typically elicited by hallucinogens, but these behaviors were increased when d-Amp injections are given 12 hrs following 4 1/2 days of continuous low levels d-Amp.

It has been shown that while both hallucinogens and d-Amp increase acoustic startle response amplitude (ASRA), they do so in a different fashions. D-amp increases ASRA by decreasing habituation and increasing sensitization to repeated tones, while the hallucinogen LSD increases the sensitization effects of background white noise on ASRA. Exposing rats to white noise preceding and during the presentation of startle-eliciting tones increases the magnitude of the rat's response to each tone (increasing ASRA). This effect is augmented by acute hallucinogen administration but not by acute d-Amp administration.

Male Sprague-Dawley rats were pretreated with the d-Amp or vehicle pellet for 4 1/2 days. The pellets were then removed and 12 hrs later animals were administered either d-Amp or vehicle and placed immediately into the startle apparatus and exposed to white noise for 15 minutes prior to the onset of a series of startle-eliciting tones. The result observed was that with as with LSD administration, ASRA was greater for the first tones in the series in the animals pretreated with d-Amp pellets and then administered d-Amp than in similarly pretreated animals administered vehicle. This effect stood in stark contrast to vehicle pellet pretreated animals, where the effect of d-Amp was to decrease ASRA on the first tones of the series. (supported by DA 02312)

92.7 CHRONIC STIMULANT ADMINISTRATION RESULTS IN INCREASED ALCOHOL AND BENZODIAZEPINE DRINKING IN RATS. Linda R. Nelson, Allen D. Potthoff*, and Gaylord D. Ellison. Dept.of Psychology, UCLA, Los Angeles, CA 90024.

Previous investigations in our lab have demonstrated that after implantation of continuous slow-release d-amphetamine (d-AMP) pellets, rats with free access to water and 10% v/v ethanol (EtOH), selectively increase their consumption of the EtOH solution over baseline levels. We have hypothesized that this represents a form of self-medication, such that the rats increase their alcohol intake to counteract the stimulatory effects of amphetamine. In order to further explore this hypothesis, we have varied both the drug solution available for drinking, and the drug chronically administered via implant.

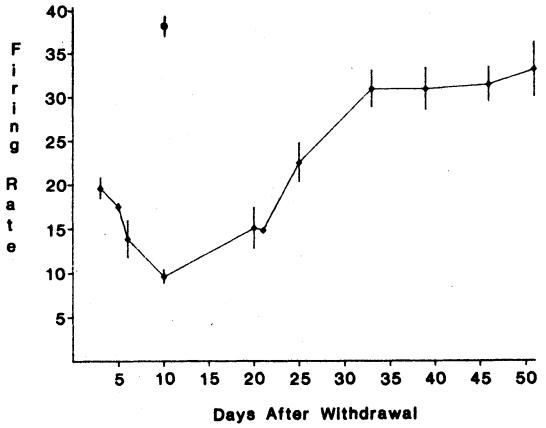
When a benzodiazepine solution (diazepam - .060 mg/ml), was substituted for the 10% EtOH, similar results were obtained. After d-AMP pellet implantation, diazepam intake rose from 25% to 40% of total fluid intake.

The following substances were administered in a chronic slow-release manner in place of d-AMP and resulted in no increase in EtOH consumption: caffeine, phencyclidine (PCP), LSD, mescaline, haloperidol, and secobarbital. However, rats treated with continuous slow-release nicotine increased their ethanol drinking from 39% to 76% of total fluid intake.

These results extend the self-medication phenomena to another stimulant: nicotine, and another depressant/anxiolytic: diazepam. Future investigations will search for neurochemical alterations produced by the chronic stimulant administration and their possible attenuation by the concomitant ingestion of alcohol or anxiolytics. (Supported by AA02969)

92.8 EFFECTS OF WITHDRAWAL FROM CHRONIC AMPHETAMINE ON SPONTANEOUS PURKINJE NEURON DISCHARGE IN RAT CEREBELLUM. S.M. Sorensen, S. Johnson* and R. Freedman. Univ. of Colorado Health Sciences Center, Denver, CO 80262.

The spontaneous discharge of rat cerebellar Purkinje (P) cells, known to be controlled by the β-adrenergic (NE) input from the locus coeruleus was studied in animals after withdrawal from chronic treatment with amphetamine (2 mg/kg per day x 21 days). Discharge rates in withdrawn animals remained significantly lower than those of controls for up to 50 days.



Disruption of central adrenergic transmission by the β antagonist propranolol or the NE-depleting agent reserpine partially restored discharge rate. P cells from amphetamine-withdrawn rats were not further depressed by acute administration of amphetamine, whereas P cells from control animals were markedly slowed. Moreover, P neurons from amphetamine withdrawn rats manifested a small subsensitivity to locally applied NE. Taken together, these data suggest that amphetamine withdrawal is associated with a long-term increase in the activity of the noradrenergic input to cerebellar cortex. (Supported by USPHS Grant # DA-02429 and NS-09199).

92.9 EFFECTS OF CHRONIC AMPHETAMINE ADMINISTRATION ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE RAT. D. Dow-Edwards, F. Orzi*, J. Jehle*, C. Kennedy, and L. Sokoloff. Lab. of Cerebral Metabolism, NIMH, Bethesda, MD 20205.

Amphetamine, a dopaminergic stimulating agent, has many biochemical and behavioral effects when administered to rats. The effects of acute amphetamine administration on local cerebral glucose utilization (LCGU) have been described (Wechsler, et al., J. Neurochem.32:15-22, 1979). Components of the extrapyramidal motor system as well as those of other dopaminergic systems showed increased metabolic rates following i.v. administration of 5 mg/kg of d-amphetamine. In the present studies we have reproduced these earlier findings and have also examined the effects of chronic d-amphetamine administration on LCGU in conscious rats. There were two methods of administering the amphetamine chronically. Two groups of rats received daily i.p. injections of either 5 mg/kg for 2 weeks or increasing doses from 5 mg/kg to 15 mg/kg for 3 weeks. Two other groups of rats were implanted with osmotic pumps (Alzet, Alza Co.) designed to release amphetamine continuously for either 1 week or 2 weeks. The dosage approximated 15 mg/kg/day for the one week treatment and 5 mg/kg/day for the two week treatment. A fifth group of rats received an acute dose of 5 mg/kg i.v. after two weeks of i.p. saline injection. A sixth group of rats received the same acute dose after 2 weeks of receiving daily i.p. injections of 5 mg/kg drug.

At the end of the drug administration or 20 minutes following the acute injection, local cerebral metabolism was studied by the [^{14}C]deoxyglucose method. Forty-nine brain regions in 30 rats were examined autoradiographically. The acute treatment resulted in significant increases in glucose utilization in several regions including the substantia nigra, caudate nucleus, several thalamic nuclei, the subthalamic nucleus, and the red nucleus. The metabolic rate in the lateral habenula was significantly decreased. Pretreatment with daily injections followed by a single acute dose of amphetamine produced similar but enhanced effects. Daily injections of amphetamine with no acute injection (a period of 6 hours was allowed between the last injection and the initiation of the deoxyglucose method) resulted in no statistically significant increases in LCGU. Continuous administration for both 1 and 2 weeks via the osmotic pump, however, did significantly increase local metabolic rate in the n. accumbens. This increase was not seen following acute or daily i.p. injections of amphetamine. This is, to our knowledge, the first demonstration of an effect of d-amphetamine on metabolism in any component of the mesolimbic system.

93.1 NEURAL CIRCUITRY FOR MATE CALLING IN MALE SOUTH AFRICAN CLAWED FROGS, XENOPUS LAEVIS. D. M. Wetzel, and D. B. Kelley. Dept. of Psychology, Princeton Univ., Princeton, NJ 08544.

Male Xenopus laevis produce a distinctive mating call during their breeding season. The aim of these experiments was to establish the neural circuitry involved in mate calling. The larynx is the structure responsible for the production of calls in frogs. Previous work in our lab has shown that the motor neurons controlling the laryngeal musculature are located in cranial motor nucleus IX-X (n.IX-X).

Retrograde transport of horseradish peroxidase conjugated to wheat germ agglutinin (HRP-WGA) was used to investigate the connections of medullary vocal nuclei. HRP-WGA was used to produce the intense and small injection site necessary for work in frog brain. Iontophoretic injections of HRP-WGA were made into n.IX-X. After 48 hrs. survival, frogs were sacrificed and perfused. Frozen sections were reacted with tetramethylbenzidine or cobalt intensified diaminobenzidine and hydrogen peroxide. Labelled cells were located in the ipsilateral and contralateral dorsal tegmental area of the medulla (DTAM, terminology of Kelley et. al, 1975, J. Comp. Neurol.) and a small ipsilateral nucleus adjacent and medial to n.IX-X. The ipsilateral DTAM was labeled more heavily then the contralateral. Injections of HRP-WGA into DTAM resulted in labeled cells in the ipsilateral preoptic area; no labelled infundibular cells were seen. The ipsilateral and contralateral n.IX-X contained HRP- filled cells. These latter data suggest reciprocal connections between the laryngeal motor nucleus and its medullary afferent nucleus, DTAM.

On the basis of electrophysiological studies in Rana pipiens, Schmidt (J. Comp. Physiol., 1976) has proposed a neural model for the generation of anuran mate calls. The connections described above support several features of the proposed model, including input from anterior diencephalic nuclei such as the preoptic area, and suggest new loci for interactions in the calling circuit. In Xenopus laevis, mate calling is under the control of steroid hormones. Many of the nuclei described above, which contribute to the generation of calling, contain hormone-concentrating cells and are thus potential candidates for mediating the powerful behavioral effects of sex steroids.

93.2 MALE AND FEMALE LARYNGEAL MOTORNEURONS IN XENOPUS LAEVIS. P. C. Hannigan* and D. B. Kelley. (SPON: S. Reingold). Dept. of Psychology, Princeton Univ., Princeton, NJ 08544.

The sex typical vocal behaviors of male and female Xenopus laevis differ. These differences are paralleled in the vocal organ, the larynx. Adult, sexually mature, males typically have larger and more muscular larynxes than adult, sexually mature females. Mean weight for males is 0.42g (range 0.30 to 0.52) and mean weight for females is 0.13g (range: 0.11 to 0.15). The objective of our studies was to determine if there is also sexual dimorphism in the motorneurons which innervate the larynx. These cells comprise cranial nerve IX-X (n.IX-X) and are located caudal to cranial nerve V (n.V) and VII and rostral to the spinal cord neurons. These neurons are found lateral to the medullary grey in a column approximately 1mm long. Adult male and female Xenopus laevis received injections of horseradish peroxidase (HRP) into the laryngeal muscles. Motorneurons labelled with HRP of females were found in approximately the same location in the medulla as those of males. Female motorneurons appeared smaller and were located more medially than their male counterparts. These differences were examined further in normal Nissl stained material. Males were found to have larger motorneurons than females. The mean cell size for males is 420.44μ^2, while the mean cell size for females is 341.63μ^2. Males were further found to have more motorneurons than females. Mean number of motorneurons for males is 620 while mean number of motorneurons for females is 373. We also counted the motorneurons of n.V. The mean number of motorneurons for males is 389 and the mean number of motorneurons for females is 299. We calculated a difference score ($\frac{X - Xf}{Xm + Xf}$). Using this measure, the number of IX-X cells were 25% greater in males than in females. The number of V cells were 13% greater in males than females. Thus laryngeal motorneurons in Xenopus laevis were found to be sexually dimorphic with response to cell number, cell size and cell position. This dimorphism may contribute to differences in vocal behavior. Differences in motorneuron number could reflect an overall difference between male and female brains as n.V neurons were also fewer in females than in males. The mechanism for these sex differences remains to be determined.

93.3 A 2-DEOXYGLUCOSE AUTORADIOGRAPHIC INVESTIGATION OF SENSORY INPUTS TO THE OPTIC TECTUM OF RANA PIPIENS. D.L. Gorlick, M. Constantine-Paton and D.B. Kelley. Depts. of Biology and Psychology, Princeton Univ., Princeton, N.J. 08544.

Radioactively labelled 2-deoxyglucose can be used to identify areas of elevated metabolic activity in the CNS (Sokoloff,L., J. Neurochem.,29:13,1977). We wanted to use this technique to investigate sensory input to the brain during prey-catching behavior in frogs. Prey-catching is comprised of a small number of discrete behavior patterns whose performance appears to be mediated in areas of the optic tectum. A visual stimulus apparatus was constructed to mimic the motion of "prey". Frogs placed in the apparatus showed orientation and strikes towards its moving spots that resembled normal prey-catching behaviors. Rana pipiens (1-5 months postmetamorphic) were injected with 2.5μCi of 14C-2-deoxyglucose and placed in the visual stimulator for 90 minutes. Autoradiograms of 12μm brain sections were prepared and all heavily labelled areas identified from counterstained source sections. Densitometry profiles of optic tecta were constructed by measuring optical density (O.D.) radially across tectal layers. Autoradiograms of intact animals (S=sighted,n=4) showed heavy labelling of all primary visual projection areas of the diencephalon and optic tectum. Areas associated with acoustic input also showed high activity, probably due to the sound of the motors of the visual stimulator. One-eyed (OE,n=5) and Blind (B,n=3) animals were prepared by cutting optic nerves 2-7 days prior to visual stimulation. OE animals showed behavior similar to that of S animals, while no behavioral response was observed in B animals. Analysis of O.D. data indicated that cutting one optic nerve significantly reduced label in the superficial neuropil and cell layer 6. However, there were no differences in cell layers 4 and 1+2 (Potter,H.D.,J. comp. Neurol.,136:203,1969) between tecta ipsilateral and contralateral to the cut optic nerve. In an attempt to remove confounding inputs, both acoustic-vestibular nerves were sectioned in two OE animals (AV+OE,n=2). These animals did not strike, and showed few orienting movements. O.D. comparisons between tectal pairs produced results similar to those of OE animals for layer 6, but suggested that differences in the visual input to cell layers 4 and 1+2 had been partially masked by acoustic-vestibular or motor activity. Tectal cell layers 4 and 1+2 may thus be involved in sensorimotor integration of prey catching behavior in frogs.
(D.L.G. supported by NIMH fellowship MH 15799).

93.4 AUDITORY RESPONSE PROPERTIES OF DORSAL THALAMIC NUCLEI IN THE BULLFROG, Rana catesbeiana. Andrea L. Megela and Robert R. Capranica, Sect. of Neurobiology & Behavior,Cornell Univ., Ithaca, NY 14853.

The dorsal thalamus has been physiologically identified as an auditory center in anurans (Mudry et al.,J.Comp.Physiol. 114: 1-13,1977). Our HRP injections into the dorsal thalamus of the bullfrog, Rana catesbeiana, reveal extensive interconnections with forebrain and midbrain areas known to be responsive to acoustic stimuli. This suggests that, as in mammals, many different thalamic nuclei may receive auditory input. We therefore recorded neuronal evoked potential and multi-unit activity in the various thalamic nuclei to determine if all areas exhibit identical auditory response properties.

Two characteristics of auditory activity were studied in detail: habituation and nonlinear facilitation. In the mammalian auditory system, habituation effects are most pronounced in thalamic sensory relay nuclei but not in intralaminar nuclei (Wester, EEG,30:52-61,1971). We found similar results in the anuran dorsal thalamus. Neural responses from the central nucleus (possible homolog of the medial geniculate) habituated in response to acoustic stimuli repeated at rates of one every 10 seconds or faster. These habituation effects were much less obvious and reliable in the anterior, lateral, and posterior thalamic nuclei, and in the ventral thalamus, all of which receive multimodal sensory input. Moreover, the time course of habituation in the central nucleus was similar to the time course of behavioral habituation of evoked calling in adult male bullfrogs. These results suggest that neuronal processing in the central nucleus plays a significant role in mediating the evoked calling behavior of the bullfrog.

Mudry et al. found that evoked potentials from the dorsal thalamus show nonlinear facilitatory responses to tone combinations that maximally excite both of the auditory (amphibian and basilar) papillae in the inner ear simultaneously: these responses were significantly larger than a simple summation of the responses to each tone separately. Our analyses of nonlinear facilitation indicate that these response patterns are most pronounced in the central nucleus, with only minor or no facilitation present in the other thalamic nuclei. Furthermore, we confirmed that facilitation does not occur in any of the auditory midbrain nuclei of the torus semicircularis.

93.5 SPECIES TYPICAL DISPLAY BEHAVIOR ELICITED BY ELECTRICAL BRAIN STIMULATION IN THE WESTERN FENCE LIZARD, SCELOPORUS OCCIDENTALIS. R. S. Tarr, Department of Physiology, Chicago College of Osteopathic Medicine, Chicago, Illinois 60615.

Previous investigations have shown that complete social displays or fragments of displays can be elicited from stimulation of the Iguanid central nervous system. However, these investigations have failed to demonstrate localization of function relative to these displays. This lack of clear localization is unusual in light of the specific localization revealed by lesion studies in Iguanid lizards. In our experiments we stimulated 166 points in the fence lizard brain (monopolar electrodes, less than 50 micron exposed tip, 96 animals). Stimuli were biphasic square waves, 1 msec duration, delivered via a Grass constant current dual stimulator. All observations were made on unrestrained animals, both while alone in the test cage and in the presence of a conspecific and food. Assertion displays were elicited (criteria was over 50% of applied stimulations resulted in a display) from 14 sites in the basal telencephalon but were absent in all but one site outside of the telencephalon. In several lizards over 80% of the applied stimulations elicited assertion display at low (less than 40 microamp) thresholds. In contrast, elementary locomotor effects (such as stimulus bound turning and circling) were confined to sites in the diencephalon and brain stem. Threshold currents eliciting these effects ranged from 3 microamps to over 100 microamps. Elements of the challenge display, such as a raised posture or lateral compression, were elicited from eight animals. In six of these eight animals the electrode was in a small area just anterior and dorsal to nucleus sphericus.

The results of these preliminary studies indicate that localization of function is a characteristic of the reptilian brain as it is in other vertebrates. It is further concluded that the lizard telencephalon functions primarily as an integrator of complex behavior and not as a primary motor system. Surprisingly, stimulation of the striatum elicited assertion displays rather than the challenge displays one would predict from lesion studies. The present results indicate that challenge behavior is integrated primarily in the posterior amygdala.

93.6 SPECTRAL SENSITIVITY IN HAPLOCHROMIS BURTONI (CICHLIDAE) E. E. Allen* and R. D. Fernald (SPON: M. Menaker). Inst. of Neurosciences, Univ. of Oregon, Eugene, Oregon 97403.

The African cichlid H. burtoni, many of whose social interactions are visually mediated, possesses three distinguishable vitamin A_1 based cone pigments, each confined to a single cone type, interspersed with rods in a regular retinal mosaic. Spectral absorbance peaks occur at 500nm for the rods, 455 nm for the single cones, and 523 nm and 562 nm for the paired cones (Fernald, R. D. & Liebman, P. A., Vis. Res. 20: 857-864, 1980). Experiments are underway to determine if this retinal pigment organization corresponds to trichromatism. Measurement of the Luminous Efficiency Function (LEF) under both dark and light adapted conditions, combined with knowledge of pigment absorption characteristics, should allow specific predictions. The LEF is determined through a two-choice, food reward operant conditioning paradigm. The dark adapted LEF conforms closely to the nomogram for a $P500_1$ pigment. The precise form of the light adapted LEF should reveal if the interactions of the various cone types are subtractive in nature, as is the case for other color opponent visual processing systems.

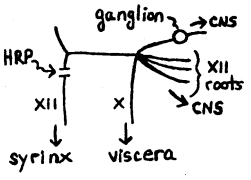
93.7 **IDENTIFICATION OF AFFERENT NEURONS IN THE HYPOGLOSSAL NERVE OF THE ZEBRA FINCH.** **S.W. Bottjer and A.P. Arnold, Department of Psychology, University of California, Los Angeles, CA 90024.**

The possible role of proprioceptive feedback from the vocal organ (syrinx) in song learning and maintenance of song by passerine birds has not been evaluated sufficiently, and anatomical pathways for such feedback are heretofore unknown. In order to determine the existence of afferent fibers from the syrinx in the zebra finch (Poephila guttata), horseradish peroxidase (HRP) was applied to the cut peripheral branch of the hypoglossal nerve that innervates the left side of the syrinx. Following tetramethylbenzidine reaction of the HRP, labeled cell bodies were found in the ganglion of the left vagus (X) nerve, but no transganglionic (anterograde) transport into the CNS was observed at transport intervals of one to five days. (As expected, motor neurons of the posterior portion of the ipsilateral hypoglossal nucleus were labeled; cf. Nottebohm et al., J. Comp. Neurol., 165: 457, 1976.) Applying HRP to the cut descending branch of the vagus also produced labeled cell bodies in the vagal ganglion as well as heavy anterograde label extending into nucleus solitarius. The reason for this discrepancy in terms of anterograde transport is unclear.

Sectioning the lower two roots of the hypoglossal nerve and applying HRP to the hypoglossus distally eliminated labeling of hypoglossal motor neurons, but not of vagal ganglion cells. Sectioning the vagus rostral to the hypoglossal roots eliminated labeling of ganglion cells, but not of motor neurons. Finally, sectioning the descending branch of the vagus caudal to the X-XII anastomosis had no effect on labeling of motor neurons or ganglion cells.

Auditory feedback is essential for song learning in young zebra finches but not for maintenance of song in adult birds (Price, J. Comp. Physiol. Psychol., 93: 260, 1979), suggesting that proprioceptive feedback from the syrinx may contribute to singing behavior. Unilateral section of either the left or right vagus rostral to the X-XII anastomosis in non-deaf adult zebra finches had no significant effect on singing behavior.



This preliminary result may imply that adult song doesn't require peripheral feedback via the afferents of the XIIth nerve.

93.8 NEURAL DETERMINANTS OF VOCAL BEHAVIOR IN BIRDS THAT DO NOT EXHIBIT VOCAL LEARNING. J. Cohen and F. Nottebohm. The Rockefeller University, New York, NY 10021.

Bird species differ with respect to how adult vocalizations are acquired. Oscine songbirds (e.g. canary) learn to sing by reference to auditory information. In contrast, the doves produce normal adult vocalizations even when deprived of auditory information. Previous studies (Nottebohm et al., JCN 165: 457, 1976) have shown that canaries possess a series of interconnected nuclei which functionally determine the bird's song. This telencephalic to motor end organ pathway takes the following form: HVc → RA → n.XIIts → syrinx. Although there are many potential sources of variability that may account for the presence of vocal learning in one species, and the lack of it in another, one likely possibility is the underlying neural substrate. We therefore report preliminary observations on the neural pathways mediating vocal behavior in ring doves, birds that do not exhibit vocal learning.

In ring doves, the proximal tracheosyringealis branches (ts) of each hypoglossal nerve extend down the trachea; the two ts branches anastomose above the syrinx and give rise to two nerves, each of which innervates one syringeal half. When horseradish peroxidase (HRP) is applied to the cut muscles of one syringeal half (distal to the anastomosis), retrogradely labeled neurons are seen, bilaterally, in the caudal portion of each hypoglossal nucleus (n.XIIts) of the medulla. When HRP is administered to one ts branch (proximal to the anastomosis), labeled neurons are seen unilaterally, in the same caudal portion of n.XIIts.

With the identification of n.XIIts, we sought to determine its afferents. N.XIIts is localized with the aid of stereotaxic coordinates and antidromic electrical stimulation. When the nucleus is found, an iontophoretic injection of HRP is made unilaterally into n.XIIts. The brain is then processed for HRP histochemistry. HRP filled axons are visualized in the occipitomesencephalic tract. Several HRP filled cells are seen, bilaterally, in lateral portions of the archistriatum.

These experiments, while still in progress, allow comparisons between canaries and doves. Although the n.XIIts to syrinx projection is present in both canaries and doves, the projection is unilateral in canaries and bilateral in doves; this probably contributes to differences in syringeal function. In canaries the projection from RA to n.XIIts is unilateral, while in doves, first indications suggest that the archistriatum → n.XIIts projection is bilateral. Such differences in laterality, as well as the structural variations in the nuclei themselves, may contribute to the neural determinants responsible for the disparate patterns in the acquisition of adult vocal behavior.

93.9 SPATIAL LEARNING ALTERED BY EXPERIENCE DURING SUCKLING. C. P. Cramer*, E. R. P. Breitinger*, D. S. Olton, and E. M. Blass (SPON: S. Mitchell). Dept. of Psychology, The Johns Hopkins University, Baltimore, MD 21218.

Numerous studies have focused on behavioral differences following differential post-weaning rearing. Suckling, the predominant waking behavior of neonatal rats, has recently been demonstrated as a suitable forum for various types of learning. In this experiment, the suckling situation was altered to allow either easier or more difficult access to the mother's nipples. At weaning, rats were tested on an 8-arm radial maze, a task with conceptual similarity to the suckling situation.

Male rats were reared from Day 5 postpartum to weaning at Day 25 in one of three maternal conditions. In the first, pups were raised in litters of 5 by normal mothers with all 12 nipples available to present a high density of nipples. In the second, siblings of pups in the first condition were raised in litters of 5 by mothers with only 4 nipples (the additional 8 nipples having been surgically removed prior to mating) to present a low density of nipples. In the third, pups were reared in normal litters of 10 by a mother with 12 nipples to provide baseline performance.

At weaning on Day 25, rats began maze acquisition testing. The maze consisted of a set of 8 arms radiating outward, like the spokes of a wheel, from a central platform, with a single food pellet at the end of each arm. The rat was placed in the center of the maze and allowed to choose freely among the arms, with choices separated by a brief period of confinement in the central platform, until all 8 pellets had been retrieved or 10 minutes had elapsed. Each rat was given one daily test session until reaching a criterion of 7 correct responses in the first 8 choices for 5 consecutive sessions.

Rats from normal litters and rats reared in litters of 5 by mothers with all 12 nipples reached criteria far more quickly than their siblings reared by mothers with only 4 nipples. Mean days to criterion were 6.8, 4.7, and 16.8, respectively.

These results demonstrate the importance of experience during suckling for later spatial learning. Rats presented early in the suckling period with contingencies characteristic of the radial maze later learned the maze task faster than their siblings whose suckling situation did not present those contingencies. The relatively poor performance of the rats reared in litters of 5 with only 4 nipples available does not reflect inadequate nutrition, as their body weights were not different from those of pups raised in normal litters. Moreover, the phenomenon appears to be task-specific, as performance on a variety of lever-pressing tasks which did not include a spatial component was the same between the groups.

93.10 EFFECTS OF CHOLINERGIC ANTAGONISTS ON INTERSPECIFIC AGGRESSION IN THE RAT. B.C. Yoburn* and M. Glusman. Dept. of Psychiatry, Columbia Univ., and N.Y. State Psychiatric Institute, New York, NY 10032

Microgram quantities of cholinergic agonists injected into lateral hypothalamic structures increase interspecific aggression in the rat. These findings suggest that a cholinergic substrate exists for the modulation of interspecific aggression. However, in the absence of data indicating suppression of this form of aggression by cholinergic antagonists, it may be premature to assume control by a cholinergic system. The present experiment investigated the effects of intracranially applied nicotinic and muscarinic antagonists on interspecific aggression. The specificity of these effects on aggression were evaluated by concurrent observations on eating, drinking and irritability.

Five male rats which spontaneously killed mice when maintained at 80% of their free-feeding weight were implanted with a 22ga guide cannula in the right lateral hypothalamus. Following recovery, 0.5 µl injections of atropine sulfate (2.5-20.0 µg) or d-tubocurarine (0.2-1.0 µg) dissolved in buffer (.1M phosphate, pH=7.0) were given through a 28ga internal cannula. Buffer was used for control injections. Animals received a series of tests at 10,20,30,40,50,60 min following an injection. Each series consisted of: (1) an aggression test, in which a white mouse was placed in the test cage and the latency to attack and kill was recorded. (2) An irritability test, in which response to handling was rated; (3) an eating test, in which the latency to eat 2, 45-mg pellets of food was recorded, and (4) a drinking test, in which the amount of water consumed every ten minutes was noted.

Atropine failed to systematically affect the behavior of any of the animals on any test. There was no evidence of suppression of aggression, even at the highest dose used. Curare suppressed aggression in a dose-dependent manner for three rats. However, suppression of aggression was accompanied by concurrent dose-dependent suppression of feeding, and no change in drinking and irritability. For the remaining two rats, Curare had no effect on aggression, but produced a dose-dependent increase in drinking, a slight facilitation of eating, and no effect on irritability.

The finding that curare suppressed aggression concurrently with feeding in 3 rats suggests a nonspecific drug effect, although a direct modulation of feeding cannot be ruled out. Together with the lack of effect of atropine, these results indicate that neither muscarinic nor nicotinic antagonists specifically inhibit interspecific aggression in the rat. (Supported by NIH Grant MH 15174.)

93.11 THE ISOLATION SYNDROME IN MICE: CHARACTERIZATION OF ISOLATION INDUCED CANNIBALISM. W. R. Pfister and D. Polito*. Pharmacology Control Section, Hoffmann-La Roche Inc., Nutley, NJ 07110.

Prolonged isolation induces compulsive, aggressive and fighting behavior in many animal species (Yen et al., Arch. Int. Pharmacodyn., 123:179-185, 1959; Welsh and Welsh, The Physiology of Aggression and Defeat, 91-142, Plenum Press, 1971), and precipitates a spectrum of behavioral alterations termed the Isolation Syndrome which is characterized by decreased exploratory and sexual activity (Valzelli, Psychopharm. (Berl.), 31: 305-320, 1973), and learning deficits.

We report for the first time the phenomenon of isolation induced cannibalism (IIC) in mice. Previously group housed (10/cage) male (17-30g) CF_1 mice were isolated, given food and water ad libitum, and either exposed daily for 24 hours to a CO_2 euthanized mouse or paired and evaluated for incidence (%) and intensity (scale: 0-4) of cannibalism or fighting behavior. Measurements of incidence - intensity of cannibalism were 15%-0.4, 67%-2.5, and 93%-3.0 following 1, 3, and 19 days of isolation, respectively. The time to development of a 50% incidence (RT_{50} and 95% CI) was 4.0 (3.3-4.7) days. In a parallel study the RT_{50} values for development of IIC and fighting behavior were similar, 2.4 (0.7-4.1) and 3.6 (2.1-6.1) days, respectively. IIC can be dissociated from other stress induced behaviors (i.e. irritability, defensive and aggressive behavior). Cage size does not alter the development of IIC, suggesting that physical isolation is sufficient to induce the behavior. IIC is facilitated by prior experience since the incidence in mice isolated for 16 days in the presence and absence of a 24 hour euthanized mouse was 75% vs 25% (χ^2=10.0, df=38, P=.002), respectively. Food deprivation (1 day) was as effective as 4 days of isolation in producing a 60% incidence of cannibalism, but cold swim stress was not. The incidence of IIC after 7 days of testing was 80%. Following an intertest interval of 3 weeks in mice that were regrouped (10/cage) or 8 weeks in mice remaining isolated, the incidence of IIC was 90% and 86%, respectively. This suggests that, in contrast to other stress induced behaviors, cannibalism is irreversible once established.

This study further demonstrates differences between individually and group housed animals, and suggests that isolation induced cannibalism, like fighting behavior, may be correlated with the development of aberrant behavior in man and may be useful in the screening of potential psychotherapeutic agents.

94.1 SENSORY SPECIALIZATION OF FREE NERVE ENDINGS IN THE RABBIT CORNEA. D.L. Tanelian and R.W. Beuerman, Division of Ophthalmology, Stanford University School of Medicine, Stanford, CA 94305.

The ability of free or morphologically unspecialized nerve endings to respond to different modalities of sensory stimulation was examined in the corneal epithelium. Albino rabbits (2-3 kg) were anesthetized with urethane (1.5g/kg) and placed in a head holder. The conjunctiva was excised just posterior to the cornea and secured over a ring to provide stability during recording and stimulation. A long ciliary nerve was isolated and sectioned centrally so an average conduction distance of 25 mm was obtained. Conventional recording techniques were utilized. Mechanical stimulation was produced by calibrated nylon filaments (170-2000 dynes). Thermal stimulation over the range of 20°C-50°C was by a jet of normal saline. The small mechanical component of the jet was subthreshold. Fifty-six identified units have been tested with both types of stimuli.

The mechanical units (n=46) were not spontaneously active, and their frequency of firing was dependent on the stimulus magnitude. The mechanical threshold for these rapidly adapting units ranged from 170-350 dynes. Thermal stimulation between 20°C and 45°C was not excitatory. The receptive fields of 20 units ranged from 5-40 percent of the total corneal surface area (213 mm^2) with an average of 12.5±9.3 percent. Conduction velocities were determined by bipolar electrical stimulation of the cornea, resulting in an average value of 2.71±1.4 m/sec, n=41. Near the limbus, where nerve trunks supplying the cornea emerge, larger conduction velocities (8.1±1.5m/sec, n=5) were obtained.

Thermal units (n=10) were spontaneously active, 10-25 spikes/sec, at the 33°C adapting temperature. Temperature changes in the cooling direction were excitatory for all units, whereas warming caused a decrease in the spontaneous firing frequency. Small temperature changes (ΔT=0.5°C) in the cooling direction produced a vigorous discharge. The time frequency histogram profiles for all temperature changes in the cooling direction were similar for these units, and the maximal frequency was proportional to the size of the temperature change. This relationship was also true for temperature changes in the warming direction except that the decrease in spontaneous activity was inversely proportional to the temperature change. These results indicate that a basis exists for functionally different receptor types in the cornea.

94.2 ADAPTATION OF TYPE I AND TYPE II CUTANEOUS MECHANORECEPTORS IN THE CAT. K. W. Horch and P. R. Burgess. Dept. Physiol., Univ. Utah Col. Med., Salt Lake City, UT 84108.

When a type I receptor (Haarscheibe) is abruptly indented and the indentation maintained, there is an increase in impulse frequency that declines over a period of minutes to levels of about 3-5 impulses/sec. Subsequent indentations cause increases in frequency that decline gradually to the level produced by the first indentation. Type II receptors (Ruffini endings) with little or no resting discharge behave in a similar fashion, except that the rate of adaptation may be slower. Type II receptors with resting discharge rates above 15 imp/sec may give a long-term signal of skin indentation or stretch, but the signal is not greater than 2-3 imp/sec.

We conclude that tonic cutaneous mechanoreceptors in hairy skin do not have a persistent discharge that varies appreciably with the position of the skin, an unexpected finding in the case of type II receptors because their resting discharge can be both increased and decreased by stretching the skin in different directions. The return of the discharge to a common resting level in the presence of different maintained stimuli appears to require different coupling mechanisms between the receptor and surrounding tissue for resting and evoked activity. Functionally, this may serve to allow these receptors to signal directional changes in skin position for a time without compromising the level of resting activity to be modulated.

94.3 STIMULUS-RESPONSE RELATIONSHIPS FOR A MECHANORECEPTOR: THE PACINIAN CORPUSCLE. S. J. Bolanowski, Jr. and J. J. Zwislocki. Center for Brain Research, University of Rochester and Institute for Sensory Research, Syracuse University.

Stimulus-response relationships in both the intensity and frequency domains were obtained for single, isolated Pacinian corpuscles of cat mesentery. The resulting characteristics interrelate the vibratory stimuli, the generator potentials and the firing rates of action potentials. The stimuli consisted of 300 msec bursts of sinusoidal displacements (20Hz-1.25KHz; 50 msec rise-fall time), and the generator potentials and firing rates were measured in the steady state. The magnitude characteristics of averaged generator potentials are linear at low displacement amplitudes and saturate at higher levels. At these higher intensity levels, full-wave rectification is often found, but is asymmetric. The degree of asymmetry varies among receptors. The generator potentials also show a time-dependent hysteresis in response to each stimulus cycle at moderate and high stimulus displacement amplitudes. The intensity characteristics for action potential firing rates are steep at low intensity levels and plateau at multiples of the stimulus frequency, as stimulus intensity is increased. Post-stimulus-time and interval histograms reveal that the plateaus occur as a result of phase locking to the stimulus. The multiples of stimulus frequency at which the phase locking occurs and the length of the plateaus depend on stimulus frequency. The plateaus that are found at firing rates of 2 spikes per stimulus cycle are produced by the asymmetric full-wave rectification. The amplitude-frequency characteristics for both a constant firing rate and a constant amplitude of the generator potential below action-potential threshold are U-shaped functions. The phase-frequency characteristics of the generator potentials below the threshold show two populations of responses. Both populations undergo phase changes of about 300° as the stimulus frequency is increased but are separated by 180° . The underlying suprathreshold generator potentials were measured in the presence of tetrodotoxin (TTX). TTX is shown not only to eliminate the action potentials but also to decrease the amplitude of the generator potential. The percentage decrease is frequency dependent but is constant at any given frequency, indicating that the measured characteristics can be corrected by a multiplicative factor. The action potential results are consistent with in situ measurements from monkey nerve fibers believed to innervate Pacinian corpuscles (Talbot et al., J. Neurophysiol. 31, 1968). This indicates that the generator potential characteristics found are not an artifact of excision. (Supported by Grants NS-03950 and NS-09940, NIH).

94.4 SPATIAL ORGANIZATION OF RECEPTIVE FIELDS OF SINGLE GUARD HAIR AFFERENT NERVE FIBERS AS REVEALED WITH MOVING AIR JET AND PUNCTATE MECHANICAL STIMULATION. R. H. Ray, L. E. Mallach and L. Kruger. Depts. of Anatomy and Anesthesiology and the Ahmanson Laboratory of the Brain Research Institute, UCLA, Los Angeles, CA 90024.

The response properties of single guard (G) hair afferent nerve fibers innervating the hairy skin of the hindlimb were studied in acute, barbiturate anesthetized cats. The purpose of the study was to identify and analyze the relative contribution of those stimulus features determining the discharge patterns evoked in single afferents by a fine air jet stimulus moving across the skin and varying in force, velocity, position, direction and orientation. Additionally, the discharge properties as elucidated with the air jet were compared with those revealed with stationary ramp indentations varying in displacement, force, area, velocity and position within the receptive field.

Punctate displacement of a locus within the receptive field (RF) of a guard hair fiber reveals a characteristic low (G_1), medium or high (G_2) velocity sensitivity, but inhomogeneities are evident within the RF. Iso-sensitivity contours constructed for constant velocity punctate stimuli similarly reflect spatial inhomogeneity within the RF.

The response of single guard hair afferents to moving air jet stimuli reveals that the responsiveness of each fiber to stimuli with arbitrary orientation, direction and position within the RF displays an optimum velocity sensitivity which is not predictable from punctate velocity data. Although the response pattern is remarkably consistent for each controlled moving stimulus condition, there are apparent significant differences in response as a function of stimulus orientation, direction and velocity. RF 'maps' constructed from the responses evoked as the air jet traverses the skin reveal multiple zones of high and low sensitivity. The distribution of sensitive and non-sensitive zones is remarkably consistent for maps constructed with stimuli varying in orientation, direction and velocity. It is apparent that the principal determinant of the response for a given stimulus traverse is the spatial distribution of sensitive spots throughout the RF. Small but significant differences in directional selectivity are probably related to hair shaft orientation and length in linking hair displacement to receptor discharge.

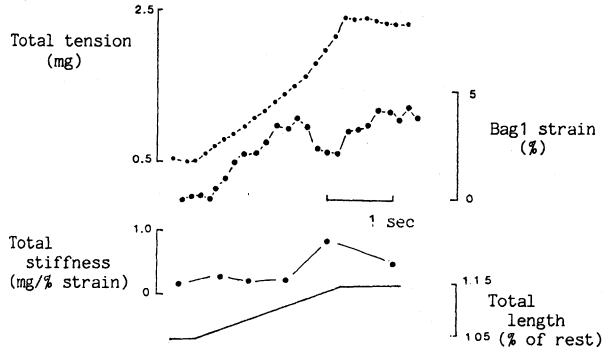
These preliminary findings indicate that guard hair afferent nerve fibers respond more vigorously to moving stimuli than to stationary displacement and display complex receptive field inhomogeneities which must be taken into account for the study of central neuronal information processing and feature extraction. (Supported by USPHS grant NS-5685)

94.5 STRETCH INDUCED CONTRACTION OF BAG1 FIBERS IN THE CAT MUSCLE SPINDLE. R. E. Poppele and D. C. Quick*, Laboratory of Neurophysiology and Department of Anatomy, University of Minnesota Medical School, Minneaplois, MN, 55455

The sensitivity of the primary endings of muscle spindle receptors to stretch is several fold greater than that of the secondary endings. This difference may be related to the mechanical properties of intrafusal muscle. In particular it may relate to a difference between the bag1 fiber which has abundant primary endings and few secondary endings and the other bag and chain fibers which have both. To test this hypothesis, we measured spindle tension and stiffness as well as intrafusal muscle strain (or the change in length per unit length) and sarcomere lengths in individual intrafusal fibers during a ramp stretch of isolated muscle spindles from cat tenuissimus muscle.

The results support the conclusion that there is a stretch induced contraction of the bag1 intrafusal muscle leading to an increased strain in the primary sensory area during a stretch. The observations leading to this conclusion are diagrammed below. There is an increasing slope of spindle tension in response to a ramp stretch that coincides with an increase in total stiffness and a decreasing slope of bag1 fiber strain. In addition there is a shortening of bag1 sarcomeres that parallels the decreased strain. Bag2 and chain fibers do not show this behavior.

Supported by grants from NSF (BNS 7825165) and NIH (NS 10969).



94.6 RECEPTOR ORGANIZATION IN HUMAN MUSCLES: A DETAILED STUDY OF RECEPTORS IN RECTUS CAPITIS POSTERIOR MAJOR. D.A. Bakker* and F.J.R. Richmond, Dept. of Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

In the cat, small muscles surrounding upper cervical vertebrae are extraordinarily rich in sensory receptors. The receptors including muscle spindles, (up to 500/g in some muscles) Golgi tendon organs and paciniform corpuscles are organized in elaborate complex groupings which may include up to 15 receptors linked together (Bakker and Richmond, 1980). Early descriptions of the sensory apparatus of human neck muscles suggest that large populations of muscle spindles are also present in muscles of the suboccipital region. However the number and distribution patterns of receptors in such muscles have never been systematically examined in the adult.

In the present study the receptor content of rectus capitis posterior major was examined in tissue obtained postmortem. Tissue was fixed in formol-saline and double embedded in celloidin and paraffin. Serial 10 um sections were cut and stained with Holmes' silver method and picrofuchsin. The distribution patterns of receptors were mapped and reconstructed diagrammatically in three dimensions.

Human muscles usually contain about 10 spindles/g. Muscle spindles were most frequently observed in rectus capitis posterior major in densities of about 35 spindles/g. More than half (58%) of the spindles were organized in complex forms with at least one other spindle. Spindle complexes often comprised 2-3 spindles linked in tandem configurations (33%) which extended well over half of the muscle length. Frequently spindles at one end of the tandem linkage contained only one nuclear bag fibre in their intrafusal fibre complements while the other spindles contained at least 2 nuclear bag fibres. Other complex forms consisted of 2-3 spindles linked by paired (40%) and parallel (1%) formations. Most single spindles and spindle complexes were attached at one end to tendinous tissue. Golgi tendon organs and pacinian corpuscles were occasionally seen in human muscle. Golgi tendon organs were located in musculotendinous junctions at sites of attachment to the skull or vertebral processes. Pacinian corpuscles were associated with the fascia surrounding the muscle.

These results suggest that the complex spindle organization may be a significant feature of human neck muscles and may be important in the sensory function of the neck muscles.

94.7 SENSATIONS FROM SELECTIVE ACTIVATION OF SINGLE HUMAN SENSORY UNITS WITH MYELINATED FIBERS. J.L. Ochoa and H.E. Torebjörk*. Dept. of Neurology, Dartmouth Medical School, Hanover, N.H. 03755, and Dept. of Clinical Neurophysiology, University Hospital, Uppsala S-75014, Sweden.

Introduction: The microneurographic technique of Vallbo and Hagbarth (1968) has substantially increased knowledge of the stimulus-response characteristics of single cutaneous receptors in humans. However, virtually nothing is known about the sensations evoked by activity in single sensory units. The aim of this work was to answer the fundamental question: what is felt when mechanoreceptive sensory units of various types are activated in isolation at a range of frequencies?

Method: Tungsten electrodes were used for microneurographic recordings of impulse activity in single afferent A fiber units in the median nerve in alert subjects. Such electrodes could also be used for electrical intraneural microstimulation (INMS) of single, identified sensory units.

Results: On INMS at liminal intensity for sensation, a pure and specific sensation (pure tapping, pure vibration, pure pressure) with a defined temporal dimension (intermittent or continuous) was typically referred to a focal area in the glabrous skin of the hand. Analysis of such sensation allowed to predict the type of stimulated unit, and the location of its receptive field. Such predictions were regularly verified when the stimulating electrodes were used for recording. Proof that the stimulated and the recorded unit was one and the same was obtained by demonstration of post-tetanic changes in excitability confined to the stimulated and recorded fiber. It was found that a single impulse in a single Rapidly Adapting (RA) unit innervating fingertip is regularly perceived. Temporal summation of several impulses is required to arouse sensation from RA units from other regions, as well as from all Slowly Adapting type I (SA I) and Pacinian Corpuscle (PC) units. RA units mediate tapping, which becomes flutter or vibratory "buzzing" at higher frequencies. PC units signal vibration. SA I units evoke sensation of pressure, its intensity being frequency dependent. No sensation is reported when individual SA II units are stimulated, regardless of frequency.

Conclusions: The sensory representation in the brain of the afferent innervation of the glabrous skin in the hand is discriminative enough to detect modality, frequency or intensity, and location of sensation from the input of individual mechanoreceptive units of certain types. This provides proof for a high degree of specificity in the sensory nervous system.

94.8 A SOMESTHETIC CODING MECHANISM FOR TEXTURE LIKE COLOR CODING IN VISION Kenneth O. Johnson and Ian Davidson Dept. Physiology, The Johns Hopkins Sch. Med., Baltimore, Md. 21205 and Dept. Physiology, Melbourne Univ., Melbourne, Australia.

The available evidence (Johnson & Lamb, J.Physiol. 310:117-144 1981; Darian-Smith, Davidson & Johnson, J. Physiol. 309:135-146, 1980) indicates that the spatial features of a repetitive surface with spacings finer than approximately 1.5 mm are not coded in the spatial structure of the afferent discharge of any of the mechanoreceptive fiber populations when a finger is scanned across the surface; however, a wide range of textured surfaces with spatial features finer than 1.5 mm are discriminated easily. Some other coding mechanism must account for this discriminative capacity. The discharge patterns of SA, QA, and PC afferents innervating the fingers of monkeys (M. nemestrina) were assessed using 9 embossed dot arrays (center-to-center spacings ranging from 0.525 to 3.25 mm; dot dia. = 0.3xspacing) applied at each of 6 combinations of contact force (20 & 60g) and scanning velocity (40, 80, & 150 mm s^{-1}). There was no detectable spatial structure in the responses of any of the afferents for spacings less than 1.5 mm; however, the mean impulse rates within and between fiber groups provided considerable information that might be used to discriminate these surfaces. Although there were a large number of variables in the experimental design (9 surfaces x2 forces x3 vel. x3 fiber types), the results are described fairly completely by the following summary:

1. The mean impulse rate, summed over all three fiber types, was approximately a linear function of center-to-center dot spacing at all forces and velocities; however, the slope generally increased with increasing force and velocity.

2. At dot spacings greater than 2.0 mm the ratios of the mean impulse rates in the three fiber groups were relatively constant at about 0.4:1.0:0.8 (SA:QA:PC relative mean rates). These ratios were affected little by force, scanning velocity or dot spacing.

3. At dot spacings less than 2.0 mm, the relative rates changed in a systematic way with dot spacing: on a relative basis PC rates increased while QA rates decreased for finer surfaces. For the finest surface, which had a smooth "feel", the relative QA and PC rates fell while the relative SA rate rose. These differences presumably represent the different frequency sensitivity profiles of the different mechanoreceptive classes.

These results indicate that the mean response rates of the three main afferent classes (perhaps four in man) provide a basis for coding both qualtitative (texture) and quantitative aspects of surface features. The relative engagement of the three classes was, like the perception of texture, relatively unaffected by changes in contact force or scanning velocity.

94.9 PSYCHOPHYSICAL FRACTIONATION MEASURES FOR CUTANEOUS THERMAL STIMULI. Sherry L. Berg* (SPON: R. S. A. Tindall). Florida State University, Tallahassee, FL 32306 and DeVry Institute of Technology, Irving, TX 75062.

Five male subjects performed a fractionation task for contact cooling stimuli presented to the right dorsal forearm. Additional warm-cool comparisons with observations from stimuli presented to both the forearm and the forehead were obtained from one subject. The stimulus site was preadapted to 32.6°C and fourteen stimulus intensities (0.3° to 6°C) were produced from thermal transients of 3 sec duration for fourteen corresponding rates of temperature change (0.1° to 2°C/sec). All five stimulating surfaces (1,2,4,7.5 and 18cm^2) were used in the primary cooling fractionation task.

Each of the fourteen stimuli were initially presented in an ascending then a descending series, afterwhich, a descending order of fractional comparisons began by introducing two consecutive presentations of the Standard Stimulus followed by a Trial Stimulus. Subjects indicated if the Trial Stimulus was greater or less than half the Standard, so that the Experimenter could manipulate the Trial Stimulus in the appropriate manner until a suitable Comparison Stimulus for one half the Standard could be obtained.

All observers demonstrated subjective fractional comparisons of one half or greater than the numerical equivalent of the Standard Stimulus when thermal cooling was measured. Reports from the one subject making fractional comparisons for warming on both the forearm and the forehead were even greater than those demonstrated in the cooling tests. Another subject showed an orderly array of psychophysical cooling functions correlating with decreases in stimulus surface area when fractionation measures were "intuitively" derived.

In a post-experimental debriefing and questionnaire, all five subjects rated the fractionation task as having a high degree of difficulty.

94.10 TWO THERMAL INFLUENCES ON TOUCH SENSATION. J. C. Stevens. John B. Pierce Fndn. Lab. & Yale University, New Haven, CT 06519.

In 1834 the German physiologist Ernst Weber noted that a cold coin placed on the forehead feels heavier than a warm one. Although the observation has been casually confirmed from time to time, not until recently has a systematic study of this phenomenon been undertaken. Weights of various temperatures and masses were applied to seven different regions of the body -- forehead, palm, forearm, upper arm, back, midriff, and thigh, and subjects judged their subjective heaviness by the method of magnitude estimation. In all regions tested cool weights were judged to feel considerably heavier than weights near skin temperature -- sometimes as much as several times heavier. Warm weights were also judged heavier -- but only in the arm and hand regions. This difference between warm and cold seems to rule out a "cognitive summation" explanation, i.e., that subjects irresistably add the thermal sensation to the weight sensation -- contrary to instruction. It also turned out that the sensitivity of the various body regions to weight correlates very strongly with measures of spatial acuity such as the two-point limen and point-localization. That is, those regions to which the weights feel heaviest also show the best spatial resolution. It seemed likely, therefore, that weight sensation and acuity are mediated by the same receptor system. If this is so then temperature of the test objects might influence the skin's acuity. Indeed, two-point limens and two-edge limens improved by an average of 41% when the stimulators were warmer or cooler than the skin of the forearm. Since the thermal senses on their own show virtually no spatial resolution the improvement probably results from warming and cooling the mechanoreceptors that mediate pressure and spatial acuity.

This research was supported by NIH Grant #NS15419.

95.1 THE ELECTRICAL PROPERTIES OF ENZYMATICALLY DISSOCIATED MÜLLER CELLS. J. D. Conner*, P. V. Sarthy, P. B. Detwiler*. Physiology & Biophysics and Ophthalmology Depts., Univ. of Washington Sch. of Med., Seattle, WA 98195.

In order to understand the electrical properties of Müller cells and to examine their role in visual function, we have studied the membrane properties of isolated Müller cells from the fresh water turtle, Pseudemys scripta elegans.

Retinae were dissected and incubated in Ca++, Mg++-free Ringer containing papain pre-activated with 10 mM cysteine. After 45 min. of incubation at 37°C, the retinae were dissociated in normal Ringer supplemented with BSA and deoxyribonuclease. Dissociated cells were mechanically stablized with chilled agarose (0.4%) and transferred to a microscope stage where they were perfused with oxygenated, normal Ringer at about 15°C. Müller cells were identified by visual inspection and impaled with intracellular electrodes

The resting potentials of freshly isolated Müller cells ranged from -60mV to -100mV. In some cases the initial resting potential was smaller, but it usually grew larger and stabilized during the first 5-10 minutes of the recording. Isolated cells continued to have large resting potentials for a period of time ranging from four to six hours post-dissociation. The observed resting potentials are comparable to those recorded from Müller cells in the intact retina.

The input resistance of Müller cells was measured using two electrodes: one for passing current and one for recording voltage. The current-voltage relation is non-linear showing inward-going or anomalous rectification. The steady-state slope resistance is 60 MΩ for depolarizing currents and 15 MΩ for hyperpolarizing currents.

The time course of the voltage change produced by current steps depends on the polarity of the applied current. The charging curve for hyperpolarizing currents is fit by a single exponential with a time constant of 9 msec. Depolarizing potential changes follow a time course described by the sum of two exponentials having time constants of 9 and 42 msec.

These observations suggest that enzymatically-isolated Müller cells are viable and may be useful for further studies of Müller cell function.

Supported by grants from the National Eye Institute.

95.2 REGIONAL DIFFERENCES IN RETINAL MÜLLER CELL MEMBRANE PROPERTIES. Eric A. Newman* (SPON: A.R.Adolph). Eye Research Institute of Retina Foundation, Boston, MA 02114.

Müller cells, like other glial elements, are believed to have high conductances to K^+ relative to other ion species. I have recorded intracellularly from these cells in the frog retina (Rana pipiens) in order to study their K^+ conductance properties. Intracellular recordings were made at the level of the inner nuclear layer in perfused, light-adapted retinal slices (~150 µm thick). Cells were identified by intracellular injection of the fluorescent dye Lucifer Yellow CH. At a control $[K^+]_o$ of 2.5 mM, Müller cell resting potentials ranged from -80 mV to -85 mV. The membrane potentials of individual Müller cells were monitored as extracellular K^+ was altered using a series of 9 isotonic perfusion solutions. Over a range of 5 mM to 30 mM the membrane potential varied linearly with log $[K^+]_o$, and had a Nernstian slope of 58 mV/decade. At lower $[K^+]_o$ (2.5 mM to 0.625 mM) Müller cell potentials deviated slightly from this idealized relation. These results demonstrate that, like other glial cells, the Müller cell membrane potential is controlled by K^+ concentrations.

Previous current source density studies of current flow patterns within the retina (Newman, Vision Res. 19:227; J. Neurophysiol. 43:1355) suggested that the endfoot region of Müller cells possesses specialized conductance properties. I have explored this possibility by monitoring intracellular Müller cell responses to localized increases in $[K^+]_o$. An isotonic 100 mM KCl solution was pressure-ejected from a second (extracellular) pipette positioned at the surface of the retinal slice. The amplitude of the resulting depolarizing K^+ responses varied with the location of the K^+ source. The largest (15 mV to 35 mV) responses were elicited when K^+ was ejected in the optic fiber layer. Responses were smaller for more distal K^+-ejection locations, although large responses were sometimes seen for K^+ ejections in the inner plexiform layer. Responses to K^+ stimuli in the fiber layer were 4 to 30 times greater in amplitude than were responses to stimuli in the inner nuclear layer. These regional differences in Müller cell K^+ responses could be due to localized differences in the cell's K^+ conductance properties, and suggest that K^+ conductance is greatest in the endfoot region of the cell.

95.3 A BEHAVIORAL DETERMINATION OF COLOR MECHANISMS IN THE TURTLE, PSEUDEMYS, USING THE TWO-COLOR THRESHOLD TECHNIQUE OF STILES. D. F. Sisson*, A. M. Granda and J. H. Maxwell. Inst. of Neuroscience, Newark, DE 19711.

We have applied the two-color threshold technique of Stiles to specify receptor mechanisms for color in the visual system of the fresh-water turtle, Pseudemys scripta elegans. Wire loops were implanted into the jaws of five turtles. A wire threaded through this loop enabled automatic positioning of the head and monitoring of responses. The turtles were trained to retract their heads in response to flashed targets of light. The experimental paradigm determined absolute and increment thresholds for 650 nm light projected onto background fields ranging from 450 to 650 nm. Threshold data for each background-test stimulus pair were used to construct threshold vs. field intensity (tvi) curves. The spectral sensitivity of the mechanism detecting the test stimulus was calculated by determining the inverse of the adapting field intensity necessary to produce an increment threshold 0.5 log units above absolute threshold using the tvi curves.

The absorption spectra of single visual pigments found in the Pseudemys retina were calculated from a nomogram for vitamin A_2-based pigments and corrected for the transmission characteristics of associated oil droplets. These curves were too narrow to account for the broad spectral shape of the behaviorally derived curve. A better correlation was found with curves derived from coupled 518 and 620 nm pigments. Such coupling is known to occur in two instances in the Pseudemys retina: Double cones contain an accessory 518 nm pigment as well as a principle 620 nm pigment, and the signals from red cones and rods are physiologically linked in later stages of the afferent pathway.

95.4 REGIONAL VARIATION IN THE PHOTORECEPTOR LAYER OF THE TURTLE, *PSEUDEMYS SCRIPTA*. E.H. Peterson School of Anatomy Univ. New South Wales Sydney, Australia 2033

Recent evidence suggests that the ganglion cell layer of vertebrate retinas exhibits regional variation in its composition and that this regional variation is maintained in the projection to central visual targets (Peterson, '81, JCN 196). In the red-eared turtle, *Pseudemys scripta*, e.g., there is a local accumulation of small ganglion cells into a horizontally aligned visual streak with a peak density area embedded in the streak at the center of the retina (Peterson and Ulinski, '79, JCN 186).

To clarify the intraretinal origin of this regional variation, I examined the composition of the photoreceptor layer in *P. scripta*. In this species, approximately 95% of the photoreceptors are cones. There are four functional classes of cones, and each is uniquely associated with a different color of oil droplet. These oil droplets completely fill the inner segment and filter light before it reaches the outer segments. Red oil droplets are found exclusively in red sensitive single cones, yellow droplets in green sensitive single cones, clear droplets in blue sensitive single cones, and orange droplets in the red sensitive major member of double cones. Thus it is possible to characterize the composition of the photoreceptor layer by describing the sizes and relative frequencies of each color of oil droplet.

This analysis suggests that the retina of *P. scripta* can be divided into three functionally distinct regions based on the composition of the photoreceptor layer. Dorsal retina is characterized by a high relative frequency of orange droplets, and droplets of all colors are larger than elsewhere in the retina. For example, red, yellow and clear droplets are larger than those at comparable distances below the streak and are 150-250% larger than in the streak. Ventral retina is characterized by a high relative frequency of yellow droplets; their density remains high in the streak and drops sharply in dorsal periphery. In contrast, the frequency of clear droplets is relatively low in ventral retina; their frequency and especially their size increase above the streak. The visual streak differs from both dorsal and ventral hemiretina. Here there is a sharp increase in the relative frequency of red, and a decrease in orange, droplets. The sizes of droplets associated with single cones decrease abruptly in the streak. In contrast, the sizes of orange droplets vary relatively little with retinal locus.

These data suggest that dorsal retina, ventral retina, and visual streak of *Pseudemys* retina are differentially specialized, and that topographic specializations in the ganglion cell layer of vertebrate retinas may be organized more distally than the ganglion cell layer, perhaps in the photoreceptor layer itself.

95.5 ADAPTATION AND THE ULTRASTRUCTURE OF RAT PHOTORECEPTOR TERMINALS. C. Brandon and D.M.K. Lam, Department of Anatomy, University of Oregon Health Sciences Center, Portland, Oregon and Department of Ophthalmology, Baylor College of Medicine, Houston, Texas.

Brief exposure of a dark-adapted retina to light causes a dramatic decrease in its sensitivity to subsequent light stimulus (Ernst & Kemp, Vision Res. 11, 1197 (1971)). The process of adaptation, whereby this sensitivity is regained, depends partly on slow photopigment regeneration and partly on a rapid neural process; at least a part of the latter occurs in the photoreceptor (PR) cell itself (Grabowski et al, Science 176, 1243 (1972)). We have studied this process in rat rod synaptic terminals by EM examination under conditions of light- and dark-adaptation. Rat retinas were fixed by immersion in phosphate-buffered glutaraldehyde, or were immersed in phosphate-buffered sucrose solution for several minutes before glutaraldehyde fixation in the same medium. The latter method preserves the extracellular space of neural tissue (Cragg, Tissue & Cell 12, 63 (1980)), and results in improved preservation of rod horizontal cell (HC) synaptic vesicles. In light-adapted rod terminals, HC processes were invaginated by finger-like and ridge-like protrusions of PR cytoplasm, which always occurred on the side of the HC process away from its point of contact with the PR ribbon. Underlying the HC plasma membrane at such invaginations was a flocculent layer, about 60A thick and 80A away from the cell membrane; this specialization was inevitably present under areas of concavity of the HC membrane. Synaptic vesicles were present throughout the HC process, but appeared to cluster around the invaginations. In dark-adapted retinas, HC membrane areas showing the specialization were straight or convex, and PR invaginations into HC's were markedly reduced in number. We found similar specializations in goldfish cone PR terminals, in agreement with Wagner (J. Neurocytol. 9, 573 (1980)), who suggested that they were neurofilamentous in nature. We speculate that the floccular specialization is a contractile apparatus which deforms localized areas of the HC membrane in response to light, altering the three-dimensional relationship between HC and PR, and that this plasticity may mediate rapid photoreceptor adaptation by altering the efficacy of the HC→PR synapse.

95.6 PHAGOCYTOSIS BY THE RETINAL PIGMENT EPITHELIUM IS STIMULATED BY THE PEPTIDE TUFTSIN. L.J. Fisher, G. Stevens, Jr.* and P.M. McCann*. Dept. of Ophthalmology, Henry Ford Hospital, Detroit, Michigan 48202

Phagocytosis by the retinal pigment epithelium of photoreceptor outer segments is an essential process in normal retinal maintenance. Tuftsin, a naturally occurring tetrapeptide, is a potent stimulator of phagocytosis by neutrophils and macrophages. Does this peptide also stimulate phagocytosis of rod outer segments (ROS) by the retinal pigment epithelium? To answer this question we tested the prediction that an intravitreal injection of tuftsin would increase the number of phagosomes (phagocytized ROS fragments) in the retinal pigment epithelium of treated over control eyes before and after the normal peak shedding period. Using 21 day-old RCS rats from a strain without retinal degeneration, we injected 2 µl of tuftsin (70 µg/ml through a 30 gauge needle on a Hamilton syringe) into the vitreous of one eye, and 2 µl of balanced salt solution into the vitreous of the other eye one hour prior to the usual onset of light. Eyes were injected in dim red light and were harvested one, two, three, and eight hours post injection.

The number of large phagosomes (diameter >1µm) within the retinal pigment epithelium were analyzed using the light microscope. The number of phagosomes in control eyes were increased at 1 and 2 hours after light onset. The number of phagosomes was considerably less than that seen in similarly treated Charles River rats. Eyes injected with tuftsin and harvested at light onset had a large number of phagosomes, while the control eyes had almost none. At 1 and 2 hours after light onset, the tuftsin treated eyes had more phagosomes than their corresponding controls. At 7 hours after light onset eyes had few phagosomes.

The results of these experiments are twofold: (1) tuftsin results in the appearance of phagosomes at light onset, (2) tuftsin stimulated the pigment epithelium to increase its phagocytosis of ROS. These results demonstrate that the tetrapeptide tuftsin stimulates phagocytosis of ROS by the retinal pigment epithelium.

95.7 A POSSIBLE CHOLINERGIC TRANSMISSION FROM CONES TO HORIZONTAL CELLS IN THE TIGER SALAMANDER RETINA. J. Skrzypek* (SPON: H. Ripps). Dept. of Ophthalmol., New York Univ. Med. Ctr., New York, N.Y. 10016.

The aim of this project was to clarify the role of acetylcholine (ACh) in the synaptic transmission to horizontal cells (HC's). These cells receive three synaptic inputs: from rods (R), cones (C), and other horizontal cells. Synaptic transmission between pairs of visually identified HC's was examined by passing current into one cell and measuring the voltage response from the other cell in the presence of ACh or cobolt. Synaptic inputs from photoreceptors to HC's were analysed by measuring current-voltage relationships of the HC's membrane in the dark and light and in the presence of acetylcholine.

It was found that neither cobolt nor ACh disrupts the coupling between neighbouring HC's and that the fluorescent dye injected into one cell often migrates, probably via coupling pathways, and stains the surrounding HC's.

Based on response spectra recorded from HC's, photoreceptor inputs to HC's can be spectrally separated into two components; R's contribute maximally when illuminated with blue/green (434-514 nm) light, and the C's dominate the HC's response when the stimulating light is red (600-650 nm). In the presence of ACh the peak of the response spectrum for the HC's shifts from long toward short wavelenghts, indicating that ACh blocks the cones' but not the rods' input to HC's.

Neither R's nor C's are affected by exposure to cholinergic medium. But it was found that HC's are depolarized by ACh and hyperpolarized by atropine. This depolarizing response of HC's to ACh can be reversed at about -70 mV and is associated with a conductance decrease. Cone-dominated response of the HC's has a reversal potential also near -70 mV and is associated with a conductance increase. On the other hand, HC's response to blue/green light, which excites mainly rods, reverses at membrane potentials near +30 mV and is associated with a conductance decrease.

These results suggest that HC's response to light consists of two spectrally separable, rod and cone components which have different reversal potentials and are associated with opposite conductance changes. The coupling between HC's is electrical and is not affected by exposure to ACh. Furthermore it seems that the rod to HC's pathway is noncholinergic while the cone to HC's transmission might be muscarinic.

95.8 THE DISTRIBUTION OF ACETYLCHOLINESTERASE ACTIVITY IN RAT RETINA. D.D. Dunning*, C.D. Ross and D.A. Godfrey. Dept. of Physiology, Oral Roberts University, Tulsa, OK 74171 (SPON: J.D. Dunn).

Acetylcholinesterase activity was determined in samples microdissected from the center of 7µm freeze-dried serial sections cut tangentially through rat retina. Dissected samples measured about 100-200 µm linear dimension. Data were plotted vs. section number, affording a possible 7 µm resolution across the retinal layers, with an error of about 1 µm because of the curvature of the retina.

Data below are averages of AChE activity (mmoles/kg dry wt/min @ 38°) ± S.E.M. in samples dissected from 4 eyes from 4 rats (n = number of samples)

			n
pigment epithelium,	outer	49 ± 4	3
	middle	90 ± 6	5
	inner	49 -	1
photoreceptor	outer	25 ± 4	13
segments	inner	23 ± 2	12
photoreceptor	outer	10 ± 1	5
nuclear layer	middle	9 ± 2	9
	inner	8 ± 2	6
outer plexiform layer		15 ± 1	3
inner nuclear layer,	outer	15 ± 3	10
(INL)	middle	84 ± 29	8
	inner	208 ± 46	5
inner plexiform layer (IPL)		323 ± 19	27
ganglion cell layer (GCL)		123 ± 42	3
fiber layer		46 ± 8	5

This distribution of AChE activity, particularly in the inner layers, is very similar to the pattern of distribution of choline acetyltransferase activity in rat retina (Ross & McDougal, 1976). A higher resolution presentation of the IPL data reveals a peak of AChE activity approximately 12 µm from the beginning of the GCL. AChE activity in serial 7 µm-thick samples of IPL beginning at the border with the INL:

		n
1st 7 µm lamina (outermost)	272 ± 11	3
2nd 7 µm lamina	285 ± 17	4
3rd 7 µm lamina	250 ± 17	5
4th 7 µm lamina	307 ± 17	5
5th 7 µm lamina	464 ± 36*	5
6th 7 µm lamina (innermost)	331 ± 57	5

(*differences significant between this value and all those from more superficial laminae, $p < .01$)

The position of this peak of AChE activity is consistent with the localization of enzyme activity by histochemical staining methods (Nichols and Koelle, 1969).

(Supported by ORU intramural research funds)

95.9 CLASSES OF CHOLINERGIC RETINAL NEURONS IN CELL CULTURE. Donald G. Puro. Laboratory of Vision Research, National Eye Institute, NIH, Bethesda, MD 20205.

Defining neurons according to their information molecules (e.g. neurotransmitters and receptors) helps in understanding how neuronal circuits assemble and function. To assess the effects of putative neurotransmitters on cholinergic neurons of the chick retina, a cell culture system was used. In culture, some embryonic retinal neurons transiently form functional synapses with striated muscle cells (Puro et al, PNAS 74:4977,1977). Myotubes are useful as postsynaptic targets since their response to acetylcholine has been well studied and because their large size permits prolonged intracellular recording. By plating a low density ($2x10^4$ µm/cell) of dissociated retinal cells onto cultures of short myotubes(~300µm), it is possible to have each innervated muscle cell receiving synaptic input from only one cholinergic neuron.

Rat myoblasts were cultured in 35mm dishes for 5-12 days under conditions which limited fusion and thus myotube length. Retinal cells from day 8 chicks were dissociated with 0.05% trypsin; $5x10^4$ cells were added to a muscle culture. After 30-50 hours, 4.2% (5/120) of randomly sampled myotubes had spontaneous synaptic input as demonstrated by intracellular recordings. Once an innervated muscle cell was found, the synapsing neuron could usually be localized by microscopic examination. Identification of the presynaptic neuron was further established by evoking synaptic input with the iontophoresis of glutamate from a high resistance micropipette positioned near the nerve cell. Glycine, γ-aminobutyric acid (GABA) or dopamine were then sequentially delivered from a multibarrel micropipette.

To determine the effect of these neurotransmitters on the output of the cholinergic neuron, the frequency and amplitude of the depolarizing responses of the postsynaptic muscle were measured. Glutamate excited 88% (44/51) of the neurons tested. Some of the glutamate responsive neurons were inhibited by GABA (43%, 9/21), glycine (29%, 6/21), or dopamine (33%, 3/9). No cholinergic neuron examined thus far has been inhibited by GABA as well as by glycine. Based on these responses, at least 5 classes of cholinergic neurons have been isolated from the chick retina.

		Responses to neurotransmitters			
		GLUTAMATE	GABA	GLYCINE	DOPAMINE
Classes	1	+	-	0	0
	2	+	0	-	0
	3	+	-	0	-
	4	+	0	0	
	5	0			

95.10 GABA INHIBITION OF ACH RELEASE FROM RABBIT RETINA: EFFECTS OF 2-AMINO-4-PHOSPHONOBUTYRIC ACID (APB). *S.C. Massey*, M.L.J. Crawford and D.A. Redburn (SPON: H.G. Sperling).* Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX 77025.

There is strong evidence for the role of ACh as a neurotransmitter in the rabbit retina. Cholinergic enzymes are present and localized in the inner portion of the rabbit retina, and ACh is released by light stimulation. In addition, both light-evoked release and resting efflux of [^{3}H]-ACh from the *in vivo* rabbit eye-cup are inhibited by GABA (1mM) or muscimol (1µM) but strikingly increased by µM concentrations of GABA antagonists. This suggests that cholinergic neurones in the retina are influenced by both tonic and phasic release of endogenous GABA.

Slaughter and Miller (Science 211: 182) have recently described the actions of 2-amino-4-phosphonobutryic acid (APB) on the mudpuppy retina. At µM concentrations this drug selectively and reversibly inhibited depolarizing bipolar cells. Complete inhibition of these cells with APB eliminated the ON pathways thus leaving only OFF responses in the inner retina. Our ERG and ganglion cell recordings have confirmed these results in the rabbit retina.

We have used APB in our examination of GABA-ACh interactions. APB (100µM) reduced the light-evoked release of ACh by 70% but did not antagonize the large increase in resting efflux elicited by GABA antagonists. This result implies that the tonic GABA input to cholinergic amacrines is unchanged by APB. Thus it appears that GABA-releasing neurones receive OFF input from hyperpolarizing bipolar cells.

[Supported by NEI grants EYO-1965 and EYO 07024-05]

95.11 Neuropeptide containing amacrine cells in the retina of a turtle, Pseudemys scripta. William D. Eldred and Harvey J. Karten, Dept. of Neurobiology and Behavior, SUNY, Stony Brook, N.Y. 11790.

The inner plexiform layers of many retinas have anatomically specialized horizontal subdivisions or bands. Recent electrophysiological studies indicate the outer bands relate to center-off responses and the inner bands relate to center-on responses. We studied the arborization patterns of identified amacrine cells to help determine the role amacrine cells play in visual processing and provide a morphological basis for future physiological and biochemical studies.

Immunocytochemical methods were used to selectively label amacrine cells which have neuropeptide-like (leu-enkephalin, glucagon, and neurotensin) immunoreactivity. Percentages can be used to represent various levels of bands of the inner plexiform layer. We chose 0% to represent the region near the amacrine cells and 100% to represent the region near the ganglion cells.

Antisera directed against leu-enkephalin label pear-shaped amacrine soma (8µm dia.) that send delicate dendrites into the 0-20% levels and the 65-100% levels. An antisera directed against glucagon labels amacrine cells with a rounded soma (10µm in dia.) and dendritic processes that ramify in levels 0-20% with thinner bands at the 40% and 80% levels. Antisera directed against neurotensin revealed two different amacrine cell types. One type has a large pear-shaped soma (10x14µm dia.) which sends a single 2µm process that divides within levels 45-70%.

The present results indicate that various neuropeptides are present in amacrine cells of the turtle retina, and that there are specific arborization patterns for each type of neuropeptide containing amacrine cell studied. In addition an individual neuropeptide can be found in more than one morphological type of amacrine cell. Our results provide the basis for ultrastructural studies to determine the pre- and postsynaptic neurons contacting identified amacrine cells. Such functional analysis will help define the roles of the horizontal bands of dendritic arborization in the inner plexiform layer. This research supported by EY02164 to HJK and EY07039 to WDE.

95.12 FOUR TYPES OF AMACRINES ACCUMULATE GAMMA-AMINOBUTYRIC ACID (GABA) IN THE CAT RETINA. M. A. Freed*, Y. Nakamura*, and P. Sterling. Dept. of Anat., Sch. of Med., U. of Penn., Phila., Pa., 19104.

Retinal neurons which accumulate GABA comprise more than one quarter of the neurons in the amacrine cell layer. Some of the GABA-accumulating neurons (8%) were previously shown to be interplexiform cells; the remainder are true amacrines but have not yet been characterized. We have partially reconstructed from serial electron microscope autoradiograms 24 of these cells and have followed an additional 18 cells through the series. Four types of GABA-accumulating amacrines were distinguished on the basis of size, cytoplasmic appearance, shape of soma, and by the appearance of primary and secondary processes.

Type 1 (21 cells) was dark with a large soma (550-700 μm^3), which was flattened against the inner plexiform layer (IPL). Multiple, moderately thick (0.6 µm) processes splayed from the margins like the appendages on a crab. Stemming from these processes, as well as from the soma margins, were thinner processes (0.4 µm) which were directed more vertically into the IPL. GABA accumulation was high (5-14X nonspecific).

Type 2 (9 cells) was pale with a middle-sized (320-430 μm^3) mitral soma. One moderate diameter (0.8 µm) process descended vertically from the center of the inner soma surface and sent off horizontal processes at either the inner or outer half of sublamina a. One or two thin (0.4 µm) processes stemmed from the soma margin. GABA accumulation, with two exceptions, was moderate (3-4X nonspecific).

Type 3 (10 cells) was dark with a small to middle-sized (200-410 μm^3) generally pyriform soma. In six cells the inner soma surface tapered into one stout (3.0 µm) process which bifurcated in the middle of sublamina a. One or two fine processes descended from the soma margin and in one case ran for 9 um in the outermost IPL. Two cells were exceptions, having loaf-shaped somas, each with one moderately thick (0.8 µm) process which descended 3 µm into the IPL without branching. Two other cells were spherical and emitted only fine (0.2 µm) processes. A diversity of morphologies may require subclassification of Type 3 after further study. GABA accumulation ranged broadly (3-8X nonspecific).

Type 4 (2 cells) was pale with the largest soma (850-870 μm^3). This was pyriform, tapering into a stout (2.0 µm) process which descended into the middle of sublamina a where it emitted smaller horizontal processes. One moderate diameter (0.6 µm) process stemmed from the soma margin. GABA accumulation was moderate (3-5X nonspecific).

It is to be expected that these four different types of amacrines, which accumulate GABA at differing levels, will have distinct functions in retinal circuitry. To understand these functions it will be necessary to characterize in detail their arborizations and synaptic connections. EY00828.

95.13 THE IDENTIFICATION AND DEVELOPMENT OF AMACRINE CELLS CONTAINING SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN CHICKEN RETINA.
I.G. Morgan, J. Oliver* and I.W. Chubb*. Department of Behavioural Biology, Research School of Biological Sciences, PO Box 475 Canberra City ACT 2601 and Centre for Neuroscience and Departments of Human Physiology and Medicine, School of Medicine, Flinders University, Bedford Park, South Australia 5032.

Transverse sections of chicken retina stained with antisera to somatostatin show well-defined amacrine cell bodies situated one to two cell layers away from the boundary between the inner plexiform and inner nuclear layers. Their processes ramify throughout the inner plexiform layer, with concentrations in Ramon y Cajal's layers 1, 4 and 5. The amacrine cells were not visible after intraocular injection of kainic acid, but they were not affected by destruction of the retinal ganglion cells by axotomy or intraocular injections of colchicine. These results were confirmed by radioimmunoassay. There was no reduction of the levels of somatostatin-like immunoreactivity after destruction of the ganglion cells, while the levels of somatostatin-like immunoreactivity were markedly reduced by intraocular kainic acid. These results may indicate that the amacrine cells containing somatostatin-like immunoreactivity receive bipolar cell input, but do not synapse onto retinal ganglion cells, presumably being involved in amacrine-amacrine or amacrine-bipolar cell interactions.

The development of these cells was followed by radioimmunoassay and immunohistochemistry. Somatostatin-like immunoreactivity was first detectable around 7 days *in ovo*, and developed slowly up until day 19 *in ovo*. The amount of somatostatin-like immunoreactivity then more than doubled to reach adult levels around the time of hatching. Histochemically, immunoreactive cell bodies were first visible around day 13 *in ovo* but clearly-defined processes in the inner plexiform layer were not visible until around days 17-19. These results indicate that the immunoreactive amacrine cells begin to synthesize somatostatin-like immunoreactive material before the final definition of their dendritic arborisations and synaptic interactions and that their development is not dependent on visual stimulation, since they reach a mature form prior to hatching.

95.14 SOMATOSTATIN-LIKE IMMUNOREACTIVE MATERIAL IN THE RABBIT RETINA.
S.M. Sagar, O.P. Rorstad,* D.M. Landis and J.B. Martin. Dept. of Neurology, Massachusetts General Hospital, Boston, MA.

As an initial step in the investigation of the function of somatostatin (SRIF) in the mammalian retina, the properties of somatostatin-like immunoreactive material (SLI) in the rabbit retina were studied. Using a specific radioimmunoassay, SLI was detected in the rabbit retina at a mean concentration of 1.1 $\pm$ 0.1 ng SLI/retina, or 0.17 $\pm$ 0.3 pg SLI/µg protein. Dilution curves of the retinal extract paralleled those of synthetic tetradecapeptide SRIF. On gel permeation chromatography, three major peaks of immunoreactivity were found. One peak co-eluted with synthetic SRIF, one with synthetic somatostatin-28, and the third eluted with higher molecular weight material. The SLI was found to be concentrated in a synaptosomal fraction prepared by differential centrifugation. The concentration of SLI in the retina was not diminished by the intravitreal injection of either 6-hydroxydopamine or 5,7-dihydroxytryptamine, neurotoxins which destroy catecholamine and indoleamine accumulating neuronal terminals, respectively. Retinal SLI, but not dopamine or substance P concentration, was decreased by cysteamine, an agent known to deplete SLI in other neural tissues. As in the investigation of other retinal neurotransmitter candidates, the rabbit retina offers a convenient system for further investigation of SRIF function.

Supported by PHS grant AM 26252. SMS is an NIH post-doctoral fellow supported by the National Eye Institute.

95.15 DOPAMINE RECEPTOR REGULATION IN AVIAN RETINA BY LIGHT/DARK ENVIRONMENT.
W.L. Klein, F.G. deMello,* A. Lucia,* and M.C.F. deMello.* Dept. Neurobiology and Physiology, Northwestern University, Evanston, Ill. 60201 and the Biophysics Institute, Rio deJaneiro, Brazil.

Avian retinas respond to dopamine with an increase in cAMP concentration (DeMello, F.G., J. Neurochem., 31:1049, 1978). It recently has been shown that long-term (6 days) dark adaptation of post-hatch chicks increases the maximal elevations in cAMP in retina elicited by dopamine (DeMello, F.G., and DeMello, M.C. F., Pont. Acad. Sci. Sc. Var., 45:343, 1980). We have investigated the possibility that this increased response is due, at least in part, to a physiologically-induced increase in dopamine receptors.

Chick neural retinas, dissected free of pigment, homogenized and incubated at 37° in 50 mM TrisCl pH 7.4 with 120 mM NaCl, 5 mM KCl, 2 mM $CaCl_2$, and 1 mM $MgCl_2$, specifically bound both 3H-ADTN and 3H-spiroperidol. High affinity 3H-ADTN binding had a K_d of 6.7 x 10^{-9} M and a B_{max} of 220 fmol/mg protein when determined using 10^{-4} M dopamine to block specific binding. 3H-Spiroperidol binding was highly sensitive to buffer composition and the use of Tris and HEPES buffers without additional salts abolished specific binding. When 10^{-4} M dopamine was used to block specific binding, the K_d for 3H-spiroperidol was 7.8 x 10^{-10} M with B_{max} equal to 40 fmol/mg protein. When 10^{-5} M fluphenazine was used to block specific binding, two components of 3H-spiroperidol binding were observed (#1: K_d = 3 x 10^{-10} M, B_{max} = 50 fmol/mg protein; #2: K_d = 4.3 x 10^{-9} M, B_{max} = 240 fmol/mg protein). When 10^{-4} M dopamine was used to block the specific binding of 5 x 10^{-9} M 3H-spiroperidol, we observed nearly a two-fold increase in binding to retina homogenates from chicks maintained in a dark-environment for 10 days (69 fmol/mg protein) compared to levels found in retinas from chicks maintained in a light-environment for the same period (36 fmol/mg protein.

Our results show that environmental stimuli can physiologically induce changes in dopamine-sensitive 3H-spiroperidol binding sites, and they provide further support for the hypothesis that dopamine receptor regulation is a modifier of synaptic communication in the central nervous system. (Supported in part by a grant to WLK from the Brazilian-American Institute of Rio de Janeiro and NIH grant NS 15299.)

95.16 EM AUTORADIOGRAPHIC LOCALIZATION OF OCTOPAMINE TO EFFERENT FIBERS OF LIMULUS VENTRAL EYE.
J.A. Evans* and B-A. Battelle. Laboratory of Vision Research, National Eye Institute, NIH, Bethesda, MD.

Previous studies suggested that the biogenic amine octopamine is synthesized and stored within efferent fibers of Limulus ventral eye (Battelle and Chamberlain. Neurosci. Abstr. 6: 720, 1980). The EM autoradiographic localization of sites of octopamine synthesis described here provides direct evidence in support of this suggestion. Ventral eyes were incubated in vitro with ^{3}H-tyramine using conditions which optimize octopamine synthesis and accumulation. The preparation was fixed, and thin sections were processed for EM autoradiography. After an 8-week exposure, sections were developed using gold latensification in combination with a physical developer (Kopriwa. Histochem.44:201 1975) to ensure formation of small, 480 A silver grains which minimally obscure underlying ultrastructure. Efferents were identified by (1) Size: efferent fiber diameter ranges from 0.16-0.77 µm. (2) The presence of pleomorphic, 0.2 µm dense granules having a periodic 110 A substructure. (3) The presence of a surrounding glial sheath.

Clusters of silver grains were localized over efferent profiles inside and near the surface of photoreceptor cell bodies and in the ventral nerve. Only low levels of diffuse label were seen elsewhere. Close examination of efferent profiles within 8 different photoreceptor cell bodies revealed that 90% were labeled; 80% of these contained diagnostic dense granules. Labeled efferents were concentrated near rhabdomes and were frequently in direct apposition to microvillar membrane at sites where the glial envelope was interrupted. Efferent axons in the ventral nerve were more difficult to recognize because profiles containing granules were infrequent. Identification was made primarily on the basis of size (0.5 µm compared to 6 µm photoreceptor axons). Virtually all labeled structures in the ventral nerve could be identified as efferents, however a systematic search for unlabeled efferent profiles in this region was not made. An unexpected observation was that labeled efferents run in bundles of 2-4 axons surrounded by glia. Results of this and previous studies implicate octopamine as a possible neurotransmitter in efferent fibers of Limulus ventral eye.

Preliminary EM autoradiographs of lateral eyes incubated with ^{3}H-tyramine and processed as described above also show clusters of silver grains over efferent fibers. This suggests that octopamine is synthesized within lateral eye efferents as well. We hypothesize that octopamine is a neurotransmitter common to efferent fibers in the Limulus visual system and that it plays a role in modulating visual function.

95.17 EFFECTS OF ASPARTATE ON RETINAL RESISTANCE AND LIGHT TRANSMITTANCE. H. Shimazaki, C. J. Karwoski and L. M. Proenza. Univ. of Georgia, Vision Res. Lab., Athens, GA 30602.

Prior to the usually reported isolation of the ERG a-wave, mudpuppy (Necturus maculosus) eyecup preparations perfused with 3.0 - 30.0 mM Na-aspartate (Asp) commonly show ERG amplitudes which more than double over control values (Shimazaki et al, ARVO abst. p39, 1980). Since both the a- and b-waves are similarly enhanced, it is possible that one of the initial effects of Asp is to increase retinal resistance. In order to determine changes in retinal resistance during Asp perfusion, a constant current of 3 μA was passed between electrodes in the vitreous humor and behind the eyecup, and the voltage developed by this current between a recording electrode in the retina and a reference electrode in the vitreous was measured. Light-evoked ERGs between these latter two electrodes were also measured, thus allowing simultaneous recordings of ERG and retinal resistance. When ERG amplitude increased during Asp perfusion, there was also a rapid increase in resistance (by a factor of from 2 to 5) between the vitreous and the depth where the maximal negative b-wave was recorded. Thus, ERG enhancement during Asp perfusion is likely due, at least in part, to an increase in retinal resistance.

Asp application to frog (Rana pipiens) retina caused changes similar to those observed in mudpuppy--specifically, ERG amplitude usually increased prior to a-wave isolation, and retinal resistance increased when the ERG was increased. Since the frog sclera is almost transparent, and the pigment epithelium layer can transmit some light through it, measurements of the effect of Asp on light transmittance through the retina were obtained by positioning a microphotometer behind the eyecup. When ERG amplitude increased, light transmittance through the retina gradually decreased and reached a minimum of about 35% when the a-wave was isolated. This decreased light transmittance was accompanied by the retina taking on a milky appearance.

These observations suggest that Asp has complex effects on the retina and ERG amplitude which must be considered when interpreting results obtained after application of this drug: On the one hand, Asp increases retinal resistance which probably contributes to the increase in ERG amplitude; on the other hand, light transmittance to the photoreceptors is diminished, which must result in some decrease of ERG amplitude. Asp effects such as the well-known lack of post-receptoral responsivity associated with a-wave isolation, the resistance and light transmittance changes, and the previously described changes in extracellular DC potentials and K^+ (Shimazaki et al, 1980), indicate that Asp induces a prolonged spreading depression type of reaction in the retina.

95.18 ABNORMAL VISUAL FUNCTION INDUCED BY DEPLETION OF RETINAL TAURINE IN THE RAT. Norma Lake, Departments of Physiology & Anaesthesia Research, McGill University, Montréal, Québec, Canada.

Taurine-free diets lead to abnormal vision in cats (Schmidt et al. Invest. Ophthal. 15: 47 (1976) but it is not known if this is a phenomenon peculiar to cats, since taurine-free diets in other species are ineffective in reducing tissue taurine levels because of increased biosynthesis and decreased excretion. This difficulty of experimentally manipulating tissue taurine levels has hindered studies of its functions. However Lake has demonstrated that in vivo administration to rats of a taurine analogue, guanidinoethyl sulfonate (which competes with taurine for transport sites) results in specific depletion of retinal taurine to 30% of control (Neurosci. Abst. 6: 345 (1980). In the present studies assessment of the functional consequences of this biochemical change was carried out by electroretinographic (ERG) studies after treatment of rats with 1% guanidinoethyl sulfonate in their drinking water for 60 days. Control animals consumed water without additives. The ERG response to 10 μsec white full field flashes at 1 Hz was recorded with wick electrodes on the cornea of ketamine-anaesthetized animals. The amplitude of the b wave of the ERG was 600-800 μV in 5 control animals while it was significantly reduced to 200-250 μV in the 6 guanidinoethyl sulfonate -treated animals. This study demonstrates the importance of the transport of taurine across the blood-retinal barrier for the maintenance of retinal function in the rat, and with the data from the cat studies suggests that this may be a mechanism important to vertebrate vision in general.

95.19 TONIC EXCITATORY AND INHIBITORY SYNAPTIC INPUTS TO MUDPUPPY RETINAL GANGLION CELLS. J. S. McReynolds, D. R. Dvorak* and J. H. Belgum*. Department of Physiology, University of Michigan, Ann Arbor, Michigan 48109.

The synaptic basis of the sustained light responses of ON- and OFF-center ganglion cells to illumination of the receptive field center was studied using intracellular recording in the superfused mudpuppy eyecup. Current-voltage relations were measured under three conditions: in steady darkness, during steady illumination of the receptive field center, and when synaptic transmission was blocked with 4 mM cobalt chloride.

In darkness, blocking synaptic input causes depolarization of ON-center cells and hyperpolarization of OFF-center cells. These changes are accompanied by large increases in input resistance and show that both types of ganglion cells receive tonic synaptic input in darkness. The net effect of this input is inhibitory in ON-center cells and excitatory in OFF-center cells.

In ON-center cells, light causes a sustained depolarization which is due to an increase in excitatory input as well as a decrease in the inhibitory input which is dominant in darkness. In OFF-center cells, light causes a sustained hyperpolarization which is mainly due to an increase in inhibitory input. It is likely that the excitatory input which is dominant in darkness is decreased during illumination, but any such change (disfacilitation) is small relative to the increase in inhibitory input.

The tonic excitatory and inhibitory inputs each act by increasing membrane conductance. The reversal potential of the excitatory input is more positive, and that of the inhibitory input more negative, than the membrane potential in darkness.

Thus it appears that in both ON- and OFF-center ganglion cells the membrane potential in darkness and during the sustained response to light are determined by the balance of tonic excitatory and inhibitory inputs acting in a push-pull manner. This is contrary to the widely held belief that the sustained responses of ganglion cells are due entirely to modulation of excitatory input from bipolar cells. The existence of tonic inhibitory inputs may result in more integration of information at the ganglion cell level than previously supposed. It is likely that bipolar cells are the source of the tonic excitatory input and that sustained amacrine cells are the source of the sustained inhibitory input.

95.20 THE EFFECT OF STRYCHNINE ON CURRENT-VOLTAGE PROPERTIES OF MUDPUPPY RETINAL GANGLION CELLS: EVIDENCE THAT GLYCINE MEDIATES TRANSIENT INHIBITION. D. R. Dvorak,* J. H. Belgum* and J. S. McReynolds (SPON: T. J. Morrow). Department of Physiology, University of Michigan, Ann Arbor, MI 48109.

In darkness and during steady illumination, the membrane potential of mudpuppy retinal ganglion cells is determined by the combined effects of tonic excitatory and inhibitory synaptic input (McReynolds, et al., Neurosci. Abstr., 1981). Changes in luminance activate additional excitatory and inhibitory synapses which contribute transiently to the response. We reported previously that the transient inhibitory input can be selectively blocked by strychnine, a pharmacological antagonist of glycine (Dvorak, et al., Neurosci. Abstr., 1980). In the present study, the properties of transient inhibition were investigated in greater detail by measuring current-voltage (I-V) relations of ganglion cells in normal Ringer and in the presence of 10 μM strychnine.

Intracellular recordings were made from ON-center, OFF-center and ON-OFF ganglion cells in superfused mudpuppy eyecups. I-V relations were measured in steady darkness and during the response to a spot of white light (200 μm dia) positioned in the receptive field center. Long duration (3-5 sec) light stimuli were used in order to easily separate the transient and maintained components of the response.

I-V relations measured at short times after the onset and termination of the light stimulus had steeper slopes and were displaced to more positive potentials in the presence of strychnine. Measurements made in darkness or during steady light showed no significant difference between the presence or absence of strychnine. The average conductance increase associated with the transient inhibitory input was 2-10 nS. Control observations on bipolar and amacrine cells indicate that the observed effects of strychnine are occuring at the ganglion cell level.

The results provide strong evidence that the transient inhibitory input to the three classes of ganglion cells is mediated by a glycinergic synapse. This synapse is inactive in steady darkness and during maintained illumination, and it is active only briefly (for less than one sec) following a step change in illumination. The data support the premise that this input derives from transient amacrine cells.

95.21 NEW CELL TYPES AT THE RETINAL GANGLION CELL LEVEL IN THE TURTLE, PSEUDEMYS. J.E. Fulbrook, J.H. Maxwell, and A.M. Granda. Inst. for Neuroscience, University of Delaware, Newark, DE 19711.

We have examined some of the spatial, temporal, chromatic, and movement-sensitive properties of retinal ganglion cells (RGCs) in the turtle. Over several years of single unit data collection, a classification of cell types has been made which includes most of the RGC types known in other vertebrates. In turtle, most receptive fields (RFs) had center and surround regions but RGC surrounds were generally silent and did not respond to flashed or moving stimuli. The RF organization of most RGCs was complex, usually asymmetric, and frequently mutable to changes in adaptation level, stimulus wavelength, or stimulus velocity. All of the cells were movement-sensitive. Most units were at least 50% more sensitive and responsive to moving rather than stationary stimuli. About 40% of the units were directionally-sensitive (DS). In addition to the above cell properties and types, several new RGC types have been characterized in the turtle. Here, we report on a few of these cell types.

LARGE-FIELD CELLS: Several cells (n=6) had RF sizes in excess of 25^{o} visual angle on any side. The largest RF was shown by a DS, ON-OFF cell with a crescent-shaped field about 75^{o} in length. Three large-field cells with only blue cone input were observed. These cells were oval-shaped, 20^{o}-40^{o} in width and length limits, gave weakly sustained ON responses to stationary, flashed stimuli (450 nm), were non-DS, and preferred slow-moving stimuli.

ANNULAR CELLS: These cells (n=3) did not respond to any type of center stimulation but gave robust responses to surround stimulation, especially to stimuli moving less than 2.0^{o}/sec. Annular cell centers were circular, 5^{o}-6^{o} in diameter; surrounds were 2^{o}-3^{o} thick. Two cells were red-sensitive (640 nm), the other was green-sensitive (560 nm). Surrounds gave ON responses to stationary, flashed stimuli, required light adaptation for any response to occur, and were non-DS.

BAR-SHAPED CELLS: These cells (n=8) resemble the simple cortical cells seen in cat and monkey. Length-to-width size ratios ranged from 2:1 to 10:1. Most units were DS with the preferred-null directions arranged orthogonal to the long axis of the RF. The RF organization consisted of 1, 2, or 3 parallel, bar-shaped response regions which produced robust ON, ON-OFF, or OFF responses to moving or flashed stimuli. The RF organization of most bar-shaped cells was independent of adaptation level. Color opponency was not observed in any of the above cell types.

Supported by N.E.I. grant #01540.

95.22 MORPHOLOGY OF RABBIT RETINAL GANGLION CELLS, D.H. Rapaport, J.M. Provis*, and B. Dreher*. School of Anatomy, Univ. of New South Wales, Dept. of Ophthalmology, Sydney Eye Hosp., and Dept. of Anatomy, Univ. of Sydney, Sydney, Australia.

Clear correlations have been established in the cat retina between physiological and morphological classes of ganglion cells. A number of functional classes of rabbit retinal ganglion cells have been described physiologically, and while some of these seem to be analogous to those distinguished in the cat, others are quite different.

The morphology of rabbit retinal ganglion cells was examined in both Golgi stained and HRP filled whole-mounted retinae. The data obtained with either method were essentially the same, so we can be confident that we are not including displaced amacrine cells in our ganglion cell classification. Class 1 cells had large cell bodies (20-40μm dia.), thick axons (0.8-2.0μm dia.) widely extending dendritic fields (200-660μm dia.), usually arising from 3-5 thick primary dendrites branching radially. These cells remind us of the alpha cells of the cat retina, and therefore are likely to be the morphological counterparts of rabbit Y cells. Class 2 cells had small to medium somas (10-24 μm dia.) and large dendritic fields (250-680μm dia.), in many ways they seemed continuous with Class 1 cells, but they had distinctly thinner primary dendrites which spread radially from the soma and branched somewhat less often. Class 3 cells were clearly distinct from 1 and 2, although soma and dendritic field diameters overlapped considerably with those of the other two classes (13-30μm soma dia.; 100-500μm arbor dia.). The dendritic tree of Class 3 cells formed a meshwork of highly branched, thin, wavy dendrites around the soma. Both Class 2 and 3 cells had finer (0.4-0.8μm dia.) axons than those of Class 1 cells.

Within each morphological class a wide range of soma and dendritic field diameters are present, and there is only a slight correlation between these two parameters. Class 1 cells in temporal retina were larger than their counterparts in other retinal areas, but we have yet to notice any systematic variation in soma or dendritic field diameter within a class that can be related to distance from the visual streak.

A small proportion of cells were found which did not fit easily into our classes. If they represent truly separate classes their scarcity in our sample suggests that they form only a small proportion of the overall ganglion cell population.

95.23 RETROGRADE LABELING OF GANGLION CELLS AND THEIR DISSOCIATION FROM THE MOUSE RETINA. G.W. Balkema and P.V. Sarthy. Dept. of Ophthalmology, Univ. of Wash., Seattle WA 98195.

We have labeled ganglion cells in the mouse retina by retrograde transport of fluorescent dyes injected into the brachium of the superior colliculus. In animals injected with the fluorescent dyes, DAPI (4'-6-diamidino-2-phenylindol-2HCl) and Primulin, and allowed to survive for 1-2 days, the whole mounts showed labeled somata across the entire retina. While Primulin appeared as bright yellow specks throughout the ganglion cell cytoplasm often filling the dendritic processes, DAPI fluorescence was confined mainly to the nucleus. In transverse sections almost all of the labeled cell bodies were found in the ganglion cell layer; occasionally, however, some labeled cells were found to be displaced into the inner plexiform/inner nuclear layer. As in the whole mounts, DAPI fluorescence was limited to the nucleus while the cytoplasm and dendrites showed Primulin fluorescence.

When animals were allowed to survive longer than 2 days, blue DAPI label could be occasionally found in cell somata within the inner nuclear layer. This DAPI fluorescence was less intense than the label found in the ganglion cells. In addition, no Primulin specks were found within the cytoplasm of these cells.

Other mice with similar injections (survival time=2 days) were enucleated and the labeled retinae were dissociated into single cells by papain treatment and mechanical dissociation. In the dissociated cell suspensions we found about 1,000-5,000 labeled cells per retina. These cells had a large labeled nucleus with a thin layer of surrounding cytoplasm. Cells with bipolar, amacrine, photoreceptor or Muller cell morphology never showed any label. During our search for fluorescent cells, we looked extensively for cells which had DAPI/Primulin fluorescence as well as ganglion cell-like morphology; we failed to find them. All brightly fluorescent cells showed only a rounded morphology.

These experiments establish that ganglion cells labeled by retrograde transport of DAPI/ Primulin retain their fluorescence even after dispersion by papain treatment and mechanical dissociation.

Supported by USPHS Research Grants EY-03664, EY-01730, and EY-07013.

95.24 CONTRALATERAL AND IPSILATERAL RETINAL PROJECTIONS IN NORMAL GOLDFISH. A. D. SPRINGER. Dept. of Anatomy, New York Med. Coll. Valhalla, N.Y. 10595.

Cobaltous-lysine applied to the distal stump of a severed optic nerve was used to study the retinal projections of normal adult goldfish. Both the termination areas of optic axons, as well as the pathways they traveled were established. Contrary to previous descriptions of the goldfish visual system, the optic nerves do not decussate completely at the optic chiasm. Fascicles that entered the ipsilateral optic tract innervated targets in the ipsilateral thalamus and optic tectum. Other optic fibers crossed the posterior commissure from the contralateral side of the brain and also innervated the ipsilateral tectum and thalamus. In addition, optic fibers bilaterally innervated a hypothalamic target in close proximity to the infundibulum that may correspond to the nucleus lateralis tuber. The contralateral preoptic region contained two discrete areas of innervation, each served by separate fascicles. The ipsilateral preoptic region was similarly innervated, but more sparsely. Fibers that entered the contralateral ventral thalamus originated from three fascicles and terminated in three distinct targets. In contrast, three targets in the contralateral dorsal thalamus were served by one fascicle, and fibers passed from one nucleus to the other two. Innervation of the ipsilateral thalamus was similar to that seen contralaterally. Each main optic tract divided into three tracts, two of which entered the optic tectum, while the other innervated several pretectal areas. Other fibers innervated an accessory optic nucleus located near nucleus glomerulosus. The contralateral tectum contained numerous radially oriented optic fascicles. These fascicles represented optic fibers that left thalamic and pretectal targets to enter the optic tectum from beneath the stratum periventriculare. Optic fibers were also observed in the transverse commissure, tractus rotundus, horizontal commissure, tectobulbar tract and fasciculus retroflexus. Therefore, it appears that many of the anomalous projections seen after tectal ablation or after optic nerve crush are not in fact aberrant. Such projections probably reflect the presence of unusually large numbers of optic fibers in tracts that normally contain optic axons, as well as increased innervation of areas that normally receive sparse retinal projections Filled tectal cells that could represent cells projecting to the retina were not observed in either tectal lobe. The ipsilateral retinal projections could not be attributed to cobaltous-lysine being transneuronally tranported in readily detectible amounts.

95.25 THE OPTIC NERVE OF THE NORTH AMERICAN OPOSSUM: AN ELECTRON MICROSCOPIC STUDY. M.A. Kirby*, L. Clift-Forsburg*, S.C. Rapisardi, and P.D. Wilson. Dept. of Psychology, University of California, Riverside, CA 92521; Dept. of Anatomy, Howard University, Washington, D. C., 20059.

The retinal ganglion cell population (from retinal whole mounts) of the North American opossum (Didelphis virginiana) has been estimated at approximately 101,000 (Rapaport, Wilson, and Rowe, J. Comp. Neur., 199, 1981, In Press). This value differs from an earlier light microscope study of the optic nerve of this species in which the total fiber population was estimated at 82,100 (Brusch and Arey, J. Comp. Neur., 77:631,1942). Analysis of the fiber population of the optic nerve of this species was undertaken (three cross sections from two animals) in order to examine this apparent discrepancy.

Electron microscopic (EM) examination of the optic nerve indicated a mean total count of 103,000 fibers (range: 91,850 to 122,742), of which less than 2% were unmyelinated. Diameters of myelinated fibers ranged between .25 um to 6.2 um (mode at .85 um) while unmyelinated fibers ranged between .25 um to 2.13 um (mode at .53 um). Frequency distributions of fiber diameters were found to be unimodal and positively skewed.

Our estimate of 103,000 fibers is within 2% of the estimated retinal ganglion cell population reported for whole mounted retinas (Rapaport, et al., 1981). This estimated fiber population represents a value 31% larger than the previous light microscopic study of Didelphis virginiana, a difference attributed to the inability of resolving small diameter myelinated and unmyelinated fibers at the light microscopic level. In addition, the present finding of a less than 2% unmyelinated fiber population contrasts sharply with the previous light microscopic estimation of 33%. We are currently exploring the possibility that the large estimated unmyelinated population of the earlier light microscopic study may have resulted from examination of the optic nerve sectioned in the region of the lamina cribrosa, as has been previously proposed (cf. Hokoc and Oswaldo-Cruz, J. Comp. Neur., 178:773, 1978).

In a similar EM study of a closely related subspecies, the South American opossum (Didelphis marsupialis aurita), the fiber population of the optic nerve was estimated at 74,700 of which approximately 20% were unmyelinated (Hokoc and Oswaldo-Cruz, 1978). Therefore, based on EM examination of the optic nerve fiber populations and light microscopic study of retinal ganglion cell populations, it would appear that major differences are evident in both the myelinated and unmyelinated fiber populations of these two closely related subspecies. (Supported by University of California Research Grant, and NIH Grant #RO1-EY02953-03.)

96.1 A PROCEDURE TO ENHANCE AUDITORY BRAINSTEM RESPONSE RELIABILITY IN UNRESTRAINED, UNANESTHETIZED RATS. Julia A. Lee*, Richard A. Abbott*, Donald W. Nielsen and Robert F. Berman. Psychology Dept., Wayne State University and Otological Research Laboratory, Henry Ford Hospital, Detroit, Michigan, 48202.

Reliability of the auditory brainstem response (ABR) is achieved through control over stimulus variables including rate, polarity, intensity, and frequency spectrum. Traditionally, control over the stimulus is achieved by anesthetizing the animal and delivering the stimulus through hollow ear bars. However, it is not always possible to anesthetize or restrain the animal. For instance, if the ABR is used as an electrophysiological measure of drug effects, there could be drug-anesthetic interactions, without apparent effects of the anesthetic alone. Restraint is a stressful procedure that may interfere with the pharmacological agents being studied. One solution to these difficulties has been to present the stimulus free-field, a procedure with less control over the stimulus reaching the ear. Even though sound pressure levels throughout an empty chamber may vary minimally, sound pressure levels at the ear do change as a function of body position. It is possible to wait for an animal to achieve a certain orientation before recording. However, the drug being studied could affect posture by altering muscle tone, so that drug and no-drug postures would differ. With our procedure these concerns are minimized. Distance between sound source and ear is standardized, and the stimulus is monitored at the entrance to the ear. The speaker-ear distance is held constant by attaching a miniature electroacoustic transducer to the rat's head. The base for the speaker unit is mounted permanently to the acrylic supporting the electrode connector. The speaker itself is fastened in the same position for each rat prior to ABR recording. The same transducer is used for all subjects. Stimulus features, including sound pressure level, time waveform, and frequency spectrum, are measured at the ear entrance via a small plastic tube. The tube is inserted, under general anesthesia, subcutaneously so that one end terminates in the entrance to the ear canal, and the other end is secured to the acrylic platform at the top of the head. At the latter end, a small, calibrated, probe microphone is inserted to measure stimulus characteristics. Since the ABR appears to be influenced by temperature, brain temperature is also measured. With our procedure it is not necessary to anesthetize the animal or wait for the animal to assume a certain orientation. It is necessary to wait for the rat to stop moving; therefore, the rat is observed on a video screen, and the EEG is monitored on an oscilloscope.

96.2 HYPOTHERMIA EFFECTS ON CAT BRAINSTEM AUDITORY EVOKED RESPONSES. G.T. Rossi and R.H. Britt. Neurosci. Dept. and Neurosurg. Div. R-155, Stanford Sch. of Med., Stanford, CA 94305 and Palo Alto Veterans Hospital, Palo Alto, CA 94304.

Five pentobarbital anesthetized cats were surgically prepared and placed on total cardiopulmonary bypass for periods of up to 8 hours. Systemic hypothermia was achieved by slowly cooling the bypass blood from 37° C to 19° C through a water heat exchanger. Brainstem auditory evoked responses (BAERs) to monaural clicks (90 dB, 10 per sec) were filtered (150-3 KHz) and averaged from differential recordings between vertex and mastoid electrodes. Arterial pressure controlled by the rpm speed of the bypass pump head (Bio-Medicus user specified) was maintained above 50 mm Hg. Temperatures were recorded from 3 thermocouple probes (Bailey) located in the left parietal lobe and in the arterial and venous return cannulas and general purpose temperature probes (Hewlett-Packard) in the esophagus and rectum. Esophageal rather than rectal temperature was found to be the more accurate indicator of temperature of the brain. Serial BAERs were recorded at 1 minute intervals as brain temperature was lowered from 37° C to 22° C and then rewarmed to 37° over a 1 hour period.

Two significant effects were produced by controlled systemic deep hypothermia. First, the latencies of each BAER wave (I-V) were linearly increased as brain temperature was lowered to 26° C. Latencies of early waves (I-III) increased less than those of late waves (IV-V) in the range from 0.7 msec for wave I to 4.5 msec for wave V. Plots of latency versus temperature for each wave are linear to first approximation. Below 26° C this function becomes non-linear. Differences do occur between the slopes (latency in msec/° C), calculated to be 0.08, 0.17, 0.19, 0.26, and 0.30 for waves I-V, respectively. Second, the wave peak amplitudes were initially increased, then decreased as brain temperature was lowered. Amplitudes increased to their maximum values between 32°-33° C; then decreased at a similar rate to 26° C for all waves and were lost completely below 26°-23° C (brain temperature). Amplitude-temperature plots for waves I-V appear to: 1) have a somewhat parabolic shape; 2) have nearly linear decreases in amplitude occurring after the maximum values and 3) have similar slopes (μV/° C) between waves. Gradual rewarming restored the BAER to its original latencies and amplitudes. The same results were repeated for sequential cooling and rewarming.

This study suggests that the BAER does not significantly change in configuration over a wide temperature range. Analysis indicates that the increase in latencies and the decrease in amplitudes of the BAER wave components can be expressed as mathematical functions over the temperature range of 37° to 26° C. Loss of the BAER occurs abruptly with temperatures below 26°-23° C.

96.3 GENERATORS OF THE FREQUENCY FOLLOWING RESPONSE. LESION STUDIES. R.L. Davis* and R.H. Britt (SPON: W.D. Neff). Div. Neurosurg., R155, Stanford Med. Sch., Stanford, CA 94305 and Palo Alto Veterans Hospital, Palo Alto, CA 94304.

An ongoing series of lesion experiments (15 to date) are designed to identify the generators which contribute to the amplitude and complexity of the frequency following response (FFR) in the cat. Histologically confirmed lesions were made in areas of the afferent auditory brainstem pathway by aspiration or radiofrequency thermocoagulation. The brainstem auditory evoked response (BAER) elicited with click stimuli was monitored throughout the experiments as an estimate of the extent of each discrete lesion. The FFR was elicited with 11 ms tone bursts (2 ms rise-fall time) presented through shielded earphones at 10 per sec. Farfield BAER and FFR responses (bandpass filtered from 150 to 8K Hz) were averaged from differential electrodes placed at the vertex and mastoid. Round window electrodes were used to record the cochlear microphonic, N1 and N2 responses.

Sequential lesions of inferior colliculi and superior olivary complexes on both sides resulted in a 500 Hz waveform envelope which maintained 50 to 75% of the baseline amplitude. Preliminary findings from similar experiments demonstrated that the 500 Hz waveform maintained 100% of the baseline amplitude when only the cochlear nucleus was lesioned; care was taken to not disrupt blood flow to the cochlea. Assuming that the cochlear nucleus was completely transected (as evidenced by the the waveform change in the BAER) these results suggest that the amplitude decreases observed after the higher level auditory brainstem structures were lesioned can be attributed to factors other than the loss of FFR neural generators. Although lesions of the cochlear nucleus did not substantially affect the waveform amplitude at any of the frequencies, a considerable decrease in waveform complexity was observed at 500 Hz. This finding suggests that the complexity of the waveform is due to neural activity in the cochlear nucleus superimposed on a cochlear microphonic sinusoidal waveform. Lesions peripheral to the cochlear nucleus which also disrupted the cochlear blood supply resulted in dramatic decreases in FFR amplitude at all test frequencies. The residual FFR and CM were completely abolished after the ipsilateral cochlea was destroyed indicating that the recordings were not influenced by stimulus artifacts.

These lesion studies suggest that the major amplitude component of the FFR lies peripheral to the cochlear nucleus, most likely from the cochlear microphonic. The complexities of the 500 Hz waveforms observed at high stimulus intensities are thought to originate from cochlear nucleus activity.

[Supported by VA Merit Review and NIH (NS15860) Grants]

96.4 EFFECTS OF ANESTHETICS ON THE BRAINSTEM AUDITORY EVOKED RESPONSE. M. Cohen* and R. Britt (SPON: R. Dooling). Div. of Neurosurg. R155, Stanford Medical Center, Stanford, Ca. 94305 and Palo Alto Veterans Hospital, Palo Alto, Ca. 94304.

A parametric study was performed comparing the effects on the brainstem auditory evoked response (BAER) of four anesthetic agents commonly used in the operating room and in the laboratory. Sodium Pentobarbitol, Ketamine, Halothane and Chloralose were administered individually to each of four cats in a different sequence. Click-evoked BAER's were compared for differences in waveform configuration, latencies and amplitudes of the component peaks, five of which (I-V) could be identified in each animal and with each anesthetic agent. There were no statistically significant differences between anesthetic agents in mean latencies of the component peaks. Amplitude differences between animals using the same anesthetic agent were too large to be compared meaningfully. This study is consistent with the use of the BAER as a useful means of monitoring the integrity of the ascending auditory pathway with little ambiguity added by the use of a variety of parenteral and inhalation anesthetic agents. (Studies supported by VA RAG/Merit review and NIH(NS 15860) Grants and the Neurosurgery Research Fund)

96.5 CHANGES IN THE AUDITORY EVOKED POTENTIALS OF THE NUCLEUS ACCUMBENS AND AMYGDALA INDUCED BY REPEATED DOSES OF d-AMPHETAMINE. C. C. Turbes, G.T. Schneider*, R. J. Morgan and J. M. Simard*. Dept. of Anatomy, Creighton Univ. Sch. of Med., Omaha, NE 68178 and Dept. of Biophysics and Physiol., Colorado State Univ., Fort Collins, CO 80521.

Slow wave brain potentials flowing in the extracellular space are important since they can be shown to alter the excitability in neuronal populations. There may be a substantial class of cooperative neural interactions which depend on synaptic and non-synaptic influences that act on synchronizing and desynchronizing mechanisms in the brain.

In these studies we investigate the action of repeated doses of d-amphetamine on auditory evoked potentials (AER) of the nucleus accumbens septi and the basal nucleus of the amygdala. The AER of the two brain regions are compared using cross correlation analysis. Data from eleven cats are used in these experiments. Recordings are made with a polygraph and an FM tape recorder using hardwire and radio telemetry methods. Auditory evoked potentials are selected and analog to digitally converted. The Fast Fourier Transform (FFT) algorithm processing is done in the frequency domain. With three repeated daily doses, there is a progressive decrease of percent normalized cross correlation. The action of d-amphetamine is associated with increasing time delays (tau) between the wave potential trains of the nucleus accumbens and the basal nucleus of the amygdala. There are also shifts in average taus, the wave trains of the nucleus accumbens leading in pre-drug period. The basal amygdala leads during the action of d-amphetamine. It is apparent that d-amphetamine at dosages used alters electrochemical processes that have a rôle in synchronization and desynchronization mechanisms of neuronal assemblies that process sensory information and function in behavior.

96.6 THE T COMPLEX OF THE HUMAN AUDITORY EVOKED POTENTIAL (AEP): RATE DEPENDENCE. S. Satya-Murti*, J.R. Wolpaw, C.A. Schaffer* and A.T. Cacace*. (SPON: R.S. Bourke). Dept. of Neurology, Albany Med. Coll., Albany, NY 12208 and Div. Labs. Res., N.Y.S. Dept. Hlth., Albany, NY 12201.

The AEP recorded from the temporal scalp contains components probably produced in auditory cortex, an 80 ms positive peak (TP 80) and a 120 ms negative peak (TN 120). These waves, designated the T complex (TC), are simultaneous with the conventional vertex potential (VP) which dominates the AEP over most scalp regions. It is unresolved if the VP originates in auditory cortex, other areas of cortex and/or subcortical regions, and if it is separate in origin from the TC. To date, the TC has been studied only at slow stimulation rates. We studied the rate dependence of the TC and compared it to that of the VP to determine 1) if the TC may be reliably recorded at faster rates and 2)if the TC and the VP display different rate dependence which could aid in their separation.

Subjects were 6 adults, ages 22-36. The stimulus was a binaural click (0.5 ms pulse, 66 dB above HTL) delivered at rates of 2, 1, and 0.3/s in successive runs followed by a second 2/s run (to monitor stability). AEPs were recorded from Cz, Fp/z (halfway between Fp and Fz), T3/5 (halfway between T3 and T5), and T4/6, all referred to a balanced noncephalic reference. A Nicolet-Apple system sampled 1 pt/ms and averaged 150 (all rates) and 300 responses (2/s rate). VP latency and amplitude were measured from the Cz AEPs. The bipolar AEPs, T3/5-Fp/z and T4/6-Fp/z, were constructed off-line. The TC latency and amplitude were measured from the bipolar AEPs. Topographic studies indicate that these bipolar AEPs show the TC in relative isolation.

The TC amplitude was 6.8 (±2.3) uV, and the VP amplitude 11.5 (±3.3) uV at .3/s. At higher rates both TC and VP were markedly smaller, by 35 (±16)% and 34 (±9)% at 1/s and 73 (±17)% and 66 (±16)% at 2/s respectively. Neither TC nor VP latencies showed consistent dependence on stimulus rate, though TP 80 occurred slightly later in 3 of 6 subjects at higher rates. VP latencies displayed more intra-individual variability than did TC latencies.

Results indicate that 1) relatively slow rates of stimulation, such as 0.3/s are preferable for recording the TC since, like the VP, it is much smaller at faster rates and 2) there is no marked difference between the rate dependences of TC and VP.

96.7 SIMULTANEOUS RECORDING OF PHOTOPIC ELECTRORETINOGRAMS AND VISUAL EVOKED RESPONSES BEFORE AND AFTER RETINAL DAMAGE BY MONOCHROMATIC LIGHTS.
R.B. Rosenberg*, R.S. Crockett and T. Lawwill* (Spon. K. Reid) Depts. of Physiol. & Biophys. and Ophthalmol. University of Louisville, Health Sci. Cen., Louisville, Ky. 40202.
Photopic electroretinogram (ERG) b-waves and visual evoked responses (VER) were simultaneously recorded by computer assisted signal averaging from Rhesus and Cynomolgus monkeys to determine the functional effect of intense monochromatic light exposure. The stimulus was a bar-pattern alternating at 1 Hertz. The dark and light bars had a 1.6 log contrast and a retinal spatial frequency of 0.367 cycle per degree. The bar-pattern was illuminated with 550 nm light providing a corneal irradiance of 0.1 $uWcm^{-2}nm^{-1}Sr^{-1}$ (5 x 10^4 Trolands). A round 38.1° test field was centered upon the macula. After pre-exposure testing the eyes were exposed for 4 hrs to monochromatic laser light of 457.9 nm (5 $mWcm^{-2}$, 4 eyes), 514.5 nm (10, 15, and 20 $mWcm^{-2}$, 2, 1, and 2 eyes, respectively) and 590 nm (20 and 40 $mWcm^{-2}$, 2 eyes each). Laser irradiances chosen were near those required to produce non-thermal or photochemical threshold retinal injuries as defined by scotopic ERG, histology and indirect ophthalmoscopy. The pre-exposure ERG b-wave amplitude was 7.0 ±0.14 uV (SEM). Pre-exposure VER was 55.4± 1.54 uV (SEM). Significant reductions in b-wave amplitude ($p< 0.05$) were found after the 457.9 nm and after the 40 $mWcm^{-2}$ 590 nm exposures. Significant reductions in VER were found after the 457.9 nm and after the 20 $mWcm^{-2}$ 514.5 nm exposures. These results are consistent with the ERG and VER changes expected after photochemical damage to the retina. Under some conditions the VER may provide a more sensitive measure of retinal insult than the ERG.

96.8 ENHANCED SOMATOSENSORY EVOKED POTENTIALS ADJACENT TO FOCAL INJURY OF RAT CORTEX. R. T. Linn, D. M. Feeney, M. G. Boyeson, W. G. Dail and H. M. Murray. Departments of Psychology and Anatomy, University of New Mexico, Albuquerque, NM 87131.

Somatosensory evoked potentials (SEPs) were recorded following stimulation of the forepaw (FP) or hindpaw (HP) in acute barbiturate-anesthetized rats with either a craniotomy (control) or a unilateral undercut laceration of the cortical HP somatosensory area. Animals were studied in independent groups immediately post or at 1, 4, 15 and 30 days post injury. Recordings were made simultaneously from both the HP and FP primary projection areas.

In control animals HP stimulation produced SEPs in contralateral HP cortex with two positive peaks (P1 at 7-8 msec; P2 at 25-34 msec) and two negative peaks (N1 at 15-17 msec; N2 at 55-75 msec). These were absent immediately post laceration and never returned to the undercut cortex.

In control animals the HP SEPs recorded from the FP area were smaller in amplitude and similar in waveform to those recorded in HP area. In injured animals, beginning at one day post (L+1) and continuing through 30 days post (L+30) injury, the HP SEPs recorded in FP area (adjacent to undercut cortex) consisted of two, sharp, high amplitude positive peaks (P1 at 13-17 msec; P2 at 22-23 msec). These responses were never seen in controls.

Normally, the FP SEP recorded in contralateral cortex was bimodal with two positive peaks (P1 at 13-16 msec; P2 at 19-23 msec) and two negative peaks (N1 at 15-18 msec; N2 at 45-70 msec). Immediately post laceration of the HP cortex the N2 component of FP SEP was greatly increased in amplitude. An enhanced FP SEP was present in L+1 through L+30 preparations. The amplitude of this FP SEP increased linearly with time post injury, reaching a maximum of 1 mV at L+30.

This abnormal, high amplitude SEP produced by stimulating HP or FP recorded in contralateral (injured) cortex was consistently found in a circumscribed location which corresponded to the center of the FP projection region at the edge of undercut cortex. The waveform of this response after HP stimulation was identical to that seen with FP stimulation, suggesting that the same generator sources were involved. Although a denervation supersensitivity hypothesis could explain the increasing amplitude of the SEP over time, such an explanation is not congruent with the immediate appearance of the enhanced response. The rapidly appearing effect may be related to a release of the FP area from inhibition and also may represent an "unmasking" of HP afferents to FP cortex. Supported by NIH Grant NS 13684-03 and NIMH National Research Service Award MH15142-04.

96.9 PERONEAL EVOKED RESPONSE IN THE DOG - EFFECTS OF SPINAL CORD LESIONS. D.H. York, R. Gaines* and C. Watts. Dept. of Physiology & Surgery, University of Missouri, Columbia, MO 65212.

The question of which specific sensory tracts carry signals ultimately constituting the scalp recorded peroneal-evoked cortical response (PECR) is of considerable interest in prognostic applications of evoked potentials in spinal cord injury. The present study was undertaken in 12 adult mongrel dogs of either sex anesthetized with either pentobarbital or halothane-oxygen. A thoracic laminectomy was performed with the removal of T dorsal process exposing the spinal cord. The PECR was recorded from two scalp pin electrodes, one inserted at the occipital promience on the midline (positive electrode) and one 3 cm. anterior to this site (negative electrode). A ground electrode was placed on the upper forelimb. The signal was amplified by 104 through a bandpass of 1-250 Hz and averaged by a Nickolet CA-1000 for 36-64 stimulus presentations. Stimulus consisted of square wave pulses (100 μsec duration, 1 pulse/2 sec) of constant current (8-12mA), delivered to the peripheral nerve through pin electrodes placed 4 cm apart inserted through the skin of the lateral aspect of the distal femur. The stimulus strength was adjusted to just produce a toe twitch consistently with each stimulus. The PECR response consisted of three waves which were reproducible across animals. The initial response was a positive going wave at 18.2±1.5(SD) msec followed by a larger negative wave at 26.6±2.1(SD) msec followed by a smaller positive wave at 42.8±2.0(SD) msec. In some animals consistent waves at longer latencies were also evident. Transection of the dorsal colums in 3 animals by scalpel cut 3-4 mm deep resulted in a transient loss of the PECR, but quickly returned to previous values within 5-10 minutes. Histological sections of the spinal cord confirmed total transection of the dorsal columns. Upper quadrant spinal cord section ipsilateral to the leg stimulated was also ineffective in abolishing the PECR response. An ipsilateral cord hemisection, or combined with a contralateral upper quadrant section was also without effect. However, total transection of the spinal cord abolished the PECR response. Thus the presence of an intact anterior quadrant contralateral to the leg stimulated appears sufficient to maintain the PECR response. Further experiments are underway to more precisely define which specific areas of the anterior spinal cord are necessary for conduction of the PECR response.
(We are most grateful to Humberto Caiaffa, MD of Barranquilla, Columbia for his surgical expertise in these experiments.)

96.10 FAR FIELD SOMATOSENSORY EVOKED POTENTIALS IN THE CAT. M. A. Cordova-Salinas*, J. G. Blackburn*, T. H. Boyer*, and S. Katz. Department of Physiology, Medical University of South Carolina, Charleston, South Carolina 29425.

Far field somatosensory evoked potentials have been previously described in the cat in response to percutaneous stimulation of the forelimb. The purpose of this study was to describe the far field potentials obtained by stimulating the hind limb of the cat.

Adult cats were anesthetized with nitrous oxide and paralyzed with pancuronium bromide. The left superficial peroneal nerve was stimulated percutaneously at a frequency of 3 Hz, 0.1 msec pulse duration and 8 mA intensity. Far field potentials were recorded from a steel screw electrode located on the mid-line of the skull at AP=0. The reference electrode was placed on the ipsilateral ear and the ground on the contralateral ear. The potentials were amplified, filtered (300 Hz to 3 KHz), summated with a microprocessor (2048 sweeps) and displayed on a digital plotter.

Five stable potentials were identified preceding the cortical component of the somatosensory evoked potential. The mean latencies (± SEM) for each of these components were:

I	5.8 ± 0.01 msec
II	7.5 ± 0.04 msec
III	8.2 ± 0.20 msec
IV	10.4 ± 0.10 msec
V	12.6 ± 0.30 msec

With the exception of component V, these values are in close agreement with latencies reported by other investigators for forelimb evoked responses, taking into account differences in conduction distances. The apparent stability of these responses indicates that far field potentials may be more useful than near field somatosensory evoked potentials in studying the effects of trauma in the central nervous system. (Supported by NINCDS 3P50 NS11066)

96.11 EVOKED POTENTIALS WITH SPINAL STIMULATION. J. Myklebust,* A. Sances, Jr., J. Cusick and S. Larson. Neurosci. Res., USVA Med. Ctr., Wood, WI 53193 and Dept. Neurosurg., Med. Coll. Wis., Milwaukee, WI 53226.

Studies in the rhesus monkey were conducted to compare the characteristics of averaged evoked potentials recorded rostrally due to lower thoracic dorsal column spinal cord stimulation (1-800Hz) with those produced by peripheral stimulation.

Potentials recorded at the upper thoracic level with spinal stimulation demonstrated less complex waveforms than those with peripheral nerve stimulation. However, in either case, the responses were unaltered at stimulation rates up to 200-300Hz and followed with diminished amplitude up to 600-700Hz.

The potentials evoked at thalamic nucleus VPL and sensorimotor cortex with spinal stimulation are larger in amplitude and are recordable through a larger volume than those with peripheral stimulation. The waveforms are similar, and the responses behave similarly with increased stimulation rates. Late portions of the waveforms are reduced at 6-10Hz, while the primary components are intact at 20-30Hz and follow at reduced amplitude up to 50-60Hz.

A short latency spike is recorded in the anterior sensorimotor cortex. The latency is consistent with a conduction velocity of approximately 50-60m/s and is similar to that of the corresponding cortex-to-cord (corticospinal) response. The short latency cord-to-cortex potentials and the corticospinal potentials respond similarly to mechanical and vascular stress. Both the short latency cord-to-cortex and cortex-to-cord potentials are unaffected by increases in stimulus frequency up to 300-400Hz. They follow at reduced amplitude up to 700-900Hz.

The latency, waveform and frequency response imply that the short-latency potential is nonsynaptic. The behavior in ischemia suggests that it is dependent upon the integrity of a cell body. Although the spinal stimulation is applied over the dorsal columns, it is reasonable to hypothesize that spinal stimulation activates the pyramidal tract. While direct spinocortical afferent connections have been reported, this response is probably due to antidromic conduction in the pyramidal tract.

The evoked potentials recorded rostral to spinal stimulation are similar to those with peripheral stimulation. Although several neural systems may be activated, the response characteristics and the stimulus level used suggest that the responses primarily reflect activity in the dorsal columns and pyramidal tract, and that spinal stimulation is a useful experimental method to monitor the integrity of primary afferent and efferent systems.

96.12 THE EFFECTS OF GRADED SPINAL TRAUMA ON SOMATOSENSORY EVOKED POTENTIALS IN CATS. J.G. Blackburn*, M. Cordova-Salinas*, R.K. Simpson, H.F. Martin and S. Katz. Department of Physiology, Medical University of South Carolina, Charleston, S.C. 29425.

The effects of graded spinal trauma on the somatosensory evoked potential were studied in adult cats anesthetized with nitrous oxide and paralyzed with pancuronium bromide. The superficial peroneal nerve was stimulated percutaneously at 0.2-0.3 Hz, 0.3 msec pulse duration and 7-10 mA intensity. Evoked potentials were taken from epidural electrodes over the contralateral leg area of the somatosensory cortex, summated with a microprocessor and displayed on a digital plotter. The reference electrode was placed on the ear contralateral to the monopolar recording electrode. Following control recordings (both before and after laminectomy) the spinal cord was subjected to impact trauma at the level of T_6. Trauma forces ranged from 150 to 220 gm-cm. Recordings were taken under acute (time of impact to 4 hours) and chronic (1 day to 2 weeks) conditions.

The SEP disappeared, then returned within 15 minutes at the 150 gm-cm trauma level. At 220 gm-cm, the SEP failed to return following impact injury. The responses between the 150 and 200 gm-cm levels were somewhat variable. However, an interesting phenomenon was observed in the SEP following trauma between 200-210 gm-cm. In some of the cats, the evoked potential disappeared, reappeared within one hour, only to disappear after several hours to 1 day following the injury. This unique response to trauma may serve as a model for future studies of spinal injury. Establishment of this model will make it possible to judge the efficacy of therapeutic intervention as determined by the duration of the period during which conduction returns following immediate loss. Extending this plateau of returned activity should provide a measure of the efficiency with which a chosen therapy retards or prevents the irreversible sequence of events reported to occur following spinal trauma. (Supported by NINCDS 3P50 NS11066)

96.13 Studies of Neural Generators of Lumbosacral Evoked Potentials in Man. P.J. Delwaide*, Milan R. Dimitrijevic, J.A. Halter*, L.D. Lehmkuhl*, Arthur M. Sherwood. Clinical Neurophysiology, The Institute for Rehabilitation and Research, Houston, Texas, 77030.

Electrical events arising from neural structures can be recorded from the skin over the lumbo-sacral portion of the spinal cord, following stimulation of peripheral nerves. A comparison with subdural recordings suggested that these potentials were generated in nerve roots and spinal cord. We have conducted a series of studies on intact, healthy adult humans to re-examine the origin of these potentials. For each trial, 128 responses to tibial nerve stimulation at the popliteal fossa were averaged from electrodes placed over the T12, L2, L4, and S1 vertebrae, referenced to an electrode at T6, while monitoring soleus EMG responses. Following control trials with single stimuli, test studies were made 1) with H-reflex recruitment techniques using double pulse separations from 2 to 150 ms, 2) conditioning of the H-reflex response with vibration, and 3), with a series of recordings in which the stimulus strength was systematically increased. The results of these studies showed that, in contrast to the previous assumption, the potentials recorded by the lower leads do not reflect simply electrical activity generated in spinal nerves nor do potentials recorded by the upper leads reflect electrical activity of a single spinal generator. We have found the second peak, or A wave, is not simply related to efferent output, but has some characteristics of a standing wave as well. In addition, the S wave, rather than being a simple homogeneous response, can be differentiated into two peaks under conditions of low stimulus intensity. Thus, it appears that the generators involved are minimally related to the peripheral neurogram, given the great distance and small fibers involved. Instead it is far more likely that the observed responses arise in several pools of neurons and their associated fibers.

Support was provided by the Bob and Vivian Smith Foundation, Houston Tx, the Rehabilitation Research and Training Center No. 4 (Rehabilitation Services Administration Grant 16-P-56813-6) and Rehabilitation Services Administration Grant 13-P-59275-6.

97.1 MORPHOLOGICAL DIFFERENCES BETWEEN THE CEREBRAL HEMISPHERES IN THE FEMALE RAT. M.C. Diamond, D. Young*, S. Sukhwinder Singh*, and Ruth E. Johnson* Department of Physiology-Anatomy, University of California, Berkeley, CA 94720.

We recently noted that throughout the lifetime of the male rat, the right cerebral cortex was thicker than the left. Specifically, this was true from birth to 650 days of age in areas 10, 4, 3, 2, 18, 17, 18a and 39, with areas 17, 18a and 39 reaching a statistically significant level. We measured the female's brain at one age only, 90 days of age, and found her left hemisphere was thicker than the right, in 8 out of 9 areas, but the results were nonsignificant in all areas. This intriguing finding led to the present group of experiments: to study if the left-right pattern was similar to the males in the early period of the life of the female.

Twenty micra, coronal, frozen, brain sections were taken from formol-saline perfused, female, Long-Evans rats at 7, 14, and 21 days of age (N=3-7 rats/area). The sections included the same areas as in the male studies. Cortical thickness was measured on thionin stained sections on microslide projected images.

At 7 days of age no dominant hemispheric pattern was noted in the 9 areas measured in the female, but by 14 and 21 days, the most consistent left-greater-than-right-pattern was evident in areas 18, 17, 18a and 39 with other areas showing less consistent differences.

Previously, we had ovariectomized the female at day-one and discovered that her cortical thickness pattern closely resembled that of the male by 90 days of age. More recently we ovariectomized the female at day-300 and examined her brain at 390 days of age. The right-left pattern in the female at 390 days of age is not as clearly left sided as at 90 days and ovariectomy does not significantly alter her pattern at this time. However, area 3 is consistently statistically significant in the left hemisphere in both the control and ovariectomized females. This finding was not evident in the 90 day old female.

These results support our previous work noting that sex steriod hormones alter cortical structure and indicate that the cortex is not as responsive to ovariectomy in the older animal as it is in the newborn.

97.2 SEX DIFFERENCES IN DENDRITIC STRUCTURE IN THE PREOPTIC AREA OF JUVENILE MACAQUE MONKEYS. William T. Greenough, David M. Ayoub*, and Janice M. Juraska. Depts. Psychol. & Anat. Sci. & Neural & Behav. Biol. Prog., Univ. IL, Urbana-Champaign, IL 61820 and Dept. Psychol., Indiana Univ., Bloomington, IN 47401.

While structural sex differences have been well documented in the rodent brain, particularly the preoptic area (e.g., Gorski, et al., J. Comp. Neur., 193:529, 1980; Greenough et al., Brain Res. 126:63, 1977; Raisman & Field, Sci. 173:731, 1971), fewer studies have examined such differences in the monkey brain. We have studied the preoptic area in juvenile macaque monkeys since this area has been implicated in male sexual behavior (Slimp et al., Brain Res. 142:105, 1978).

We examined Golgi-Cox stained neurons in the preoptic area (defined as a rectilinear solid extending 0.2mm anterior to anteriormost midline anterior commissure (AC), 0.2mm posterior to posteriormost midline AC, ventrally from AC to a distance equal to 40% of the distance from midline corpus callosum to midline AC, and laterally beginning 0.3mm from the third ventricle and extending to a distance equal to half the distance to medialmost internal capsule, to adjust for brain size differences) of 4 male and 4 female Macaca fascicularis which were 8-9 months old. All well-stained neurons not seriously truncated by sectioning (at 100μ) were included in sample, 980 neurons from males and 809 neurons from females. Camera lucida drawings of neurons were categorized by soma shape (round, oblong, intermediate) and analyzed in terms of spine density ($\leq$ .1/μ,>.1/μ to .5/μ,>.5/μ), dendritic thickness ($\leq$ or >.2μ, thickest dendrite at one soma diameter from soma) and cell size. Dendrites were analyzed in terms of lengths of branches and numbers of bifurcations.

Neurons of males had approximately 20% more bifuractions than those of females ($p<.01$). This difference was most pronounced in intermediate shaped cells, although a tendency in this direction was also apparent in the oblong cell type. There was no sex difference in mean dendritic length per neuron overall, nor were there differences related to soma shape. Females also had a higher proportion of sparsely spined neurons. This difference (significant overall) was specific to large and oblong cells and not evident in small and round cells. Dendritic density distribution, which differs by sex in the hamster (Greenough et al.) is currently under investigation, since a difference in numbers of bifurcations without a difference in total dendritic length suggests a difference in dendritic pattern.

Supported by NS 13421, MH 28529, RR07030, and the core grant (NIHRR00166) of the Univ. Wash. Reg. Primate Research Center. We thank C.-H. Hsü and H. D. Schwark for assistance.

97.3 EXPERIMENTAL SEX REVERSAL OF THE SEXUALLY DIMORPHIC NUCLEUS IN THE PREOPTIC AREA OF THE FEMALE RAT BRAIN. A. Coquelin, K.D. Döhler*, R.A. Gorski and J.E. Shryne*. Dept. of Anatomy and Lab. of Neuroendocrinology, Brain Research Inst., UCLA School of Medicine, Los Angeles, Ca. 90024.

There is a morphological sex difference within the medial preoptic area of the rat brain (Gorski et al., Brain Res. 148: 333, 1978). The volume of an intensely staining component, now called the Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA), is several fold larger in adult male rats as compared to that of females. The development of this nucleus depends largely, if not totally, on the hormonal environment during the critical period of sexual differentiation. Treatment of neonatal females with a single injection of 1 mg testosterone propionate (TP) increased the volume of the SDN-POA, but did not result in complete sex reversal. Neonatal castration of males reduced SDN-POA volume, but again did not completely sex reverse it (Gorski et al., 1978). The present study was designed to determine whether development of the SDN-POA is exclusively hormone dependent, or relies, in addition, on a genomic component. From day 16, pregnant Sprague-Dawley rats were injected sc daily with 2 mg TP in sesame oil or with oil only. After birth the pups were injected sc with 0.1 mg TP/day or with oil throughout the first 10 days of life. By giving multiple injections, which covered the total period of sexual differentiation, we tried to imitate as closely as possible the natural influence of testicular testosterone. At 60 days of age all rats were perfused with 10% neutral formalin. The brains were sectioned at 60 μm and stained with thionin. SDN-POA volume was determined as described previously (Gorski et al., 1978). The results are listed in the following table:

Sex (N)	Male(5)	Male(6)	Female(6)	Female(8)
Treatment	OIL	TP	OIL	TP
g Body Wt	278±11	232± 7	204± 6	209± 6
g Brain Wt/100g BWt	0.64±0.02	0.80±0.02	0.85±0.02	0.87±0.02
mg Gonad Wt/100g BWt	913±26	448±42	32.6±1.7	12.5±0.8
SDN-POA Vol ($mm^3 x10^{-3}$)	18.5±1.3	18.1±0.5	5.8±0.9	17.5±1.1

All TP treated females were anovulatory. The TP treated males had very small testes and 33% of them lacked spermatazoa. Oil treated rats showed the sexual dimorphism observed in previous studies. TP treatment resulted in complete sex reversal of SDN-POA volume in females, but it did not increase SDN-POA volume any further in males. These results demonstrate that differentiation of the SDN-POA seems to be totally dependent on the hormonal environment during the critical period of sexual differentiation. The involvement of a genomic component seems unlikely. (Supported by NIH grant HD 01182 and by the Heisenberg Program.)

97.4 FORMATION OF THE SEXUALLY DIMORPHIC NUCLEUS OF THE PREOPTIC AREA OF THE MALE RAT. Carol D. Jacobson, Fred C. Davis*, Erna Freiberg* and Roger A. Gorski. Dept. Vet. Anat., Iowa State Univ., Ames, Iowa and Dept. Anat., UCLA Sch. Med., Los Angeles, CA.

In the Sprague-Dawley rat, the Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA) is larger in volume in the male sex. This sex difference is at least partially dependent upon gonadal hormones during early postnatal life. Moreover, the neurons which reside in the adult SDN-POA can be specifically labeled by the prenatal administration of 3H-thymidine (*thy). We have used this fact to describe the pattern of formation of the SDN-POA during the perinatal period. A sperm-positive vaginal smear on estrus was defined as day 1 postfertilization (PF). On day 13PF, each pregnant rat was implanted with a right atrial cannula through which an injection of *thy (5μCi/g. B. wt.) was given on day 18PF. Fetal and neonatal male pups were sacrificed and perfused with neutral formalin either 2 hours after injection (day 18PF) or on day 20, 22, 24, 26, 28 or 32 PF (days 18, 20, 22 of gestation and 2, 4, 6 or 10 of postnatal life (PN), respectively). Autoradiograms were prepared on 6μm coronal sections. The location of labeled neurons within the MPOA was analysed during this period of formation of the SDN-POA. Two hours after injection of *thy, labeled cells are concentrated in the ependymal lining of the third ventricle (3V); the SDN-POA is not visible at this age. Two days after injection (day 20PF), there is a dense accumulation of labeled cells in the ventral aspects of the ependymal lining of the 3V and the adjoining region of the base of the brain dorsal to the optic chiasm (OC). From day 20 the SDN-POA can be identified. In general, labeled neurons are located in the more posterior parts of this nucleus. Four days (day 22PF) after *thy injection, labeled neurons are scattered between the OC, 3V and SDN-POA, but there are very few labeled neurons dorsal to the SDN-POA. From day 24PF through day 32PF the number of labeled neurons between the 3V and the SDN-POA decrease to such an extent that by day 10PN, labeled neurons are restricted to the region of the SDN-POA. Furthermore, the labeled neurons form a dense cluster within the nucleus. These data suggest that the SDN-POA is formed both by the migration and loss of neurons during the perinatal period. During the late prenatal period presumptive SDN-POA neurons migrate into the forming SDN-POA from the ventral aspects of the 3V and the base of the brain just dorsal to the OC. Moreover, death postnatally of neurons in the MPOA in general appears to contribute to the specific labeling o the SDN-POA. Future studies of the pattern of formation of the SDN-POA in the female as well as quantitative analyses of neuron al labeling in both sexes may elucidate the mechanisms which lea to this anatomical sex difference. NIH Grants HD-01182, RR07034

97.5 TRANSPLANTATION OF NEONATAL MALE PREOPTIC TISSUE INTO THE PREOPTIC AREA OF NEONATAL FEMALES INCREASES MASCULINE SEXUAL BEHAVIOR. G. W. Arendash* and R. A. Gorski. Laboratory of Neuroendocrinology of the Brain Research Institute and Department of Anatomy, UCLA School of Medicine, Los Angeles, California 90024.

Recent studies indicate that perinatal brain tissue can survive transplantation into a host brain. Since the medial preoptic area (MPOA) has been strongly implicated in the neural regulation of male sexual behavior, the MPOA of 1-day old male rats was transplanted stereotaxically into the MPOA of 1-day old female rats using a 0.7mm metal cannula for tissue punching and implantation (transplant volume about 0.2mm^3). Additional females received transplants of amygdala (Amyg) or caudate (Caud) tissue from male donors or were sham-operated. Immediately following bilateral transplantation, the recipients were injected sc with either oil or 8µg testosterone propionate (TP) in oil. After ovariectomy in adulthood, they were tested for female sexual behavior, then implanted sc with a testosterone-filled silastic capsule for subsequent male behavioral testing. Those females that received male MPOA transplants plus oil neonatally showed dramatically higher levels of masculine sexual behavior compared with those of the sham-oil or Caud-oil groups. Similarly, MPOA-implanted females given 8µg TP neonatally also had substantially elevated levels of copulatory activity compared to those of sham-TP controls. Not surprising in view of the modulatory influence exerted by the Amyg on male sexual behavior, some female hosts implanted with male Amyg tissue (plus oil or TP) showed behavioral scores comparable to those of MPOA-implanted animals. Female sexual behavior after minimal priming with estradiol benzoate (2µg EB/3 days) was markedly enhanced by the neonatal transplantation of male MPOA or Amyg in combination with 8µg TP. Interestingly, those females that received MPOA tissue plus oil neonatally (but not Amyg plus oil) also showed a significant, though less dramatic, increase in receptivity after minimal EB priming. Histological examination of the MPOA in all host brains indicated that tissue from the great majority of transplants survived and was characterized by apparently normal neurons. These studies show that the neonatal transplantation of male brain tissue bilaterally into the MPOA of female recipients can dramatically affect sexual behavior in adulthood, thus suggesting the development of functional connectivity between the transplanted neurons and host brain tissue. Note that the implanted tissue included the Sexually Dimorphic Nucleus of the MPOA, the development of which has been shown to be modified by gonadal hormones. Functional connectivity of exogenous neurons from this specific nucleus could contribute to the present behavioral observations. (NIH Grant HD-01182.)

97.6 THE EFFECT OF GONADECTOMY ON HALOPERIDOL-INDUCED CATALEPSY IN THE RAT. C.A. Hardy* and L.P. Spear. Dept. of Psychology, SUNY-Binghamton, Binghamton, N.Y. 13901.

Previous research has suggested a differential sensitivity to haloperidol-induced catalepsy during development. Periadolescent rats (P42) have shown enhanced cataleptic sensitivity to haloperidol when compared to weanling age (P30) or to young adult animals (P54) (Spear, Shalaby, and Brick, 1980). One possible explanation for the enhanced cataleptic response to dopamine antagonists during this period of development may be the state of hormonal fluctuation in the puberal animal. In the present study, this hypothesis was tested. Male and female Sprague-Dawley rats were either bilaterally gonadectomized or sham operated at weaning (P21). Each litter was assigned to be tested at either 28, 38, or 48 days of age. On the day of testing male and female, gonadectomized and control animals were given 0,1,2,or 4 mg/kg/2 cc haloperidol, IP. The first catalepsy testing session began 30 min from the time of injection and subsequent test sessions were spaced 30 min apart, for a total of 8 testing sessions over a period of 4 hrs. Testing was always conducted between 11:00 am and 4:00 pm. Each testing session consisted of individually placing the animal's forelimbs over a raised horizontal bar, adjusted for each age, such that the animal was at a 45° angle to the testing table. An animal was considered cataleptic if it remained stationary with both forelimbs over the horizontal bar for a period longer than 30 sec; 60 sec of catalepsy was the maximum amount of time allowed for each animal in all testing sessions. The total number of cataleptic test periods and total seconds of catalepsy were summed across the 8 testing sessions for each animal.

Results indicate a systematic decreasing sensitivity to the dose-dependent effects of haloperidol on cataleptic behavior with age. Moreover, adult male and female gonadectomized rats were consistently less cataleptic than their control counterparts, and adult males were less cataleptic than adult females. A similar trend was found in periadolescent rats, but not in weanling animals. These results indicate that gonadal hormones do appear to play a role in psychopharmacological sensitivity to haloperidol, but only in post-puberty animals that are sexually mature. Further implications of these results will be discussed.

97.7 PRENATAL CANNABINOID EXPOSURE ALTERS PITUITARY-GONADAL FUNCTION IN ADULT MALE MICE. S. Dalterio,* G. Chamness,* A. Bartke,* A. Ruiz* and D. Mayfield.* (SPON: W.B. Stavinoha) Depts. of Pharmacology and Ob-Gyn, The University of Texas Health Science Center, San Antonio, TX 78284.

Marihuana and its major psychoactive component, Δ^9-tetrahydrocannabinol (THC) have been reported to suppress the function of the pituitary-gonadal axis in male laboratory animals and in men. In our earlier studies, we have observed a decrease in plasma testosterone (T) levels in adult, immature and fetal male mice after THC exposure. In addition, perinatal exposure to THC or cannabinol (CBN), a non-psychoactive component of marihuana, results in long-term alterations in body weight regulation, pituitary-gonadal function, responsivity of vas deferens *in vitro* to norepinephrine and enkephalin and decreased sexual behavior in the adult (Subs. Alc. Act./Misuse 2:1, 1981). The present studies examined effects of prenatal exposure to THC or cannabidiol (CBD), a non-psychoactive cannabinoid, on pituitary-gonadal function in adulthood. Female mice received THC or CBD (50 mg/kg) or sesame oil (20 µl) daily by oral feeding starting day 18 of pregnancy until parturition, which occurred after 2 or 3 treatment days. Litters were culled to male pups. In adulthood, there were no significant differences on any parameter in controls dependent on treatment length. However, in cannabinoid-exposed males, testis weights were increased after 3, but not 2, prenatal treatments (366±23 THC; 318±16 CBD vs. 279±9 mg OIL; $p < .05$), although body weights were not different. In contrast, in animals prenatally exposed to CBD for 3 days, testicular weights were reduced and body weight was increased, so that testis:body weight ratio was decreased (6.9±.09 vs. 8.00±.08, $p < .02$). Concentrations of estrogen receptor (ER) in pooled hypothalami appeared to be reduced in 2-day, but not 3-day, THC-treated males; however, there were no effects of cannabinoid treatment on hypothalamic androgen receptors. The concentration of androgen receptors in seminal vesicles (SV) in all THC-exposed males was significantly reduced (105±13 vs. 160±20 fm/mg protein, $p < .05$), a finding which may be related to our observation of reduced SV weights after perinatal THC treatment. Post-castration, a single s.c. dose of 20 µg T appeared to reduce plasma LH levels to a greater extent in prenatally THC-treated mice compared to controls (62 vs. 46%), whereas plasma LH levels were reduced by only 19% in CBD-exposed males. Thus, cannabinoid effects on any specific parameter during sexual differentiation may depend greatly on the developmental events or timing of "critical periods" relative to drug exposure and may reflect both immediate changes in the hormonal milieu of the developing animal and/or alteration in receptor development which may affect later neuroendocrine function or target tissue responsivity.

97.8 SEXUAL DIMORPHISM IN THE DORSOLATERAL MOTOR NUCLEUS OF THE RAT LUMBAR SPINAL CORD AND ITS RESPONSE TO NEONATAL ANDROGEN. C.L.JORDAN*, S.M.BREEDLOVE AND A.P.ARNOLD. Dept. of Psychology, UCLA, Los Angeles,CA., 90024.

The spinal nucleus of the bulbocavernosus (SNB) in the rat lumbar spinal cord contains motoneurons innervating the bulbocavernosus and levator ani, two perineal muscles. The SNB is present in males and reduced or absent in females (S.M.Breedlove and A.P.Arnold, Science, 210:564, 1980). We report a second sex difference in the dorsolateral nucleus (DLN) of the rat lumbar cord, which is the origin of motoneurons innervating the ischiocavernosus muscle, a third sexually dimorphic perineal muscle. We also made neuron counts in the retrodorsolateral nucleus (RDLN), a group of motoneurons innervating muscles apparently not sexually dimorphic. Finally, we assessed the effect of neonatal androgen on the adult DLN and RDLN.

32 male and female rat pups received s.c. injections of 1 mg of testoserone propionate (TP) or oil on day 2 of life. On day 60, animals were sacrificed and spinal cords removed. Using thionin stained 50 um transverse sections of eight animals per treatment group, a blind observer made corrected counts of the number of nuclei of densely staining cells in the regions of the DLN and RDLN. 25 randomly chosen cells from each nucleus in each animal were traced through a camera lucida and the area of their somas and nuclei were measured.

Gonadally intact oil treated males have significantly more neurons in the DLN(360.86±28.44)than oil treated females (206.98±24.56,$p < .01$). There was no sex difference in neuron size. A single TP injection on day 2 of life had virtually no effect on DLN number in adult males(347.60±23.38), whereas the effect of early TP treatment in females was to increase the adult number of neurons(262.44±22.60) although not significantly. Neither DLN nuclei nor somas were significantly altered in size by the neonatal dose of TP. For the RDLN, no significant sex differences were found.

The deficit in motoneurons in the female DLN is probably related to the absence of neurons innervating the ischiocavernosus muscle, which females lack. Although the direction of change induced by neonatal androgen in female neuronal number is consistent with the hypothesis that androgens are involved in the sexual differentiation of the DLN, the effect of hormone treatment was not significant. Our finding no sex difference in the RDLN indicates that morphological sex differences are not characteristic of all lumbar motoneuron groups.

97.9 THE SEXUALLY DIMORPHIC SPINAL NUCLEUS OF THE BULBOCAVERNOSUS (SNB) IS MASCULINIZED BY PERINATAL ANDROGEN. S.M.Breedlove & A.P.Arnold, Dept. Psychology, UCLA, Los Angeles, CA 90024.

In the male rat lumbar spinal cord there is a discrete nucleus consisting of motoneurons innervating two striated perineal muscles: the bulbocavernosus and levator ani. This nucleus, the spinal nucleus of the bulbocavernosus (SNB), and its target muscles are reduced or absent in normal female rats (Breedlove & Arnold, Science, 210:564, 1980). We now report that prenatal treatment of females with testosterone propionate (TP) significantly increases the number of SNB neurons. Dihydrotesterone propionate (DHTP) treatment just after but not before birth also masculinizes the SNB of females. These results support the hypothesis that androgens act both before and after birth to influence the sexually dimorphic development of the SNB.

Rat pups were treated with hormone during one of three developmental periods. Prenatal hormone was delivered by s.c. injections of the pregnant dam with 2 mg of TP or DHTP daily from days 17-22 of gestation (late prenatal). Postnatally, 1 mg TP or DHTP was injected s.c. into the pups on 3 alternate days: either days 1,3 and 5 (early postnatal), or days 7,9 and 11 (late postnatal). On the day of birth all treated pups were ovariectomized. Control rats were either gonadectomized and oil treated at birth, or sham operated and oil treated, or not disturbed with neonatal treatment. Rats sham operated at birth were gonadectomized on day 40. Beginning on day 68 all rats were treated with 2 mg/kg TP daily until sacrifice on day 102. A "blind" observer made corrected counts of the number of nuclei of densely thionin-stained neurons in the region of the SNB.

The table below presents the mean number ± standard error of the mean (N = number of animals) of SNB cells in females from each of the hormone treatment groups.

	LATE PRENATAL	EARLY POSTNATAL	LATE POSTNATAL
TP -	108.8 ±7.1(8)	82.5 ±7.9(8)	76.6 ±4.4(8)
DHTP -	55.0 ±5.0(8)	91.8 ±6.2(8)	63.0 ±3.7(8)

Females neonatally ovariectomized and oil treated had 66.6 ±4.5(7) SNB cells. Sham operated, oil injected females had 63.0 ±5.4(8), and undisturbed females had 72.3 ±3.0(8) cells. Sham operated males had 159.3 ±12.0(8) while undisturbed males had 188.1 ±13.1(8) SNB cells. The ano-genital distance in newborn females was masculinized by both prenatal TP and DHTP. DHTP was effective in masculinizing females during the early postnatal period, and TP was effective prenatally. The disparate effects of TP and DHTP suggest that the two hormones act via separate mechanisms.

97.10 ORGANIZATIONAL EFFECTS OF SEX STEROIDS ON SYMPATHETIC AXONAL SPROUTING INTO THE HIPPOCAMPUS. Teresa A. Milner and Rebekah Loy. Dept. Neurosciences, University of California at San Diego, La Jolla, CA 92093

Removal of the septal input of the rat hippocampal formation elicits an ingrowth of vascular-associated sympathetic axons into the deafferented regions of the hippocampus. The extent of sympathetic ingrowth is influenced by both the sex and developmental stage of the animal. First, female adult rats show a greater amount of ingrowth when compared to male adult rats. This is especially apparent in the hilus and supragranular layer of the dentate gyrus and the stratum oriens of CA3. Second, the sprouting, which is reduced in adult and juvenile (postnatal day 13) males relative to females, is equivalent in the two sexes after fimbrial transections at postnatal day 3. These findings suggest that sex steroids may exert activational and/or organizational influences on the initiation and proliferation of the post-lesion axonal growth.

The activational effects of circulating sex hormones on sprouting were investigated by comparing the extent of sympathetic ingrowth following fimbrial lesions in normal or adult castrated male and female rats. The organizational effects of differential hormone exposure during development on synaptic reorganization in the adult was examined by comparing sympathetic axonal sprouting after fimbrial lesions in male and female rats which were castrated (male) or supplemented with silastic implants of testosterone (females and castrated males) at postnatal day 2. Thirty to ninety days post-lesion, the brains of these animals were analyzed using the cryostat glyoxylic acid method of fluorescence histochemistry for the demonstration of catecholamines.

We find that (1) castration of either female or male adult rats does not affect the sprouting response, but (2) neonatal castration of male rats permits sprouting equivalent to normal females, while neonatal testosterone treatment of females or castrated males results in a sprouting response identical to that of normal males.

This suggests that sex steroids exert organizational rather than activational effects on the sympathetic axonal sprouting in the hippocampus, since alterations in the hormonal environment during development but not in adulthood alters the extent of ingrowth. Sex differences in the development of the septohippocampal input could account for these effects.

Supported by NIH grant NS-14372.

97.11 ADRENAL CHROMAFFIN CELLS FROM ADULT RHESUS MONKEYS IN DISSOCIATED CELL CULTURE: RESPONSE TO NERVE GROWTH FACTOR AND GLUCOCORTICOIDS. L. E. Lillien* and P. Claude. Neurosciences Training Program and Regional Primate Research Center, University of Wisconsin, Madison, WI 53706.

It has been reported that Nerve Growth Factor (NGF) will enhance the outgrowth of neurite-like processes from young rat, and adult human and bovine chromaffin cells in vitro, and that this NGF-dependent outgrowth is inhibited by glucocorticoids (Unsicker, K., et al., Proc.Natl.Acad.Sci.USA 75:3498, 1978; Tischler, A.S., et al., Lab.Invest., 43:399, 1980.) We have observed similar effects in cultures of chromaffin cells from rhesus monkeys. Adrenal medullae from adult females were dissociated with collagenase and trypsin and cells were plated on collagen-coated glass or plastic cover slips in Liebowitz L-15 medium supplemented with 10% newborn calf serum (NCS). In some cases the serum was stripped of endogenous steroids with dextran-coated charcoal. Cells were characterized by catecholamine histofluorescence and by electron microscopy. The major cell types observed in the cultures were rounded or cuboidal chromaffin cells containing characteristic chromaffin granules, glial-like cells, and fibroblast-like cells. The number of non-chromaffin cells was reduced by differential plating and by treatment with cytosine arabinoside. Chromaffin cells accounted for at least 90% of the cells in the culture.

Cultures were initially grown in L-15 or L-15 plus glucocorticoids (10^{-5} M dexamethasone or $5x10^{-5}$ M hydrocortisone). After four days, various concentrations of NGF were added to some of the cultures, both with and without glucocorticoids. After eight days in the different experimental conditions, cultures were processed for catecholamine fluorescence; the proportion of fluorescent cells showing outgrowth and the average length of the processes was determined. Exposure to 250 ng/ml 7S NGF in the presence of unstripped serum resulted in a 60% increase in the proportion of the process-bearing cells and an increase in the average length of processes. In stripped serum, the same concentration of NGF produced a 170% increase in the proportion of process-bearing cells. The maximum proportion of chromaffin cells bearing processes did not exceed 10%, even in stripped serum. Exogenous glucocorticoids completely inhibited the NGF-dependent increases. The stimulation of process outgrowth by NGF was not further enhanced by higher doses of NGF (500 ng/ml or 1 µg/ml). Similar results were obtained using dissociated chromaffin cells from seven- to ten-day-old rats.

Supported by NIH Training Grant GM07507, NIH Grant RR00167 and by a Research Grant from the Muscular Dystrophy Association.

97.12 BEHAVIORAL AND STRUCTURAL MANIFESTATIONS OF PERINATAL GLUCOCORTICOID ADMINISTRATION: HIPPOCAMPAL INVOLVEMENT. A. J. Nonneman, S. T. DeKosky and S. W. Scheff. Departments of Psychology, Neurology, and Anatomy, Univ. of Kentucky, Lexington, KY 40506

Relatively large injections of steroids in the perinatal period have been associated with disrupted maturation of the cerebellum and hippocampus. Animals with such injections have been shown to manifest deficits in motor coordination, presumably because of alterations in cerebellar development. The present study was designed to assess the influence of perinatal steroid injections on morphology and behaviors associated with the hippocampus.

Litters of Sprague-Dawley rats were culled to 8-10 animals and randomly assigned to control and experimental treatment groups. Experimental animals received a single injection of dexamethasone (100 mg/kg) at 4 days of age. Some litters were sacrificed at 10 or 20 days of age for histological and microchemical analysis. Other animals received behavioral testing as young adults and were then sacrificed for microchemical and histological analyses of CNS changes associated with the behavioral results. These animals were weighed weekly prior to behavioral testing.

At 60 days of age, each animal's ability to spontaneously alternate was assessed. Alternation testing was conducted in a T-maze, 3 trials per day for 3 days. At 90 days of age the animals were tested for their ability to acquire and reverse a spatial learning task in a circular water tank. The rats were required to swim to a submerged platform, 8 trials per day. The learning criterion consisted of 6 of 8 trials with latencies to reach the platform of 5 sec or less on each of two consecutive days. Following attainment of the acquisition criterion the animals were begun on the reversal task and tested to the same criterion.

Body weight of steroid injected animals was significantly lower than that of age- and sex-matched controls throughout the experiment. The spontaneous alternation experiment revealed reduced alternation in the steroid treated animals as compared to controls. There were no detectable differences between groups in swimming ability, but there was a significant effect of steroid treatment on the spatial learning task in the water tank. Injected animals were significantly impaired, requiring more trials to criterion on both acquisition and reversal. These results indicate a change in behavior that may be due to disruption of hippocampal development.

97.13 PERINATAL ALCOHOL EXPOSURE AFFECTS NEONATAL CORTICOID LEVELS BUT NOT DEVELOPMENT OF THE CIRCADIAN PITUITARY-ADRENAL RHYTHM IN RATS. A.N. Taylor, B.J. Branch* and R.E. Poland*. Brentwood VA Med. Ctr. and Brain Res. Inst. & Depts. of Anatomy & Psychiatry, UCLA Sch. of Med. & Harbor UCLA-Med. Ctr., Los Angeles, CA 90024.

Exposure to altered hormone levels during development exerts organizational influences on the CNS and persistent effects on adult behavior. We have shown that neonatal corticoid treatment delays development of the circadian rhythm of plasma corticosterone (CS) in rats. We therefore sought to determine whether fetal or neonatal exposure to ethanol (E), an agent which activates the hypothalamo-pituitary-adrenal axis, produces similar effects.

Fetal-exposed subjects were the offspring of Sprague-Dawley dams who were fed a 5.0% w/v E-containing casein-supplemented liquid diet (BioServ) ad lib or pair-fed (P) the isocaloric liquid diet without E from gestation day-8 to birth, when pups were cross-fostered to normally-fed (N) dams (lab chow and water ad lib). Neonatal-exposed subjects were born to N dams and were cross-fostered at birth to the E and P dams. These dams continued to receive the E and P diets during lactation week-1, when they were replaced on N diet for the remainder of lactation. Rats were housed with lights on from 0300-1700 h. Plasma was collected following decapitation of 2-3 pups from each of 5-6 litters at the time of the nadir (0800 h) and peak (1700 h) of the adult adrenal rhythm and assayed by RIA for CS.

Maternal E consumption (12 g/kg/day) did not affect number and weight of offspring at birth. CS levels at 0800 h on day-1 were significantly ($p=.004$) higher in fetal E-exposed pups (100.9±6.4 (n=10) ng/ml) than in P (53.1±8.2) or N (57.1±9.0) controls. When next examined on day-9, the differences had disappeared. The first significant ($p<.001$) nadir-peak difference in CS levels, i.e. onset of the CS rhythm, occurred on day-18 in all 3 groups.

Weight gain was significantly retarded in the neonatally E-exposed and P pups on days 7 ($p<.05$) and 14 ($p<.01$); by day-21, body weights were normal. Significant nadir-peak differences in plasma CS levels ($p<.001$) in the neonatal-E exposed rats first occurred on day-21, when neonatal P-controls did not yet show a rhythm. These delays surely reflect nutritional deficits.

These results indicate that despite elevated CS levels at birth, fetal exposure to E (in a better diet than we used in a preliminary positive report) does not affect the onset of the pituitary-adrenal rhythm. On the other hand, we have reported that adult rats exposed to E in utero respond to neural stressors with significantly greater CS responses than do P or N controls. The mechanism for this persistent action of fetal alcohol exposure, whether hormone-induced or otherwise, remains to be determined. (Supported by VA Medical Research Service.)

97.14 EARLY ADRENALECTOMY STIMULATES SUBSEQUENT GROWTH AND DEVELOPMENT OF THE RAT FOREBRAIN. Jerrold S. Meyer. Dept. of Psychology, University of Massachusetts, Amherst, MA 01003.

Male and female rats (Wistar strain) were either adrenalectomized (ADX) or sham-operated (SHAM) on day 11 of life. Groups of animals were then killed at approximately day 35 or 65 and their forebrains subjected to various analyses. ADX rats consistently displayed heavier forebrains than their SHAM counterparts (1.32 ± 0.01 vs. 1.24 ± 0.01 at day 35; 1.48 ± 0.03 vs. 1.30 ± 0.02 at day 65; all values = mean ± S.E.M.). This effect could not be explained by an increase in brain water content nor by a general stimulation of growth (ADX rats had significantly lower body weights than controls). Biochemical analyses performed just on 65-day-old subjects revealed that the whole-forebrain contents of DNA, galactocerebroside, and sulfatide (galactocerebroside sulfate) were all elevated as a consequence of early adrenalectomy. The DNA results may reflect enhanced glial cell proliferation, inasmuch as most of the neuron formation in rat forebrain occurs prenatally. Higher galactolipid levels suggest that myelinogenesis may be stimulated by the removal of adrenal hormones. This was confirmed in separate studies showing an increased recovery of purified myelin from ADX vs. SHAM forebrains. Friedrich and Bohn (Soc. Neurosci. Abst. 6: 380, 1980) previously demonstrated that neonatal hydrocortisone administration suppresses myelination in rat optic nerve. It seems likely, therefore, that the present findings can be attributed to the withdrawal of glucocorticoids from the young animal, suggesting an important role for these hormones in regulating normal brain development.

97.15 CHARACTERIZATION OF TRANSIENTLY NORADRENERGIC CELLS OF EMBRYONIC GUT IN VIVO AND IN VITRO. G.M. Jonakait, J.A. Kessler, M. Goldstein, K. Markey and I.B. Black, Div. of Developmental Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021 and Dept. of Psychiatry, N.Y.U. Med. Center, New York, N.Y. 10016.

We have been investigating a population of cells, located in embryonic rat gut, which transiently expresses the noradrenergic phenotype. Appearing at 11.5 days of gestation (E11.5), these cells lose immunoreactivity to tyrosine hydroxylase (T-OH) and dopamine-β-hydroxylase as well as catecholamine (CA) fluorescence by E13.5. Earlier studies have shown that treatment at E11.5 with either nerve growth factor (NGF) or with agents (e.g., reserpine) that increase maternal glucocorticoids causes persistence of CA fluorescence in these cells through E13.5 (Kessler et al, 1979; Jonakait et al, 1980).

Since CA levels are affected by many non-physiologic variables, we also measured the specific gene product, T-OH, after treatment of pregnant rats with reserpine, transuterine injection of embryos with NGF or a combined regimen. Each treatment on E11.5 significantly increased T-OH catalytic activity at E13.5 in cells located at the pyloric sphincter and in paraganglia at the gastroesophageal junction. Simultaneous treatment resulted in increased paraganglion T-OH activity greater than either treatment alone, suggesting independent mechanisms of action. Sequential treatment with reserpine on E11.5 and NGF on E13.5 resulted in a dramatic increase in T-OH immunoreactivity in cells throughout the gut and persistence through E16.5. Reversal of the treatment sequence (NGF followed by reserpine) did not dramatically prolong the appearance of T-OH-positive cells, suggesting that initial exposure to glucocorticoid hormones alters the cells' ability to respond to subsequent treatment.

To examine these effects at the cellular level, we have developed a method for growing embryonic intestine in culture. E12.5 guts have been explanted to Millipore filters on wire-mesh rafts suspended over wells containing Eagles MEM with 15% rat serum. Guts grown for 4 days showed a 50% increase in T-OH activity, suggesting ongoing development of catecholaminergic cells. We are now examining the effects of glucocorticoids and NGF in culture. 97.16 DEVELOPMENT AND THYROXINE DEPENDENCE OF THE IPSILATERAL RETINOTHALAMIC PROJECTION IN XENOPUS. S. Hoskins and P. Grobstein. Depts. of Biology and Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637.

In Xenopus, the crossed retinotectal and retinothalamic projections are established during days 2-4 of embryogenesis, while the ipsilateral retinothalamic projection appears weeks later, in association with metamorphosis. We have used anterograde transport of HRP in tadpole optic nerves to define the stages during which the projection to ipsilateral rostral thalamus develops, and to examine the influence of thyroxine on its development.

Optic nerves were filled in tadpoles ranging from stages 50-66 (end of metamorphosis; 6-8 weeks). Evidence of a terminal zone in ipsilateral rostral thalamus was first detected at stages 53-54. Between stages 56 and 66, increasingly well-defined terminal zones were seen in the rostral thalamus.

Since the rise in circulating thyroxine associated with metamorphosis begins at stage 54, we examined the correlation between thyroxine presence and the development of the ipsilateral projection. Tadpoles raised continuously in 0.01% propylthiouracil (PTU) fail to metamorphose due to an inability to produce thyroxine. These animals reach stage 53-54 on a normal time course and then increase in size without progressing morphologically. We assessed the ipsilateral projections of PTU reared tadpoles after times sufficient for normal metamorphosis. The projection patterns to ipsilateral rostral thalamus were similar to those seen in normal stage 54 tadpoles. Tadpoles shifted from PTU to normal rearing medium completed metamorphosis and acquired ipsilateral projections on a normal time course.

In additional PTU reared (stage 53-54) tadpoles we made 50 nl injections of .17-.35 mg/ml thyroxine in oil into one eye. The animals were returned to 0.01% PTU, and their optic nerves filled 4-10 weeks later. At this time, most had advanced to stage 57, suggesting some systemic effects of the injection. In 6 cases, labelling in rostral thalamus ipsilateral to an injected eye was heavy, comparable to that normally seen at stage 65. In two cases in which the uninjected eye's optic nerve was filled, normal stage 57 ipsilateral terminal zones were seen. Counts of retinal ganglion cells added to the thyroxine-injected and uninjected eyes indicated that the thyroxine had much greater effect on mitosis in the injected eye.

We conclude that the ipsilateral projection to rostral thalamus is thyroxine-dependent. Refinements of thyroxine dosage may allow us to eliminate systemic effects, and determine whether thyroxine action on the eye alone is sufficient to produce an ipsilateral projection. (Supported by NSF BNS 791422.)

97.17 EFFECT OF EARLY HYPOTHYROIDISM ON NORADRENERGIC REGENERATIVE GROWTH IN THE CEREBELLUM OF RATS TREATED NEONATALLY WITH 6-HYDROXYDOPAMINE. Ranbir K. Bhatnagar. Department of Pharmacology, University of Iowa, Iowa City, IA 52242

Neonatal administration of 6-hydroxydopamine (6OHDA) produces almost total loss of norepinephrine (NE) in the cerebellum followed by an increase of up to 200% of normal. This regenerative growth of NE in the cerebellum is a useful model for the developmental growth of locus coeruleus axons and might be controlled by the target cells (Schmidt and Bhatnagar, Br. Res. 191: 173, 1980). This study was undertaken to assess the growth of noradrenergic neurons following hypothyroidism-induced alterations in the differentiation of their terminal field in the cerebellum. Early hypothyroidism produces delayed maturation, reduced density of dendritic spines and reduced dendritic arborization of Purkinje cells and reduced density of molecular layer (Nicholson and Altman, Br. Res. 44: 13, 1972; Br. Res. 44: 25, 1972). Hypothyroidism was produced by feeding 50 mg of propylthiouracil (PTU) daily to the Sprague-Dawley mother rats via a gastric tube either prenatally starting on the 18th day of gestation or postnatally starting on the day of parturition. Control rats received 3 ml of water daily. One half of each litter was injected subcutaneously with 6OHDA (100 mg/kg) on postnatal days 1, 2 and 3. The other half received vehicle injections. Rat pups were decapitated at 9 and 22 days of age. Brains were removed and dissected into cerebellum, pons and medulla for NE assay.

In PTU treated groups the weight of body and cerebellum but not that of pons and medulla was significantly reduced. PTU administration to non-6OHDA group did not alter the NE content of any tissue examined. In the group receiving PTU prenatally, at 9 days of age the regenerative growth of NE neurons in the cerebellum was significantly greater than either in the groups receiving water or PTU postnatally. At 22 days of age postnatal administration of PTU also elicited a significant increase in noradrenergic regenerative growth. In all cases the increase in regenerative growth after PTU administration was reflected in both the content and concentration of NE. 6OHDA administration resulted in a significant increase in NE content of pons and medulla. PTU did not modify the NE content or concentration of pons and medulla in rats treated with vehicle or 6OHDA. Thus, the effects of hypothyroidism are restricted primarily to the terminal field and not the field of origin of noradrenergic projections. In conclusion, the perturbation of differentiation of target tissue can alter the rate and extent of noradrenergic innervation and such alterations may have a temporal basis.

97.18 THE SPINAL TRACT OF V IN RAT FETUSES MADE HYPOTHYROID BY PROPYLTHIOURACIL, C. H. Narayanan and Y. Narayanan*, Dept. Anat., LSU Sch. Med., New Orleans, LA. 70119.

It has been previously shown by our laboratory that there is a correlation between the progressive development of the spinal tract of V and motor neurons of cervical levels on the one hand, and the nature and extent of responses to stimulation of perioral regions in rat fetuses at the other. The present study was performed to examine the development of the spinal tract of V in rat fetuses made hypothyroid by propylthiouracil (PTU). Timed pregnant rats (Holtzman) were raised on a goiterogenic diet consisting of 0.3% PTU mixed with powdered Teklad mouse diet beginning from seven days of pregnancy. Control animals were raised on powdered Teklad mouse diet. Beginning from 12 through 20 days of pregnancy both experimental and control animals were prepared for surgery and recordings of activity were made according to established procedures in our laboratory. Recordings of the frequency of movements of the head, forelimbs and oral region were made. Evoked activity was studied at each stage using an esthesiometer. Fetuses from each age group were sacrificed, serially sectioned in toto and stained according to the reduced silver method. The experimental group of fetuses without exception showed a drastic reduction in overall activity. In particular, synchronous movements of head and forelimbs and oral area activity were greatly reduced. The response to stimulation of of the perioral region was observed only at 19 days of gestation age, but is seen as early as day 16 in the control group of fetuses. The responses to stimulation in the experimental group for all ages at best were weak and low in amplitude. The spinal tract of V was identified by following the descending fibers of the Vth nerve from the region of entrance in the pons. At 15 days of gestation age, the fibers of the spinal tract are very poorly developed and extend as far as C-1. It is only at 19 days that the fibers forming the dorsal funiculus show some differentiation into a f. gracilis and f. cuneatus and is comparable in its overall development to that seen in a 15 day control fetus. The fibers of the maxillo-mandibular division is somewhat greater in area than the ophthalmic division. These descending pathways form part of a reflex pathway that is late in its appearance in the hypothyroid fetuses. It is concluded that the descending pathways which are disrupted by PTU administration are involved in the emergence of this behavior pattern.

97.19 EFFECTS OF THYROXINE ON THE MATURATION OF PURKINJE CELLS AND CLIMBING FIBERS IN THE FROG CEREBELLUM. K. F. Hauser* and A. G. Gona. Dept. of Anatomy, CMDNJ-New Jersey Medical School, Newark, N.J. 07103.

In bullfrog tadpoles (Rana catesbeiana) two populations of Purkinje cells can be discerned during development. One population of Purkinje cells located in the dorsal (apical) region of the cerebellum show an advanced pattern of dendritic development 1 to 2 years prior to establishment of the external granular layer (EGL), while a majority of Purkinje cells present remain immature until EGL formation during metamorphosis (Uray and Gona, J. Comp. Neur., 180:265, 1978). The purpose of this study was to examine the response of Purkinje cells to premature metamorphic change. Ultrastructural observations of the corpus cerebellum were made following thyroxine-induced metamorphosis (T4, 0.25ug/g body weight, administered intraperitoneally on alternate days during the first week, followed by increased dosages, 0.38ug/g body wt, during the last two weeks). Premetamorphic tadpoles induced to metamorphose 1 to 2 years prematurely, were sacrificed after 1, 2, or 3 weeks of T4 treatment. After the second week, immature Purkinje cells in the ventral cerebellum showed rapid maturational change. Most notably, Purkinje cell perisomatic processes (stellate stage) were observed as elaborate growth cones. These processes were frequently observed synapsing with developing climbing fiber varicosities. This study demonstrates that precocious maturation of the Purkinje cell-climbing fiber system can be induced by T_4 treatment. It is postulated that thyroid hormone acts in one of the following ways: (1) directly influences maturation of the climbing fiber system, secondarily inducing Purkinje cell development, (2) directly influences Purkinje cell development, secondarily inducing climbing fiber development, or (3) indirectly influences Purkinje cell development, e.g., by the trophic influence of newly formed parallel fibers, which in turn influences climbing fiber development.

97.20 CENTRAL CONTROL OF THE DEVELOPING PITUITARY INTERMEDIATE LOBE. M. Duff Davis*, Walter Lichtensteiger, Margret Schlumpf and Arie Bruinink*. Pharmacology Institute, University of Zurich, CH-8006 Zurich, Switzerland.

During human fetal ontogeny, a rudimentary intermediate lobe of the pituitary forms, which is not found later in the newborn. Since the pars intermedia (PI) of other mammalian species secrete melanotropins, it is interesting to speculate on some type of developmental function for these peptides. The purpose of our current study is to investigate the development of CNS control over pars intermedia MSH release.

Fetal (from ED 18) and postnatal rat blood samples were collected and bioassayed for MSH-like peptides using adult Rana pipien skins. Pituitaries were removed and, when possible, the neurointermediate lobes (NIL) separated from the anterior lobes. Some NILs were used for release studies where the glands were incubated with or without dopamine at 10^{-6}M and the media assayed for hormone. Others were homogenized for dopamine receptor binding studies (using ^{3}H-spiperone in competition with cold spiperone, flupenthixol and sulpiride). Some specimens were processed for histofluorescence of catecholamines in order to study the stage of innervation of the PI by the tuberohypophyseal system.

A small amount of serum MSH was detected throughout the prenatal period, rising slowly on postnatal days 1-2 and more rapidly to a peak on days 4-5. Levels quickly fell to prenatal values until the end of the third week when there was another rise in hormone. NILs incubated with dopamine resulted in strong inhibition of MSH release on postnatal day 2 (the first day tested) through later stages. Basal levels of secretion showed a continual increase from the first week of birth. Dopamine binding studies confirmed previous reports of prevailing D_2 receptors in the adult PI. Catecholaminergic nerve terminals were seen infiltrating the lobe during the first postnatal days. These data indicate that CNS regulation of pars intermedia MSH probably begins in the first week postnatally. The type of neural or humoral signals which initiate the inhibitory control of MSH is under investigation.

98.1 SIZE OF MOTONEURONE POOL IS RELATED TO NUMBER OF MYOTUBES IN DEVELOPING MUSCLE. I. S. McLennan* (SPON: G. Pilar). Physiology Section U-42, Univ. of Connecticut, Storrs, CT 06268.

The extent of motoneurone cell death can be altered by varying the size of the target tissue, suggesting that the neurones are competing for some aspect of their target (Hamburger, V., Neurosci. Res. Prog. Bul. 15, Suppl. April 1977). What is limiting in the target tissue is, however, unknown. Motoneurone cell death occurs early in neuromuscular development (Stg. 29-35), at a time when the muscle consists of cell clusters composed of large primary myotubes and less differentiated muscle cells. As the muscle develops, secondary and tertiary myotubes are formed, resulting in a large increase in the number of fibers (Ontell, M., Anat. Rec. 189, 669, 1977). In this paper I have compared the size of various motoneurone pools (Landmesser, L., J. Physiol. 284, 371, 1978), in the chick lateral motor column with the number of myotubes which occur in the corresponding muscle at the time of cell death.

Stg. 29 and 35 chicken embryos were fixed in 4% glutaraldehyde and 5% formaldehyde with their hindlimbs pinned in an extended position. The limbs were embedded in wax, serially sectioned and stained for glycogen by the PAS method. The midpoint of each muscle was located and camera lucida drawings of the myotubes profiles were made.

At the onset of cell death (Stg. 29) there are 2623 ± 240 myotube profiles in the muscle mass from which the sartorius, iliotibialis and femorotibialis are derived. The number of neurones which innervate these muscles in the adult is 2852 (Landmesser, L., J. Physiol. 284, 371, 1978). At this stage there are fewer myotubes in the ventral and dorsal shank of the lower limb than neurones in their mature motoneurone pool. By the end of the period of cell death (Stg. 35), however, a one to one relationship exists between the number of myotubes in the lower limb and the number of neurones innervating these muscles in the adult.

I therefore suggest that motoneurone cell death results from a competition by the neurones for occupancy of a limiting number of myotubes (target cells), thus establishing a relationship between the size of a motoneurone pool and the prospective size of its corresponding muscle.

98.2 DEVELOPMENTAL CHANGES IN THE LATERAL MOTOR COLUMN OF THE CHICK EMBRYO FOLLOWING EITHER SPINAL TRANSECTION OR NEURAL CREST REMOVAL. N. Okado* and R.W. Oppenheim (SPON: I-W. Chu-Wang). Lab. of Neuroembryology, Dorothea Dix Hospital, Raleigh, N.C. 27611.

Although some investigators have reported that cell number in the lateral motor column (LMC) of the chick embryo is altered by spinal transection or neural crest removal, others have failed to find such effects. Part of the reason for this apparent discrepancy may be that the effect of these manipulations only becomes manifest at a specific developmental stage. If so, then the choice of when to look for such effects becomes critical. Consequently, we have been examining the effects of such manipulations on the period during as well as following natural cell death in the LMC.

Spinal transection (cervical or thoracic) and neural crest removal (lumbar) was performed at Stages 13-15. Animals were sacrificed at various ages between 8 and 18 days of incubation. Cell number in the LMC was determined from serial sections of paraffin embedded lumbar spinal cords.

At 10 days cell number was not significantly different from controls following spinal transection. At 16 days, however, there were about 25% fewer motoneurons in the LMC of spinal animals. In the case of neural crest removal, our initial results indicate that as long as there was no significant damage to the spinal cord -- a frequent inadvertent side-effect of neural crest removal -- cell number in the LMC was unaffected, at least up to 10 days of incubation; observations on older embryos are in progress.

Our results suggest that neither spinal transection nor neural crest removal alters the course of natural cell death in the LMC, a phenomenon which begins on day 5 and is virtually over by day 10 in the lumbar spinal cord. Although at present we do not know why motoneuron numbers are decreased on day 16, after spinal transection, two explanations have occurred to us. First, some neurons in the LMC may project to the brain; spinal transection would prevent them from reaching their normal synaptic targets. A second, and more plausible, explanation is that after day 10 cells in the LMC become dependent on descending input for their maintenance. Experiments are currently in progress to determine which, if either, of these explanations is correct.

98.3 PHARMACOLOGICAL MODULATION OF NEUROMUSCULAR TRANSMISSION AND CELL DEATH IN THE LATERAL MOTOR COLUMN OF THE CHICK EMBRYO. R.W. Oppenheim and J.L. Maderdrut*. Neuroembryology Lab., Dorothea Dix Hospital, Raleigh, N.C. 27611.

Either pre- or post-synaptic blockade of neuromuscular transmission between Stage 26-28 (day 5-6) and Stage 36 (day 10) sufficient to reduce the spontaneous motility of chick embryos by more than 60-70% resulted in an increased number of neurons in the lateral motor column (LMC) at Stage 36. Both competitive (e.g., curare and benzoquinonium) and depolarizing (e.g., decamethonium) post-synaptic nicotinic receptor blocking agents increased the number of neurons in the LMC. However, doses of hexacarbacholine (a depolarizing neuromuscular blocking agent) that produced almost complete cessation of spontaneous motility had no detectable effect on the number of neurons in the LMC. The increased number of neurons in the LMC was the result of a decreased naturally-occurring loss of motoneurons between Stages 26 and 36. The decreased loss of motoneurons following either pre-synaptic (hemicholinium-3) or post-synaptic (curare and decamethonium) blockade of neuromuscular transmission was accompanied by a decrease in the number of pyknotic (degenerating) cells in the LMC at Stages 34 and 36. Embryos treated daily with 2.5 mg of curare from day 5 to day 9 that survived for two days beyond the normal time of hatching on day 20 (but were unable to emerge from the egg) had an increased number of neurons in the LMC.

Administration from day 5-6 to day 9 of doses of either nicotine, carbachol, or choline spanning a range from those that had no significant effect on spontaneous motility to those that resulted in almost complete cessation of motility had no detectable effect on either the time-course or the quantity of naturally-occurring cell death in the LMC. Administration of either 10 or 100 µg of eserine from day 5 to day 9, however, produced a small, but significant, decrease in the number of motoneurons in the LMC at Stage 36 (day 10). Daily administration of 10-100 µg of 4-aminopyridine (a potassium channel blocking agent) from day 5 to day 9 had no apparent effect on either spontaneous motility or cell death in the LMC.

Substantial reductions in spontaneous motility appear to be a necessary but not a sufficient condition for the prevention of naturally-occurring cell death in the LMC by cholinergic drugs. Substantial increases in the stimulation of nicotinic acetylcholine receptors in skeletal muscle by the chronic administration of cholinergic drugs were without apparent effect on naturally-occurring cell death in the LMC of the chick.

98.4 KINETICS OF ROHON-BEARD NEURON DISAPPEARANCE IN *Xenopus laevis* Janet E. Lamborghini. Biology Dept., UCSD, La Jolla, CA 92093

Rohon-Beard neurons, large dorsal cells in the spinal cords of embryonic fish and amphibians thought to be primary sensory neurons (Coghill, '14, DuShane, '38), disappear during development. The ∿ 200 Rohon-Beard cells found in *Xenopus laevis* are gone well before resorption of the tail during metamorphic climax (Nieuwkoop & Faber, '56, Hughes, '57). Because there is no obvious hiatus in sensory function during the time of their disappearance, whatever role Rohon-Beard cells play in the mediation of cutaneous sensitivity is considered to be assumed smoothly by dorsal root ganglion cells. The cause of the disappearance of Rohon-Beard neurons remains unknown. Before possible hypotheses can be tested, a detailed description of this phenomenon is necessary. Therefore, a study of the kinetics of disappearance of Rohon-Beard cells and associated cytological changes was undertaken.

Counts of Rohon-Beard neurons in fixed and sectioned specimens of increasing age and developmental stage revealed a gradual loss of cells starting at Nieuwkoop & Faber stages 45-46 (4-5d of development). The number of Rohon-Beard cells decreased to half by stages 49-50 (12-15d) and only a few were found after stage 57 (41d, 7d before tail resorption). Counts of Rohon-Beard cells in animals whose development was retarded by crowded conditions suggest that the rate of Rohon-Beard cell loss is stage- rather than age-dependent. Acid phosphatase activity, a common histochemical correlate of cell death, was assayed by the Gomori technique in both whole mounts and frozen sections of larval spinal cords. Coincident with the time of onset of disappearance of Rohon-Beard cells, an increase in acid phosphatase staining of the cytoplasm was observed. Increased staining was present first in cells at the anterior end of the spinal cord but by stage 47 had spread to cells over the whole length of the cord. Ultrastructural studies of Rohon-Beard cells in stage 47 larvae revealed the presence of many lysosomes in the cytoplasm, swelling of the endoplasmic reticulum and mitochondria, and a decrease in nuclear density. Participation of macrophages was not evident.

The disappearance of Rohon-Beard neurons can be attributed to autophagic cell death involving lysosomal acid hydrolases. This process begins only a day or two after the appearance and maturation of voltage- and chemically-dependent membrane conductances and electrical uncoupling of these neurons (Baccaglini & Spitzer, '77, Spitzer, '80, Bixby & Spitzer, this volume).

This work was supported by the NIH (NS15918) and the ONR (N00014-79C-0798).

98.5 THE TIME COURSE OF THE LOSS OF RED NUCLEUS NEURONS AS A RESULT OF T_{5-6} HEMISECTION IN THE NEONATAL RAT. J. Prendergast and R. Bates.* Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Mid-thoracic hemisection in the neonatal rat results in a massive loss of red nucleus neurons (Prendergast and Stelzner, '76). The loss may be due to: 1) axotomy of the rubrospinal tract, 2) the inability of growing rubrospinal tract axons to reach their target, or 3) both. A plug of gelfoam saturated with HRP in 2.0% DMSO was placed in the spinal cord at birth and at fifteen days of age to determine: 1) if the tract had grown at birth beyond the point where the lesion was to be made, and 2) if a similar number of red nucleus neurons would fill at the two ages. Twenty-four to forty-eight hours following the surgery the animals were perfused. The brains and spinal cords were sectioned and reacted using the TMB procedure. At birth a few of the red nucleus neurons were filled with HRP and this indicated that at least part of the rubrospinal tract had grown beyond the mid-thoracic cord. By fifteen days more of the red nucleus neurons were filled than at birth and this suggested that at birth part of the rubrospinal tract was still growing into the thoracic cord. Other neonatal rats sustained the hemisection (T_{5-6}) and were allowed survival times of varying lengths which began at 18h. The brains and spinal cords were cut and stained with cresyl violet. Compared to controls significant reductions in the number of red nucleus neurons were evident at three days after the lesion. By five and one-half days there was an even greater cell loss than that at three days following surgery.

The loss of some red nucleus neurons following hemisection at birth may be attributed to axotomy. Death of other parent red nucleus neurons may be explained by the fact that their axons were still growing and were prevented by the lesion from reaching their targets. The protracted time course of cell death may be due: 1) to the rate that cells of differing sizes die, 2) to the time it takes for the cell body to be influenced by the loss of its target, or 3) both of these.

Supported by NIH grant NS15893.

98.6 DEGRADATION OF PROTEINS IN $CaCl_2$-INDUCED MYELOPATHY IN RAT SPINAL CORD. N. L. Banik, E. L. Hogan, L. J. Whetstine* and J. D. Balentine*. Departments of Neurology and Pathology (Neuropathology), Medical University of South Carolina, Charleston, S.C. 29425

We have previously shown that experimental spinal cord trauma in animals results in vesicular degradation of myelin, granular degeneration of axons, loss of myelin proteins and accumulation of calcium (Balentine, J.D., Lab. Invest., 39:254, 1978; Banik, N.L. et al., J. Neuropath. Exp. Neurol., 39:232, 1980; Happel, R.D. et al., Brain Res., in press). In order to test the hypothesis that calcium may be involved (possibly by activating proteinases) in the degradation of myelinated axons, a model of calcium-induced myelopathy in rats has been developed. Thus, rats were anesthetized and a 10% solution of $CaCl_2$ at pH 7.4 was dripped onto the exposed thoracolumbar spinal cord (after removal of dura with the leptomeninges remaining intact). This consistently resulted in paraplegia and spongiosis with ultimate necrosis of the spinal cord at the drip site. There was progressive axonal degeneration, vesiculation of myelin and phagocytosis (Balentine, J.D. and Hilton, C., J. Neuropath. Exp. Neurol., 39:339, 1980). To extend the previous study of morphological alterations the changes in proteins in the lesion sites were examined and compared to normal spinal cord at 1, 3 and 5 days following Ca application. The proteins of the cord were separated by 5-25% gradient slab and 10% disc polyacrylamide gel electrophoresis according to Laemmli. The gels were stained with Fast green, destained, scanned and the proteins quantitated by weighing peak areas. There was a loss over a period of hours of all classes of neurofilament proteins, myelin proteins, actin and other proteins. Thus, 60%, 77% and 58% of the 200,000, 150,000 and 69,000 dalton neurofilament proteins, respectively, were lost at 5 days compared to control. Large losses of myelin proteins (PLP 50%; large basic protein 68%) as well as actin and other proteins were also observed. The protein alterations observed correlate well with morphological changes we reported earlier and resemble those previously found with physical trauma. We believe that Ca++ plays an important role in the degeneration of axons and myelin sheath in both Ca++-induced myelopathy and spinal cord injury.

Supported in part by P.H.S. grant No. 11066.

98.7 DIFFERENTIAL CELL DEATH DURING DEVELOPMENT PREDICTS LATER NEOCORTICAL AREA SPECIALIZATION. M. Slattery* and B. L. Finlay. Department of Psychology, Cornell University, Ithaca, NY 14853.

The incidence of degenerating cells as a proportion of normal cells as seen with light microscopy was calculated for four areas of posterior neocortex (29, 18, 17 and 18a) for hamster pups 5-10 days old. At 5 days of age, migration into and differentiation of the external cortical laminae are still proceeding; by day 10 all layers have differentiated. Differences in both the timing and the amount of cell degeneration were observed across cortical areas and laminae.

The order of cell degeneration generally reflected the order of cell generation. Layer VI peaked in cell death before layers V, III, and II across all cortical areas. Layer IV showed a variable pattern across areas.

Immature neocortex was divided into subareas with reference to the adult neocortical map. These divisions were found to correspond to striking local differences in overall cell death rate. Presumptive area 29 had a general cell death rate 2-4 times higher than areas 17, 18 and 18a on all observed days. Areas 17, 18 and 18a, quite similar in thickness in adult hamster cortex, did not show an overall difference in cell death rate, but showed variation in the pattern of cell death by lamina over days.

The pattern of cell death by cortical lamina corresponded to the eventual thickness of that lamina in adult neocortex. In the adult, laminae II and III of area 29 are quite thin compared to the same laminae in adjacent neocortex, and the rate of cell death is 2 to 10 times higher in laminae II and III of area 29 than in adjacent areas. Laminae similar in their adult thickness are similar in cell death rate: laminae chosen for similarity in thickness (less than 5% difference) show similar cell death rates (average ratio .83). Dissimilar laminae (more than 5% difference) have more divergent cell death rates (average .62). These results suggest that cortex is generated uniformly and reaches its local adult differentiation by differential degeneration during early development.

98.8 REGULATION OF NEURONAL NUMBER IN RETINA, THALAMUS, AND MIDBRAIN FOLLOWING EARLY MONOCULAR ENUCLEATION. D. R. Sengelaub, L. F. Jacobs*, M. S. Windrem*, and B. L. Finlay. Department of Psychology, Cornell University, Ithaca, NY 14853.

The hamster visual system shows a substantial amount of normally occurring cell death during early postnatal development. Following neonatal removal of one eye, this system also exhibits a marked plasticity in its connectivity. After the removal of one eye at birth, alterations in the normal magnitude and spatial pattern of cell degeneration were studied in the retinal ganglion cell layer of the remaining eye, lateral geniculate, and superior colliculus for the first 10 postnatal days to determine the role of cell death in early visual system plasticity.

In the remaining retina, cell degeneration in the ganglion cell layer occurred within the same period as that for normal retinas. Cell degeneration rates were lower in the temporal retina during postnatal days 1-5, resulting in an increase in ganglion cells relative to normal. This lowered cell death may reflect a reduction in competition at normally bilaterally innervated terminal areas. Retinal whole mounts from adults who had received a monocular enucleation at birth also showed increased numbers of retinal ganglion cells, principally in temporal retina.

In the superior colliculus contralateral to the enucleation, cell degeneration had a normal time course but the rate was twice as large as that of the ipsilateral colliculus. In the intermediate and deep layers of the colliculus, which are not retinal targets, no differences from normal cell degeneration were found in the period of normally occurring cell death.

Normal neuronal degeneration in the dorsal lateral geniculate coincides with degeneration in the retina, peaking at postnatal day 5. As in the superficial layer of the colliculus, cell death is greatest in areas innervated by peripheral retina. A second wave of cell death on postnatal day 8 does not show this center/periphery disparity, and may relate to the establishment of cortical connectivity. In enucleates, cell death in the contralateral geniculate was greater than in the ipsilateral geniculate and coincided with the period of normally occurring cell degeneration.

Observations of cell degeneration in mammals is a sensitive measure of size adjustments in neuronal populations following damage. Normally occurring cell death can be both reduced and increased following alterations in interconnecting populations.

98.9 MYASTHENIA GRAVIS IMMUNOGLOBULIN AUGMENTS MOTOR NEURON SURVIVAL. G. S. Sohal, R. T. Leshner* and T. R. Swift*. Departments of Anatomy and Neurology, Medical College of Georgia, Augusta GA 30912.

A significant number of motor neurons degenerate during embryogenesis in many neural centers. The factors regulating motor neuron survival during embryonic development remain uncertain. We have studied the effects of application of sera or immunoglobulin concentrates (Ig) of patients with acquired myasthenia gravis (MG) on embryonic cell death in the trochlear nucleus of white Peking duck. A significant increase in motor neuron survival occurred following application of MG sera or MGIg during the period of embryonic cell death. Normal sera or Ig precipitates in identical dosage produced no alteration in motor neuron survival. Sera from MG or normal controls without the Ig fraction had no effect on neuron survival. Embryos treated with MG sera before or after the period of normal cell death had neuron numbers similar to that of normal embryos. No diminution of limb or extraocular muscle movement was noted during development. Trochlear motor neuron survival persisted after sera or Ig treatment was discontinued. MGIg is therefore unique in preventing motor neuron death without producing muscle paralysis and in promoting a prolonged augmentation of motor neuron survival. Previous studies have shown effects of MG sera only postsynaptically in muscle. This is the first demonstration that MGIg affects structures in the CNS. (Supported by a grant from Muscular Dystrophy Association).

98.10 ULTRASONIC EVALUATION OF THE CONTUSED SPINAL CORD OF THE CAT. D.D. Rigamonti, P.M. Gammell*, J.D. Hestenes*, D.W. Scharre* and W.E. Prominski*. Department of Anatomy, Georgetown Medical School, Washington, D.C. 20007 and the Jet Propulsion Laboratory, University of California, Pasadena, CA 91103.

Contusion of the spinal cord produces both anatomical and physiological alterations, immediately in the central gray and subsequently in the long tract axons coursing in the white matter. The extent of focal damage can be measured using behavioral (neurological testing), physiological (somatosensory evoked responses) and anatomical (histological) techniques. We have developed a procedure using ultrasound to assess the extent of damage to the adult mammalian spinal cord.

Adult cats anesthetized with pentobarbital were used in acute experiments designed to establish the normative data in animals receiving an immediate contusion produced by forceps crush of the lower thoracic spinal cord following a laminectomy. The animal was held in a rigid holding device (DKI) and a pool of saline between the probe and exposed spinal cord was formed. The A-scan ultrasound system was a Panametrics pulser receiver and the resultant signal was displayed on an oscilloscope and photographed. The transducer had a 5 MHz center frequency, 0.5" diameter crystal with a nominal 1.25" spherical focus. The 6 dB width of the beam was measured to be 1.0 to 1.2 mm at 0.5 to 1.5" range. The A-scan traces were recorded at locations 1.0 mm apart, along the spinal cord through the normal region and at 0.5 mm intervals in the injured region using a micropositioner.

In vitro experiments were performed on an isolated thoracic spinal cord segment mounted in a holding device submerged in a bath of distilled water. The transducer, a Panametrics Videoscan, 10 MHz, 0.5" diameter with a spherical focus, was moved in 1/8 mm intervals with a Beckman stepper motor. The record of the 2048 points length were digitized to 8 bits resolution at 10 ns intervals by the Biomation 8100 transient recorder. Further image enhancement techniques (Gammell, Ultrasonics, 1981) were used to produce a refined printout of the spinal cord and injury site showing the connective tissue scar and cyst formation typical of a chronic (8 week) injury. The ultrasonic image correlated with a model of the spinal cord reconstructed from paraffin embedded histological sections.

Details of the various procedures and application of these findings will be discussed.

98.11 FURTHER OBSERVATIONS ON THE DEVELOPMENT OF THE NUCLEUS OF ORIGIN OF CENTRIFUGAL FIBERS TO THE AVIAN RETINA. D.D.M. O'Leary and W.M. Cowan. The Salk Institute, La Jolla, California 92037.

During the normal development of the nucleus of origin of the centrifugal fibers to the retina (the isthmo-optic nucleus - ION) some neurons have been found to migrate to ectopic loci and others have been shown to send their axons aberrantly to the ipsilateral eye (Clarke and Cowan, PNAS, 1975, 72:4455). We have re-examined the number, distribution, and fate of these two classes of neurons using the retrogradely transported dyes true blue and nuclear yellow.

With this more sensitive method it is evident that the number of ectopic neurons is considerably greater than had been suggested previously and that many are located much further away from the borders of the ION (up to 1500 μm). On the 13th day of incubation (i.e., shortly after all the fibers from the ION reach the retina) about 2,000 ectopic ION neurons can be labeled on the side of the brain contralateral to the eye injected with a dye. Such ectopic cells represent approximately 10% of the total number of ION neurons generated. By the end of the period of naturally occuring cell death in the ION (on day 17), this number is reduced to about 800. The disappearance of 60% of the ectopic neurons is comparable to the percentage of naturally occurring cell death seen in the ION itself. It has been suggested that the surviving ectopic neurons persist because their axons form synapses within the retina and because they receive an input from the optic tectum, as do the neurons in the ION itself. In support of this hypothesis we have found that when large lesions are placed in the optic tectum shortly after hatching, there is both a severe anterograde transneuronal degeneration in the ION and also a proportional loss of ectopic ION cells.

Intraocular injections of true blue on day 13 label about 40 neurons in the ipsilateral ION and the immediately surrounding area. Of these roughly a fifth can be doubly-labeled by injections of nuclear yellow into the opposite eye, which suggests that at least some of the aberrant ipsilateral projections are due to axon collaterals. Only 25% of the cells with ipsilaterally projecting axons survive the period of naturally occurring cell death in the ION. Since only rarely has it been possible to doubly-label these cells in post-hatched animals with dye injections into the two eyes, it seems likely that most of the neurons with aberrant ipsilateral collaterals either die during the period of naturally occurring cell death or withdraw their collaterals to the ipsilateral retina.

98.12 CELL DEATH AND PROLIFERATION IN THE ELECTRIC LOBES OF TORPEDO MARMORATA. G.Q.Fox and G.P.Richardson. Department of Neurochemistry, Max-Planck Inst. für biophy. Chemie, Göttingen, W. Germany.

A quantitative analysis of electromotoneurons has been made during the development of the electric lobes in Torpedo marmorata. The study was started at the 26mm body length stage shortly after the majority of the neurons have apparently differentiated as judged by the disappearance of columnar epithelia. Degenerating cells with unequivocal pycnotic profiles have been quantified and are found during a period from 38mm to 74mm embryo body length. The onset of this period coincides with the onset of differentiation of myotubes into electrocytes in the electric organ as well as the onset of differentiation of the electromotoneurons from an immature monopolar form to a mature multipolar neuron. The period also overlaps slightly with the onset of synaptogenesis in the electric organs. No obvious decline in total neuron numbers occurs during this period although following it an apparent increase in numbers has been noted which continues into adulthood. This suggests that there is a continual slow proliferation of neurons during the entire growth and development of the animal although we have not been able to locate the source of these additional cells.

The results indicate that cell death in this system can not be attributed to a failure to compete successfully for synaptic sites because it begins prior to the onset of synaptogenesis and terminates at a time when developing synapses occupy only about 15% of the available postsynaptic membrane(unpublished observations).

98.13 LOCAL ELECTROLYTE ALTERATIONS FOLLOWING ACUTE INJURY TO THE CAT SPINAL CORD. R. C. deGroof†, J. L. Alderman and J. L. Osterholm. Depts. of Pharmacology and Neurosurgery, Jefferson Med. College of Thomas Jefferson Univ., Philadelphia, PA 19107.

It has been proposed that the early block of conduction in the long tracts following spinal cord injury may be due to a substantial shift in ionic equilibrium at the site of injury. Studies by other laboratories demonstrate a significant loss of K+ from the injured cord tissue which, since blood flow is seriously impeded, presumably moved into the CSF. While those studies generally support a role for K+ in axonal blockade, they give limited information on the regional spinal cord distribution and thus the potential influence of K+ or other electrolytes in discrete functional areas of the injured cord. In order to obtain more information on the regional behavior of electrolytes in response to trauma, the spatial redistribution of the electrolytes K+ and Na+ were determined separately in the anterior, posterior, and lateral white regions, as well as in the central grey region of the experimentally injured spinal cord 1 hour after trauma. Analyses by atomic absorption spectrophotometry were made on specimens taken by the punch sampling technique from subsections taken serially along the rostral caudal axis above, through and below the actual injury site (T8). Values were corrected for protein content and expressed as percent change from remote thoracic T3-4 control regions.

K+ content of all white matter tracts was reduced by 50% from control within 5 mm both rostral and caudal to the impact site. At 10 mm in both directions, the K+ content had returned to near control level. Na+ content of white tracts was increased by 100% at the impact site and in all cases returned to near control at 10 mm both rostral and caudal. The K+ content of the central grey area was depressed by 75% at the site of impact. This depression was about 50% at 10 mm both rostral and caudal. The Na+ content of central grey depression was increased 100 to 200% near the site of impact but returned to near control level 10 mm in both directions. These results show that spinal cord injury has a profound effect on the electrolyte content of spinal tissue. This loss of potassium and increase of sodium was localized to the area near the injury, and was of generally equal magnitude in all white regions. If electrolyte alterations are responsible for depressions of conduction through the long tracts, these results indicate that conduction in all spinal areas would be similarly blocked (USPHS 5-R01-NS12287-03).

98.14 RELEVANCE OF RETINAL GANGLION CELL DEATH TO THE PATTERN OF NEURON DEATH IN THE SUPERIOR COLLICULUS. Timothy J. Cunningham and Debra L. Giordano.* Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Neuron death during development has now been documented in several areas of the normal nervous system of several different species. A number of studies have concentrated on cell death within individual cell groups but there is little information on the interrelationship of neuron death in connecting central nervous system regions. The retino-collicular pathway of neonatal rats is an ideal system for such a study because natural neuron death has been documented in both the ganglion cell layer and superior colliculus (Cunningham et al. 1981; Giordano et al. 1980), and because the topography of connections between these structures is well understood. We examined 1µ plastic sections from the normal superior colliculus and ganglion cell layer of neonatal rats. Counts of degenerating cells were made from sections of the rostral and caudal thirds of the colliculus and sections of nasal and temporal parts of the ganglion cell layer. At ages when the numbers of degenerating cells appear maximal in both structures (i.e., 6-7 days postnatal), the nasal ganglion cell layer and caudal superior colliculus (which are normally connected) have an average of 2 times as many degenerating profiles as temporal retina and rostral colliculus (which are also connected). Therefore, the patterns of natural degeneration at least to some extent, parallel the topography of retino-collicular connections. These regional differences may represent gradients of cell death and may reflect reciprocal control of neuron survival. On the other hand, studies of embryonic chick retina indicate that the nasal-temporal differences in cell death are independent of the optic tectum and may be intrinsic to the retina (McLoon and Hughes, 1979). We sought to determine if the caudal-rostral differences in collicular cell death are dependent on the projection from the retina. Rats were enucleated at birth, examined each day thereafter to postnatal day 14, and then compared to normal rats. Counts in the normal rats on days 1-8, (after which the numbers of profiles decline significantly), show more degenerating cells in the caudal third of superior colliculus compared to rostral and middle thirds. In enucleated rats, cell death has a similar time course but there is no significant difference between rostral, middle and caudal thirds of the colliculus. The results suggest that the spatial pattern of cell death in the colliculus depends on optic afferents and may indicate peripheral to central adjustments of neuron numbers in this system.

98.15 VARIABILITY IN THE CELL DEATH OF IDENTIFIED NEURONS IN GRASSHOPPER EMBRYOS. Curtis M. Loer* and Corey S. Goodman. (SPON: J. Wine). Dept. Biol. Sci., Stanford University, Stanford, CA

Every segment in the nervous system of the grasshopper embryo has a single midline precursor 3 (MP3) which divides once to give rise to two progeny (Goodman, Bate, Spitzer, 1981). In the meso- (T2) and meta- (T3) thoracic segments, one of these two progeny differentiates into the "H" cell. In some abdominal segments, one or both of these two cells dies (Bate, Goodman, Spitzer, 1981). Although there is a trend in the segment-specific differences of survival vs. cell death, the precise pattern varies from embryo to embryo.

In the present study, we examined the variable pattern of survival vs. cell death in 14 contiguous segments of 378 grasshopper embryos, after the stage at which cell death occurs. The pattern of cell death was examined in 6 different clutches each of Schistocerca americana and S. nitens, and 11 different clutches of Melanoplus differentialis (n greater than 100 for each species). The 'typical' pattern is for one cell to survive in S3, both cells to survive in T1-T3 and A1, one or no cells to survive in A2-A7, and one or two cells to survive in A8 and A9. There is, however, considerable variability from embryo to embryo. One of the striking differences between species is the survival in the A2 segment, where two cells survive in 42% of the S. americana embryos, in only 7% of the S. nitens embryos, and in only 9% of the M. differentialis embryos. There is even more overall variability, however, between different clutches of the same species. Since the clutches of eggs are raised in nearly constant and identical environmental conditions, the clutch-specific differences suggest a genetic component to the pattern. We plan to further study the genetic component of this variable pattern of cell death by examining the pattern in embryos from different isogenic clones.

99.1 ELECTROMICTURITION: HISTOPATHOLOGICAL EVALUATION OF SACRAL NERVES FOLLOWING ELECTRICAL STIMULATION. W.F.Agnew, T.G.H. Yuen*, L.A. Bullara*, R.A.Schmidt*, and E.A.Tanagho*. Neurological Research Laboratory, Huntington Institute of Applied Medical Research, Pasadena, Ca. and Dept. of Urology, Univ. California School of Medicine, San Francisco, Ca.

The feasibility of controlling micturition in the spinal injury patient by electrical stimulation of the sacral nerves of spinal dogs has been investigated in previous studies(Schmidt and Tanagho, Urol.Int.34:199,1979. This report describes the histopathological evaluation of stimulated and non-stimulated sacral nerves in 18 dogs of either sex. Twelve dogs were subjected to chronic electrical stimulation of the sacral nerve and six were unstimulated either with or without electrode implantation and with or without dorsal rhizotomy. The two types of electrode arrays evaluated included a silastic cuff array with bipolar platinum electrodes and a silastic spiral matrix with tripolar platinum electrodes. Animals subjected to stimulation had an electrode implanted on S2, the sacral root producing the strongest bladder contraction with stimulation. Electrodes were implanted at various sites on the ventral root of S2 with rhizotomy of the dorsal root with or without ganglionectomy and with or without division of the Pudendal trunk within the ischiorectal fossa. The animals were stimulated once daily for 60 seconds using 2.5 to 3.0 volts using an implantable receiver and transmitter system (Avery Model I-110). Micturition was assessed by use of an uroflowmeter and measurement of residual volume by fluoroscopy. The two types of electrodes were evaluated for periods ranging from 1.5 to 10.5 months following surgical implantation. At the time of sacrifice the dogs were perfused via the ascending and descending aorta with either 10% formalin (for light microscope) or a mixture of 2% GTA and 4% paraformaldehyde (for electron microscope) studies. In general, stimulation with either cuff or spiral electrode effectively produced micturition. However, the cuff-type electrode proved to be unsatisfactory for chronic stimulation due to buildup of connective tissue within the cuff lumen, often to the extent of almost complete extrusion of the sacral nerve. Despite severe mechanical distortion of the S2 nerve, micturition was readily induced in many of the animals and microscopic examination revealed a normal axon population. In some instances, however, there was a marked diminution of the number of axons, with hypomyelination of many axons, and endoneurial connective tissue accumulation. The spiral electrode array proved superior in that a good electrode-tissue contact was maintained with minimal connective tissue encroachment and both morphological and functional preservation of the nerve. (Supported by NINCDS Contract # NO-1-NS-0-2275).

99.2 CHANGES IN EXTRACELLULAR POTASSIUM ACTIVITY DURING STIMULATION OF THE CEREBRAL CORTEX AT DEFINED CHARGE DENSITIES. D.McCreery and W.F.Agnew, Neurological Research Laboratory, Huntington Institute of Applied Medical Research, Pasadena, Ca.

In cats anesthetized with nitrous oxide and halothane, ion selective microelectrodes were used to monitor continuously the activity of potassium (a_K) in the extracellular compartment of the sensorimotor cortex during up to 4 hours of continuous electrical stimulation of the cortical surface above the ISMs. The electrical stimulus was a continuous train of biphasic constant current pulses through a disc electrode 1.1 mm in diameter. Charge densities correlated in previous studies in this animal with various degrees of neural damage were used. The compound action potential evoked by the surface stimulation was monitored continuously by means of an electrode in the ipsilateral pyramidal tract.

A stimulus charge density of 20 microcoulombs/cm^2. phase (20μc/cm^2.ph) (found in previous studies to produce only very minimal histological changes during 50 hours of continuous stimulation) evoked no or only a small transient increase in a_K within the grey matter, followed by return to the pre-stimulus base line activity within one minute. Higher charge densities produced larger initial increases in a_K and a slower return towards the pre-stimulus base line value. Continuous stimulation at a charge density of 100 μc/cm^2.ph (shown to produce severe neural damage if maintained for as little as 4 hours) at 20 pulses/sec produced an initial increase in a_K of 8-10 mM in the grey matter, followed by a gradual return within 1 to 2 hours to within 2 mM above the pre-stimulus value. After 2-3 hours of continuous stimulation a_K again began to increase. At a charge density of 100 μc/cm^2.ph and 50pps the magnitude and overall time course of a_K was very similar to that seen at 20 pps except that the initial increase was slightly larger and periodic "waves" of sequential increases and decreases of a_K were seen beginning one half to one hour after initiation of stimulation. These waves lagged slightly behind periodic increases and decreases in the amplitude of the earliest secondary (probably synaptically evoked) component of the compound action potential recorded from the pyramidal tract. In general, during continuous stimulation of the cortical surface, the time course of a_K followed that of the amplitude of the secondary component of the pyramidal tract potential. Although the local mechanisms for maintaining potassium homeostasis between brain compartments remains functional during several hours of intense stimulation, its inability to correct completely the increase in a_K may contribute to the neural damage occurring during such stimulation. Supported by NINCDS Contract # NO-1-NS-0-2275.

99.3 INTRACORTICAL CAPACITOR ELECTRODES: A PRELIMINARY EVALUATION. E.M. Schmidt, F.T. Hambrecht, and J.S. McIntosh. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Electrical stimulation has long been used by neurophysiologists to modify and control the electrical activity of cortical neurons. When conventional noble metal electrodes are used (such as platinum, platinum alloys, or iridium), oxidation-reduction reactions can occur during current passage between the electrodes and the extracellular fluid surrounding them. Some of the products of these reactions are toxic to tissue and their generation is proportional to the charge density at the electrode-tissue interface. As intracortical electrodes are made smaller to increase their selectivity, charge density increases because the electrode surface area decreases faster than the total charge required to effectively stimulate neurons. The possibility of toxic reaction products accumulating is therefore increased and becomes even more significant if long-term stimulation is required. Capacitor electrodes can be used to stimulate nerve or muscle tissue without oxidation-reduction reactions because their insulating dielectric does not allow electrons to pass, even though ions in the tissue can be attracted or repelled by the charge on the electrode. The only capacitor electrodes available for neural tissue stimulation have been relatively large cylindrically shaped slugs (1mm diameter) obtained from capacitor manufacturers. These are suitable only for surface electrodes. However, some applications require long-term stimulation of cortical neurons at various depths with penetrating electrodes. For these we designed conically tipped tantalum/tantalum pentoxide capacitor electrodes with a maximum diameter of roughly 190 um and an exposed length of 500 um.

In vivo evaluation of these intracortical capacitor stimulating electrodes was carried out by chronically implanting 9 electrodes in the motor cortex of a monkey. The electrical characteristcs of each electrode were determined by passing a single 100 ua, 0.1 ms current pulse and measuring the resulting voltage between the electrode and a large indifferent platinum electrode located in the cerebrospinal fluid above the cortex. These measurements remained relatively stable over the 57 days of implantation. The effectiveness of the electrodes in stimulating cortical structures was evaluated by determining the minimum pulse train current required to produce a palpable forelimb muscle contraction. The threshold currents and muscles activated were determined during the period of implantation. These intracortical capacitor electrodes are effective for stimulation of small populations of neurons and are electrically stable during chronic implantaion without the hazards of oxidation-reduction reactions associated with noble metal electrodes.

99.4 SENSORY CODING IN NATURAL & ARTIFICIAL RECEPTORS, G. S. Wasserman. Sensory Coding Lab., Purdue Univ., West Lafayette, IN 47907.

There are two ways in which one can study the sensory codes used by receptors: One way is to compare the responses of natural receptors with the behavior of whole organisms when equivalent stimuli are delivered in both cases. Sensory codes are then extracted by searching for the features of the receptor responses that have the same formal properties as the behavior. Previous work along these lines suggested that the receptor code was task dependent and that different sensory codes mediated performance in detection and recognition tasks. For detection tasks, the initial transient peak of the receptor potential accounted for behavior; for recognition tasks, the integral of the receptor potential accounted for behavior. The weakness of this approach is twofold: It is correlational and it often compares receptor data taken from animals with behavioral data taken from humans. These weaknesses have led us to consider the advantages of studying the performance of artificial receptors implanted in human patients whose natural receptors have been destroyed. A review of the work done with these artificial receptors supports the suggestion we obtained from studying natural receptors: Adequate recognition occurs when artificial receptors use the recognition code; otherwise, sensation is limited to stimulus detection. However, coding variables have not been the explicit focus of this previous work with artificial receptors and hence this support is limited. We have therefore begun to study the effects of coding variables on recognition performance in patients fitted with artificial receptors. Preliminary results of these investigations will be presented.

99.5 Visual Prosthesis: Use by an Infant Macaque. E.R.Strelow* (SPON: A.H.Riesen).Dept. of Psychology, Univ. of California, Riverside, CA. 92521

An infant macaque monkey (M.arctoides) was born in the dark and subsequently reared for 35 days with its eyes covered, but using a head-mounted electronic prosthesis to assist space perception.The prosthesis (the Binaural Sensory Aid) provided distance, direction and object class information by an auditory display,and the head-worn portion of this device weighed 28 gm.

The animal was reared in a large cage with a cloth surrogate in place of its mother, and with a number of toys to interact with. The monkey showed a gradual increase in 'looking-type' head-turning behavior and after two weeks would reach for otherwise silent objects presented in a controlled setting. He thus showed a degree of behavioral plasticity in accepting artificial sensory input in place of normal visual stimuli, although the use of the prosthesis was rudimentary compared to visual skill, and compared to performance of the long-term blind who have used similar devices as aids to mobility.

Among issues raised for discussion are:1) the extent to which it is possible to create conditions which will encourage self-initiated learning of such novel sensory stimuli; 2) the adequacy of the sensory prosthesis as a source of spatial information; and 3) what would be the limits of this sensory substitution even with ideal prostheses and rearing conditions?

99.6 SENSORY THRESHOLDS ON TOES TRANSPLANTED TO THE HUMAN HAND. J. H. Solomon*, R. W. Dykes, D. C. Donderi* and R. K. Daniel. Depts. Psychology, Physiology, Surgery, Neurology and Neurosurgery, McGill University, Montreal, Quebec, H3A 1A1.

More than one year after surgery was performed to transfer the great toe to the hand to replace a missing thumb, cutaneous thresholds were measured in the transferred digit and compared to thresholds for normal thumbs. It has been known for many years that there is a correlation between tactile acuity on a particular body site and the density of cutaneous receptors in that region. This correlation has often been used to imply a causal relationship between the receptor density and tactile acuity. However, it has never been subjected to an empirical examination. The transplanted digits provide an opportunity to test this presumption of causality. Each patient underwent several hours of psychophysical tests designed to obtain pressure thresholds, two-point thresholds, and point localization thresholds. Thresholds were obtained on the normal thumb, transplanted toe, and normal toe. These were compared to equivalent data from 20 healthy, age-matched normal subjects. The results show that thresholds from the thumbs of normal subjects were not significantly different from thresholds on the normal thumb of the patients. Similarly, the thresholds on the normal toes of the subjects and patients did not differ significantly. The thresholds on the transferred toes were strikingly different from the thumbs of either subjects or patients. However, when compared to the thresholds on the normal toe, the values for the transplanted toes were within the normal range. Thus, despite the surgical manipulations, the transplanted toes functioned within the normal range for toes. This result suggests that the limiting factor in this series of sensory tests is the receptor density in the skin region from which the tissue originated. Further, it implies that there are limitations to the ability of regrowing axons to induce new sensory endings in glabrous skin.

100.1 SACCADIC INTRUSIONS IN TRACKING EYE MOVEMENTS OF SCHIZOPHRENICS. S. Levin, A. Jones*, L. Stark, P.S. Holzman, E. Merrin*. Mailman Research Center, McLean Hospital and Harvard University, Belmont, MA 02178.

Schizophrenic patients have abnormal smooth-pursuit eye movements (SPEM) (Diefendorf & Dodge, 1908; Holzman, et al, 1974). These abnormalities are not due to drug medication and probably reflect a stable trait under genetic influence, as suggested by longitudinal, family, and twin studies. (Holzman, et al., 1977, 1980; Iacono & Lykken, 1979, 1980). The precise nature of the SPEM impairment must be determined with high-precision reflected light technique. We tested 6 chronic schizophrenics using an infra-red limbus-tracking technique with a total system bandwidth of 1 kHZ. In 4 of the patients we tested so far (67%), the main characteristics of the eye movement abnormalities appeared to be saccadic intrusions which are small amplitude eye movements in opposite directions. These saccadic intrusions were seen during smooth pursuit, visual fixation, vergence eye movements, and saccadic fixation rests, but not in VOR in the dark or during head-eye coordination. The dynamic characteristics of the saccadic intrusions were on the main sequence (Bahill & Stark, 1979) and cannot be distinguished from the saccadic intrusions which appear sometimes in normal fixation or pursuit.

In contrast to the impairement of SPEM and other fixation eye movements, saccadic eye movements, following a predictable or unpredictable target, had normal latencies and normal dynamic characteristics, confirming the results of a previous investigation using EOG recordings with a larger sample of patients (Levin, et al., 1981).

Although these results are preliminary, they clarify the nature of the primary irregularity previously seen during SPEM, and confirm that it consists of eye movements rather than bioelectric noise. Tracings of these eye movements are quite different from saccadic smooth pursuit seen often in a variety of benign and serious eye movement control disorders.

100.2 DISTURBED OCULAR MOTOR CONTROL IN HUNTINGTON'S DISEASE (HD). R. J. Leigh, S. A. Newman*, S. E. Folstein* and A. G. Lasker*. Depts. of Neurology, Ophthalmology and Psychiatry, The Johns Hopkins Univ. Sch. of Med., Baltimore, Maryland 21205

We have studied the eye and head movements of 37 patients with HD using video, D.C. electro-oculography and magnetic search coil methods. Fixation was abnormal in 20/27 patients because of small extraneous saccades which were most evident when a rich visual background surrounded the fixation target. Saccades were slow to clinical examination, in 19/35 patients. In some early-affected patients whose eye movements looked clinically normal, recordings showed disturbed peak-velocity/amplitude relationships, particularly in the vertical plane. Difficulty in initiating saccades was manifest by prolonged latency in 24/32, "mandatory" blinks in 12/34 and obligatory head movements in 33/36. Smooth pursuit was clinically abnormal in 14/29 patients; eye movement records showed that this was sometimes due to decreased pursuit gain but more often the abnormality was one of extraneous saccades such as those that interfered with fixation. Similarly, vergence was abnormal in 9/26 patients due to difficulties in fixating a stimulus target. The vestibulo-ocular reflex, assessed by eye movement recording and a bedside ophthalmoscopic test appeared normal in 36/37 patients. Gaze-holding ability was normal in 33/37 patients. Eye movements in patients who were receiving psychotropic medication did not appear to differ significantly from those receiving no treatment.

We postulated that the disturbances of fixation and saccadic initiation were due to frontal lobe involvement in HD since patients with frontal lobe lesions make saccades to behaviorally-inappropriate but visually-attractive stimuli (Buchtel, H. A. and Guitton, D., Neurosci. Abstr., 6:316, 1980). To test this, we studied 6 early-affected patients. They were instructed to fixate a central light-emitting dioded (LED) in darkness and ignore the appearance of a peripheral distracting LED until the central fixation light went out. All 6 patients made inappropriate saccades to the distracting stimulus in more than 50% of trials, even though the instructions were clearly understood. Four normal subjects tested in the same way showed less than 5% of trial errors. Thus frontal lobe involvement in HD may be the substrate for fixation instability. An alternate explanation is that the diseased striatum causes impaired function of units in the pars reticulata of the substantia nigra (Hikosaka, O. and Wurtz, R. H., Neurosci. Abstr., 6:15, 1980) that inhibit superior collicular neurons.

100.3 VESTIBULO-OCULAR REFLEX DYSFUNCTION IN PARKINSON'S DISEASE O.B. White*, J.A. Saint-Cyr and J.A. Sharpe, Playfair Neuroscience Unit, Division of Neurology, Toronto Western Hospital, University of Toronto, Toronto, Canada.

Horizontal pursuit and vestibular smooth eye movements, in response to predictable target motion and passive whole body rotation at frequencies from 0.3 to 1.0 Hz, were quantified in 9 patients aged 45-74 with idiopathic Parkinson's disease. One patient had had a previous thrombotic stroke without residua and one had had a previous unilateral thalamotomy. All patients were receiving pharmacotherapy (L-dopa with a peripheral decarboxylase inhibitor with or without anticholinergics). Eye movements were measured by infra-red oculography and d.c. electro-oculography. Data were analysed off-line with a digital computer. Results were compared to those of 16 control subjects.

Vestibulo-ocular reflex (VOR) gains measured in alert patients in darkness were significantly reduced at 0.3 and 0.5 Hz in mild to moderately affected patients. Gain reduction was more marked in patients with severe hypokinesia and rigidity and evident at higher rotational frequencies. Fixation of a stationary target significantly increased VOR gain. During attempted cancellation of the VOR by fixating a target moving with the head, VOR gain was higher than in darkness. Cancellation was defective. Voluntary (non-visual) enhancement and cancellation of the VOR by attempted fixation of imagined stationary and moving targets respectively, accompanied defective visual control of the VOR. Smooth pursuit velocities were significantly reduced.

Impaired visual modulation of the VOR may be explained by the smooth pursuit defect. Defective voluntary modulation of the VOR indicates that Parkinson's disease also involves circuits that mediate non-visual control of the VOR. Disparity between reduced VOR gains in darkness and higher gains during attempted VOR cancellation, indicates that an alternate mode of compensatory smooth eye movement generation is available during passive rotation and is inappropriately activated in Parkinson's disease.

100.4 CHANNELS IN THE VESTIBULO-OCULAR REFLEX (VOR). S.G. Lisberger and F.A. Miles, Laboratory of Neurophysiology, National Institute of Mental Health, and Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20205

It has been usual to represent the mechanism underlying adaptive gain control of the VOR as a single pure gain element. We now report observations that cannot be explained by such a minimal model; we suggest that the VOR operates as a series of parallel channels with differing dynamics, and that the adaptive process can adjust the gain of each channel separately.

Four rhesus monkeys were subjected to passive whole-body oscillation while viewing either a) the stationary surroundings through x2-telescopic spectacles or b) a visual scene that oscillated with them (equivalent to x0-spectacles). VOR gain was estimated as peak-to-peak smooth eye velocity divided by peak-to-peak head velocity during sinusoidal oscillations of $\pm$25 deg/s at frequencies ranging from 0.1 to 4.0 Hz in darkness.

The passive oscillation paradigm produced larger changes in VOR gain at the adapting frequency than at adjacent frequencies. For example, adaptation at 0.2 Hz produced larger changes in VOR gain when tested at 0.2 Hz (average for the 4 monkeys reaching high gains of 1.66 and low gains of 0.42) than when tested at 2.0 Hz (up to 1.35 and down to 0.63). Similarly, adaptation at 2.0 Hz produced larger changes in VOR gain at 2.0 Hz (up to 1.62 and down to 0.39) than at 0.2 Hz (up to 1.10 and down to 0.62). While eye velocity remained 180 deg out of phase with head velocity at the frequency of adaptation, consistent small changes in phase shift were seen at adjacent frequencies. At frequencies above that used for adaptation, increases in VOR gain caused eye velocity to lag a perfect VOR while decreases caused eye velocity to show phase lead. Conversely, at frequencies below that used for adaptation, increases in VOR gain caused eye velocity to lead a perfect VOR while decreases caused phase lag.

Such frequency-selective adaptation suggests the existence of temporal frequency channels in VOR pathways. The complex dependence of VOR phase on gain and frequency can be explained if individual channels are also differentiated on the basis of phase shift. In this scheme, higher frequencies would tend to activate channels carrying signals with greater phase lead; the extent of overlap between the channels excited by the adapting and test stimuli would determine the magnitude of the phase shift seen in the VOR. An adaptive mechanism that can operate selectively over narrow bandwidths constitutes a highly-flexible and tuneable interface between afferents and motoneurons. By compensating in narrow bandwidths for frequency-dependent variations in primary afferent responses, this interface could provide a means of establishing frequency-independent performance in the adult VOR.

100.5 OPTICALLY-INDUCED CHANGES IN THE NEURAL COUPLING BETWEEN VERGENCE EYE MOVEMENTS AND ACCOMMODATION IN HUMANS. F.A. Miles and S.J. Judge*. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20205, and University Laboratory of Physiology, Oxford University, Oxford OX1 3PT, England.

Transfer of fixation between targets at different viewing distances involves changes in vergence eye movements and accommodation that operate to eliminate disparity and blur, respectively. However, during monocular viewing, when disparity cues are absent, changes in accommodation due to blur also result in linear changes in vergence: Accommodation-vergence (A-V). Similarly, during binocular pinhole viewing, when blur cues are minimal, changes in vergence due to disparity also result in linear changes in accommodation: Vergence-accommodation (V-A). We now report that these open-loop responses undergo adaptive modification when the apparent separation of the eyes is more than doubled with laterally-displacing, periscopic spectacles.

A-V and V-A were measured in two human subjects using a haploscope incorporating a laser optometer with Badal lens viewing to determine the accommodative state of the right eye. For measurement of A-V, the right eye fixated cross-hairs through a mixing cube and Badal lens, providing accommodative stimuli of 0-4D with fixed size and brightness cues; the left eye viewed a blank screen with alignment markings (offset to avoid fusion) through a mirror galvanometer system that, when aligned by the subject, indicated the horizontal position of that eye. A-V was expressed as a dimensionless gain parameter equal to the measured change in vergence per unit change in accommodation divided by the required change in vergence to maintain correct alignment of the eyes during that same change in accommodation. Initial A-V gains were 0.86 and 1.16, and after wearing the periscopic spectacles for 30 min, these increased to 1.43 and 1.89, respectively. For measurement of V-A, each eye fixated cross-hairs in Maxwellian view; blur cues were minimized by using pinhole light sources (<0.5 mm diam) and vergence was varied systematically by rotating the optical system in the left limb of the haploscope about the center of rotation of the left eye. V-A was expressed as a dimensionless gain parameter equal to the measured change in accommodation per unit change in vergence divided by the required change in accommodation to maintain correct focus of the eyes during that same change in vergence. Initial V-A gains were 1.09 and 0.86, and after wearing the periscopic spectacles for 30 min, these decreased to 0.51 and 0.41, respectively. Thus, challenged with optical devices that increase the separation of the two lines of sight, A-V and V-A gains show increases and decreases, respectively, that are appropriate for improving the rapid alignment and focussing of the two eyes.

100.6 ON THE MECHANISM OF VISUAL-VESTIBULAR INTERACTION. O. Bock* (SPON: C.M. Oman). Inst. of Physiol., Free Univ., Berlin, Germany.

The visual and vestibular systems interact in the control of eye movements, induced by head rotation. We investigated the mechanism of this interaction by using a conflict between the two systems, concerning the appropriate direction of eye movements. 10 human subjects were rotated sinusoidally at different frequencies in a rotating chair. They were in total darkness except for a small stationary target light (LED), seen via a chair-fixed mirror. In this way, relative motion of the LED with respect to the subjects' head was reversed in direction, (i.e. in phase with the head.) Under these conditions, the smooth pursuit system, driven by visually perceived target motion, is expected to initiate eye movements in phase with the motion of the subjects. The vestibulo-ocular reflex (VOR), activated by head motion, is, however, expected to initiate eye movements 180 degree out of phase with the subjects' motion. We recorded eye position by DC-EOG and calculated phase and gain of the smooth components of eye movement with respect to the stimulus. A strong dependency of eye motion on stimulus frequency was found up to about 0.8 Hz. The eyes were, within a few degrees, in phase with the stimulus, and the gain was near unity, decreasing with frequency. This suggests that in this low-frequency range, eye movements are predominantly controlled by the pursuit system. At frequencies above 1.6 Hz, eye motion was, within a few degrees, by 180 degrees out of phase with the stimulus, and the gain was near 0.7, suggesting a predominance of the VOR in the high-frequency range. Of particular interest are findings at frequencies between 0.8 and 1.6 Hz. No gradual transition from visually to vestibularly dominated phase and gain could be demonstrated with increasing frequency. Rather, for any given frequency in this range, the eyes repeatedly switched between movement unequivocally in phase, and movement unequivocally by 180 degrees out of phase with respect to the stimulus. This finding can be best explained by assuming that the control of eye motion repeatedly switches between the pursuit system and the VOR. Our results demonstrate that the interaction of VOR and smooth pursuit is non-linear, since a linear relationship would require a smooth transition from visually to vestibularly dominated eye movements. Rather, the two systems appear to compete for the control of eye motion in a frequency range, (0.8 to 1.6 Hz), where no clear dominance of either system exists.

100.7 VESTIBULOOCULAR COMPENSATION DURING TRANSIENT HEAD ROTATION: IS IT ADAPTIVELY REVERSED BY LONG-TERM VISION REVERSAL? G. Melvill Jones and A. Berthoz*. Dept. of Physiol. McGill Univ., Montréal, Québec, Canada and Laboratoire de Physiologie Neurosensorielle, 75270 Paris, France.

Long-term vision reversal eventually leads to apparent reversal of the vestibuloocular reflex (VOR) as tested by low frequency (0.17 Hz) sinusoidal rotation in the dark. The present study examines the question: Does similar adaptive reversal occur in the reflex eye movements induced by rapid stepwise rotation of the head between 2 stationary targets?

METHODS: A human subject wore horizontally reversing dove prisms for 19 days, during which time head and eye movements were measured in the following dark-tested conditions: 1) Sudden, passively induced, rotation of the head between two fixed angular locations separated by roughly 10° in a horizontal plane. 2) Similar actively induced head rotation.

RESULTS: Control tests showed normal VOR in these circumstances (eg Barnes, J. Physiol. 287:127), yielding mean values of VOR gain (eye vel./head vel.) ranging from 0.75 (SE 0.03,n=20) to 1.01 (SE 0.03,n=18) with passive and active rotation respectively. During adaptation to vision reversal a variety of modified patterns of oculomotor behaviour developed. Thus with passive head rotation the VOR (identified by its fixed latency) was always either of reduced gain (mean values ranged from 0.27 to 0.48), or completely absent. Particularly noteworthy is the fact that all identified VOR responses occurred in the normal direction. With active head movement the VOR was also of reduced gain and normal direction, but its occurrence was relative -ly infrequent. Instead, there was an interesting variety of different response patterns, described and interpreted in another communication (Berthoz & Melvill Jones, European Neuroscience, 1981). One of these patterns might readily be misinterpreted as a successfully reversed VOR, of gain close to unity. However, owing to its highly variable, and often negative, latency, this functionally effective form of adapted activity must have derived from a source other than the VOR.

It is CONCLUDED that maintained vision reversal produced substantial attenuation of the VOR in both active and passive conditions, including the ability to effect its complete blockage. However, although the adaptive process also appears to have produced a functionally effective form of reversed ocular compensation manifest during the actively generated head movement, this reversed response cannot be attributed to the VOR.

100.9 ARE SACCADIC REACTION TIMES MODULAR IN STRUCTURE? AN ANSWER FROM A WAITING-TIME ANALYSIS. P.E. Hallett and H. Doma*, Dept. of Physiology, University of Toronto, Toronto M5S 1A8, Canada.

1. Saccadic latencies in several tasks from this laboratory and the literature have been interpreted as being composed of fixed and variable parts (e.g. Hallett and Adams 1980 Vision Res. 20, 329), where the fixed delay is about 120 msec. Thus the mean latency $\bar{N}$ in the normal single-step tracking task (or N-task) is supposedly the sum of one fixed and one variable delay, while the mean latency $\bar{A}$" of successful attempts at our "anti" task (or A-task), in which the subject makes a saccade opposite to the step, is supposedly one fixed delay plus about two variable delays.

2. On a plot of mean (y) versus standard deviation (x) of latency the y-intercept should be the fixed delay, and the square of the slope the number of stages of waiting that make up the variable delay, if the variable delay is a gamma-distributed waiting time. Plots for the 8 subjects of Hallett and Adams, plus 1 new subject, give a fixed delay of 136 ± 6 msec in the N-task (105 ± 22 msec in the A-task) and a variable delay of 8 ± 2 stages in the N task (22 ± 6 in the A task). So this new approach supports the idea that these tasks are based on a common fixed delay, plus one or more doses of variable delay.

3. We have repeated these experiments and plots for 5 new subjects. More importantly we have fitted the present model (fixed delay plus gamma-distributed waiting time) to the actual latency distributions for the N and A tasks, using the chi-squared criterion. The ratio for the two tasks (Anti/Normal) between the fixed delays was 1.00 ± .14, between the mean waiting times 2.04 ± .66, and between the numbers of stages of waiting 2.61 ± .33 (these data are mean ratios ± standard deviations across the 5 subjects). The value for the fixed delay was 129 ± 11 msec, with 8 ± 1 stages of waiting in the N-task and about twice as many (17-21) stages in the A-task. Thus the essential hypothesis is well supported by these new data for bright stimuli (100 x foveal threshold, subject otherwise dark-adapted).

4. At low light levels (down to 1/30 x foveal threshold) latencies become so protracted and dispersed that the full waiting-time analysis is impractical, but the fixed delay may well increase - as it should do if it contains a retinal delay as Hallett and Adams claimed.

100.10 NEURAL SIGNAL ENVELOPE SHAPES AND OPTIMIZATION OF MOTOR PERFORMANCE

L. Stark, S. Lehman* and T. Waite*
Neurology Laboratory, University of California, Berkeley 94720

Optimization was early applied to physical systems using Euler's calculus of variations. Bellman-Pontriagin optimization theory employs control signal variations to achieve optimal performance for a fixed plant and a particular optimality criterion. Dynamical behavior of saccadic eye movements when measured precisely achieves enough observability to define the controller signals by means of inverse modelling. Assuming a time optimality criterion, detailed studies of first, second and third order controller signals have been performed (Cook, Clark, Lehman, and Stark). New behavioral properties of saccades such as dynamical overshoots, have been explained. Unfortunately animal nerve impulse recordings have been both inadequately sampled and have not been oriented toward contributing to this problem. Again for optimization studies on human locomotion, there is only sparse controller signal data (Pedotti, Krishnan and Stark). Recent experiments on the 'saccadic' trajectories of head movements have provided us with considerable amounts of EMG, behavioral, and modelling data (Zangemeister et al). The controller signals for fast head movements appear to be fourth order. Ensemble averaging of pre-edited EMG signals provide direct evidence for this. In addition, confirming inverse modelling evidence has been obtained in a similar manner to that in the eye movement studies.

100.11 LESIONS IN AVIAN ACCESSORY OPTIC SYSTEM SEVERELY DISRUPT OPTOKINETIC NYSTAGMUS IN NON-HORIZONTAL DIRECTIONS. Josh Wallman, Jose Velez* and Olivia C. McKenna. Biology Dept., City College, City University of N.Y., New York, N.Y. 10031.

A major role of the accessory optic system appears to be the signalling of information about the movement of the visual world (retinal slip) to the brain. Indeed, the accessory optic system seems to provide the major source of visual afference for non-horizontal optokinetic eye movements. These assertions are based on evidence of appropriate single unit characteristics and appropriate anatomical projections in both mammals and birds. We report here additional evidence resulting from the effects of lesions to the accessory optic system of birds.

Stereotaxic electrolytic lesions were made in the nucleus of the basal optic root (nBOR; also called ectomamillary nucleus) of chickens. The optokinetic eye movements were evaluated by measuring the average slow phase velocity of optokinetic nystagmus (OKN) to stimuli moving in each horizontal direction at a number of different stimulus speeds and to stimuli moving in various non-horizontal directions ranging from vertical to torsional.

The results were that complete lesions of nBOR proper and of its dorsal cap resulted in virtually complete loss of OKN to stimulus movement in vertical, torsional and intermediate directions. Partial lesions of nBOR proper caused changes in the relative sensitivity to stimulus movement in different directions. In most cases, even with the complete lesions, the deficits were accompanied by horizontal OKN within the normal range. (We are uncertain at this point about the effect of lesions of nBOR lateralis, which may be homologous to the mammalian dorsal terminal nucleus and which, along with a pretectal nucleus, probably signals horizontal retinal slip.)

These results support neurophysiological and anatomical evidence for the accessory optic system being the principal source of non-horizontal retinal slip signals to the oculomotor system; furthermore, they demonstrate the relative independence of the afferent subsystems concerned with different directions of retinal slip. (Supported by NIH EY-2937.)

100.12 VISUAL TRACKING IN CHICKENS. D. W. Pratt* (Spon: M. Romagnano) Dept. Biology, City College, CUNY, New York, N. Y. 10031.

The head and eye movements used by chickens to maintain fixation of moving objects were examined by cinematography. Chickens were filmed as they pecked at individual food pellets moving past them on a conveyor belt. Both linear horizontal and sinusoidal horizontal motion were used. Stimulus velocities from 3°/sec. to 130°/sec. were used. The photographic measurement technique has an angular resolution of better than 50' of arc and a bandwidth of up to 64 Hz. Pellets were tracked under all conditions as indicated by the fact that the chickens pecked accurately at them.

During tracking the head movements follow the pellet's movements. The angular change in the horizontal head position follows the angular change in the direction of the pellet from the head. Saccadic eye movements are used to change the direction of gaze. Between saccades the eyes compensate for angular head movements and maintain the direction of gaze in space. The pellet's image therefore moves across the retina. The chickens do not show an optokinetic response to this movement Smooth pursuit eye movements were not seen at stimulus. velocities down to 3°/sec.

101.1 DIFFERENTIAL BINDING OF LOTUS TETRAGONOLOBUS AND ULEX EUROPEUS LECTINS TO FUCOSYL-GLYCOCONJUGATES ON RAT CEREBELLAR CELL SURFACES. Lee N. Minier, Paul F. Erickson and Robert S. Lasher. Anatomy Dept., Univ. Colo. Hlth. Sci. Ctr., Denver, CO 80262

Several roles have been postulated for the various glycoconjugates (glycoproteins in particular) which are known to be components of the external neuronal cell surface. Among those functions suggested are involvement in the processes of cell recognition, cell-substrate adhesion, memory and synaptogenesis. During the course of our studies on the composition of the neuronal cell surface, we investigated the binding patterns of several plant lectins to rat cerebellar cells maintained in dispersed cell culture. With respect to the distribution of fucosyl residues on cerebellar neuronal and nonneuronal cell surfaces, two distinct binding patterns were observed for the lectins derived from Lotus tetragonolobus (Lotus A) and Ulex europeus (UEA), both of which have been shown to have binding specificities for α-L-fucose. Dispersed cell cultures prepared from 2-day old rat cerebellums were grown on glass coverslips for periods between 4 and 28 days. Selected cultures of various ages were washed with Saline G and were incubated for 15 min in solutions of Lotus A or UEA that had been radiolabeled with NaI^{125}. Control incubations included the presence of 0.1M α-L-fucose in the wash and incubation steps. The cells were washed, fixed in 2% paraformaldehyde, and then were processed for light microscope radioautography. The resultant radioautographs indicated that Lotus A bound almost exclusively to the neuronal cell aggregates in the cultures at all time points investigated. In particular, the grain density appeared to be greatest over the interconnecting fiber fascicles and neuropil comprising the central portion of the aggregates. Most nonneuronal cells exhibited surface labeling only marginally greater than background. The presence of α-L-fucose in the reaction medium completely inhibited binding of the radiolabeled lectin. Conversely, parallel experiments indicated that UEA did not bind to any appreciable extent to the surfaces of either neuronal or nonneuronal cells. Allied experiments showed conclusively that radiolabeling had not altered the biological activity of either lectin. In efforts to determine the nature of the fucosyl-conjugates detected by Lotus A, cerebellar cells at different ages were incubated in medium containing H^3-fucose. Radioautographs of these cells prepared for light microscopy revealed that fucose was preferentially incorporated into the processes and neuropil of the neuronal cells; little carbohydrate was taken up by nonneuronal cells. Preliminary studies using polyacrylamide gel electrophoretic methods have indicated that the H^3-fucose was incorporated primarily into 4-5 major polypeptide groups. (Supported by NIH Grants NS-13133 and NS-09199 (RSL)).

101.2 LECTIN RECEPTORS IN COCKROACH MUSCLES: DISTRIBUTION AMONG VARIOUS MUSCLES AND CHANGES AFTER DENERVATION. J. L. Eastburn*, R. T. Caldwell*, and J. L. Denburg. Zoology Department, Univ. of Iowa, Iowa City, Iowa 52242.

We have been studying the reformation of connections between axotomized, identified motor neurons and leg muscles in the cockroach, Periplaneta americana, the end result of which is the original innervation pattern. A role for cell surface glycoproteins in this possible intercellular recognition is examined by determining whether the various muscles possess different glycoproteins on their surfaces and whether there are any changes in these glycoproteins upon denervation. The presence of glycoproteins is detected by the binding of fluorescent derivatives of an array of plant lectins to frozen sections of muscles and to muscle proteins in SDS polyacrylamide gels after fractionation by electrophoresis.

The set of six coxal depressor muscles (CDMs) were studied in detail. It is composed of muscles 178 and 179 innervated by a single motor neuron, D_f; muscles 177d and e innervated by motor neuron D_s; muscles 177d' and e' in which every fiber is innervated by both D_f and D_s. These muscles are readily identified in frozen sections of the coxal segment of the leg. Fluorescent derivatives of all lectins which bound to these sections did so only to the cell surfaces and extracellular matrix. Lectins with binding sites for α-D-mannosyl and α-D-glucosyl residues and wheat germ agglutinin with a specificity for N-acetylglucosamine bind uniformly to all CDMs. Lectins from peanut, soybean and Bandieraea simplicifolia which recognize terminal α-D-galactose also bind to each of the CDMs but in different amounts. Binding to 177d',e'> 177d,e > 178,179. Binding of all lectins except WGA was totally eliminated in the presence of 0.5M sugars that are specific for each site. No binding was detected of the lectins from Dolichos biflorus, Ricinus communis and Ulex europaeus. These results of the histochemical examination are confirmed by the biochemical analysis of lectin receptors after fractionation by SDS polyacrylamide gel electrophoresis. However, it is additionally demonstrated that for lectins like ConA, which bind uniformly to all muscles, there are qualitative and quantitative differences in the population of glycoprotein receptors among the CDMs. These receptors may be classified according to their distribution among the CDMs and by the various effects which denervation has on their levels. Some of the characteristics found in these receptors might be expected to be expressed by macromolecules either involved in cell adhesion or cell recognition or affected by trophic interactions between the cells. (Funded by PHS research grants NS 14295 and NS 15350)

101.3 LECTIN BINDING OF DEVELOPING MOUSE RETINA. J.C. Blanks and L.V. Johnson*. Doheny Eye Foundation and Departments of Ophthalmology and Anatomy, University of Southern California, Los Angeles, CA.

Glycosylated cell surface macromolecules are likely to be of importance in the establishment of synaptic junctions. Consistent with such a role are reports of age-related modifications in cellular glycoprotein composition during development of the central nervous system. The neural retina provides an ideal model for the study of cell differentiation and cell-cell interactions in development as it is comprised of a relatively small number of identifiable cell types arranged in discrete layers. In these studies, the carbohydrate composition of the early postnatal and adult mouse retina has been examined by the use of carbohydrate-specific lectins. A battery of 8 lectins of differing carbohydrate sequence specificities was employed; these included concanavalin A (Con A), wheat germ agglutinin (WGA), soybean agglutinin (SBA), peanut agglutinin (PNA), Ulex uropeaus agglutinin (UEA), Ricinus communis agglutinin I (RCA), Dolichos biflorus agglutinin (DBA) and Limulus polyhemus agglutinin (LPA). Unfixed frozen sections (8-10 μm) of adult and early postnatal (days 0-18) mouse retina were treated with fluorescin isothiocyanate conjugated lectins and examined by fluorescence microscopy.

The results obtained reveal selective lectin binding by all retinal layers in the adult and throughout postnatal development. In general, an increase in the intensity of fluorescent staining by Con A (α-D-Glu, α-D-Man), WGA (β-D-NAcGlc), DBA (α-NAcGal), LPA (sialic acid) and UEA (α-L-fucose) is observed in association with retinal development, suggesting an increase in the expression or accessibility of complex carbohydrates. SBA (α or β-D-Gal, α-NAcGal) and PNA (Gal-GalNAc) show little to no binding to retinal layers but are bound by scleral components. All lectins binding to retinal layers show some degree of reactivity with rod inner segment regions. However, only Con A and WGA bind to rod outer segments, suggesting a significant alteration in the glycosylated components of outer segment membrane. Another striking observation is the appearance of intense fluorescent staining of the ganglion cell and inner nuclear layers by LPA during development. Concomitantly, an almost complete lack of detectable LPA binding is observed on establishment of the inner synaptic layer. These results indicate that sialic acid moieties may be of importance in establishing the structural and functional integrity of this portion of the retina. Current studies are analyzing the relationship between membrane density and the intensity of fluorescent lectin staining in the various layers of the developing retina. Retinal degenerative mutants are also being examined to determine if abnormalities in carbohydrate composition are detectable.

101.4 BRAIN GANGLIOSIDES: CONTENT AND PATTERN IN FROG, TOAD, AND SALAMANDER. L.N. Irwin. Dept. Biol., Simmons College, Boston MA 02115.

Gangliosides are cell-surface macromolecules of unknown function concentrated in brain tissue. Their content and pattern are known to vary phylogenetically but the extent of this variation has not been systematically studied below the class level; therefore, I have analyzed the content and pattern of brain gangliosides from five amphibian species. Wole brains were collected from three anurans -- Rana pipiens, Bufo marinus, Xenopus laevis -- and two salamanders -- Ambystoma tigrinum (At) and Necturus maculosa (Nm). Gangliosides were isolated from a total lipid extract (Irwin & Irwin. Anal. Biochem. 94:335) and quantified by a thiobarbituric acid assay for sialic acid. Ganglioside patterns were developed by thin-layer chromatography and quantified by scanning densitometry. Total ganglioside content was similar in all five species, with the two salamanders yielding the highest (362 μg/g wet weight for At) and lowest (176 μg/g wet weight for Nm) values. The chromatographic separations for gangliosides showed two distinct qualitative patterns. For the three anurans, the ganglioside pattern was dominated by three bands migrating at the rate of the mammalian disialoganglioside D1b or slower, as previously observed by several workers. However, both salamanders showed a distinctly more mammalian-like pattern, with 30% (At) and 47% (Nm) of total ganglioside sialic acid comigrating with the mammalian disialoganglioside D1a. This suggests that the preponderance of slowly-migrating gangliosides usually reported for frogs may not be typical of amphibian gangliosides generally. Among the three anurans, and between the two salamanders, quantitative differences in ganglioside pattern were also noted, suggesting that ganglioside patterns may be more variable, and hence of greater taxonomic significance, at the infraclass level than previously assumed. It also follows that a systematic study of ganglioside diversity as a function of phylogenetic, ontogenetic, and ecological variables may shed light on the biological role of these molecules. (Supported by grants from NIH and the Simmons College Fund for Research.)

101.5 THE STRUCTURE OF THE EXTRACELLULAR MATRIX ASSOCIATED WITH AXONS DIFFERS IN NERVE AND MUSCLE. D.P. Kuffler, Dept of Neurobiology Stanford Univ. Sch. of Med., Stanford, Calif. 94305

The extracellular matrix (ECM) of nerve and muscle plays an important role in the regeneration of the neuromuscular junction after trauma. To learn more about the ECM of axons I examined the organization of the ECM associated with different types of axons that innervate frog cutaneous pectoris muscle. I found that axons, regardless of type, have a different sheath of ECM when they are in nerve bundles than when they are free within muscle.

Frog peripheral nerves are enclosed by perineurium and each axon is ensheathed by Schwann cell processes. Surrounding each Schwann cell is a 20 nm thick basal lamina, an anatomically well defined component of the ECM. Within muscles the axons exit from the perineurium to run free for varying distances before terminating. At the point of exit from the perineurium the myelinated motor axons lose their myelin, but retain a Schwann cell sheath as do the unmyelinated autonomic axons. I found that at points of exit from the perineurium the Schwann cells of both the myelinated and unmyelinated axons acquire a dense particulate layer of extracellular matrix that extends the entire length of the axon and ranges up to 2 um thick. At the neuromuscular junction this thick particulate layer blankets the Schwann cell cap of the axon terminal. The particulate material is sparsely invested with collagen fibrils except at its perimeter; thus it forms a well-defined extracellular structure around each free axon.

Additional observations include: 1) A thick coat of material similar to that of free axons surrounds capillaries and certain other cells within the muscle, but is not found in extrajunctional regions of myofibers which have a basal lamina a few 10's of nm thick. 2) A basal lamina-like structure around free axons was best and most consistently seen in preparations where the ECM was poorly fixed and much of the thick particulate coat had "washed out"; perhaps the thick ECM coat of free axons is an expansion of the basal lamina characteristic of axons in nerves. 3) The thick ECM coat is stable in the absence of cells; it persists for months after removal of myofibers, axon terminals and Schwann cells from the neuromuscular junctions.

One explanation of these findings is that the characteristics of extracellular matrix around axons and their Schwann cells is influenced by the axon's environment which differs inside and outside a nerve. Alternately, the Schwann cells inside and outside a nerve may be of different types. (Supported by a USPHS NRSA Postdoctoral fellowship, and USPHS Grant NS14506.)

101.6 STUDIES ON THE SYNAPTIC BASAL LAMINA FROM THE ELECTRIC ORGAN. Bernardita Mendez* and Nibaldo C. Inestrosa*.(SPON.Ralph J. Greenspan). Division of Neurobiology, University of California, San Francisco, CA 94143, USA and Lab. Neurophysiology, Catholic University, P.O.Box 114-D, Santiago, CHILE .

Recent evidence suggests that the synaptic basal lamina (BL) may contain specific sites for the anchorage of the acetylcholinesterase (AChE) and some of its components may serve important regulatory roles in the pre- and postsynaptic differentiation of previously formed neuromuscular structures. However, no direct biochemical demonstration has been provided for the association of the collagen tailed forms of AChE with the BL,nor has formal characterization of the molecules involved in these functions been achieved. We report here experiments on the relationship between the asymmetric AChE forms and BL components, as well as a preliminary characterization of the polypeptide composition of the BL from the electric organ, a rich source of synaptic macromolecules.

BL was purified from Electrophorus electricus, Torpedo californica and Discopyge tschudi. The AChE molecular forms were characterized by sucrose gradient analysis.

Results indicate that the asymmetric AChE form (A_{12}) copurifies with a crude BL fraction obtained by subcellular fractionation followed by discontinuous sucrose gradient (17-60%). Eighty percent of the AChE activity remains in this fraction after treatment with Triton X-100. Thus, these results provide direct biochemical evidence for the association of the A_{12} AChE form with the synaptic BL.

BL from Torpedo and Discopyge are closely related, containing fifteen percent of total AChE activity, the A_{12} AChE form and a similar pattern of peptides as visualized by SDS-polyacrylamide gel electrophoresis. Differences are observed with respect to Electrophorus BL, both in total AChE activity (30%) and in peptide composition. However, in BL from all three at least nine polypeptides are common and the three most prominent ones show similar molecular weights (200 K, 55 K and 47 K daltons) and could represent, together with A_{12} AChE, basic components of the postsynaptic BL. Partial purification of some of these peptides can be obtained by succesive salt treatments with 1M NaCl, 1M $MgCl_2$ and 4M Guanidine-HCl.

Current studies are directed to establish the collagenous and non-collagenous domain of the BL as well as to determine the identity of some of the peptides present in it.

101.7 GENERATION OF MONOCLONAL ANTIBODIES TO GALACTOCEREBROSIDE. A. Rostami*, P.A. Eccleston*, R.P. Lisak and D.H. Silberberg. Dept. of Neurology, Univ. of Pa. Med. Sch., Philadelphia, PA 19104.

Galactocerebroside (GalC) is a membrane glycolipid of glial cells. Rabbit anti-GalC has been used to identify oligodendroglia and Schwann cells in culture and to produce experimental demyelination in vivo and in vitro. These studies have been limited by the nature of polyclonal antisera which contain a family of antibodies, and by the inconsistency of titers of rabbit antisera. To circumvent these problems, we have produced monoclonal antibodies to GalC. BALB/c mice were repeatedly sensitized with bovine GalC in bovine serum albumin and complete Freund's adjuvant. Spleen cells from the sensitized animals were fused with a non-secreting mouse myeloma line (SP_2) using polyethylene glycol. Supernatants from the successful fusions were screened for the presence of anti-GalC antibody by a solid phase radioimmunoassay (RIA) which we developed, using ^{125}I-rabbit anti-mouse $F(ab')_2$ as second antibody. Four anti-GalC secreting hybrids were detected and one successfully cloned. The supernatants and ascitic fluids produced by injecting clones into BALB/c mice have high titer, consistent, and reproducible anti-GalC activity. Using immunofluorescence, the antibody binds only oligodendrocytes in rat central nervous system (CNS) culture as assessed with immunofluorescence. Double staining with rat anti-glial fibrillary acidic protein and anti-large external transforming substance antisera reveals no binding of monoclonal anti-GalC to astrocytes or fibroblasts. Schwann cells, but not fibroblasts, are stained in short-term cultures of rat Schwann cells. Similar percentages of oligodendrocytes were stained in 1, 3 and 7 day old rat CNS cultures with either monoclonal antibody or rabbit anti-GalC. Monoclonal anti-GalC binds strongly to GalC and monogalactosyldiglyceride, but not to ceramide, ganglioside and glucocerebroside in the RIA. These "immortal clones" are a supply of high titer, monospecific antibodies with constant biological properties. This monoclonal antibody should prove useful for highly specific cell surface identification, sorting, and studies of demyelination and related cytotoxicity.

101.8 ANTI-N6, AN ANTISERUM THAT SPECIFICALLY BINDS TO MANY TYPES OF NEURONS. William Stallcup*, Leslie Arner* and Joel Levine* (SPON: P. Brehm) Neurobiology Lab., Salk Institute, San Deigo, CA 92138

We have prepared antisera against PC12 cells in order to define cell surface antigens specific to neurons. The cellular specificity of the antisera was assessed by immunofluorescent staining of primary cultures of embryonic rat brain, cerebellum, and spinal cord and neonatal dorsal root (DRG) and superior cervical ganglia (SCG). Double label experiments using cell type specific markers [tetanus toxin for neurons (TT), anti-galactocerebroside for oligodendrocytes (GC), anti-glial fibrillary acidic protein for astrocytes (GFAP) and anti-fibronectin for fibroblasts] demonstrated that anti-PC12 specifically stains different types of neurons but does not react with astrocytes, oligodendrocytes or fibroblasts.

We immunized rabbits, mice, and guinea pigs with PC12 cells and absorbed the antisera with 2 glial cell lines, B9 and B92, and with the PC-G2 pheochromocytoma cell line. The resulting antisera, which we call anti-N6, react with both differentiated and undifferentiated PC12 cells as well as with process-bearing cells in primary cultures of embryonic cerebellum and brain. These N6 positive cells could not be labeled with anti-GC or anti-GFAP but were labeled with TT demonstrating that they are neurons. Anti-N6 binds to neurons in primary cultures of neonatal DRGs and SCGs and also stains adrenal chromaffin cells in culture. When anti-N6 was absorbed with adrenal medullary tissue, it no longer stained chromaffin cells but continued to stain central and peripheral neurons. Conversely, anti-N6 absorbed with particulate fractions of brain stained chromaffin cells but no longer stained neurons. Thus, anti-N6 defines at least 2 cell surface specificities; one found on neurons and one found on adrenal chromaffin cells.

To determine whether anti-N6 recognizes any proteins or glycoproteins on the cell surface, we prepared detergent extracts of 125-I labeled PC12 cells and subjected the extracts to immune precipitation. Autoradiographic analysis of SDS gels of the immune precipitates indicated that anti-N6 recognizes polypeptides with molecular weights of 230,000, 180,000, 170,000 and 140,000 daltons. The 230K component is likely to be a glycoprotein since it can be biosynthetically labeled with 14-C galactose. Anti-N6 precipitated polypeptides of similar molecular weights from extracts of labeled cerebellar, spinal and DRG neurons. Absorption with brain but not adrenal medulla removed the ability of anti-N6 to precipitate the 230K polypeptide. These results demonstrate that anti-N6 is a general surface marker for several different types of neurons. It is likely that a 230K glycoprotein is present on the surface of these neurons.

101.9 IMMUNOLOGICAL ANALYSIS OF HUMAN NEURONS. Lois A. Lampson* (SPON: E. Stellar). Dept. of Anatomy, Univ. of Penn. Sch. of Med., Philadelphia, PA 19104.

A panel of monoclonal antibodies that react with human neuroblastoma-derived cell lines has been raised. The majority also react with normal human brain, as well as normal nervous tissue of mice, rats, and cats. The majority retain their antibody activity after the target tissue has been fixed with 4% aldehydes. These properties have been exploited in two ways. (1) The antibodies have been used to visualize their antigens in well-fixed cat tissue at the light and EM level, using the unlabeled antibody peroxidase-antiperoxidase method of Sternberger. For example, antibodies that react with human neural tissue have been shown to label different parts of neurons, or selective populations of cells by using cat retina as the target tissue. (2) The antibodies have been used to characterize their antigens biochemically, using cell lines as a source of homogeneous material. This includes comparisons of the amount of antigen carried by different cell types, as well as gel analysis of the molecular weight and chain structures of the molecules. For example, the expression of the major histocompatibility antigens on cells of neuronal, glial and lymphoid origin have been compared.

Major obstacles to the systematic study of human neurons have been the difficulty of obtaining optimally preserved tissue, coupled to the more general problems of the heterogeneity of normal nervous tissue and the lack of mono-specific reagents. The abundance of monoclonal antibodies that react with well-fixed tissue of small animals as well as with human tissue and cell lines makes it possible to circumvent these problems, allowing both anatomical and biochemical analysis of normal human neuronal antigens.

101.10 EXPRESSION OF THE THY 1 ANTIGEN IN LONG-TERM CULTURES OF EMBRYONIC MOUSE SPINAL CORD R. H. Brown, Jr.,* J. S. Schweitzer,* and M. A. Dichter* (SPON: W. F. White). Mental Retardation Center, Children's Hospital, Boston, Ma. 02115

The theta or Thy 1 antigen is a cell surface differentiation molecule present on certain cell types including thymocytes, T-lymphocytes and neurons. It has been suggested that this molecule may facilitate cell-cell interactions. Several authors have reported its presence on neurons in short-term cultures and it has been detected transiently on cultured myoblasts prior to fusion. We have studied the time course of appearance of the theta antigen in long-term cultures of thirteen day fetal mouse spinal cord. We used indirect immunofluorescence with a monoclonal IgM antibody to Thy 1.2 and two cell markers, tetanus toxin and rabbit anti-glial fibrillary acidic protein (GFAP) which label neurons and astrocytes respectively. We observed:

(1) Neuronal Thy 1.2 antigen appears at seven days and is maximally evident (30% of neurons positive) at three weeks. This extent of neuronal positivity does not differ significantly from that seen after up to eight months. The positive neurons include several morphologies but most typical are large, multipolar cells, round cells resembling neurons in dorsal root ganglia and small, bipolar cells.

(2) Astrocytes, as defined by double labelling with anti-GFAP and anti-Thy 1.2, first express the Thy 1.2 antigen at four or five days. Maximum positivity (30 - 50% of astrocytes) occurs at three weeks and persists up to eight months or more.

(3) Within the first five days two cell types were Thy 1.2 positive: (a) flat, polygonal cells, often clustered and closely resembling those which eventually become GFAP positive, and (b) a smaller population of elongate, sometimes fusiform cells typically appearing at the periphery of the polygonal cell clusters.

(4) In general, neuronal growth is most dense around islands or clusters of astrocytes. In these regions the Thy 1.2 antigen is most abundant.

101.11 IMMUNOCHEMICAL STUDIES OF THE NERVE GROWTH FACTOR-INDUCIBLE LARGE EXTERNAL GLYCOPROTEIN (NILE). S.R.J. Salton*, L.A. Greene*, C. Richter-Landsberg* and M.L. Shelanski*(SPON: R. Margolis). NYU Sch. of Med., New York, NY 10016.

In the current studies, NGF-treated PC12 rat pheochromocytoma cells grown in monolayers were extracted with sodium deoxycholate and the extract enriched for glycoproteins by chromatography on wheat germ agglutinin columns. The resultant glycoproteins were further purified by SDS-polyacrylamide gel electrophoresis. The NILE (M=230kD) band was excised and used to raise an anti-serum. This antiserum (anti-230) selectively precipitated the NILE glycoprotein from a 2.5% Triton extract of PC12 cells which had been metabolically labeled for 72 hrs with ^{3}H-fucose. Rocket immunoelectrophoresis of PC12 cells grown for two weeks with NGF reveals a 3-4 fold increase in NILE per mg protein as compared to untreated cells. Triton extracts of cultured N115 neuroblastoma, rat sympathetic neurons and rat cerebellum all showed the presence of a cross-reactive immunoprecipitable glycoprotein of similar or slightly lower molecular weight. A soluble glycoprotein (M=210Kd) released into the medium by PC12 cells was also selectively precipitated by this serum. By indirect immunofluorescence, anti-NILE was localized on the cell surface of NGF-treated and -untreated PC12 cells in a widespread, somewhat granular pattern. N115 neuroblastoma, cultured rat sympathetic neurons and cultured rat cerebellum cells also stained positively for NILE. In cerebellum, the cells stained by anti-NILE were distinct from those labeled with anti-GFA in double-label studies. Cultured rat fibroblasts, gerbil fibroma cells and C_6 glioma cells lack surface NILE. Stretch preparations of rat iris show staining in a similar distribution as that found for formaldehyde-induced catecholamine fluorescence. Trypsinized PC12 cells show NILE staining. This is consistent with the precipitation of an immunoreactive 100,000 dalton carbohydrate-containing fragment from Triton-extracts of trypsinized cells. These data suggest that NILE is a widely distributed component of neuronal surfaces which is, as yet, functionally undefined. (Supported by grants NS15076, NS16036 from the NIH, the March of Dimes and the McKnight Foundation. S.R.J.S. is a MSTP Fellow.)

101.12 CHARACTERISTICS OF AN A_{12} FORM OF ACETYLCHOLINESTERASE IN C_2, A MOUSE MUSCLE CELL LINE. Nibaldo C. Inestrosa* and Zach W. Hall (SPON. Pamela D.Gorin).Division of Neurobiology, Univ. of Calif., San Francisco, CA 94143

In vertebrate muscles, a particular form (A_{12}) of acetylcholinesterase (AChE) is concentrated at the neuromuscular junction. The characteristic feature of this form is a long, collagen-like tail. Although circumstantial evidence suggests that A_{12} is associated with the basal lamina, there has been no direct demonstration of its cellular localization. We have found that C_2, a cell line derived from adult mouse skeletal muscle, accumulates the A_{12} AChE form in culture after myoblast fusion. We report here experiments on the localization of the enzyme and on its regulation.

The A_{12} AChE form is at the cell surface as evidenced by protection from DFP inactivation by the impermeable inhibitor BW-284c51, and solubilization by collagenase digestion. The A_{12} enzyme is extracted by high salt, but not by Triton X-100; thus, it is probably associated with the extracellular matrix. Histochemical localization of AChE reveals a patchy distribution of the surface enzyme. Collagenase digestion, which removes only the A_{12} form, abolishes this staining pattern, indicating that the patches consist of the A_{12} enzyme.

Muscle activity has been reported to be essential for the expression of AChE at developing nerve-muscle contacts and for the synthesis of the A_{12} form in rat primary muscle cultures. We examined the effect of muscle activity on A_{12} synthesis by C_2 cells. Spontaneous contractions were suppressed by blocking action potentials with 1uM TTX. This treatment resulted in a 40% decrease in total AChE activity, but all forms were equally affected. Thus the A_{12} AChE on C_2 myotubes is not selectively regulated by muscle activity, and does not require muscle activity for its expression.

We conclude that C_2 cells produce and secrete, or assemble in the extracellular matrix, an A_{12} AChE that resembles that found at adult endplates, although its mode of regulation may be different. We have reported elsewhere(Miller & Hall, these Abstracts) that these cells produce clusters of AChRs and also three antigens that are found in the basal lamina of synapses in adult muscle fibers (Inestrosa et al. (1981) J. Supra. Mol. Struct. 5:297). Thus, C_2 cells, in the absence of nerves produces several specialized postsynaptic components of the neuromuscular junction.

Supported by MDA,NIH,NSF,and postdoctoral fellowship from MDA to N.C.I. We thank to D.Yaffe for giving us the C_2 cell line.

101.13 REGULATION OF ACETYLCHOLINESTERASE (ACHE) FORMS IN QUAIL MUSCLE CULTURES. J.E. Bulger*(1), G.T. Patterson, W.R. Randall* and B.W. Wilson. Departments of Avian Sciences and Biochemistry and Biophysics(1), University of California, Davis, CA 95616.

Cultured Japanese quail muscle cells are one of the few systems reported to possess a high molecular weight form of ACHE (Emmerling et al. Soc. Neurosci. Abs. 5,479, 1970). This study confirms the presence of a 20S form of ACHE in cultured quail muscle, suggests that it is at the surface of the cells and shows its level can be regulated by factors in the sera used to grow the cells. Nine day old quail embryo pectoral muscle was dissociated into single cells and grown on collagen coated dishes in a medium of 10% horse serum, 2% quail embryo extract and 88% MEM. ACHE activity was determined by a radiometric method after extraction of the cells with a buffer containing 1M NaCl, 0.5% Triton X 100 and 0.2mM EDTA. When cultures grown 11-12 days in vitro were incubated for 24 hours in a medium lacking serum, extractable cell ACHE fell 21%, ACHE released to the medium fell 50% and incorporation of leucine into protein fell 43% compared to cells maintained in complete medium. Sucrose gradient centrifugation of control cell extracts showed three major peaks of ACHE activity with S values of approximately 7S, 12S and 20S. The amounts but not the sedimentation coefficients of the ACHE forms changed when the cells were incubated in serumless medium. Although the total amount of ACHE activity decreased, that portion attributable to the 20S ACHE form increased from an average value of 1.0×10^{-2} to 1.3×10^{-2} IU/dish. Activities of the smaller ($7S_2$ and 12S) ACHE forms decreased from 5.3×10^{-2} to 3.6×10^{-2} IU/dish in the same 3 experiments. 7S and 12S, but not 20S ACHE was released into the serumless media. Measuring the hydrolysis of acetylcholine by intact cells (Rotundo and Fambrough, Cell, 22, 583, 1980) provided evidence that the increase of 20S ACHE in cells kept in serumless media was due to increased accumulation of enzyme on the cell surface. Surface ACHE activity was 1.15±0.05 (SD) higher in cells incubated in serumless than in control medium. The results confirm the presence of a 20S ACHE form in quail mucle cultures and raise the possibility that factors in the sera are involved in the regulation of the synthesis and assembly of ACHE on the muscle cell surface during development. (Supported by NIH grant ES 00202 and the MDA).

101.14 COMPARISON OF PNS MYELIN SPECIFIC PROTEINS AND CELL SURFACE POLYPEPTIDES OF CULTURED SCHWANN CELLS. Jun E. Yoshino* and George H. DeVries (SPON: R. Krieg), Department of Biochemistry, Medical College of Virginia, Richmond, Virginia 23298

Our laboratory previously reported the ability of axolemma-enriched fractions isolated from both CNS and PNS tissue to stimulate the proliferation of quiescent cultures of Schwann cells (Minier and DeVries, Soc. Neurosci. Abstr. 7, 550, 1980; Yoshino and DeVries, Trans. Am. Soc. Neurochem. 12, 200, 1981). In order to study the molecular changes which the surface of the Schwann cells undergoes during proliferation, the polypeptide composition of quiescent Schwann cell populations was determined by radiolabeling with ^{125}I. Primary cultures of Schwann cells were prepared from dissociated sciatic nerves of newborn rat pups using a modification of the procedures of Brockes et al. (Br. Res. 165, 105, 1979). The polypeptides on the surface of the Schwann cells were labeled by both lactoperoxidase and Iodogen catalyzed iodination. Analysis of the iodinated proteins by autoradiography after SDS-polyacrylamide gel electrophoresis (PAGE) revealed no difference in the polypeptides which were labeled by the two techniques. Eight polypeptides of molecular weights 160K, 82K, 70K, 45K, 40K, 32K, 28K and 15K were identified on the surface of the Schwann cells. However, after a week in culture the 160K protein was no longer accessible to labeling with ^{125}I, and the ^{125}I labeling of the 82K polypeptide band was also diminished. The two most rapidly migrating polypeptides possessed molecular weights similar to the peripheral myelin proteins, P_o and P_r. In order to determine whether the 28K and 15K polypeptides were related to either P_o or P_r, the iodinated peptide maps generated by trypsin digestion were examined using the procedures of Elder et al. (JBC 252, 6510, 1977). The location of the two labeled Schwann cell polypeptides was determined by radioautography, and the proteins were excised from the gel and re-iodinated. P_r, obtained from peripheral myelin after SDS-PAGE, and purified P_o were also iodinated as standards. Examination of the two dimentional peptide maps generated by P_o and the 28K polypeptide as well as P_r and the 15K protein did not reveal any significant homology between the myelin specific proteins and the polypeptides present on Schwann cell membranes. The inability to detect myelin proteins on the surface of quiescent cultures of Schwann cells by labeling with ^{125}I is in agreement with the results obtained by Brockes et al., who reported a lack of immunoreactive antigens on cultured Schwann cells using specific antibodies directed against P_o and P_r (J. Neurocyto. 9, 67, 1980). (Supported by NIH grant NS 15408-02)

101.15 FIBRONECTIN AND SURFACE SPECIALIZATIONS ON CULTURED CHICK MYOTUBES. Thomas G. Burrage and Thomas L. Lentz. Section of Cell Biology, Yale University School of Medicine, New Haven, CT 06510.

Surface specializations or patches consisting of a thickened plasmalemma, subsarcolemmal density, and amorphous surface coat occur on intact and cultured myotubes and contain a high density of acetylcholine receptors (Burrage and Lentz, 1981, Dev. Biol., in press). To characterize these patches further, we have studied the distribution of fibronectin, a cell surface glycoprotein involved in cell adhesion. An antibody to fibronectin was incubated with chick myotubes cultured for 6 days and localized at the electron microscope level with a ferritin-labeled antibody. Fibronectin was localized in a discontinuous fashion on the myotube surface. It occurred in the heaviest concentration in association with the well developed extraneous matrix where the cells were in close proximity to the substrate. Ferritin label also occurred in high density in the extraneous material of the specialized patches located elsewhere on the surface. It was not restricted to patches and occurred less densely in small, discontinuous clusters along the plasmalemma of the entire cell surface. Double labeling of the myotubes with a horseradish peroxidase-α-bungarotoxin conjugate (HRP-α-BTX) and fibronectin antibody revealed a co-localization of regions of high density acetylcholine receptors and fibronectin. Patches binding the HRP-α-BTX conjugate also bound fibronectin antibody, but the latter had a wider distribution and occurred in patches and on unspecialized cell surface which did not bind the conjugate. The presence of the greatest amounts of fibronectin in specialized patches of the myotube surface indicates these regions may be preferential sites of adhesion, either to the substrate or an advancing nerve. However, the ubiquity of the fibronectin on the surface indicates that other factors are involved in the localization of a high density of receptors and in specifying the site of innervation. (Supported by NIH fellowship F32-NS06144 and NSF grant BNS 80-18520).

101.16 SURFACE REPLICA TOPOGRAPHY OF RETINAL PIGMENT EPITHELIUM. Barbara J. McLaughlin and Lou G. Boykins*. Department of Anatomy. University of Tennessee Center for the Health Sciences, Memphis, TN 38163

Retinal pigment epithelial cells (PE) are phagocytic cells which continually phagocytize specific particles, namely photoreceptor outer segments (OS). The initial phagocytic step is thought to be mediated by complementary recognition molecules on the PE microvillous and OS membrane surfaces, which may also display a characteristic surface morphology. In order to explore this possibility we have studied surface replicas of the PE apical membrane surface and microvillous membranes from retinas of Long-Evans rats. Retinas are dissected in RPMI 1640 medium with Hepes buffer and the PE cell layer is detached from the neural retina and glued to a cover slip (microvillous border up) and fixed for 1 hr in 2% glutaraldehyde and 0.5% osmium in 0.1M sodium cacodylate buffer, dehydrated in graded methanol and critically point dried. The tissue is replicated in a Balzer's freeze-fracture apparatus using either rotary or unidirectional platinum coating and then digested and the surface replicas examined in the electron microscope. Corresponding blocks of the PE cell layer are also processed for EM thin sectioning and stained in heated uranyl acetate to enhance membrane surfaces for comparison with surface replica topography. The replicated PE topography is characterized by circular bumps (35 nM in diameter) irregularly dispersed on the apical membrane surface. The PE microvilli exhibit more numerous and densely packed bumps along their entire membrane surfaces, giving a "cobblestone" appearance to the surface topography. When viewed on their surface these bumps measure approximately 50 nM in diameter and when viewed from a side angle the bumps measure approximately 20 nM. Thin sections of the replicated PE cell layer show periodic tufts of electron-dense material along the microvillous membranes which may correspond to the microvillous cobblestones observed in surface replicas. The tufts measure between 30-35 nM wide and protrude 20 nM from the membrane surface. Previous studies in our lab using lectin cytochemistry have demonstrated periodic labeling of these tufts along retinal PE microvilli (Wood and McLaughlin, Invest. Ophthal. Vis. Sci. 19:728-742, 1980) which suggests that they are glycoconjugates. Future studies will be aimed at defining the nature and function of these PE surface features and their relation to phagocytic recognition in the retina. Supported by USPHS EY 02853.

101.18 EXFOLIATION AND REPLACEMENT OF PLASMA MEMBRANE ECTO-5'-NUCLEOTIDASE IN CULTURED BRAIN CELLS. Norman Salem, Jr.* and Eberhard G. Trams* (SPON: M. Goldstein). NINCDS, NIH, Bethesda, MD 20205

C6 glioblastoma cells express about half of their 5-nucleotidase activity as an ecto-enzyme. Membrane derived microvesicles or "exosomes" are released from cells in culture containing ecto-enzymes. The membrane impermeant trinitrobenzenesulfonic acid (TNBS) irreversibly reacts with and inactivates ecto-5'-nucleotidase and was used to study 5'-nucleotidase metabolism and its regulation. C6 (rat brain) glioblastoma monolayer cultures were washed and treated with 0.5 mM TNBS for 15 min at 37°C and pH 8.1. Reagent was removed, cells washed, and the usual growth media was added for 0-72 hrs before enzyme assay. Monolayer ecto-5'-nucleotidase activity was assayed by measurement of ^{32}P released from ^{32}P-AMP. We found that 70-80% of ecto-5'-nucleotidase activity was lost after this treatment but that the cells were viable as measured by trypan blue staining, containment of intracellular LDH, incorporation of ^{3}H-thymidine into DNA, and cell growth. This inactivation was selective because ecto-ATPase was only slightly inactivated and acetylcholinesterase remained unaffected. After 24 hrs of incubation with growth medium C6 cell ecto-5'-nucleotidase activity had nearly recovered (88±4% of control). Fetal calf serum was not necessary for recovery as cells deprived of serum for three days also recovered activity. The rate of increase in ecto-5'-nucleotidase activity of TNBS treated cells exceeded that of control cells but there was no general increase in membrane biosynthesis as evidenced by normal specific binding of ^{125}I-cholera toxin to GM_1. There was no recovery of surface activity in the presence of the protein synthesis inhibitor cycloheximide (0.2 ug/ml) but recovery began when cycloheximide was removed. TNBS treatment causes a concomittant loss in exosomal 5'-nucleotidase during the active recovery period but exfoliated enzyme activity approaches normal levels as the membrane enzyme recovers. Exosome production is normal during the recovery period as measured by GM_1 and protein content. Our data indicate that ecto-5'-nucleotidase replacement occurs via de novo synthesis rather than by insertion of preformed enzyme. Decrease in exfoliated 5'-nucleotidase activity indicates either release of inactivated plasma membrane enzyme or a selective conservation of the enzyme in the exfoliative process.

101.19 "SEROTONECTIN": EVIDENCE FOR THE LOCALIZATION OF THIS SEROTONIN-BINDING GLYCOPROTEIN TO PLATELET PLASMA MEMBRANE AND ITS INVOLVEMENT IN SEROTONIN UPTAKE. W.J. Kupsky*, M.D. Gershon, Y.L. Huang* and H. Tamir, Dept. of Anat., Columbia Univ., Coll. of P&S and N.Y. State Psych. Inst., New York, NY 10032.

Cells that store serotonin have been found to contain serotonin-binding proteins. These proteins differ and can be categorized according to the developmental origin of the serotonin-containing cell; thus, the neuroectodermal serotonin-binding protein, found in central and enteric serotonergic neurons, differs from the serotonin-binding proteins of platelets, mast cells, and enterochromaffin cells, and these, in turn, differ from one another. Platelets, because of their ability to take up serotonin, are often considered models of neurons. One of the two platelet proteins that bind serotonin is a glycoprotein (K_D = 10nM). We have purified this protein by molecular sieve chromatography, affinity chromatography (using a Con-A-sepharose column) and gel electrophoresis. Rabbit antibodies were raised against this protein and were shown to be specific by testing on Ouchterlony plates and by rocket immunoelectrophoresis. We propose to call this protein serotonectin. Serotonectin-like material was localized immunocytochemically in rat platelets using the unlabeled antibody PAP bridge technique. Platelets were examined by light and electron microscopy. Serotonectin immunoreactivity was found to be associated with the platelet plasma membrane. Gentle washing of platelets with salt solution (Krebs) removed up to 76% of the extractable serotonectin present in platelet suspensions. Washing, in contrast, released no detectable lactic dehydrogenase and removed less than 25% of the intracellular serotonin-binding platelet albumin. Antibody to serotonectin (4.5 mg/ml of the gamma globulin fraction of immune sera) inhibited the uptake of ^{3}H-serotonin (0.2 uM) by rat platelets. These data suggest that serotonectin is present on the external surface of platelet plasma membranes; however, it is probably not an integral membrane protein. Serotonectin seems, nevertheless, to be involved in platelet uptake of serotonin. Supported by grants, NSF 09335, NS07062, NS12969.

102.1 CHOLINE UPTAKE IN CULTURED Y79 RETINOBLASTOMA CELLS:EFFECT OF MEMBRANE POLYUNSATURATED FATTY ACID COMPOSITIONAL CHANGES.
B.T. Hyman* and A.A. Spector* (SPON: R.E. Fellows)
Dept. Biochemistry, University of Iowa College of Medicine, Iowa City, Iowa 52242.

Neural tissue membranes are highly enriched in essential polyunsaturated fatty acids, especially arachidonic acid (20:4 n-6) and docosahexaenoic acid (22:6 n-3). However, the functional significance of these polyunsaturates is unknown. In an attempt to elucidate the functional significance of the high polyunsaturated fatty acid content on membrane-related processes in neural tissues, we have examined the effect of changes in polyunsaturated fatty acid content on the transport of choline in cultured human Y79 retinoblastoma cells. When grown in fetal calf serum, the phospholipid composition of these cells of neural origin is low in polyunsaturates. By contrast, when grown in a medium supplemented with polyunsaturated fatty acids, the phospholipid composition of the cells can be enriched with varying amounts of the unsaturates of the n-9, n-6, and n-3 families. In this way, the average number of double bonds of the fatty acids present in a membrane-enriched microsomal preparation can be increased by over 50%. Choline uptake in these cells occurs by at least two kinetically distinguishable processes, classified as high affinity (K_m' = 2.2±0.13 μM, V_{max}' = 27.0±2.9 pmol $min^{-1}mg^{-1}$) and low affinity (K_m' = 20.4±1.2 μM, V_{max}' = 402±49.1 pmol $min^{-1}mg^{-1}$) (mean ± SE; n = 4). The kinetic parameters for high affinity choline uptake were altered when the cells were enriched with essential polyunsaturates of the n-6 or n-3 classes, but they were not different from control values when cells were enriched with the nonessential n-9 class of unsaturated fatty acids. The K_m' of the high affinity system decreased to 0.89±0.05 μM when the cells were grown in a medium supplemented with an n-3 precursor, linolenic acid (18:3 n-3), to 1.01±0.19 μM with docosahexaenoic acid, and to 1.25±0.08 μM with arachidonic acid. The V_{max}' also decreased in cells which had been enriched in essential polyunsaturates, but the decrease was significant only in the case of arachidonic acid supplementation (15.8±1.0 pmol min^{-1} mg^{-1}). Supplementation with oleic acid (18:1 n-9) produced no change in either the average number of double bonds per fatty acid or in these kinetic parameters. These findings suggest that one effect of the large amount of essential polyunsaturates in neural tissue membranes if the facilitation of choline uptake at low concentrations. Further this facilitation is a property of both the n-3 and n-6 classes of essential polyunsaturated fatty acids. (Supported by research grants HL14,781 and GM07331).

102.2 MEMBRANE SUBFRACTIONS FROM PURIFIED OLIGODENDROGLIA IN CULTURE.
S. E. Poduslo. Dept. of Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Oligodendroglia, isolated in bulk from subcortical white matter from adult bovine brain, can be maintained as suspension cultures. While in culture they produce whorls of membrane lamellae adjacent to the cell soma. The cells remain in good health during this event, are metabolically very active, and synthesize a variety of lipids and proteins, especially lipids found in myelin. When subcellular fractions are prepared from the cells in culture, three membrane subfractions are obtained. These are a glial light fraction (at 0.32 M sucrose) consisting of large vesicles; an intermediate fraction (at 0.5-0.6 M sucrose) that contains whorls of membrane lamellae; and a plasma membrane fraction (at 1.0 M sucrose) consisting primarily of small vesicles. The intermediate subfraction is enriched in 2',3'-cyclic nucleotide 3'-phosphodiesterase while the plasma membrane subfraction is enriched in Na^+, K^+-ATPase and 5'-nucleotidase.

Gradient slab gel electrophoresis was used for analysis of the proteins in the plasma membranes and the intermediate subfractions. Coomassie stained gel patterns of the plasma membranes show a minimum of 40-50 proteins with average approximate molecular weights ranging from >200,000 to 12,500. Some 15 proteins are more prominently stained in this subfraction. The membrane lamellae subfraction has fewer prominently stained bands. Autoradiography was used to detect binding of radioiodinated lectins to glycoproteins after electrophoretic separation on the gradient slab gels. Multiple glycoproteins were observed. Thus both membrane subfractions are complex structures composed of a heterogeneous mixture of proteins and glycoproteins. In general the membrane lamellae produced in culture tend to have a somewhat less complicated pattern with fewer proteins and glycoproteins than the plasma membranes. (Supported by funds from the Kroc Foundation, the Multiple Sclerosis Society and NS-14577)

102.3 DOES TRANSMETHYLATION INCREASE FLUIDITY OF ONE LEAFLET WHILE INCREASING THE VISCOSITY OF THE OTHER? Rodman G. Miller
Dept. of Anat.,Univ.of Calgary Med. Sch.,Alberta,T2N 1N4 Canada

Hirata and Axelrod (see Nature 275:219,1978 and 288:278,1980) have correlated adrenergic receptor binding, phosphatidylethanolamine methylation and translocation (transmethylation, TM)across the membrane with a decrease in RBC ghost membrane viscosity (measured with diphenyl hexatrine, DPH). They propose changes in membrane viscosity are responsible for subsequent effects of receptor activation. Vance and Kruijff (Nature 228:277,1980) have questioned whether the change in viscosity (1.6 to 1.1 poise) could be brought about by the observed degree of TM (less than .01% of membrane lipids). This report indicates how even a small ammount of TM could produce a large effect on the apparent membrane viscosity as measured with DPH.

At the center of the controversy is the use of DPH to measure viscosity. DPH is shorter than palmitic acid and thus a DPH molecule will reflect the microviscosity within a single leaflet. DPH should partition into the leaflet with the lowest surface tension. In general, this leaflet will have the greater fluidity.

TM will alter the surface tension of the two leaflets. The effect of translocation of less than .01% of the total surface area from one leaflet to the other is difficult to assess precisely. However, the proportion of the membrane which is reactive to changes in surface tension (i.e.can stretch to fill in) and accessible to DPH can be estimated at much less than 28%: 50% of the RBC ghost surface area is protein and 22% is occupied by nonsterol lipids bound to protein (figures computed from freeze fracture morphometry assuming that all proteins observed as particles traverse the membrane). Thus 72% of the surface should not react to changes in surface tension and should exclude DPH. In the remaining 28% of the membrane, slightly over half of the lipid is cholesterol (.35nm^2) which binds to phospholipids (.63nm^2) to form a complex (.82nm^2). This large condensing effect of cholesterol suggests that the complex should be rather rigid, not very reactive to surface tension changes and, again,will exclude DPH.

If the RBC membrane is composed of units which are as rigid as this would suggest, small ammounts of TM could have a profound effect on microviscosity as measured by DPH. One leaflet will become more viscous while the other more fluid. DPH, however, allows us to observe only the latter leaflet. This analysis suggests that DPH may a general probe for detection of alterations in membrane lipid symmetry.

102.4 SUBSTRUCTURE IN ASTROCYTIC ASSEMBLIES DEMONSTRATED BY RAPID FREEZING AND LOW-TEMPERATURE FREEZE FRACTURING.
D.M.D. Landis, T.S. Reese, R.L. Ornberg, and W.F. Graham. Dept. Neurology, Harvard Medical School, Boston, MA 02114; LNNS, NINCDS, NIH, Bethesda, MD 20205.

Freeze fracture techniques reveal that mammalian astrocytic plasmalemma contains rectangular or square aggregates of uniform, small particles packed in orthogonal array. We have examined the structure of these aggregates, termed "assemblies," in cerebellar tissue rapidly frozen by contact against a copper block cooled by liquid helium. Frozen tissue was further cooled to 10-85°K on the stage of a modified Balzers freeze-fracture apparatus helium-cryopumped to a vacuum of approximately 10^{-8} torr. The tissue was then fractured once with a cold sapphire knife, and then replicated with Pt/Ir/Ta alloy to produce a high resolution replica (grain size less than 10 angstroms). In such rapidly frozen, cryo-fractured tissue, the particles of assemblies appear to fracture at two levels within the membrane. Plane I fractures reveal bullet-shaped particles associated with the cytoplasmic membrane half, packed in orthogonal order, similar to the particles seen in fixed or conventionally fractured material. Plane II fractures appear to break into the particle structure close to the cytoplasmic membrane half, such that the aggregate constituting the assembly appears as a flat mesa elevated only slightly above the cytoplasmic membrane half fracture face. With low angles of shadowing, the mesa exhibits a regular pattern of pits. Both planes of fracture may be evident in a single assembly, revealing hemispherical particles distributed over the mesa-like surface, aligned between the rows of pits in the mesa. It seems probable that the mesa actually consists of closely-packed disc-like particles, and that hemispherical particles cap such discs to form the bullet-shaped particle of the fracture plane I image. Prolonged etching does not alter the appearance of the particle arrays, but does reveal a subtle pattern of particles on the true outer surface of the membrane in register with the plane I particles. We are still uncertain whether the particles on the true outer surface of the membrane are the tops of the particles seen with fracture plane I, or whether the plane I fracture breaks the particles somewhat deeper in the membrane. We have not recognized filaments or other structures inserting into the true outer surface of the membrane at sites of assemblies. Thus the (presumed) protein represented by the particles of the assemblies extends from the outer surface of the membrane into the hydrophobic interior. It is possible that the two planes of fracture within the particles reflect substructure in the protein.

102.5 GOLGI APPARATUS AND COATED VESICLES IN MEMBRANE CIRCULATION IN RANA PIPIENS RETINAS: STUDIES WITH CHOLERA TOXIN AND MONENSIN. Mary Lou Matheke* and Eric Holtzman. Dept. of Biological Sciences, Columbia University, New York 10027.

Several aspects of membrane genesis and cycling have been studied in frog photoreceptors, a favorable system for the study of such processes since they are compact and show a highly polarized distribution of specialized membranes.

Retinas incubated in cholera toxin-HRP (gift of N. Gonatas) show accumulation of the toxin in Golgi associated sacs and tubules and in small vesicles in the cell body, axon and terminal. This suggests that Golgi associated membrane systems of the photoreceptor participate in the degradation and/or reutilization of membrane retrieved from the cell surface by endocytic processes. As in Gonatas' work on conventional neurons, some of the toxin-labeled structures are of the sort that show acid phosphatase activity.

Monensin, a sodium ionophore,blocks the exit of newly synthesized proteins from the Golgi region of some secretory cells. We have used this agent to manipulate the migration of proteins in photoreceptors without abolishing protein synthesis. In monensin-treated isolated retinas, the Golgi region of the photoreceptor myoid shows numerous large vacuoles. Smaller numbers of similar vacuoles are present in the terminals and at the tip of the ellipsoid. The agranular reticulum normally present in the rod axon is diminished or absent. Instead, the axon contains many vesicles similar in size to those seen at synapses. In autoradiographic studies with ^{3}H-leucine, retinas incubated in monensin show inhibition of the formation of bands at the base of the rod outer segment (ROS) and fewer than normal numbers of grains over the remainder of the outer segment. Most of the grains are located in the myoid region, especially in the supranuclear zone. These findings are consistent with the central role postulated for the Golgi apparatus in the biogenesis of outer segment membranes and suggest that monensin blocks the migration of this membrane.

Coated vesicles are seen attached to the plasma membrane at the apical region of the rod inner segment. In HRP preparations, endocytic vesicles are found in this region even after incubations of only a few minutes and under conditions that depress encytosis at the terminal (light; presence of cobalt). These vesicles might participate in membrane recycling phenomena linked to the genesis of outer segment membranes and/or in specific endocytic uptake processes occurring in the apical portion of the outer segment.

102.6 CHANGES IN MEMBRANE SPECIALIZATIONS AT THE NODE OF RANVIER DURING TELLURIUM-INDUCED DEMYELINATION AND REMYELINATION. Clayton A. Wiley-Livingston and Mark H. Ellisman, Department of Neurosciences, University of California, San Diego, School of Medicine, La Jolla, CA 92093.

We have studied the effects of tellurium-induced demyelination and subsequent remyelination on the thin section and freeze-fracture morphology of rat peripheral nerves. Early demyelinative changes include: increased concentrations of neurofilaments and mitochondria in axons; fragmentation of the annulus of particles composing the E-face nodal specialization; and an increase in Schwann cell cytoplasm. Demyelination was characterized by vesicular and lamellar disruption of entire sheath segments, maintenance of basement membranes but little inflammatory response. Junctional specializations at the paranode disappeared only after destruction of the sheath had led to retraction of glial loops. Large denuded axons displayed fracture faces with a uniform distribution of particles except for infrequent small patches of particles in the axon E-face. The demyelinated axons underwent a rapid remyelination after removal of the 1% tellurium diet proceeding as described in normal developing animals. Early myelin wrappings were found adjacent to patches of particles in the axonal E-face at sites destined to become nodes of Ranvier. As new wrappings were laid down, terminal loops of myelin, along with associated rows of dimeric particles in the axonal P-face, were wound into their paranodal location. The size of the axonal E-face particle patch increased along with the number of paranodal windings until an annulus of particles was obtained. The thin section and freeeze-fracture morphology of remyelinated fibers was indistinguishable from the morphology of control fibers. This sequence of events and correlated physiology may help elucidate functions of membrane specializations in myelination and nerve conduction.

102.7 NORMAL FUNCTION IN SARCOPLASMIC RETICULUM FROM MICE WITH MUSCULAR DYSTROPHY. R. E. Mrak* and S. Fleischer* (SPON: F.R. Freemon). Depts. of Molecular Biology and Pathology, Vanderbilt Univ.; and Research and Laboratory Services, Veteran's Administration Medical Center; Nashville, TN 37235.

A new technique, which is rapid and gentle, has been developed for the isolation of sarcoplasmic reticulum (SR) from small amounts of muscle tissue. This involves gentle homogenization (two minutes at 1140 RPM) in a Waring Mini-Sample Container, two differential centrifugations followed by KCl extraction and a three-step discontinuous sucrose density gradient, with recovery of SR at the 29/41% sucrose (w/w) interface.

Normal and dystrophic SR were indistinguishable by electron microscopy (EM). Thin sections of full-thickness pellets of normal and dystrophic SR showed typical small vesicles with membrane asymmetry as demonstrated by tannic acid fixation. Occasional tubular and triad forms are present and more rarely mitochondria. Freeze-fracture EM showed typical asymmetric particle distribution. Assays for surface membrane markers (acetylcholinesterase, 5'-nucleotidase, adenylate cyclase) and mitochondrial markers (succinate-cytochrome c reductase) demonstrated only low levels of contamination by these organelles.

Isolated SR from normal mice had the following characteristics: Calcium loading rate (oxalate-assisted) 2.5 µmoles/mg-min and capacity 5.6 µmoles/mg, calcium-stimulated ATPase 1.9 µmoles/mg-min, calcium pump content 65% (as measured by densitometry of Coomassie-blue-stained sodium dodecylsulfate polyacrylamide electrophoretic gels). Corresponding numbers for dystrophic SR were 2.1, 4.7, 1.5, and 56. Thus the dystrophic/normal ratios were 0.84, 0.84, 0.79, and 0.86.

The kinetics of calcium removal and the final limiting free calcium concentration achieved were the same in experiments in which the total SR capacity exceeded the total free calcium available.

Calcium-insensitive ("basal") ATPase was 3.5-fold higher in dystrophic as compared with normal SR (0.7 vs 0.2 µmoles/mg-min). This activity correlated with the surface membrane markers 5'-nucleotidase and adenylate cyclase both in the two SR fractions and in a light membrane fraction (isopycnic density 10-29% sucrose [w/w]) enriched in surface membranes.

We conclude that the small differences in calcium pumping ability and calcium-stimulated ATPase are due to small differences in purity of the two isolated fractions, and that the calcium-insensitive ("basal") ATPase activity is attributable to contaminating surface membranes. 102.8 REVERSIBLE LOSS OF HIGH-AFFINITY, SODIUM-DEPENDENT γ-AMINOBUTYRIC ACID UPTAKE BY SYNAPTIC PLASMA MEMBRANES DEPLETED OF CHOLESTEROL. Paula North* and Sidney Fleischer* (SPON: L. Aulsebrook). Dept. of Molecular Biology, Vanderbilt University, Nashville, TN 37235.

The cholesterol/phospholipid (Ch/PL) ratio of synaptic plasma membranes from rat forebrain was varied using a general lipid exchange protein [Biochemistry 19:1433 (1980)] purified from beef liver. Ch/PL ratios from 0.18 to 1.12 were produced, from a normal value of 0.51, by incubation of the membranes with exchange protein and an excess of either egg phosphatidylcholine (PC) or cholesterol/egg PC liposomes under mild conditions (60 min at 32°C). The degree of cholesterol loading and depletion, which was minimal without exchange protein, was controlled by varying the amount of exchange activity present. Liposome sticking, which represented 5-15% of total phospholipid, was corrected for using a non-exchangable marker. Cholesterol depletion or loading was accompanied by an increase or decrease, respectively, in the phospholipid/protein ratio, and changes in the cholesterol and phospholipid content (per mg protein) were reversible. Cholesterol which had been incorporated into the membranes exchanged back out into egg PC liposomes in the presence of exchange protein at the same rate as the bulk pool of synaptic membrane cholesterol. The normal and cholesterol modified membrane vesicles were morphologically alike by freeze-fracture.

The ability of synaptic plasma membrane vesicles to take up γ-aminobutyric acid (GABA) by a Na^+ gradient-dependent mechanism was studied using the method of Kanner [Biochemistry 17:1207 (1978)] in which the vesicles were soaked in K phosphate and then diluted into NaCl containing 0.15µM 3H-GABA, followed by filtration. Cholesterol loaded vesicles took up GABA at the same rate as controls (29.7 pmoles/min/mg). However uptake was progressively lost with cholesterol depletion, reaching 70-100% loss at Ch/PL ratios near 0.2. Uptake was largely restored by reloading the vesicles with cholesterol. The passive permeability of the cholesterol depleted membranes to various ions and GABA was not altered relative to controls as measured by light scattering and isotope dilution. These observations indicate that the Na^+-dependent GABA uptake mechanism is directly influenced by membrane cholesterol content.

In summary, a general lipid exchange protein from liver can be used under minimally perturbing conditions to reversibly vary the Ch/PL ratio of synaptic plasma membranes over a wide range. This allows a definitive study of the influence of cholesterol content on membrane function. We find that Na^+-dependent GABA uptake by synaptic plasma membrane vesicles is reversibly lost upon depletion of membrane cholesterol.(Supported, NIH AM 14632).

102.9 HUMAN CNS MEMBRANE PROTEINS RESOLVED BY TWO-DIMENSIONAL GEL ELECTROPHORESIS WITH SILVER STAINING. K.S. Kosik*, D.J. Selkoe, J.M. Gilbert and P. Strocchi*. Mailman Research Center, McLean Hospital, Belmont, MA 02178. (SPON: J.M. Gilbert)

Fractions enriched in synaptic membranes, neuronal cell bodies, rough endoplasmic reticulum (RER) or smooth endoplasmic reticulum (SER) were isolated from frontal cortex of brain obtained 2-15 hours post-mortem. Enrichment of organelles in each fraction was verified by electron microscopy. The neuronal cell bodies were further fractionated into a soluble and insoluble fraction by centrifugation at 100,000 g. Protein determinations revealed that greater than 75% of the protein in these neuronal fractions remained insoluble. The proteins in each fraction were analyzed by two-dimensional gel electrophoresis (2DGE) using a first-dimensional pH gradient of 5.1 to 6.4 by a modification of the O'Farrell procedure. Proteins were detected by the method of Oakley (Ann Biochem 105:361-363, 1980) using the ultrasensitive silver stain. Comparison was made to protein staining of the electrophoretograms with Coomassie brilliant blue. With equal loading of protein the number of spots visualized could be increased five-fold. In all fractions examined all proteins which stained with Coomassie also appeared on the silver stained gels. Furthermore, Coomassie staining of a silver stained gel revealed no new spots. However, some spots clearly of high density on the silver stained gels did not appear on gels stained with Coomassie. Since it is accepted that the intensity of Coomassie staining reflects relative protein concentration, densitometric analysis of silver stained gels may not reflect the relative concentrations of component proteins.

The isolated human fractions were analyzed in comparison with each other. It was apparent that each fraction by 2DGE showed a unique protein array, hence permitting identification of a subcellular fraction by its own two-dimensional pattern. Specific differences in the polypeptide composition of the various fractions will be described. Among other changes, the configuration of proteins in the tubulin region showed differences among fractions. These overall patterns were highly reproducible in samples from different human brains, although minor individual differences occurred. The fractions also bear a great similarity to identical fractions isolated and analyzed by 2DGE in the rat (Strocchi et al. Trans Am Soc Neurochem 12:113, 1981). We are pursuing these results by determining the effect of post-mortem interval on the protein arrays as well as assessing individual phenotypic differences and selective protein alterations in human disease states. (Supported by National Huntington's Disease Fellowship Award (KSK) and NIH grants AG 02126 (DJS, JMG) and MH 70713 (JMG).)

102.10 VARIATIONS IN VESICULAR MORPHOLOGY IN THE FROG PERINEURIUM DEMONSTRATED WITH LANTHANUM AND STEREOSCOPIC ELECTRON MICROSCOPY N.L. Shinowara, M.E. Michel and S.I. Rapoport. Laboratory of Neurosciences, GRC, Natl. Inst. Aging, Baltimore, MD 21224.

The perineurium, an extension of the pia arachnoid sheath, enwraps all peripheral nerves to form the blood nerve barrier. EM studies of the frog perineurium have shown that the thin layers of flat cells are characterized by the presence of numerous pits and vesicles at or near the surface membranes. Recent papers have discussed the formation of channels by vesicular fusion as a mechanism of transcellular transport (Bundgaard et al., Proc. Natl. Acad. Sci. USA 76: 6439, 1979; Frokjaer-Jensen, J. Ultrastruc. Res. 73: 9, 1980). In order to better visualize the various vesicular patterns, we used colloidal and ionic forms of lanthanum as tracers. Sciatic nerves of adult Rana pipiens were fixed in situ or removed and placed into buffered fixative (2-4% glutaraldhyde for 30 min or changes of 0.05% OsO_4/1.5% glut. for 15 min) and then left in fresh buffered glutaraldhyde with tracer for 3-5 hr. The tied cut ends of the nerve were first secured above the fixative solution to prevent leakage of tracer into the nerve. Tracer was in all solutions up to dehydration. Plastic embedded sections (50-100nm) were viewed on a JEOL-TEM equipped with a goniometer and tilting stage. Each area of interest was examined at a wide range of tilting angles (-30^{o} to $+30^{o}$) to obtain a 3-dimensional picture of each vesicular profile. Lanthanum was seen intermittently in all layers of the perineurium, down to the inner "barrier" layers, but never within the endoneurium. In areas of lanthanum penetration, tracer was observed in the extracellular space laterally for long distances, between unconnected ends of cellular processes, and within vesicles attached to surface membranes. In general, the vesicles appeared as small round bottomed or oval flasks extending from both cell surfaces. Occasionally a filled vesicle appeared free within the cytoplasm. When specimens were tilted, several variations in vesicle shape were noted. Flasks which had appeared to fuse with the opposite membrane to form a channel were actually unattached. "Free" vesicles were often either attached by necks to the cell surface or formed clusters with other flasks. Although some chains or clusters of vesicles were observed, they were attached to only one surface membrane. These results indicate that under these experimental conditions, a large number of vesicles, connected to the surface membranes, appear at the inner cellular layer of the perineurium. However, vesicle fusion and transcellular channels do not signi cantly contribute to the passage of material between perineurial layers.

102.11 REACTIVATION OF MYOTOXIC PHOSPHOLIPASE A_2-INACTIVATED SARCOPLASMIC RETICULUM. S. Helmke*, J.W. Morrow and B.D. Howard. Dept. of Biol. Chem., UCLA, Los Angeles, CA 90024.

Certain snake venoms contain phospholipase A_2 (PLA) neurotoxins that inhibit acetylcholine release from nerve terminals. Some of these neurotoxic PLAs are also myotoxic in that they cause a degeneration of muscle independent of their effects on neurons. The PLA activity appears to be necessary for their toxicity, but it is not sufficient to account for their toxicity. Indeed, most known PLAs are not neurotoxic or myotoxic in spite of having a specific enzyme activity that is greater than that of the toxic enzymes. There is good evidence that these toxins act by altering ion fluxes across neuronal and muscle membranes, most likely by degrading lipids near an ion channel or pump. The myotoxic PLAs inhibit Ca^{2+} uptake into sarcoplasmic reticulum (SR) vesicles from skeletal muscle, and this effect has been shown to be a relevant correlate of their toxicity. Notexin, which is a myotoxic PLA, and IVa PLA, which is nontoxic but has greater enzyme activity than notexin, were compared with respect to ability to inhibit Ca^{2+} uptake into SR vesicles. The efficacy of notexin, but not that of IVa PLA, was markedly dependent on SR concentration. With dilute SR, notexin was more effective than IVa PLA; however with concentrated SR, notexin was very much less effective than IVa PLA. These results are interpreted to indicate that SR has a site to which notexin, but not IVa PLA, can bind with high affinity. Reconstitution studies have shown that this site is not a lipid unique to SR, but more likely the site is a protein in the SR membrane. Native SR vesicles were completely inactivated by treatment with notexin, then solubilized with detergent and reconstituted by detergent removal, in some cases with soybean phospholipids added. The reconstituted SR vesicles regained the ability to take up Ca^{2+}. Supported by grants from USPHS and Muscular Dystrophy Association.

102.12 AFFINITY PARTITIONING AND CHARACTERIZATION OF POSTSYNAPTIC MEMBRANES FROM MAMMALIAN BRAIN. S.D. Flanagan, B. Yost* and G. Crawford*. Division of Neurosciences, City of Hope Res. Institute, Duarte, CA 91010.

Asymmetric or Gray's Type I synapses contain a prominent postsynaptic density (PSD) structure, whose functional role is largely unknown. The morphology of the PSD is largely unaffected by moderate amounts of nonionic detergents, and this fact has been successfully utilized to prepare fractions highly enriched in the PSD structure. Unfortunately, the use of nonionic detergents results in the extraction of most of the lipid from the membrane bilayer and is likely to substantially alter the structure of the overlying postsynaptic membrane.

Crawford, Osborne and Potter (J. Neurocytol., in press) developed an extraction procedure, not dependent upon detergents, for rendering postsynaptic membranes detached from presynaptic structures. Ratner and Mahler (JCB 83: 271a) utilized this extraction procedure followed by intense homogenization and discontinuous sucrose density centrifugation to prepare fractions enriched in postsynaptic membranes with attached PSD structures. Their fraction, from the 1.5 M / 2.0 M sucrose interface, contains only a portion of the total PSD structures. We analyzed the basis for this purification procedure by utilizing continuous sucrose density gradients in a Z-60 zonal rotor. In order to analyze the relative content of PSD in the various fractions, we developed a novel gel electrophoresis method for analyzing the PSD content of the fractions by quantitative densitometry of electrophoretic bands in deoxycholate insoluble residues. It is apparent that a major fraction of the PSD structures overlap with mitochondria remaining from the synaptic plasma membrane preparation. We have developed a convenient aqueous polymer two-phase extraction procedure for largely removing mitochondrial membranes from the postsynaptic membranes containing PSD structures. We achieved further purification of PSD enriched structures by utilizing affinity partitioning to purify membranes on the basis of their sulfhydryl content. Tubulin and the PSD protein, major components of the PSD structure based upon previous reports, are also the major components of our postsynaptic membrane fraction and contain the predominant content of reduced sulfhydryl groups. We are examining the efficacy of our separation procedures by morphological analysis at the electron microscopic level. Preliminary results suggest that our highly enriched fractions contain the PSD structure and neurotransmitter receptor binding sites. Since this procedure obviates the requirement for detergent treatment, we expect to observe enzymes characteristic of the native synapse. (Supported by NS-14281 and NS-12116.)

102.13 SUBCELLULAR FRACTIONATION OF THE CHICK RETINA. Nigel G.F. Cooper*, Hue-ly Guan* and Barbara J. McLaughlin. Department of Anatomy. University of Tennessee Center for the Health Sciences, Memphis, TN 38163

We report here on the isolation of synaptosomes (SS), synaptic plasma membranes (SPM) and postsynaptic densities (PSD) from fractions rich in photoreceptor synaptic terminals and their characterization by electron microscopy (EM) and polyacrylamide gel electrophoresis (PAGE). By EM analysis, minimal hand homogenization (5-10 strokes) of chick retinas (8-20 retinas) in 0.32M sucrose does not lead to a significant release of SS, most of which remain with the pre-P_1 or nuclear pellet (150g-10 min). In our hands, a large yield of SS into the P_1 pellet (800g-10 min) requires more extensive homogenization of this pre-P_1 pellet (3x20 strokes). Fractionation of the SS rich P_1 pellet on a sucrose gradient for 2 hrs at 82,500g yields 4 fractions of photoreceptors. By EM, two of the fractions (1.6M/1.8M and 1.8M/2.0M interfaces) contain large synaptosomes in groupings of two or more, along with nuclear contaminants. Many of these large synaptosomes contain several synaptic ribbons, numerous synaptic vesicles, and have retained their dyad and triad postsynaptic elements. Two fractions (1.4M and the 1.4M/1.6M interface) contain large, ribbon-containing single and double synaptosomes, without nuclear contamination. The double synaptosomes most likely represent synaptic terminals from principle and accessory members of double cone photoreceptors whereas the single synaptosomes could represent terminals from cones or rod photoreceptors. Using a modification of the method of Cohen et al (1977), lysed synaptosomes are put on a second sucrose gradient (0.85M, 1.0M, 1.5M and 2.0M) at 90,000g for 30 min. SPM and PSD are obtained at the 1.0M/1.5M and 1.5M/2.0M interfaces, respectively. PAGE of 10 ug of the SDS solubilized PSD fraction yields four faint Coomassie blue stained bands which may be doublets. The molecular weights are approximately 48K, 65K, 70K and 74K Daltons. PAGE of 10-20 ug of SDS solubilized SS fractions yields 10 prominent Coomassie blue stained bands at 32K, 39K, 40K, 46K, 48.5K, 52K, 64K, 65K, 70K, and 74K Daltons. Preliminary EM of the PSD fractions shows densely stained oval PSD's in the en face plane of section and some contamination by synaptic junction complexes. In conclusion, a protocol has been established based on cell isolation techniques used elsewhere that appears to be suitable for characterizing the macromolecular components of photoreceptor synapses within subcellular fractions of the retina. Supported by USPHS EY 02708.

102.14 CALCIUM-PROMOTED FLUORESCENT RESONANT ENERGY TRANSFER IN AGGREGATING CHROMAFFIN GRANULE MEMBRANES. S. J. Morris, T. C. Südhof and D. H. Haynes (Spon: H.B. Pollard). Neurotoxicology Section, NINCDS, NIH, Bethesda, MD 20205; Dept. of Neurochemistry, Max Planck Institute for Biophysical Chemistry, Göttingen, FRG and Dept. of Pharmacology, U. of Miami Medical School, Miami, FL 33101

Isolated adrenal medullary chromaffin granules will aggregate and fuse upon the addition of Ca^{2+}. These reactions may serve as a model for exocytosis in vivo. We have previously reported on the kinetics of granule aggregation using light scattering techniques. Reactions consonant with or subsequent to granule-granule contact can be followed using resonant energy transfer between suitably placed donor and acceptor fluorophores.

Proteins of intact granules are labelled with sulfhydryl-specific maleimide and mercury acetate agents, then lysed and washed extensively to remove soluble or loosely bound proteins. The quenching of donor fluorescence is followed as an unambiguous signal of probe interaction. When both donor and acceptor are placed on proteins of the same membrane, Ca^{2+} increases donor quenching with a K_m of ~ 200 μM. This Ca^{2+}-concentration is too low to promote significant aggregation. The effect is also independent of membrane concentration and must result from intra-membrane protein clustering or patching. This constitutes the first demonstration of the fluid mosaic nature of a subcellular organelle. If the donor and acceptor labels are placed on separate membranes, mixing in the absence of Ca^{2+} produces a slow decline in donor fluorescence. This effect can be greatly reduced by extensively washing the membranes and is ascribed to exchange of membrane proteins either through the medium or by granule-granule collisions. If the two sets are mixed and Ca^{2+} added immediately or if they are incubated overnight to allow for complete protein exchange, addition of Ca^{2+} produces protein concentration-dependent energy transfer with a K_m of ~ 2 mM and rates 5-10 times slower than Ca^{2+}-promoted aggregation (K_m ~ 4 mM) measured in parallel. We attribute this fluorescence change to slow rearrangements of membrane components which follow aggregation.

We have postulated that granule-granule aggregation is mediated by proteins which protrude several Å from the membrane p-surface (Haynes, Kolber and Morris, J. Theoret. Biol 81:713 (1979)). No component with rates similar to aggregation is seen by this labelling method. Ca^{2+} aggregates labelled or unlabelled granules at the same rate. If such proteins are responsible for granule-granule recognition, they either contain no free sulfhydryl groups or the labelled sites are far enough apart when the proteins interact for no significant Förster energy transfer to occur.

103.1 CHOLINEACETYLTRANSFERASE: PURIFICATION AND IMMUNOFLUORESCENT LOCALIZATION IN RETINA OF FOUR VERTEBRATE SPECIES. F. Eckenstein*, M. Schwab* and H. Thoenen. Max-Planck-Institute for Psychiatry, Dept. of Neurochemistry, D-8033 Martinsried, FRG.

The acetylcholine (ACh) synthesizing enzyme choline acetyltransferase (ChAT), which represents the only undisputable marker for cholinergic neurons, has been purified from pig brain by ammonium sulphate fractionation, ion exchange and hydrophobic chromatography, followed by elution of the enzyme from blue dextran Sepharose by 100 µm coenzyme A. After concentration on hydroxylapatite ChAT was purified by high pressure liquid chromatography to a final specific activity of 150 µmoles ACh·min^{-1}·mg^{-1} protein and to a purity of over 90% as judged by SDS-gel electrophoresis. Antisera to this preparation raised in mice were specifically directed against ChAT as demonstrated in double immunodiffusion tests.

By indirect immunofluorescence cholinergic neurons were demonstrated in the retina of the rat, chick, goldfish and frog (Xenopus). In all four species amacrine cells located mostly at the inner margin of the bipolar cell layer and less often in the ganglion cell layer were stained. Their fibers projected into the inner plexiform layer where their terminals form a double band. In the frog retina, a second type of labeled cells - probably ganglion cells - was found in the ganglion cell layer.

103.2 HORSERADISH PEROXIDASE LABELING OF INDIVIDUAL LATERAL HYPOTHALAMIC NEURONS. M. J. Wayner, F. C. Barone and S. L. Scharoun. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210.

Electrical recordings were made from lateral hypothalamic (LH) neurons in urethane anesthetized rats. Single barrel electrodes or the center barrel of seven barrel electrodes, filled with 1% horseradish peroxidase (HRP, Sigma Type VI) in 2 M NaCl, were used to record neuronal activity. Following establishment of a stable baseline in a single neuron, the effects of mesencephalic central gray and reticular formation single pulse electrical stimulation and/or the microiontophoretic ejection of dopamine or norepinephrine were determined. HRP was then ejected from the recording electrode utilizing 500 nA anodal current for 30 sec. Only if the discharge frequency was not affected by the HRP was the tissue retained for further histological examination. Animals were perfused with wash and fix solutions and stored overnight at 4°C. Hypothalamic tissue was sliced at 40 µm and sections were processed with DAB for the brown reaction and counterstained with neutral red. Sequential sections were examined and positively labeled neurons were identified and photographed. In most cases, individual neurons in the LH were densely labeled and had a Golgi-like appearance. Dendritic and axonal processes could be easily identified and followed for several hundred micrometers. Since small ejection sites were located adjacent to the cell bodies and no other neurons could be identified nearby in the Nissl stained tissue, labeled neurons were apparently those cells from which electrical recordings had been made. Labeled neurons were located within and adjacent to the medial forebrain bundle (MFB). In general, the dendritic processes of these neurons spread out perpendicularly to the path of the MFB fibers and are similar to the "path" neurons identified previously (Millhouse, Brain Res. 15: 341-363, 1969). The location of these neurons within the MFB allows for a great amount of synaptic convergence from within the hypothalamus and other MFB associated structures. (Supported by NIH Grant NINCDS USPHS No. 13543.)

103.3 ORGANIZATION OF NEOCORTICAL PROJECTION NEURONS IN RAT NUCLEUS LOCUS COERULEUS. B.D. Waterhouse, C.-S. Lin, R.A. Burne, W.K. Smith and D.J. Woodward. Dept. of Cell Biology, The Univ. of Texas Health Science Center, Dallas, Texas 75235.

The present study was conducted to examine the spatial organization of locus coeruleus (LC) neurons that project to rat cerebral cortex. Twenty-three Long-Evans hooded rats (180-275 gm) received unilateral pressure injections (0.6-1.5 µl) of HRP (Miles Lab., conc. in Tris buffer) in either frontal (n=3), somatosensory (n=7) or visual (n=7) cortex in the rostro-caudal plane or lateral to somatosensory (n=3) or visual (n=3) cortex in the medio-lateral plane to localize LC neurons projecting to specific cortical areas. Coronal and sagittal sections (40-100 µ) through the LC were examined after incubation with TMB and H_2O_2 and counterstaining with neutral red. The locations of retrogradely labeled cells were recorded relative to a three dimensional biological coordinate system maintained by a computer linked to a light microscope.

LC neurons labeled from cerebrocortical injections of HRP were primarily located in the ipsilateral nucleus and to a lesser extent (5-10% of total labeled cells) in the contralateral nucleus. Routinely, cortical projection neurons were concentrated in the caudal half of LC. Within this region, the most rostrally labeled cells were observed after frontal cortex injections. In the dorso-ventral dimension, neurons labeled from neocortical injections were scattered in the dorsal division of the caudal LC, with a tendency for individual groups of cells projecting to visual, somatosensory or frontal areas of cortex to be aligned in a dorsal to ventral pattern. Only the frontal cortex received a projection from the ventral division of the caudal LC. Neurons projecting to lateral regions of the neocortex tended to be localized toward the medial aspect of the ipsilateral LC, in contrast to a more lateral tendency for cells projecting to medial portions of the cortex. The zone of labeling resulting from injections confined to neocortical areas overlapped with but was not coextensive with that observed following injections into 1) neocortex and caudate, 2) neocortex and hippocampus and 3) parafloccullus of the cerebellum.

In summary, the data from the brains analyzed has delimited a portion of the ipsilateral LC nucleus which projects to rat cerebral cortex. Moreover, the results suggest that within this zone of LC there exists a rough topographic organization reflecting the rostro-caudal and medio-lateral distribution of noradrenergic axons within the cortex. In view of this evidence, the hypothesis may now be considered that selective noradrenergic interaction with various CNS regions may occur as a result of activity in topographically organized subsets of LC neurons. (Supported by NIDA DA-02338 and Biological Humanics Foundation)

103.4 MORPHOLOGY AND ULTRASTRUCTURE OF AN ACETYLCHOLINE AND NEUROPEPTIDE CONTAINING NEURON IN A MOLLUSK. B.Masinovsky*, P.E.Lloyd* and A.O.D.Willows. (SPON: K.Graubard). Dept. of Zoology and Friday Harbor Labs. Univ. of Washington, Seattle WA 98195.

A large white appearing neuron (B11) is located on dorsal surface of each of the paired buccal ganglia in the gastropod, Tritonia diomedia. This neuron innervate the animal's gut and has been shown to contain acetylcholine and neuropeptide, SCP$_A$ (Lloyd, Neurosci. Abstr., 5, 252; Lloyd et al, Neurosci. Abstr., this volume). Because of these interesting properties, we have analyzed the morphology of B11 in detail.

We visualized the peripheral axonal morphology of B11 by intracellular injection of Lucifer yellow into the cell body. By combining this procedure with an electrophoretic gradient, we were able to fill even small axonal branches at distances of over 1 cm from the cell body. Each B11 is an unipolar neuron which sends its axon into the ipsilateral gastro-esophageal ganglion where it divides into one major and two minor branches. The minor branches exit gastro-esophageal ganglion in small nerves and immediately ramify over the muscle surface apparently innervating the most proximal part of the esophagus. The major axonal trunk travels along the gastro-esophageal nerve and occasionally sends out small branches which also ramify into the gut. We have not been able to fill the axon to their final termination but they may contribute to the neural plexus on the surface of the stomach. This morphology is consistent with known physiological properties of B11.

Intracellular injection of HRP was used to visual the neurites of B11 in the neuropil of the buccal ganglia. Each B11 produces a relatively sparse network of neurites, and although a few processes extend towards the buccal commissure, none cross over to the contralateral ganglion.

The cell body of B11 contains large quantities of acetylcholine and a neuropeptide. We were therefore interested in the vesicular content of the cytoplasm. Ultrastructural examination of the cytoplasm of B11 soma, using 2.5% glutaraldehyde in 0.2 M s-collidine buffer (pH 7.35; 970 mOsmols) as a primary fixative, indicated that B11 contained a large number of vesicles, many associated with Golgi complexes. These vesicles were electron luscent and varied from round to ellipsoid. The average diameter in the longest plane was 141±29 nm (mean ± S.D.; N=80). These vesicles are largerthan those associated with cholinergic neurons and are not electron dense as are many peptide containing granules. (Supported by NSF BNS 7906280).

103.5 ULTRASTRUCTURE OF SPECIALIZED NEUROMUSCULAR JUNCTIONS IN A BLOOD VESSEL OF APLYSIA.

C. H. Price and W. H. Fowle*.
Department of Biology, Boston University, Boston, MA. 02215

Electrophysiological evidence for multiple neurotransmitter involvement in the excitation and inhibition of Aplysia vascular smooth muscle prompted an ultrastructural study of neuromuscular junctions (NMJ) in the largest vessel, the anterior aorta (AA). The wall of the AA is composed of three layers: an inner, single-cell thick myoendothelial lining of the lumen with adherent amebocytes; a 2-5 cell thick layer of circular muscle (~5 μm dia); and an outer, several cell thick layer of longitudinal muscle (~8 μm dia) and small nerves embedded in a matrix of collagen and connective tissue. Circular muscle fibers are tightly grouped with extensive membrane interdigitation and are rarely innervated. Longitudinal muscle cells occur as well-separated single fibers with rare inter-fiber contact and are extensively innervated. Contact between circular and longitudinal muscle was seen and possible regions of specialization identified.

Three distinctly different types of NMJ's were observed. Type I: rare, relatively flat terminal with long, straight contact with sarcolemma; spherical clear vesicles (~70 nm dia) with no obvious clustering; pre-synaptic densities and electron dense cleft material present but little post-synaptic specialization. Type II: common, large volume terminal with junctional area often several μm long and enwrapping sarcolemma; small dense core vesicles (~85 nm dia) and more numerous small clear vesicles (~55 nm dia) and clustering of clear but not dense core vesicles; pre- and post-synaptic membrane specializations were minor. Type III: very common, small volume bulbous terminals with small but well-defined synaptic regions; numerous large vesicles (~160 nm dia) of variable electron density and fewer numbers of small clear vesicles (~65 nm dia) clustered primarily at synaptic area; pre- and post-synaptic membranes thickened, pre-synaptic triangular-shaped densities, cleft contains little material.

On the basis of earlier electrophysiological work on the AA (Sawada et al., Brain Res., 207:486-490, 1981) and the anatomical and neurochemical evidence from this study, speculation on the neurotransmitter content (Type I=ACh; II=5-HT; III=glycine) and function of each terminal type is made and probable parent neurons in the parietovisceral ganglion identified. The pattern of innervation observed and frequency of muscle-muscle contacts are discussed in relation to the overall contractile performance of the aorta.

104.1 APOMORPHINE-INDUCED HYPOTHERMIA IN MICE TREATED PRENATALLY WITH PHENOBARBITAL. R. Kuprys, P. Hoffman and B. Tabakoff. Dept. of Physiol. Biophys., Univ. of Illinois Med. Ctr. and VA Westside Med. Ctr., Chicago, IL 60612.

Our previous work indicates that central dopamine (DA) receptor sensitivity is altered in adult mice exposed prenatally to phenobarbital (PB). In the present study, the effects of the DA receptor agonist apomorphine (APO) upon body temperature was further examined in these mice.

Heterogeneous strain mice were fed a milled diet containing 3 mg PB/g diet or control diet and water ad libitum on days 9-18 of pregnancy. Male and female offspring of PB and control (C) dams were subsequently tested as adults for their hypothermic response to APO HCl (0.3-3 mg/kg, ip). Rectal body temperature was measured up to 120 min. after drug injection, using a telethermometer probe.

Body weights and baseline body temperatures of both male and female PB mice did not differ from their respective C values. Male PB mice were less sensitive than male C mice to the hypothermic effects of APO following treatment with 0.4 or 0.5 but not 1 mg/kg APO. In contrast, female PB mice were more sensitive than female C mice to the hypothermic effects of APO following treatment with 0.3 or 0.5 but not 1 or 3 mg/kg APO. The differences observed between PB and C mice could not be attributed to changes in metabolism of APO. Following ip injection of 3 mg/kg APO, wholebrain µg/gm levels of APO (obtained spectrofluorimetrically) in C and PB male mice were 0.95±0.29 (n=5) and 0.94±0.18 (n=5), respectively, at 15 min. post-injection, and 0.53±0.21 (n=5) and 0.46±0.06 (n=5), respectively, at 30 min. post-injection. For C and PB female mice, wholebrain APO levels were 0.50±0.39 (n=10) and 0.61±0.45 (n=10), respectively, at 15 min. post-injection. In addition, the differences in APO-induced hypothermia could not be attributed to alterations in environment-dependent thermoregulation capacity, or to changes in α-noradrenergic regulation of body temperature following acute administration of clonidine HCl.

The results suggest that prenatal PB exposure produces long-term changes in the sensitivity of DA receptors which regulate body temperature and that the alteration produced is expressed differently in the male and female adult offspring.

104.2 EFFECTS OF ETHANOL ON CENTRAL DOPAMINERGIC FUNCTIONS IN THREE INBRED STRAINS OF MICE. B. Tabakoff and K. Kiianmaa*. West Side VA Medical Center, Chicago, IL 60612 and Department of Physiology and Biophysics, University of Illinois Medical Center, Chicago, IL 60680.

The effects of an acute dose of ethanol on the synthesis and release of dopamine (DA) were studied in the striatum of Balb/c, C57Bl/6 and DBA mice. The rate of DA synthesis and release was monitored by measuring the accumulation of DOPA and DOPAC levels, respectively, after inhibition of the aromatic amino acid decarboxylase with NSD-1024. The DA precursor and metabolite were quantitated using high performance liquid chromatography with electrochemical detection. Ethanol, in doses ranging from 0.8 - 3.5 g/kg i.p., stimulated the rate of DA synthesis in Balb and DBA mice in a dose-dependent manner. The highest dose of ethanol (3.5 g/kg) increased the levels of DOPA in DBA and Balb mice by 200-300%, relative to the saline-injected controls. However, the lower doses of ethanol (0.8 - 2.0 g/kg) did not significantly affect the rate of DA synthesis in C57Bl mice, while administration of 2.5 - 3.5 g/kg of ethanol stimulated synthesis only 90-130%. Ethanol was found to have a biphasic effect on DA release. Thus, ethanol decreased the DOPAC levels in the striata of Balb and DBA mice by 25-40% in doses of 0.8 - 1.35 g/kg, and increased them 20-70% when higher doses of 2.5 - 3.5 g/kg were injected. The C57Bl mice showed only a small suppression of DA release at the lower dose range of ethanol, whereas the higher doses induced an increase of 75-135% in DOPAC levels. These results show that the central DA systems of Balb and DBA mice are, in general, more sensitive to the effects of ethanol than those of C57Bl mice.

The behavioral effects of a hypnotic and non-hypnotic dose of ethanol in these strains of mice are being studied. The results of these experiments will be discussed in terms of whether the ethanol-induced changes in the central dopaminergic functions found here can explain differences in the stimulatory and depressant effects of ethanol between these strains of mice.

104.3 ALTERATIONS IN BEHAVIOR AND BRAIN CHOLINERGIC FUNCTION AFTER CHRONIC ALCOHOL AND DIHYDROERGOTOXINE MESYLATE (HYDERGINE) TREATMENT OF AGING MICE. K. Persson* and T. Samorajski. Texas Research Institute of Mental Sciences, Houston, TX 77030.

It is now well established that cholinergic deficits in the brain may be responsible for some motor and cognitive impairments that may occur in normal aging and age-related neurodegenerative disorders. We sought to determine whether the ergot alkaloid dihydroergotoxine mesylate (Hydergine, a potent α-adrenergic blocking agent with significant glycolytic activity in the brain) might prevent brain deterioration associated with aging and/or prolonged ingestion of alcohol. Two hundred aging male mice of the C57BL/6J strain were used. The animals were distributed according to weight into four equal groups of 50 mice each. One group received 1mg/kg of Hydergine orally, 3 times per week. A second group (controls) received corresponding volumes of distilled water. A third group was maintained on a 10% v/v ethanol-water solution. The fourth group received both Hydergine (1mg/kg orally, 3 times per week) and 10% ethanol in their drinking water. To preclude residual treatment effects, behavioral and neurochemical tests were conducted two weeks after termination of treatment. We found age-related decreases in choline acetyltransferase (ChAT) and cholinergic muscarinic binding in the cortex and striatum of mouse brain. Alcohol treatment increased ChAT activity only in the striatum. Receptor binding, however, was not effected by alcohol ingestion. The administration of Hydergine increased barbiturate narcoses, indicating an adverse effect on the liver and/or brain. Hydergine treatment had no effect on cholinergic muscarinic receptor binding or ChAT activity in the corpus striatum, cortex or cerebellum of the mouse brain. Combined administration of alcohol and Hydergine had a "sparing effect" on alcohol induced impairments in ChAT activity. Neuronal redundance, plasticity and recovery offer some prospects for intervention by drugs (and possibly hormones, and neurotransmitter precursor substances) in brain disorders caused by chronic alcohol ingestion.

104.4 RESPONSE TO PENTOBARBITAL OF PIGMENTED VS. ALBINO LONG-EVANS RATS. I. S. Westenberg and J. M. Bolam* (SPON: K. R. Swiatek). Instit. for Study of Developmental Disabil., Chicago, IL 60608.

Compared to pigmented strains of rats, albino strains are more susceptible to pentobarbital. In such between-strains comparisons the single-gene variable of albinism is confounded with other genetic variables (strain). To eliminate this problem we made a within-strain comparison of partially inbred pigmented vs. albino rats. Subjects were pairs of male rats, an albino and a black-hooded littermate from each of three breeding lines of Long-Evans ancestry [Sim:(LE), coefficient of inbreeding 0.67 to 0.73]. In each pair the rats differed in one gene at the albino (c) locus but were otherwise genetically very similar. They weighed about 500g and were 16 to 17.5 months old at the beginning of the study. Each rat was housed with its littermate with food and water ad libitum. Each rat was injected i.p. weekly with sodium pentobarbital; its dosage began at 10 mg/kg and increased 10 mg/kg/wk until the rat died. To measure the onset of drug effects we recorded the post-injection times for the rat to fall off a walkway (droptime) and lose righting reflexes (LRR-time). To measure the duration of drug effects we recorded the time of the return of righting reflexes (RRR) and calculated the time from LRR to RRR (sleeptime).

In the few cases of significant pigmented-albino differences in the onset measures, the pigmented rats showed the more rapid onset of the drug's effects. In neither onset measure did an albino appear consistently more susceptible than its pigmented counterpart. Sleeptimes generally increased steadily with increasing dosage. In two pairs the pigmented rats consistently slept longer than their respective albino littermates, and the pigmented-albino difference grew steadily as dosage increased ($p<0.01$, rank correlation coefficient). In the third pair results for the albino and its pigmented littermate were more similar. In no case did an albino consistently sleep longer than its pigmented littermate as dosage increased. Thus, in the duration measure, as in the onset measures, an albino never appeared consistently more susceptible than its pigmented counterpart. Hence, the rapid onset and long duration of pentobarbital effects in some albino strains are related to genetic variables other than just the albino mutation.

Supported by NIH grants EY01888 and EY03013, Fight For Sight, Inc. (NY) grant G-599, and the Illinois Department of Mental Health and Developmental Disabilities.

104.5 THE EFFECTS OF ETHANOL AND TEMPERATURE ON CRAB NEUROMUSCULAR PHYSIOLOGY. P.J.Stephens and R.E.Lazarus* Dept. of Biology, Villanova Univ. Villanova, Pa. 19085.

The stretcher muscle in the crab limb is innervated by branches from three motor axons; the excitor (E), the specific inhibitor (SI) and the common inhibitor (CI). Preparations were made from autotomized limbs of the shore crab Pachygrapsus so that the three motor axons could be electrically stimulated either individually or in combination. At normal temperatures E axon shocks produced single excitatory junctional potentials (ejp's) in stretcher muscle fibers. Increasing the temperature caused a decline in ejp amplitude until, above a critical temperature threshold, a single E axon shock provoked the generation of spikes in the peripheral E axon branches and concomitant ejp's in the stretcher muscle fibers (Stephens and Atwood, Soc. Neurosci. 6, 1980). Further temperature increases caused an increase in the number of ejp's and E axon spikes following an E axon shock, whereas cooling reversibly abolished the repetitive response.

Bathing preparations in a crab saline containing low levels of ethanol (<5%) decreased the temperature threshold at which repetitive axon spikes and ejp's were recorded. Latency measurements and extracellular recordings from two locations along the E axon confirmed that the spikes produced after the initial orthodromic action potential were generated peripherally.

Synchronous stimulation of the E and SI axons abolished the peripherally generated E axon response. Furthermore, when trains of spikes and ejp's were produced by E axon shocks, stimulation of the SI axon shortly after the E axon shock abolished only a portion of the peripherally generated E response. These results suggest that SI axon activity can modulate the peripheral generation of spikes in the E axon branches. CI axon activity was not observed to modulate the peripheral E axon response.

We conclude that ethanol decreases the threshold temperature for the peripheral generation of E axon activity. This result, together with the observation that the threshold temperature is dependent upon acclimation (Stephens and Atwood, J.Comp.Physiol. In press 1981), suggests that the peripheral generation of E axon spikes is closely related to membrane fluidity.

104.6 EFFECT OF PENTOBARBITAL IN A GERBIL MODEL OF STROKE. Charles J. Hannan, Jr. and Robert A. Patterson*. Clinical Investigation Department, Eisenhower Army Medical Center, Ft Gordon, GA 30905

A previously described modification of the gerbil stroke model (Neurosci Abstr 6:826, 1980) developed in this laboratory allows the production of regional ischemia leading to infarction and death in about 80% of prepared gerbils within 3 days. A further 10% of animals survive with histological evidence of infarction. The procedure involves the total occlusion of the left common carotid artery, restriction of the right common carotid artery (to about 1.4mm with a tantalum ligating clip), and the i.p. injection of 2.5 gm/kg glucose in ketamine anesthetized gerbils. To evaluate the sensitivity of the model to therapeutic measures, the effect of pentobarbital on edema formation 6 hours post occlusion was measured. Edema was shown to be demonstrable by 6 hours in a group of 13 gerbils not given pentobarbital. Brains were removed, divided into quadrants, and a wet weight followed by a dry weight was obtained. The calculated percent water was significantly greater in the left hemisphere, both anterior and posterior quadrant, when compared to the right hemisphere by students t-test. When pentobarbital was used as the anesthetic (50 mg/kg) rather than ketamine, there was no difference in percent water between left and right hemispheres:

	MEAN % WATER	
QUADRANT	LEFT HEMI	RIGHT HEMI
NO TREATMENT:		
Anterior	82.2±0.90*	81.7±0.64
Posterior	80.9±1.06**	79.8±0.66
PENTOBARBITAL:		
Anterior	81.6±0.64	81.6±0.61
Posterior	80.6±0.96	80.3±0.73

*:p>.05; **:p>.01

The regional ischemia produced by this model is considered a more appropriate model for evaluation of experimental therapies than total global ischemia, and the high incidence of infarction is an advantage over the simple single common carotid occlusion model most widely used.

104.7 RESPONSE OF LOCUS COERULEUS NEURONS TO DIRECT APPLICATION OF ETHANOL. Jean C. Strahlendorf and Howard K. Strahlendorf. Departments of Physiology and Medical and Surgical Neurology, Texas Tech University Health Sciences Center, Lubbock, Texas, 79430.

Ethanol (ETOH) is one of society's oldest and most widely used drugs yet the neuropharmacological actions of alcohol at the cellular level are poorly understood. The pharmacologic profile of ETOH bears many similarities to that of the benzodiazepines and opiates, e.g., anti-anxiety activity. Some recent reports indicate ETOH may influence GABA-ergic neurotransmission in the spinal cord and cerebral cortex. The noradrenergic neurons of the locus coeruleus (LC) possess GABA receptors and are strongly inhibited by iontophoretically applied GABA. Furthermore, the LC may be involved in the expression of anxiety, fear and stress reactions. We are currently examining the effect of ETOH applied directly to LC neurons by microiontophoresis (electro-osmosis) and micropressure ejection.

Chloral hydrate anesthetized male rats were used in all experiments. Conventional 5 or 7 barrel micropipettes containing 2M NaCl saturated with fast green in the center barrel were employed to record single LC units. Drug barrels contained 0.3M ETOH, 1M ETOH, 0.2M GABA, 0.1M glycine (all in distilled water) and 0.01M clonidine HCL in 165mM NaCl. Four molar NaCl was used in the balance barrel. LC neurons were identified by characteristic electrophysiologic criteria at the time of recording and verified histologically at the end of an experiment. Preliminary results indicate ETOH markedly slows LC firing in the absence of any detectable membrane effects when applied directly to the neuron. Percent inhibition of firing rate ranged from 6% to 24% over a "dose" range of 100nA-sec to 300nA-sec (n=10 cells). ETOH was applied for periods of up to 40 sec with 60 sec off times between ejections. With this protocol there was no evidence of cumulative (carry-over) effects or of rebound excitation. One cell appeared to become tolerant to repeated applications of ETOH at high ejection currents. These data demonstrate ETOH can directly suppress LC unit activity and suggest that the LC may be an important substrate for some pharmacologic actions of ETOH.

104.8 BEHAVIORAL AND BIOCHEMICAL CHANGES IN RATS EXPOSED TO CHRONIC ETHANOL TREATMENT. S. Liljequist*, J. Engel and K. Yoshida*.

Previous studies from our laboratory have indicated that chronic ethanol treatment (ethanol administered in various concentrations as the sole drinking fluid for up to 270 days)produced significant alterations in the behavior and in the activity of central catecholamine neurons in rats. One such change was characterized by the observation that local application of dopamine into the nucleus accumbens caused a marked locomotor stimulation in chronic ethanol rats in doses which per se had no effect on the locomotor activity of age-matched control rats thus indicating that chronic ethanol treatment increased the functional responsiveness of central dopaminergic mechanisms at or beyond postsynaptic dopamine receptors.

In order to further characterize the observed alteration of central dopamine receptor sensitivity, we have examined the effects of various doses of the specific dopamine receptor antagonist haloperidol on the catecholamine synthesis (measured as the accumulation of DOPA after inhibition of aromatic amino acid decarboxylase by NSD-1015) in various brain regions. It was observed that haloperidol significantly less enhanced the accumulation of DOPA in dopamine-rich brain structures of chronic ethanol rats as compared to the biochemical changes seen in age-matched control rats, thus lending further evidence to the hypothesis that chronic ethanol treatment may increase the sensitivity at or beyond central postsynaptic dopamine receptors.

The interaction between central dopaminergic and cholinergic neurons in the brain is well established. To investigate whether the present ethanol regimen affect central cholinergic mechanisms we have studied the binding of ^{3}H-nicotine to membranes of the hippocampus, thalamus, and hypothalamus of chronic ethanol rats. Chronic ethanol treatment for 150 days significantly decreased the binding of ^{3}H-nicotine to membranes of the hippocampus while increased binding of ^{3}H-nicotine was observed in the thalamus and in the hypothalamus.

Taken together, the results from the present study seem to further support the view that various central neurotransmitter mechanisms are affected by chronic ethanol treatment.

Supported by the Swedish Medical Research Council no 4247, the Swedish Council for Planning and Coordination of Research, and Torsten och Ragnar Söderbergs Stiftelse.

104.9 Behavioral Effects of Apomorphine and Ethanol in Lines of Mice Which Differ in Neurosensitivity to Alcohol. Michael E. Abbott* and Bruce C. Dudek. Dept. of Psychology, SUNY-Albany, Albany, NY 11222.

The selective breeding program of McClearn and Kakihana (Behav. Genet.3:409-410, 1973) produced lines of mice which differ markedly in sensitivity to the hypnotic effect of ethanol (ETOH). This reflects a differential neurosensitivity to ETOH. Furthermore, SS mice(Short sleep) are highly activated by subhypnotic doses while LS(Long sleep) show depressed locomotion and severe uncoordination. ETOH reduces dopamine (DA) turnover more in the LS mice than in SS mice. Additionally several agents which affect DA function have differential behavioral and biochemical effects in these mice, implicating DA systems as a basis for the differential response to ETOH. The present studies examined the effects of the DA agonist apomorphine(APO) in these mice and replicated earlier work showing that APO could block the activitional effects of ETOH on locomotor activity. The first experiment examined the APO dose response curve. Mice were treated with one of seven doses of APO (.15-2.5 mg/kg i.p.). Ten minutes later they were placed in a photocell apparatus and locomotor activity was recorded for 15 min. Both lines showed similar depression to .6075 mg/kg, slight activation to 2.5 mg/kg, and depression to 5 mg/kg. The second experiment assessed APO-induced stereotypy with similar doses. Dose dependent stereotypy did not differ between the two lines. Thus from the first two experiments it appears that the agonist actions of APO are similar in these lines. However, the third experiment shows that the ability of APO to modify the dose response curve of ETOH is different in these two lines. The mice were treated with APO at 0, .15, .6075 or 2.5 mg/kg. Ten minutes later they received ETOH at 0, 1.5, 2.0, or 2.5 g/kg, and locomotor activity was recorded for 15 min. At the lower doses of APO (.15 and .6075) the activational effects of 1.5 g/kg ETOH were blocked in the LS mice and slightly diminished in SS mice. The 2.5 mg/kg dose of APO blocked the depressant effects of 2.5 g/kg in the LS mice and reduced the activational effect in the SS mice. Thus both presumed presynaptic and postsynaptic effects of APO on the ETOH responses were genotype dependent, providing added evidence that DA systems may control the differential response of these mice to ethanol. Althougn the genetic control of the ETOH response is complex (polygenic), it appears that at least one major neurotransmitter system(s) may have been strongly affected by the selective breeding. These mice thus serve as a valuable tool for investigations of DA involvement in ETOH actions.

104.10 EVIDENCE FOR ALTERATION OF THE BRAIN MEMBRANE CALCIUM BINDING IN ETHANOL-DEPENDENT RATS PROBED BY TERBIUM (TB^{3+}) FLUORESCENCE. Harish C. Pant*, Charles E. Swenberg*, Edward Majchrowicz*, and Forrest F. Weight. (SPON: J. S. Hong). Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852

Calcium (Ca^{2+}) interaction with biological membranes in the presence of ethanol has attracted considerable attention since many cellular processes are controlled by Ca^{2+}. However, reported data on Ca^{2+}-membrane interaction after chronic treatment with ethanol or after in vitro addition of ethanol to isolated synaptosomal plasma membranes (SPM) are conflicting. In the present study, we utilized Tb^{3+} fluorescence to probe membrane Ca^{2+} binding in the cerebellum and cerebral cortex of ethanol dependent and withdrawing rats. Ethanol was administered to male Sprague-Dawley rats (250-350 g) using the intubation technique of Majchrowicz (Psychopharmacolgia 43: 245, 1975). Four groups of rats were studied: (1) water treated controls; (2) acutely treated rats (4 hr after po dose of ethanol, 6 g/kg); (3) dependent-intoxicated (prodromal detoxication phase), blood ethanol concentration usually 300-500 mg/dl; (4) ethanol withdrawal syndrome group (4-6 hr after the onset of overt signs of CNS hyperexcitability). SPM were prepared by the method of Whittaker (Ann. N.Y. Acad. Sci. 137:982, 1976). Fluorescence measurements were performed with an Aminco-Bowman Spectrophotofluorometer (excitation wave length 285 nm, emission wave length, 545 nm). The addition of Ca^{2+} decreased the Tb^{3+} fluorescence in all synaptosomal preparations. A double reciprocal analysis of the Tb^{3+} fluorescence as a function of Tb^{3+} concentration indicates a decrease in the Ca^{2+} dissociation constant relative to control for Ca^{2+} binding in dependent-intoxicated animals and its partial restoration during withdrawal. No change in the Ca^{2+} dissociation constant was observed in the acutely intoxicated rats. The data suggest that membrane Ca^{2+} binding is modified in the cerebellum and cerebral cortex of ethanol-dependent rats.

104.11 CHANGES IN GLUCOSE UTILIZATION IN THE BRAIN DURING THE WITHDRAWAL SYNDROME IN ETHANOL-DEPENDENT RATS. Gerald A. Campbell*, Michael J. Eckardt, Edward Majchrowicz*, Cheryl A. Marietta* and Forrest F. Weight. Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, Md. 20852

EEG and behavioral studies have indicated that sudden reduction in blood ethanol concentration (BEC) due to abstinence in humans and experimental animals which are physically dependent on ethanol can result in the development of CNS hyperexcitability and a withdrawal syndrome characterized by hyperactivity, hyper-reflexia, tremors, spasticity and convulsions. We have used 2-deoxy-D-[^{14} C]-glucose (2-DG) as a metabolic tracer to investigate whether there are local differences in glucose uptake in the CNS of ethanol-dependent rats exhibiting the withdrawal syndrome. Male Sprague-Dawley rats (200-300g) were made physically dependent upon ethanol using the intubation technique of Majchrowicz (Psychopharmacologia, 43:245, 1975). The last dose of ethanol in the early evening of the fourth day of ethanol administration marked the beginning of the withdrawal period. The onset of the behavioral signs of the withdrawal syndrome typically occurred about 12 hours later. Following the onset of the withdrawal syndrome, the animals were observed for 4-6 consecutive hours and rated for the severity of withdrawal. Animals were selected to be studied using the 2-DG technique when the manifestations of the withdrawal syndrome appeared maximal; at that time, the BEC had fallen to negligible levels. Glucose utilization was determined by means of the autoradiographic 2-DG method of Sokoloff (J. Neurochem., 28:897, 1977). Examination of the autoradiographs of brain sections from withdrawing animals revealed alternating light and dark columnar bands in frontal-sensorimotor and parietal cortex and in cerebellar vermis. Such columnar bands were not observed in controls. Cerebellar flocculus and paraflocculus showed patchy increases in density, whereas these structures were relatively uniform in controls. In addition, in controls, the globus pallidus, the zona incerta, the preoptic area of the hypothalamus, and several specific thalamic nuclei had little contrast compared with adjacent structures; however, in withdrawing animals, the density of these areas was considerably greater than that of adjacent structures.

104.12 The Actions of Ethanol on Basal and DA-Stimulated Adenylate Cyclase: Alteration of the Energy of Activation. S.N. Deyo*, M.V. Wagner*, S.J. Henriksen, W.J. Shoemaker, L.M. Randolph* and F.E. Bloom. A.V. Davis Center for Behavioral Neurobiology, LaJolla, CA 92037.

Ethanol (E) may produce its central pharmacological actions in part by disrupting the organization of neuronal membranes. Indeed, E increases the mobility of a membrane viscosity probe. This effect of E is dose dependent and may be interpreted as an indication that E decreases regional membrane viscosity. Proteins embedded in the membrane are thought to be dependent on the lipid environment for the maintenance of their structure and function. Therefore, it is possible that low and intoxicating doses of E might induce their pharmacological effects by altering the activities and interactions of membrane-bound proteins. We have studied E's affect on the kinetics of a membrane-bound enzyme, as reflected by the energy of activation (Ea) for the reaction that is catalyzed by the enzyme, to examine E's action(s) on membrane-embedded proteins. The Ea is determined from an Arrhenius plot which relates the rate of a reaction to the reaction temperature. In many cases the Ea's of reactions that are catalyzed by membrane-bound enzymes have been found to be directly related to membrane microviscosity. Therefore, changes in membrane viscosity induced by E may be expected to alter the rate of a membrane protein catalyzed reaction by changing the Ea. We have performed in vitro experiments that examine the effect of low concentrations of E (20-100 mM) on the Ea for basal and dopamine (DA)-stimulated adenylate cyclase from the rat striatum. In these experiments adenylate cyclase activity was measured in crude, striatal homogenates. E was added at the start of the incubation period, and the samples were incubated for 0, 3, 6, 9 or 12 minutes. From these data an equation relating cAMP production to time was generated. The velocities of enzyme activity and of DA activation of enzyme activity were determined from the first and second derivatives, respectively, of the equation. E (40 mM) decreased the Ea for the stimulation of adenylate cyclase activity by DA (Ea-control = 17.8 kcal/mole;Ea-Etoh = 5.3 kcal/mole), but it did not change the Ea for non-stimulated (basal) adenylate cyclase activity (Ea-control = 8.9 kcal/mole;Ea-Etoh = 9.8 kcal/mole). These results suggest that low concentrations of E facilitate the activation by DA of adenylate cyclase activity by enhancing the lateral mobility of the DA receptor. This is consistent with the idea that E produces some of its pharmacological effects by decreasing the viscosity of membranes and modifying the interactions between membrane proteins. (supported by AA 03504 and AA 07273)

104.13 THE EFFECT OF CHRONIC ALCOHOL CONSUMPTION ON NEUROTRANSMITTER SYSTEMS IN ALCOHOL-PREFERRING RATS. J.M. Murphy, W.J. McBride, D.J. Ciancone,*L. Lumeng* and T.-K. Li*, Depts. Psych. Med. & Biochem., Indiana Univ. Sch. of Med. & VA Medical Center, Indianapolis, IN 46223.

Selectively bred alcohol-preferring (P) rats voluntarily drink large quantities of alcohol that approach their daily metabolic capacity. In three experiments, the effects of chronic alcohol consumption on brain transmitter systems were assessed by comparing P-line animals maintained on water (P-W) with P rats allowed free choice between water and a 10% ethanol solution (P-EtOH) for 6-8 weeks.

In the first experiment, five P-W and eight P-EtOH rats were killed by the near-freezing technique; the brains were dissected into cerebral cortex, striatum, hippocampus, thalamus, hypothalamus, midbrain, pons-medulla, and cerebellum. The brain regions were then assayed for the content of GABA, glutamate, aspartate, and tryptophan. No significant differences occurred in any brain region between the P-W and P-EtOH groups for any of the amino acids measured. The results suggest that chronic EtOH consumption does not alter steady state CNS levels of the amino acid neurotransmitters and does not compromise dietary availability of tryptophan. The second experiment compared 10 P-W and 10 P-EtOH rats for CNS levels of norepinephrine (NE), dopamine (DA) and serotonin (5-HT), 3,4-dihydroxyphenylacetic acid (DOPAC) and 5-hydroxyindoleacetic acid (5-HIAA) in the cerebellum, hippocampus and hypothalamus. EtOH consumption had no effect on NE levels in the three regions and did not alter DA or DOPAC levels which were detected in sufficient amounts only in the hypothalamus. The levels of 5-HT and 5-HIAA were 5-20% lower for P-EtOH rats, but only 5-HIAA in the cerebellum (0.33 $\pm$ 0.02 nmoles/g tissue) differed significantly from the P-W group (0.42 $\pm$ 0.03 nmoles/g). The third experiment compared receptor binding to synaptic plasma membranes (SPM) from the telencephalon (TEL) and dienmesencephalon (D-M) of P-W and P-EtOH rats. The binding of [^{3}H]-5-HT, -dihydroalprenalol (DHA), and -spiroperidol were decreased 15-25% in the P-EtOH group relative to the P-W group while [^{3}H]-GABA binding was not affected by EtOH consumption. Binding of [^{3}H]-5-HT and -DHA to SPM from D-M was not significantly changed by EtOH consumption.

Taken together, the findings indicate that a major consequence of chronic ethanol consumption at the receptor level occurs in the TEL. Some evidence was also obtained to suggest that chronic EtOH consumption decreased 5-HT synthesis, release and/or turnover, as indicated by lower 5-HIAA in the cerebellum. (Supported in part by AA 003243, MH 00203, and Assoc. Adv. Mental Health Res. & Ed., Inc.).

104.14 MODULATION OF BENZODIAZEPINE AND GABA RECEPTORS BY BARBITURATES. R. J. Fanelli, M. J. Iadarola, W. A. Wilson* and J. O. McNamara (SPON: R. R. Miller). Departments of Medicine (Neurology) and Pharmacology, Duke University; and Epilepsy Center, VA Medical Center; Durham, NC 27705

We have examined the ability of a series of barbs to enhance 1) GABAergic recurrent inhibition and 2) GABA stimulated and basal BDZ binding.

Transverse 400μ slices of hippocampus were maintained in vitro and drugs were added to the bath. Extracellular field potentials were recorded from the pyramidal layer of CA1. The time course of recurrent inhibition was mapped by varying the latency between stimulation of the alveus and stratum radiatum. The amplitude of the orthodromic population spike was reduced if it fell into the inhibitory period of the recurrently evoked IPSP. Pentobarb (PB, 100μM) enhanced the efficacy and greatly prolonged the duration of recurrent inhibition. Modest effects were observed at 10μM and intermediate effects obtained at 50μM PB. Secobarb (SB) also caused a dose dependent enhancement and prolongation of recurrent inhibition. In contrast phenobarb (PhB) or diphenylbarbituric acid (DPB; 50-500μM) appeared to produce only a minimal enhancement of inhibition in our system; DPB being less effective than PhB. However doses of PhB or DPB in this same range were capable of altering abnormal discharges induced by bicuculline methiodide (50μM) indicating that the drugs were active in the tissue.

The effect of SB, PB, PhB, and DPB on BDZ ([^{3}H]-flunitrazepam) binding in the presence and absence of chloride ion (Cl^-, 100mM) and/or maximal concentrations of GABA (10μM) was studied in extensively washed freeze-thawed membranes from rat forebrain. BDZ binding could be stimulated by Cl^- alone (24% enhancement), GABA alone (49% enhancement), and in a dose-dependent fashion by either SB or PB (maximal effect 76% and 29% respectively). Stimulation of BDZ binding by SB and PB could be significantly enhanced by inclusion of GABA in the assay. In contrast, PhB and DPB alone and in the presence of GABA failed to augment BDZ binding. Also, Cl^- stimulated BDZ binding was markedly enhanced by SB and P B but not by PhB and DPB. These data demonstrate a striking correlation between the efficacy of barbs to enhance GABA-coupled BDZ binding as well as a GABA-mediated synaptic response and suggests that the molecular action may be related to the synaptic action. The slice experiments also suggest that, at least in this preparation, enhancement of GABAergic inhibition may not be essential for the anticonvulsant activity of the barbs.

104.15 NEURONAL PHOSPHOLIPID METABOLISM IN C57/6 MICE MADE PHYSICALLY DEPENDENT TO ETHANOL. Thomas L. Smith and Mary Gerhart*. Dept. Pharmacol., University of Arizona and Veterans Administration Medical Center, Tucson, AZ 85723.

Alteration of the physical state of neuronal membranes is believed to play a central role in the expression of functional tolerance and physical dependence to ethanol. Recent evidence suggests that these changes may occur in the lipid bilayer.

To test this hypothesis, mice were subjected to a liquid diet containing 7% (v/v) ethanol for 8 days. Mice were judged to be physically dependent by monitoring tremor and convulsions during withdrawal. At the time of sacrifice blood ethanol levels were > 250 mg%. Lipid analyses were performed on forebrain subcellular fractions (crude, myelin, light and heavy synaptosomes) isolated by discontinuous sucrose - density gradients. Lipids were extracted with chloroform - methanol (2:1) and in some cases were further separated by TLC. Neither total phospholipid content per mg protein nor the degree of phospholipid fatty acid saturation was altered in any of the above fractions. However, small increases in total cholesterol were observed in the crude synaptosomal fraction after ethanol treatment. This is in agreement with previous observations with DBA mice (Biochem. Biophys. Acta, 513:358, 1978).

In a series of in vitro experiments, neither basal nor muscarinic stimulation of ^{32}P incorporation into various phospholipids of light synaptosomes was affected by ethanol treatment. These results do not support the hypothesis that changes in phospholipid metabolism/levels or saturation of their fatty acids play a critical role in the development of physical dependence to ethanol. (Supported by Veterans Administration High Priority Alcohol Research Grant).

104.16 CALMODULIN ACTIVATED CA UPTAKE DURING ETHANOL TOLERANCE D.H.Ross,Div.Mol.Pharm.,Univ. Texas Health Sci.Center San Antonio,Texas 78284

Calcium ions are required for neuronal membrane stability and neurotransmitter release. The influx of calcium during depolarization and subsequent levels of free cytosolic calcium are buffered by a Ca ATPase and ATP dependent uptake of calcium by the membrane. This buffering mechanism is regulated by calmodulin(CM). Since ethanol has been shown to interfere with release of neurotransmitters and calcium movements across the membrane it was of interest to study the CM activation of Ca uptake during short and long term ethanol exposure. Male mice were exposed to a seven day ethanol-Sustacal(7%) drinking regimen. Behavior was measured by bar holding following a 1.5gm/kg dose of ethanol. Behavioral tolerance was 65% by day 4 and 100% by day 7. Synaptic membranes were prepared and ATP dependent Ca uptake measured by millipore filtration. Uptake was inhibited 35% on day 1, 22% on day 4, and 7% on day 7. Membranes were treated with EGTA to strip off CM and the uptake studies were repeated. CM addition to EGTA treated membranes increased uptake by 35% and 50% on day 4 and 7. These results demonstrate that Ca uptake is inhibited following one day of ethanol. This inhibition disappears by day 7 in parallel with the development of behavioral tolerance. CM addition to membranes produces maximal stimulation on day 7.These results suggest that during ethanol drinking, more calmodulin binds to the membrane such that by day 7 the membranes have increased CM content compared to pair fed controls. The increase in bound CM parallels the development of tolerance and may account for part of the adaptation to ethanol seen in nerve cells.

104.17 FACILITATORY EFFECTS OF ETHANOL ON NEUROMUSCULAR TRANSMISSION IN INTERCOSTAL MUSCLE FROM PATIENTS WITH MYASTHENIA GRAVIS.

Bruce R. Johnson* and James F. Howard, Jr. (SPON: D.B. Sanders) Department of Neurology, University of North Carolina, Chapel Hill, NC 27514

Ethanol potentiates synaptic transmission at normal vertebrate neuromuscular junctions by both pre- and post-synaptic actions. It has been suggested that ethanol might improve the efficacy of neuromuscular transmission in diseases such as myasthenia gravis (MG) (Bradley, R.J., et. al., Nature 284:60, 1980) where an apparent curare-like block caused by antibody binding to the post-synaptic membrane impairs receptor function. We have investigated the facilitatory effects of ethanol on neuromuscular transmission in intercostal muscle from patients with MG.

Conventional, intracellular recording techniques were used to measure miniature end-plate potentials (MEPP) in in vitro experiments. MEPP amplitudes from myasthenic muscles were small, ranging from 0.1mV to 1.0mV. Ethanol concentrations of 0.01, 0.05, 0.1% (found in humans after alcohol consumption), 0.5 and 1.0% were applied to different muscle bundles and MEPP amplitudes and waveform characteristics were analyzed. At 0.05, 0.1, 0.5 and 1.0% ethanol, MEPP amplitudes were larger than in the control solution and the duration of the MEPP was increased. No increase in MEPP amplitude was seen with 0.01% ethanol but MEPP duration was slightly prolonged. The concentrations of ethanol used in this study appear to enhance the post-synaptic response to the neurotransmitter and thus antagonize the disease-induced neuromuscular blockade of MG.

105.1 ACTIONS OF IDENTIFIED ACETYLCHOLINE/PEPTIDE CONTAINING NEURONS IN REGULATION OF MOLLUSKAN FEEDING BEHAVIOR. A.O.D. Willows, P.E. Lloyd*, and B. Masinovsky*. Dept. of Zoology and Friday Harbor Laboratories, University of Washington, Seattle, WA 98195.

Feeding behavior in the gastropod mollusk, Tritonia diomedia is controlled principally by neurons of the buccal ganglia, some of which are large (100-200 um. dia.) and individually reidentifiable. Certain of these neurons control the initiation, and execution of a cyclic pattern of motor output which ressembles the pattern observed during feeding behavior (Willows, A.O.D., J. Neurophysiol. 44:849). One pair of buccal ganglion neurons, the large dorsal white cells (LDWC, since re-named B11) contain a neuroactive peptide which has been isolated, and purified. We have found recently that this same neuron pair also contains the neurotransmitter, acetylcholine(Lloyd, P.E., et. al. Soc. Neurosci. Abst. this volume). Thus it is of increasing interest to know the site and mechanisms of action of these neurons.

The B11's are electrically active during spontaneously occurring or electrically driven episodes of the cyclic motor output in buccal ganglion neurons. Recordings of co-ordinated bursting activity in B11 and other neurons reveal low frequency bursts of impulses (3-7 Hz.) in the B11's phase coupled to the output of the motor pattern generator. Increases in the frequency and number of endogenously occurring impulses in B11 are accompanied by similar increases in motor neurons and in the amplitudes of the motor output measured with a phototransducer. Brief stimulation of both B11's simultaneously elicits first a polysynaptic excitatatory synaptic volley, and then one or more complete cycles of motor output. In spontaneously active preparations, stimulation of B11's results in prolonged enhancement of the bursting output. The excitation of the motor pattern generating system by B11 is apparently not mediated by electrical junctions because simultaneous strong hyperpolarization of B11 bilaterally has no detectable influence on the frequency of bursting output from spontaneously active motor neurons.

Earlier, we showed that the peptide from B11 directly applied to the buccal ganglia elicits or (in spontaneously active preparations) enhances the cyclic motor output (Lloyd P.E. and Willows, A.O.D., Soc. Neurosci. Abst. 240.9, 1980). As yet we have not determined what, if any, role acetylcholine plays in this control mechanism. However, B11 and its central and peripheral targets offer an unusual opportunity to determine whether there is an interaction between this neural peptide and the acetylcholine originating in the same neuron.

105.2 DIFFERENTIAL ACTION OF CHOLINERGIC AGENTS ON THE BODY WALL MUSCULATURE OF A SABELLID WORM. L.Córdova*and C. Escalona de Motta.Lab.Neurobiology UPR Sch. Med.San Juan,PR 00901.

The somatic muscles of annelid worms exhibit multicomponent contractile responses to ACh and related agonists(Alvarez et al,Comp.Biochem.Physiol. 29:931,1969). This could imply the existence of cells with different pharmacological properties in apparently homogeneous muscles. A pharmacological analysis of the responses displayed by strips of dorsal longitudinal muscles of S. magnifica was undertaken to explore this possibility. Strips 2-3cm long were isolated from fresh specimens and placed in a sea water chamber at 26°C to record isometric tension. Addition of 10^{-6} to 10^{-4} w/v ACh evoked a 'fast'contraction (time to peak:44s^{+} 4s, SE,n=38) that returns slowly to resting tension with an average half time of 158s^{+} 15s,SE,n=31. In 10^{-6}w/v d-tubocurarine(dtC) contraction time is slightly increased but in the presence of $2x10^{-6}$w/v α bungarotoxin (αBuTX) no change occurs.$2x10^{-7}$to $5x10^{-5}$w/v nicotine elicits a biphasic response: an early relaxation followed, at concentrations above 10^{-5}, by a slow contraction that reaches a maximum in 10 to 25 min. dtC blocks the contraction phase without affecting the relaxation while αBuTX does not affect either phase. No early relaxation component was revealed in the response to ACh by 10^{-6}w/v atropine. Methacholine, a classical muscarinic agent, produces biphasic responses similar to nicotine. Neither of these agents alone is able to evoke responses with the same time course as those initiated by ACh in this preparation.

105.3 PEPTIDE MODULATION OF THE ISOLATED APLYSIA HEART. Sandra Wernham and Ken Lukowiak*. Dept. of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

In the past 20 years investigations performed on the molluscan cardiovascular system and its central control have yielded some valuable information in relation to cardioactivity not associated with the usual neurotransmitters serotonin(5HT), acetylcholine(Ach) and catecholamines. Although most of this cardioactivity has been characterised as resulting from endogenous peptide extracts, with few exceptions further identification of these peptides and their mode of action remain to be determined.

In the marine mollusk, Aplysia californica, however, the presence in the anterior ganglia of an arginine vasotocin (AVT)-like neuropeptide has been positively identified (Moore et al, Brain Res., 206:213-218, 1981). We have shown that AVT has both long-term positive chronotropic and inotropic effects on the isolated Aplysia heart at concentrations as low as 10^{-14} M. In comparison, perfusion of 10^{-12} M AVT is sufficient to increase basal heart rate to the same level achieved by a 10^{-9} M 5HT perfusion of the same heart tissue. The inotropic effects produced by AVT are both cummulative and of greater amplitude than those produced by 5HT. Further, the effects produced by AVT are not immediate - they have a consistent latency of 10$\pm$1 mins; and both the chronotropic and inotropic effects persist for hours following washout compared to minutes as found for 5HT.

Preliminary evidence also suggests that dopamine, met-encephalon and angiotensin-II may have varying degrees of long-term effects as well on heart behavior when applied directly to the isolated Aplysia heart at similar concentrations as those found for AVT. The effects of these and other neuropeptides, therefore, will also be discussed in comparison to similar, shorter-term effects produced by 5HT and Ach, known molluscan cardioregulators (Liebeswar et al, J. Neurophysiol., 38:767-779, 1975).

This research was supported by the Alberta Heart Foundation and an Alberta Heritage Research Predoctoral Scholarship in Medical Research (S.W.).

105.4 ENDOGENOUS HISTAMINE IN THE LOBSTER STOMATOGASTRIC NERVOUS SYSTEM. Brenda J. Claiborne. Department of Biology, Univ. of Calif., San Diego, La Jolla, CA 92093

Physiological and pharmacological studies suggest that histamine may function as a neurotransmitter in the lobster stomatogastric ganglion (Claiborne, B., Neurosci. Abstr., 6:626, 1980). The thirty neurons in the stomatogastric ganglion control the rhythmic movements of the lobster stomach and receive inputs from neurons located in other ganglia of the stomatogastric nervous system. I report here the presence of endogenous histamine in the ganglia and nerves of the stomatogastric nervous system of the spiny lobster, Panulirus interruptus.

Histamine was assayed according to the procedure of Weinreich, Weiner and McCaman (Brain Res., 84:341, 1975). Extracts of individual nerves or ganglia were incubated at 37°C for 30 minutes with ^{3}H-S-adenyl-L-methionine and histamine methyltransferase in phosphate buffer. The reaction was stopped by the addition of NaOH, the ^{3}H-methylhistamine was extracted into chloroform, and, following two washes with NaOH, aliquots of the organic phase were counted in a liquid scintillation counter. The results indicate that histamine is distributed throughout the system, but not uniformly: the stomatogastric ganglion contains 115 pmoles of histamine per mgram of tissue protein, the commissural ganglia contain 60 pm/mg, and the esophageal ganglion contains 12 pm/mg. The nerves connecting these ganglia contain between 3 and 11 pm/mg, and the motor nerve exiting the stomatogastric ganglion contains 5 pm/mg. These histamine levels are similar to those found in ganglia and nerves of the mollusc Aplysia, for which there is extensive evidence that histamine functions as a neurotransmitter.

Preliminary data from assays of individual cell bodies and the neuropil region of the stomatogastric ganglion indicate that the histamine present in the stomatogastric ganglion is located in the neuropil region and is not present in neuronal cell bodies. Further, results from nerve ligation experiments suggest that histamine is transported into the stomatogastric ganglion from neuronal somata located in other ganglia. Current work is therefore focused on locating histamine-containing neurons in the commissural, esophageal or supraesophageal ganglia, all of which are known to send inputs to the stomatogastric ganglion.

105.5 SYNTHETIC OCTOPAMINE AGONISTS: STRUCTURE-ACTIVITY RELATIONSHIPS OF THE FORMAMIDINE PESTICIDES. James A. Nathanson. Depts. of Neurology and Pharmacology, Harvard Medical School, Mass. General Hospital, Boston, Massachusetts 02114.

Octopamine appears to be an important neurotransmitter and neuromodulator in invertebrates. Electrophysiological studies suggest that more than a single receptor for octopamine may exist, and biochemical experiments indicate that at least some octopamine receptors may activate adenylate cyclase. A significant handicap in the investigation of octopaminergic function has been a lack of potent octopamine analogs. However, a recent report (Nathanson and Hunnicutt, Mol. Pharmacology, in press) indicates that the formamidine pesticide, demethylchlordimeform, is a potent activator of octopamine-sensitive adenylate cyclase in the firefly light organ (a tissue rich in octopamine-sensitive adenylate cyclase). We now find that several other formamidine analogs are also potent octopaminergic compounds.

Octopamine-sensitive adenylate cyclase activity was measured in washed particulate preparations of firefly light organs. The assay system contained 80mM Tris-maleate, pH 7.4; 10mM theophylline; 8mM $MgCl_2$; 0.1mM GTP; 0.5mM EGTA; and 2mM ATP, plus or minus drug. The formamidines tested were chlordimeform (CDM); N-demethylchlordimeform (DCDM); N,N-didemethylchlordimeform (DDCDM); BTS 27271 (DCDM with methyl substituted for chloro); and two symmetrical triazapentadienes, BTS 27419 and BTS 23376, with structures derived from BTS 27271 and DCDM, respectively.

Compared with octopamine, all compounds with the exception of CDM (K_a = 30 micromolar; Vmax = 9% of octopamine) were more potent than octopamine. DCDM (K_a = 2.6 micromolar) and its symmetrical analogue, BTS 23376, were both about 6 to 10 times more potent than octopamine. The dechloro methylated derivatives, BTS 27271 (K_a = 8 micromolar) and BTS 27419 (K_a = 10 micromolar, were about 4 times less potent than DCDM. DDCDM was considerably more potent than CDM but less potent than DCDM, indicating that, as with octopamine, synephrine and N,N-dimethyloctopamine, the N-monomethyl analogue is the most potent. All of the formamidines except CDM showed a Vmax of between 70 and 90% that of octopamine. In other experiments, DCDM and CDM were found to have little effect on either dopamine- or isoproterenol-activated adenylate cyclase. The results indicate that the formamidines are very potent octopamine analogs which appear to have a degree of specificity for certain octopamine receptors.

105.6 DOPAMINE ACTION ON THE CRUSTACEAN CARDIAC GANGLION. M. W. Miller*, R. E. Sullivan, J. A. Benson* and A. Berlind (Spon: D. Russell) Bekesy Laboratory of Neurobiology, University of Hawaii, Honolulu, HI 96822

Dopamine (DA) has been shown to be present in the neurosecretory pericardial organs of decapod crustacea. We have examined the mechanisms by which this catecholamine exerts its effects upon the semi-isolated cardiac ganglion, an autonomously rhythmic 9-cell neural network which controls the heartbeat. Dopamine ($5X10^{-8}$ M - $5X10^{-6}$ M) has strong excitatory effects on the cardiac ganglion of the crab Portunus sanguinolentus. It increases the burst rate, prolongs burst duration, and increases the number of impulses per burst. Moreover, DA appears to have an 'organizing' effect on ganglia in which bursting is irregular.

Experiments designed to determine the locus of DA action indicate that its principle effects are on the small "pacemaker" cells. In experiments utilizing a two-pool chamber, DA effects were limited to applications to the posterior small cell region. When DA is applied to the whole ganglion, its enhancement of small cell intraburst spike frequency is especially pronounced. Also, in ligatured ganglia in which small cell activity could be recorded via electrotonic coupling with a posterior large cell, DA was noted to exert strong excitatory effects on small cells while having minimal effects on anterior large cells.

One means by which dopamine could have such excitatory action is via an effect upon the driver potential (DP), a slow (200-300 msec), Ca^{++}-dependent (TTX-resistant), voltage- and time dependent potential which underlies burst formation in the cardiac ganglion (Tazaki & Cooke, 1979). In the presence of TTX ($3X10^{-7}$ M), DA produces small (1-5 mV) repetitive potential oscillations in large cell recordings in Portunus. The occurrence of these oscillations is limited to posterior application in two-pool experiments and their time-course and form suggest that they are electrotonically conducted small cell DP. Although DA has minimal effects on the form of the DP of large cells, it does slightly decrease the threshold for evoked large cell DP and cause a small decrease in the apparent large cell input resistance.

These experiments suggest 1) that the excitatory actions of dopamine on the crustacean cardiac ganglion are primarily produced by effects upon the small cells and 2) that these effects are due to enhancement of DPs and/or lowering of threshold for DP generation in these cells.

105.7 METACEREBRAL GIANT CELL AND SEROTONIN EFFECTS ON SALIVARY ACINAR CELLS IN THE TERRESTRIAL MOLLUSK, LIMAX MAXIMUS. Jonathan Copeland. Department of Zoology, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin 53201.

A re-identifiable serotonergic neuron, one in each cerebral ganglion, has been found in a number of different species of gastropod mollusks. This neuron, called the metacerebral giant cell (MGC) in Limax maximus, produces conventional and modulatory effects at buccal ganglion synapses, modulatory effects at buccal mass neuromuscular junctions and muscle, and an overall facilitory effect on the neural networks that underlie feeding. I have found that the MGC and serotonin also have a modulatory (excitatory) effect in Limax at an unusual type of neuroeffector, secretory epithelium.

Limax possesses paired salivary glands (SGs), each innervated by a salivary nerve (SN) which arises from the ipsilateral buccal ganglion (BG), paired BGs, and paired cerebral ganglia. Previous work has shown that each SN contains several thousand axons. One axon is that of the MGC, and two axons are from the paired bilateral salivary neurons (BSNs). One BSN soma is found in each BG, and each BSN has an axon in the ipsilateral and contralateral SN. BSN is a secretomotor neuron and it innervates less than 10% of the secretory salivary acinar cells (SACs). BSN-evoked EJPs can be recorded from these SACs, and these occasionally give rise to action potentials. BSN is an autoactive burster neuron with slow, regular bursts. Intracellular stimulation of MGC delays or accelerates BSN burst frequency.

Cobalt nitrate fills reveal that the axon of the MGC travels the length of the ipsilateral SN and enters the SG. Intracellular stimulation of MGC (10 spikes/2sec.) produces changes in BSN-evoked EJPs recorded in SACs. Both EJP amplitude and EJP number increase within seconds of MGC stimulation and remain elevated for up to 14 seconds. SAC potential hyperpolarizes slightly (2 - 5 mv) and input resistance increases (< 43%) within 2 seconds of MGC stimulation, and these effects last for 30 seconds. Superfusion of an isolated SG with a saline containing 10^{-9} M serotonin produces a small (4 - 6 mv) depolarization of the SAC resting potential, an increase in input resistance, and an increase in excitability. After treatment with serotonin for 5 minutes, SACs, previously silent in response to current injection, now produce action potentials when stimulated. SACs respond to superfusion of an elevated (10^{-3} M) serotonin-containing saline and intracellular current injection (1 nanoampere) with a tonic train of action potentials.

Collectively, these results are consistent with the hypothesis that the MGC and serotonin modulate the excitability of a secretory epithelium.

105.8 OCTOPAMINE AND DOPAMINE EVOKE VOLTAGE-DEPENDENT INWARD CURRENTS IN APLYSIA. T. Pellmar. Lab. Preclin. Stud. NIAAA, Rockville, MD 20852.

In LB and RB neurons of the abdominal ganglion of Aplysia californica, serotonin elicits a slow inward current which is present only at potentials more depolarized than -40mV and has a maximum amplitude near 0mV. To determine if this voltage-dependent response was unique to serotonin, several transmitters were tested in these two cell clusters. Dopamine (in LB cells) and octopamine (in both RB and LB cells), but not histamine, acetylcholine, gamma aminobutyric acid or glutamate, elicit a similar current. Like the serotonin-evoked response, the slow inward currents resulting from iontophoretic application of octopamine and dopamine reach a maximum amplitude in 10 to 20 seconds and last at least one minute. The currents are insensitive to changes in extracellular potassium concentration, persist after replacement of sodium with bis tris propane, are not reduced by a decrease in chloride concentration and are blocked by 2 mM cadmium. Because of the similarities in voltage-dependence, time course and ionic sensitivities, the responses to octopamine, dopamine and serotonin are concluded to have the same ionic mechanism. Associated with the voltage-dependent response to serotonin, appears to be a broadening of the action potentials recorded in the presence of 50 mM tetraethylammonium. Like serotonin, octopamine is capable of increasing spike duration in LB cells.

Because intracellularly injected cyclic AMP elicits an identical voltage-dependent current in LB and RB cells (Pellmar, Cell. and Molec. Neurobiol., 1981), it is tempting to suggest that the currents evoked by serotonin, dopamine and octopamine are all mediated by the cyclic nucleotide. Yet pharmacological data for the response to serotonin tend to dispute this hypothesis. Agents which alter cyclic AMP metabolism do not affect the serotonin-induced current in the predicted way. Although it seems unlikely that current evoked by serotonin is mediated through cyclic AMP, it is possible that the responses to octopamine and/or dopamine are activated through the second messenger. This would result in an interesting situation where two transmitters would elicit nearly identical responses through very different intracellular mechanisms.

105.9 (^{3}H)SPIROPERIDOL BINDING IN CILIATED TISSUES OF THE MARINE BIVALVE MYTILUS CALIFORNIANUS. J. R. SMITH* (SPON: C. SCHASTEEN). Marine Sci. Center, Oregon St. Univ., Sch. of Pharm., Corvallis, OR 97331.

Pharmacological, biochemical, and histochemical evidence suggests that the endogenous substance dopamine (DA) acts as a neurotransmitter in marine mussels in a cilioregulatory capacity (Malanga, C.J., Comp. Biochem. Physiol., 51C:25-34, 1975). In an effort to further clarify the role of DA as a neurotransmitter in this species we have carried out a series of experiments designed to identify and characterize putative DA receptor sites in ciliated tissues. The DA antagonist (^{3}H)spiroperidol (SPDL) (New England Nuclear; specific activity=25.7 Ci/mmole) was used as the radioligand in all experiments. Tissue suspensions were prepared in a manner similar to that previously reported by Burt et al., (Mo. Pharmac., 12:800-812, 1976). Incubation buffer consisted of 50mM Tris, 0.1% ascorbic acid, and 10μM pargyline (pH=7.4 at 4°C). Samples were incubated for 60 min. in an ice bath after which they were filtered through a glass fiber filter and given 3 (5ml) washes under vacuum pressure. The protein concentration in each tube ranged from .1 to .2 mg and the (^{3}H)SPDL concentration was .2nM. All samples were run in triplicate and data from 2-6 separate experiments were pooled for estimates of K_D, B_{max}, and IC_{50}. Total (^{3}H)SPDL binding never exceeded 10% of the total (^{3}H)SPDL added. All competition experiments utilized 6-8 concentrations of competing agents. Specific binding of (^{3}H)SPDL was defined as the difference between the amount of (^{3}H)SPDL bound in the absence of unlabeled SPDL and that bound in the presence of excess SPDL (10^{-6}M). (^{3}H)SPDL binding to gill tissue homogenates was found to be saturable with an apparent K_D of 0.6nM and a B_{max} of 92pmoles/gm protein. Competition experiments using d and l-butaclamol show that the pharmacologically active d-form had an IC_{50} of 1.5nM while the l-form showed no competition up to a 10^{-6}M concentration. DA (up to 10^{-4}M) also failed to compete for (^{3}H)SPDL binding sites. Serotonin also showed no competition up to a 10^{-6}M concentration. The addition of 440mM NaCl (mussel body fluid concentration) to the incubation media shifted the K_D for (^{3}H)SPDL to 0.1nM while the addition of 9.5mM $CaCl_2$ resulted in a rise in K_D to 80nM. We conclude that gill tissue of Mytilus c. has high affinity binding sites which appear to be highly specific for dopamine antagonists. This offers further support for the theory that DA acts as a neurotransmitter in ciliated tissue of bivalves and indicates that gill tissue may be a valuable source of a relatively pure DA-receptor type. This study was funded by PHS grant ES01926.

105.10 PROTEIN BIOSYNTHESIS IN THE X-ORGAN-SINUS GLAND COMPLEX OF DECAPOD CRUSTACEANS. E. Stuenkel* (Spon: C. Zomzely-Neurath). Bekesy Laboratory of Neurobiology, University of Hawaii, Honolulu, HI 96822.

The x-organ-sinus gland (XOSG) peptide neurosecretory system located in the eyestalk of decapod crustaceans is morphologically and functionally subdivided into a cell soma biosynthetic region, an axonal transport and processing portion and a discrete nerve terminal storage and release area. The XOSG from the land crab Cardisoma carnifex was utilized for in vitro radiolabeling studies on crustacean neuropeptide biosynthesis. In vitro studies designed to determine the time dependence of tritiated leucine (20 µM) uptake into the x-organ indicate ^{3}H-leucine accumulates and reaches a plateau in approximately 3 hours. Incorporation of ^{3}H-leucine into protein is directly proportional to incubation time for up to 7 hours. Additionally, radiolabeled proteins produced in the x-organ are axonally transported to the sinus gland as determined in preparations with intact versus ligated XOSG nerves.

In all experiments ^{3}H-leucine incorporation into protein was determined by analyzing counts remaining at the origin after high voltage paper electrophoresis (50-60 V/cm) at pH 1.9 for 1-2 hours. The protein nature of origin counts was confirmed by acid hydrolysis and subsequent electrophoresis. ^{3}H-leucine incorporation into origin counts was reduced 90% by puromycin, an inhibitor of eukaryotic protein synthesis. Moreover, origin counts eluted in the void volume of Sephadex G-25 and Biogel P-2, suggesting a molecular weight greater than 2500. A 5 hr pulse 24 hr chase paradigm (at 20°C) was found to optimize conditions for examining this high MW protein fraction. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of non-radiolabeled XOSG revealed at least two distinct protein bands of <10,000 MW which are specific to the XOSG neurosecretory system. One of the bands (MW ≃ 6000) has previously been identified as hyperglycemic hormone by other workers and represents 10% of the total sinus gland protein. Electrophoretic examination of extracts of ^{3}H-leucine incubated XOSGs using SDS-PAGE revealed at least three distinct peaks of radiolabel incorporated into protein. One of these peaks corresponds with a band of approximately 6,000 MW which exhibits hyperglycemic hormone activity. This appears to be the first demonstration of in vitro biosynthesis of an identified peptide neurohormone in the arthropods. Supported by NIH grant NS15453 to I. M. Cooke.

106.1 DIFFERENTIATION OF RAT BRAIN GABA RECEPTOR SITES. M. Browner*, J. W. Ferkany*, and S.J. Enna (SPON: S.J. Strada). Depts. of Pharmacology and Neurobiology, Univ. Texas Med. Sch., Houston, Texas 77025.

Using in vitro ligand binding assays, studies were undertaken in an attempt to identify pharmacologically and functionally distinct receptor binding sites for γ-aminobutyric acid (GABA) in rat brain membranes. The results indicated that there were regional differences in the potency of bicuculline, a GABA receptor antagonist, to inhibit specifically bound ^{3}H-GABA. Bicuculline was most active in midbrain and cerebral cortex, while being significantly weaker in the corpus striatum and cerebellum. In the presence of 50mM ammonium thiocynate (SCN), the potency of bicuculline to inhibit specific ^{3}H-GABA binding was increased 10-100-fold in the brain regions studied. The possible biological relevance of this finding was indicated by the fact that 50mM SCN also increased the potency of bicuculline to inhibit GABA-activated benzodiazepine (BZ) receptor binding, a biochemical measure of GABA receptor function. In contrast, SCN did not affect the potency of GABA to activate BZ binding. Analysis of GABA receptor site saturation data indicated that SCN treatment selectively abolished the high affinity binding site for this amino acid, without altering the low affinity component. These findings suggest the existence of GABA receptor sites having a differential sensitivity to bicuculline and they provide direct evidence to support the hypothesis that only low affinity GABA binding sites are linked to the BZ receptor. Thus, SCN may be useful in identifying and defining pharmacologically and functionally different GABA receptor sites. (Supported in part by USPHS grants NS-13803, NS-00335 and MH-07688).

106.2 SOLUBILIZATION OF THE PICROTOXININ RECEPTOR: EVIDENCE THAT PICROTOXININ AND DIAZEPAM DO NOT BIND TO THE SAME PROTEIN. W.C. Davis* and M.K. Ticku. Dept. Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284

The binding sites for [^{3}H]-α-dihydropicrotoxinin (DHP), which is a radioligand for the picrotoxin-sensitive site at the benzodiazepine-GABA receptor-ionophore complex, were solubilized from rat brain with 1% Lubrol. Lubrol-solubilized fraction bound [^{3}H]-DHP to two sites (K_{D1}=0.038 μM; K_{D2}=1.85 μM), in contrast to only one site observed for membrane receptors (Ticku et al, Mol. Pharmac. 14:391, 1978). DHP binding to the crude Lubrol-solubilized fraction was inhibited by depressant and convulsant drugs with potencies similar to those required to inhibit DHP binding to membrane receptors. The signal-to-noise ratio of DHP binding was significantly improved from 0.14 in membranes to 0.35 in the Lubrol fraction. Besides [^{3}H]-DHP binding, specific binding of [^{3}H]-diazepam and [^{3}H]-muscimol was present in the crude Lubrol fraction. Furthermore, GABA agonists (muscimol), pentobarbital and ethanol produced a dose-dependent enhancement of [^{3}H]-diazepam binding in the Lubrol fraction. Pentobarbital inhibited the binding of [^{3}H]-DHP in the Lubrol fraction. These results indicate that under the conditions used for this study, Lubrol solubilizes the benzodiazepine-GABA receptor-ionophore complex. Gel filtration of the Lubrol-solubilized fraction revealed that [^{3}H]-DHP and [^{3}H]-diazepam bind to two distinct fractions, with apparent molecular weights of 185,000 and 61,000 daltons, respectively. [^{3}H]-DHP bound to the 185,000 dalton fractions with two binding constants and [^{3}H]-flunitrazepam bound to the 61,000 dalton fraction to a single site. [^{3}H]-Muscimol and [^{3}H]-GABA binding (∿90%) co-migrated with the 185,000 dalton fraction, and approximately 10% was associated with the 61,000 dalton fraction. Muscimol, pentobarbital and ethanol, while enhancing [^{3}H]-diazepam binding to membrane and crude Lubrol-solubilized fractions, failed to enhance [^{3}H]-diazepam binding to the 61,000 dalton fraction. Pentobarbital produced a dose-related inhibition of [^{3}H]-DHP binding to the 185,000 dalton fraction with an IC_{50} value of 60 ± 12 μM. Binding of [^{3}H]-DHP to the 185,000 dalton fraction was inhibited by several depressant and convulsant drugs (e.g. barbiturates) which affect GABAergic transmission. These results provide evidence that picrotoxinin and diazepam bind to two distinct proteins. Furthermore, these results support our earlier contention (Ticku and Olsen, Life Sci. 22:1643, 1978; Ticku, Br. Res. Bull. (Suppl. 2) 5:919, 1980) that the picrotoxinin site may be a receptor site for depressant and convulsant barbiturates.

Supported by NIH Grant #NS 15339

106.3 IN VITRO BINDING STUDIES WITH [^{35}S] CYSTEINE TO RAT SYNAPTIC MEMBRANES. C. H. Misra, R.C. Smith and J.C. Schoolar. Section of Biological Psychiatry, Texas Research Institute of Mental Sciences and Department of Pharmacology, Baylor College of Medicine, Houston, TX 77030.

Cysteine was shown to have neurotoxic property (Olney, J.W. et al, Brain Res. 5: 309, 1972) like other exicitatory amino acids (Curtis, D.R. and Watkins, J.C., J. Physiol. 166, 1, 1963), glutamic and asparatic acids. However, recently it has been shown that cysteine has a unique high affinity uptake system in a synaptosomal preparation of rat cerebral cortex (Misra, C.H., J. Neurosciences Res. 5, 507, 1980; Wang and Seigal, J. Neurochem 33, 1303, 1979) which is considered one of the characteristic properties for amino acid neurotransmitters (Logan, W.J. Snyder, S.H., Brain Res. 42, 413, 1972). Now we have found that [^{35}S] cysteine can bind to the synaptic membrane preparation from rat cerebral cortex, in a very elegant fashion. Binding of [^{35}S] cysteine (0.254 Ci/mmole, Amersham Searle) to synaptic vesicles fraction from rat cerebral cortex was studied by incubating 0.1 μm [^{35}S] cysteine for 5 min. at 0°C and then finally terminating by filtration through GF/B glass fiber filters. Non-specific binding was estimated with 20 mM non-radioactive cysteine. The binding was greater in buffer (50 mM Tris-HCl, pH 7.0 containing KCl, $MgCl_2$ and $CaCl_2$) containing sucrose instead of Na^+ in the same molarity. Binding was found satusable between 0.4 to 1.5μm concentration of [^{35}S] cysteine; and a K_n, 1.0μm and B_{max} 250 P-mole/ mg of protein were estimated in rat cerebral cortex membrane. About 90% of bound [^{35}S] cysteine was detected unmetabolized by TLC, using a solvent butanol-acetic acid water (120: 30:50 v/v) after reacting with N-ethyl-maleimide. As with other amino acid ligands, the binding of cysteine reaches equilibrium very quickly. DL-homocysteine, and L-glutamic acid were weak inhibitors while N-ethyl-L-cysteine and butaperazine were most potent inhibitors of [^{35}S] cysteine binding.

106.4 ^{3}H-NIPECOTIC ACID (Nip) SPECIFICALLY IDENTIFIES GABA UPTAKE SITES IN MEMBRANES PREPARED FROM CEREBRAL TISSUE. K.G. Lloyd and F. Vargas, LERS, 31 Ave. P.V. Couturier, F. 92220 Bagneux, France.

Nip is reported to be a relatively specific inhibitor of GABA uptake in rat brain slices (Krogsgaard-Larsen and Johnston, J. Neurochem., 25, 797, 1975). As this compound is available commercially at a relatively high specific activity (Amersham, 41 Ci/mMole) we have attempted to use ^{3}H-Nip as a radioligand for the GABA neuronal uptake site. In brief, fresh or frozen rat brains were homogenized (Polytron, 1:20, w/v) in Tris-citrate buffer (pH 7.4, 50 mM, 4°C), centrifuged at 50,000 x g x 10 min and the pellet washed thrice in buffer. The final pellet was resuspended in buffer containing 100 mM NaCl and an aliquot was exposed to predetermined concentrations of ^{3}H-Nip for 12 min. The binding was terminated by centrifugation (20 min x 50.000 x g) followed by a rinse of the pellet with buffer. "Blanks" to account for non-specific binding consisted of all components plus 5 mM GABA. The protein was dissolved with Soluene and the radioactivity determined in Demilume. Saturation curves (0.1 - 100 μM ^{3}H-Nip) showed a single Kd of 12 μM for fresh, and 5 μM for frozen tissue, with a Bmax of 100 pmol/mg. prot. for fresh and 75 pmol/mg. prot. for frozen tissue. ^{3}H-Nip (5 μM) was displaced from frozen tissue by (IC50's in parentheses) : Nip (9 μM) ; GABA (4 μM); Chlorpromazine (160 μM) ; diaminobutyric acid (DABA, 150 μM) ; muscimol (1600 μM) but not by beta-alanine, THIP or isoguvacine (all with IC50's greater than 5 mM). Boiled membranes did not exhibit any specific binding for ^{3}H-Nip. These results parallel similar studies on : (1) ^{3}H-Nip uptake into purified synaptosomes from rat brain : Km = 4.2 μM, Vmax = 304 pmol/mg. prot./min ; IC50's = Nip, 5,5 μM ; GABA 4 μM ; chlorpromazine, 30 μM ; DABA, 85 μM ; beta-alanine, 1300 μM; isoguvacine, and THIP inactive at 2 mM ; (2) ^{3}H-GABA uptake into purified rat brain synaptosomes : Km = 3.4 μM, Vmax = 570 pmol/mg. prot./min ; IC50's = Nip, 4.5 μM ; GABA, 5 μM; chlorpromazine, 30 μM ; DABA, 75 μM, beta-alanine, 1100 μM; isoguvacine and THIP were inactive at 1 mM. Both ^{3}H-Nip and ^{3}H-GABA uptake were temperature and sodium dependent, were sensitive to osmotic shock and to ouabain. Thus, these studies indicate that ^{3}H-Nip specifically identifies the GABA uptake site in either fresh or frozen membranes or in cerebral synaptosomal preparations.

106.5 CHARACTERISTICS OF Na^+ AND Cl^--DEPENDENT BINDING OF ^{3}H-GABA (γ-AMINOBUTYRIC ACID) TO GABA TRANSPORT SITES. Diana N. Krause, Esther Wong* and Eugene Roberts. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

Na^+-dependent GABA binding sites are thought to reflect the recognition sites for GABA transport systems. We have been characterizing these sites in mouse brain microsomal membrane fractions that were well-washed, osmotically-shocked, and stored frozen in liquid nitrogen with no loss of binding capacity. ^{3}H-GABA binding, which was assayed at 0°C by filtration, was found to have a definite requirement for Cl^- as well as Na^+. Hill plot analyses indicated that at least two molecules of Na^+ and one of Cl^- are necessary at each site. Divalent cations inhibited Na^+, Cl^--dependent ^{3}H-GABA binding with uranyl being the most potent cation tested (IC_{50} = 0.6 mM) followed in decreasing potency by Ca^{2+}, Sr^{2+}, Mn^{2+} and Mg^{2+}. Preincubation of the membranes with Na^+ (but not Cl^-) also decreased binding. Ouabain had no effect, but the Na^+ ionophores gramicidin, monensin and nigericin all inhibited association of ^{3}H-GABA with the membrane fraction. Tributyltin, which can act as a Cl^- ionophore, also inhibited binding, suggesting that Na^+ and Cl^- gradients may be involved in the process under study. However, no effects were observed in attempts to reverse the gradients by subsequently incubating the ^{3}H-GABA-associated membranes in lowered Na^+ and Cl^- concentrations. Bound ^{3}H-GABA also did not appear to be sensitive to hypo-osmotic conditions. The nature of the Na^+, Cl^--dependent "binding," including such possibilities as ^{3}H-GABA accumulating into osmotically-insensitive particles or partitioning into the membrane itself, is being investigated. Supported by USPHS grant NS-12116 and Nelson Research and Development Company.

106.6 AN INTRACELLULAR ANALYSIS OF AN UPTAKE SYSTEM FOR GABA AND ITS ANALOGUES AT THE CAT DORSAL ROOT GANGLION (DRG). Joel P. Gallagher, Jun Nakamura* and Patricia Shinnick-Gallagher, Dept. of Pharmacology and Toxicology, Univ. Texas Med. Br., Galveston, TX 77550.

We are using the cat DRG as a model system to study the pharmacology of a mammalian GABA receptor with electrophysiological techniques. We have previously demonstrated that GABA produces a Cl^--dependent depolarization of these neurons. Although a GABA synapse is not present, there have been conflicting reports as to whether or not an active uptake system for GABA is present in these neurons. To test this possibility we applied several GABA analogues by bath superfusion and/or iontophoresis to isolated DRG and recorded the resultant membrane changes. We determined complete concentration (10^{-6} to 10^{-2}M) response curves for muscimol (M), GABA, and 3 aminoproprane sulfonic acid (3-APS) under voltage clamp conditions. Muscimol was the most potent at all concentrations, however at concentrations greater than 10^{-4}M, GABA was more potent than 3-APS while at concentrations less than 10^{-4}, 3-APS was more potent than GABA. Using a low Na^+-Krebs solution or the GABA uptake inhibitor, nipecotic-acid, produced a shift in the GABA concentration curve to the left and upwards throughout its concentration range. It appears that at concentrations less than 10^{-4}M, GABA was taken up by glial cells in the DRG whereas 3-APS which is not a substrate for glial uptake was effective. Other GABA agonists whose action could be facilitated during uptake inhibition included isoguvacine and SL75102. Thus, we have concluded that there is an active uptake process for GABA in the cat DRG and this process must be considered when evaluating drugs at the DRG. Supported by NIH Grant NS 13727.

106.7 REGIONAL GABA BINDING DIFFERENCES BETWEEN AGGRESSIVE AND NON AGGRESSIVE HAMSTERS. A. Perumal, M. Potegal, A. Barkai, G. Cannova* and A. Blau*. N.Y. State Psychiatric Institute, New York, NY 10032.

Previous pharmacological and neurochemical studies suggest that the aggressive behaviors of mice and rats may correlate with endogenous GABA activity (Mandel, et al, 1979). However, the specificity of this relationship is not entirely clear. We pursued this question in a study of GABA mechanisms in ovariectomized female hamsters selected for either high or low aggressiveness. Neuroanatomical specificity was established through comparisons of regional rather than whole brain values. Neurochemical specificity was evaluated by (1) assaying more than one neurotransmitter and (2) evaluating neurotransmitter receptor binding rather than neurotransmitter concentrations. Behavioral specificity was determined by also measuring behaviors other than aggression.

Experiment 1: Six singly-housed, ovariectomized adult female hamsters which attacked a small methotrimeprazine treated target hamster (Potegal, et al., Psych. Rec., 30:191, 1980) 4 or more times in 10 min were the aggressive group; 6 subjects failing to attack formed the non-aggressive group. After decapitation, the following 4 regions were pooled within groups: cortex, "mid-region" (limbic, striatal and diencephalic structures), cerebellum and pons/medulla. GABA binding was evaluated by using ^{3}H-GABA as ligand; non-specific binding was carried out in presence of 2mM cold GABA. Noradrenergic binding was assayed with ^{3}H-DHA and specific binding was calculated after subtracting the non-specific binding obtained in presence of an excess of alprenolol. The "mid region" GABA binding in the aggressive animals was 32% higher than that of the non aggressive animals on two replications. Differences in GABA binding in other regions and differences in DHA binding in all regions were 14% or less.

Experiment 2: Ten hamsters were screened twice for aggression. Between screenings they were tested for activity, reactivity to handling, sexual behavior after hormonal priming, hoarding and nest building. The differential "mid region" GABA binding for aggressive vs non aggressive subjects was replicated in a statistically significant fashion; there were no significant differences between the other regions. There were also no significant differences in behaviors other than aggression between the two groups.

The higher level of GABA binding in aggressive animals suggests lower endogenous GABA levels consistent with the previous evidence for an aggression-inhibitory effect of GABA.

106.8 PURIFICATION AND PARTIAL CHARACTERIZATION OF A GLUTAMATE BINDING PROTEIN FROM BOVINE BRAIN MEMBRANES. E. Michaelis, L. Chittenden*, B. Johnson*, J. Fennimore* and M. Adamson* Dept. of Human Development, Neurobiology Section, Univ. of Kansas, Lawrence, KS. 66045.

A small molecular weight glycoprotein (M_r~13,000) which binds L-glutamic acid with a high degree of stereoselectivity and specificity has been purified in the past from rat brain synaptic plasma membranes (Michaelis, BBRC 65, 1004, 1975). Binding of L-[^{3}H] glutamic acid to this protein has been shown to be competitively inhibited by the neuroexcitatory amino acids L-aspartate, L-cysteine sulfinic acid, and D,L-homocysteic acid, and by the antagonist of glutamate physiologic activity, L-glutamate diethyl ester. On the other hand γ-aminobutyric acid, glycine, and some non-neuroactive amino acids did not displace L-[^{3}H] glutamate bound to this protein. This protein purified from rat brain synaptic membranes was considered to be the recognition site of the physiologic glutamate receptors. We have recently been able to purify larger quantities of a glutamate binding protein from bovine brain cerebral and cerebellar cortex which has many of the characteristics described for the rat brain binding protein.

The purification scheme involves the preparation of a crude mitochondrial fraction which is subsequently treated with 0.5% (w/v) Na-cholate according to the procedure described in Michaelis et al., FEBS Lett. 118, 55, 1980. The membrane pellet obtained after 39,000 x g for 60 min centrifugation contains all of the glutamate binding activity. These membranes are solubilized in an alkaline Triton X-100 medium (Michaelis et al., BBA 367, 338, 1974) and the glutamate binding proteins are isolated by batch affinity separation on glass fiber with co-reticulated L-glutamate as described previously (Michaelis, BBRC 65, 1004, 1975). The final eluate of the glutamate binding protein after treatment with 6% glycerol and concentration against polyvinyl pyrrolidone contains only one protein as determined by SDS-PAGE. On SDS gels this protein migrates to a position identical to that of the purified glutamate binding protein from rat brain. Its affinity for the L-[^{3}H] glutamic acid varies within the range of 0.4 - 1.1 µM for different batches. L-Aspartate and L-cysteine sulfinic acid are the most potent competitive antagonists. In terms of its binding activity, of its molecular size, of its amino acid composition, and of its isoelectric point, this bovine brain glutamate binding protein is very similar to that purified from rat brain synaptic membranes. (This research was supported by grant # DAAG 29-79-C-0156 from the U.S. Army Research Office and by grant AA 04732 from NIAAA).

106.9 UPTAKE AND RELEASE OF PUTATIVE AMINO ACID NEUROTRANSMITTERS BY CHICK EMBRYO RETINA NEURONS AND NONNEURONAL CELLS IN PURIFIED CULTURES. Arnold Hyndman[++] and Ruben Adler[+]. [+]Dept. of Biology, University of California, San Diego, La Jolla CA 92093 and [++]Dept. of Biology, Livingston College, Rutgers University, New Brunswick NJ 08903

Selective combinations of media and substrata allow the preparation of different monolayer cultures from chick embryo neural retina cell suspensions, namely: i) glia free, purified neuronal cultures; ii) complex cultures, containing a confluent monolayer of nonneuronal flat cells of apparent glial origin underlying a network of multicellular clumps; and, iii) purified nonneuronal monolayers, derived from complex cultures by mechanical removal of the clumps. They are used here to investigate the development of uptake and release mechanisms for several putative amino acid neurotransmitters with autoradiographic and biochemical techniques.

At 3 days in vitro (d.i.v.), 65% of the neurons in purified neuronal cultures become labeled when incubated with 5 x 10^{-8}M [^{3}H]GABA. As expected from a high affinity uptake mechanism, neuronal labeling is totally abolished at 0-4°C or in a Na^+-free medium. Uptake is also completely blocked by diaminobutyric acid (DABA), but not by β-alanine. High (56 mM) K^+ does not cause any significant increase in GABA release. Important developmental changes occur between 3 and 6 d.i.v., namely: i) GABA high affinity uptake is only present in 50% of the neurons; ii) in 80% of these neurons the uptake is insensitive to DABA, and iii) high K^+ causes a 2-3 fold increase in GABA release, which can be partially blocked by 10 mM Co^{++}, suggesting the development of synaptic terminals in the cultures. Nonneuronal cells present in complex cultures show Na^+-dependent GABA uptake only during the first 10 d.i.v.; this uptake is insensitive to β-alanine but is reduced 85% by DABA. Neurons as well as nonneuronal cells can also be labeled by incubation in micromolar concentrations of radioactive glutamate, aspartate, glycine or taurine. The properties of these uptake mechanisms are currently under investigation.

Supported by USPHS grant EY 02854.

106.10 COMPARISON OF THE γ-AMINOBUTYRIC ACID UPTAKE SITE DERIVED FROM RAT MIDBRAIN SYNAPTOSOMES OR MOUSE GLIAL ASTROCYTES GROWN IN CULTURE. B. R. Lester, M. Burman*, G. I. Moonsammy*, and L. M. Yunger. Smith Kline & French Labs., Dept. of Biol. Sci., Box 7929, 1500 Spring Garden St., Philadelphia, PA 19101

γ-aminobutyric acid (GABA) uptake sites are present on neurons and glia. It has been conjectured that diaminobutyric acid (DABA) and cis-3-aminocyclohexanecarboxylic acid (cis-3-ACHC) exhibit a putative preference for neuronal GABA uptake and β-alanine, β-proline and 4-hydroxynipecotic acid display a selectivity for glial GABA uptake. We have examined the pharmacologic preference of these various ligands for their ability to compete with [^{3}H] GABA using both cultured glial astrocytes from neonatal Swiss mice and synaptosomal preparations from the diencephalon-midbrain of rats. The accumulated data indicates that these compounds display a relatively constant ratio of IC_{50}'s (glial astrocytes:synaptosomes) of from 4.0 to 9.0 with little or no selectivity observed between the preparations employed. This lack of specificity could be due to glial contamination of the synaptosomal preparations or neuronal overgrowth of astrocytic cultures which would result in heterogenous patterns of GABA uptake as measured by saturation kinetics as well as mixed patterns of inhibition using the putative selective GABA analogs. These possibilities were examined by characterization of uptake saturation kinetics using [^{3}H] GABA and [^{3}H] cis-3-ACHC and by inhibition studies utilizing the putative selective GABA analogs to challenge labelled GABA uptake. It was observed that cis-3-ACHC challenge of [^{3}H] GABA uptake exhibited a competitive inhibition pattern indicating a single site in both cultured glial astrocytes (K_i=41 μM) and synaptosomal preparations (K_i=43 μM) by an apparently single site homogenous mechanism. The putative glial selective analog, 4-hydroxynipecotic acid, exhibited a high affinity for the GABA uptake site in cultured astrocytes, as predicted (IC_{50}=43.9 μM); however, it also appeared to inhibit synaptosomal uptake with an even higher affinity (IC_{50}=4.6 μM). These data indicate a lack of differential specificity towards glial versus neuronal GABA uptake by these GABA analogs at least in so far as cultured astrocytes and synaptosomes represent populations of glial and neuronal cells respectively.

106.11 TAURINE BINDING IN RAT RETINAL MEMBRANES. J.B. Lombardini. Department of Pharmacology and Therapeutics, Texas Tech University Health Sciences Center, Lubbock, Texas 79430.

While taurine is highly concentrated in the retina especially in the photoreceptor cells (Kennedy et al., J. Neurochem. 29, 157, 1977) the role of taurine in retinal function is not well defined. It has been postulated that taurine may act as an inhibitory neurotransmitter and as a regulator of intracellular calcium levels in the retina (Pasantes-Morales et al., Brain Res. 172, 131, 1979). In taurine binding studies utilizing chick retinal membranes, López-Colomé and Pasantes-Morales (J. Neurochem. 34, 1047, 1980) have demonstrated two sodium dependent components with different affinity constants (K_{D_1}=0.68 μM; K_{D_2}=9.32 μM).

In the present study the binding of taurine to retinal membranes obtained from the rat was studied. Retinal membranes were prepared from adult Wistar rats by homogenizing in 30 volumes of distilled water in a glass homogenizer. The homogenate was centrifuged for 20 min at 15,000 x g. The pellet was washed once in distilled water and once in Krebs-Tris buffer (pH 7.4; 118 mM NaCl; 1.2 mM KH_2PO_4; 4.7 mM KCl; 2.5 mM $CaCl_2$; 1.17 mM $MgSO_4$; 26 mM Tris-HCl) and recentrifuged after each wash as above. After the final wash the pellet was resuspended in Krebs-Tris buffer. Scatchard analysis of the taurine binding profile demonstrated the presence of two distinct components of taurine binding with a K_{D_1} for the high affinity binding site of 20 μM and a K_{D_2} for the low affinity binding site of approximately 900 μM.

Optimal binding of taurine to retinal membranes required sodium ions. In the absence of sodium ions approximately 60% of the total binding was observed. Removal of potassium ions from the incubation medium decreased taurine binding to 20% of total. No binding was observed in the combined absence of sodium and potassium ions nor in the absence of calcium ions.

Structural analogues of taurine, β-alanine and guanidinoethanesulfonate, at a final concentration of 1 mM inhibited taurine binding by 70% (taurine concentration = 30 μM). 2-Aminoethanephosphonic acid (isosteric replacement of the sulfonic acid moiety with a phosphonic acid moiety) decreased taurine binding by 20%. Aminomethanesulfonic acid, the one carbon analogue of taurine, was ineffective in displacing taurine as was isethionic acid (the hydroxy analogue).

106.12 SOLUBILIZATION OF A NON-NEURONAL BENZODIAZEPINE BINDING SITE. J. W. Thomas and J. F. Tallman. Section on Biochemistry and Pharmacology, Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

While initial attempts using nonionic detergents were unsuccessful, the benzodiazepine binding site in mammalian kidney has been solubilized using a bile salt detergent. A single extraction step releases approximately 15% of the membrane-bound binding sites into the high-speed supernatant. The affinity of the binding site is decreased about 5 fold by solubilization (apparent K_D for membrane-bound site, 10 nM; apparent K_D for soluble site, 51 nM), and a series of drugs inhibited [^{3}H]flunitrazepam binding to the soluble binding site with the same relative potencies observed for the membrane-bound binding site. In particular, RO5-4864, a specific inhibitor at peripheral and glial benzodiazepine binding sites (D.W. Gallager et al., J. Neurosci. 1: 218-225, 1981), when included at a concentration of 100 nM, decreases the binding of 5 nM [^{3}H]flunitrazepam by 68.5%. In contrast, drugs which specifically inhibit binding to the neuronal site are considerably less potent at the soluble kidney binding site; clonazepam at a concentration of 1 μM decreases binding of 5 nM [^{3}H]flunitrazepam only 7.0% and CL 218,872 at a concentration of 10 μM decreases binding only 15.2%. While further analysis of the soluble non-neuronal binding site is required, these results suggest that the pharmacological differences in the neuronal and non-neuronal benzodiazepine binding sites are due to the inherent properties of binding sites since an intact membrane is not required. Properties of the neuronal and non-neuronal sites will be compared.

106.13 SELECTIVE RETROGRADE LABELLING OF CENTRAL AND SPINAL GANGLION NEURONS AFTER INJECTIONS OF D-ASPARTATE AND GABA IN THE SPINAL CORD AND CUNEATE NUCLEUS OF RATS. A. Rustioni and M. Cuénod. Brain Research Institute, University of Zürich (Switzerland) and Dept. of Anatomy Univ. N. Carolina, Chapel Hill, NC 27514 (USA).

Recent studies have shown that after injection of ^{3}H-D-Asp in CNS structures the perikarya of some but not all pathways projecting to the injected structure are labelled. Since the labelled neurons are believed to use glutamate (glu) and/or aspartate (asp) as neurotransmitter(s) and since D-Asp is known to compete for the L-glu and L-asp high affinity sites, it is postulated that a transmitter-related affinity might be at the basis of the selective retrograde transport. In the present experiments the selectivity of the retrograde labelling of neurons has been tested after injection of ^{3}H-D-Asp in the cuneate n. and in the cervical cord of rats. Twenty-four hours after injections in the cuneate n., autoradiographic labelling is present over the pyramidal tract, internal capsule and over layer V pyramids of the sensorimotor cortex. No perikarya of the other central sources of afferents to the cuneate n. appear labelled. After ^{3}H-GABA injections in the same nucleus no labelling attributable to retrograde translocation can be detected in spinal segments, brain stem or cortex. These observations are consistent with existing evidence indicating that the cortico-cuneate path uses glu and/or asp as neurotransmitter. ^{3}H-D-Asp injections in the cervical cord label some perikarya of the substantia gelatinosa and larger neurons in laminae IV to VI for three to five segments above and below the injection. No brain stem neuron is labelled though silver grains overlie pyramidal tract fibers on the side contralateral to the injection. Retrograde labelling of corticospinal axons for at least some distance may suggest a special affinity of their terminals for glu and/or asp. This also is consistent with previous indications of a transmitter role for glu or asp in the corticospinal tract.

Silver grains accumulation overlies about one third of cervical ganglia neurons whose perikarya is 100 um^2 or more 24 hours after injection of ^{3}H-D-Asp, but not of ^{3}H-GABA, in the cuneate nucleus. After spinal injection of the same ^{3}H-amino-acids, labelled neurons of cervical ganglia have mainly large perikarya and represent approximately 5% (after D-Asp injection) and 12% (after GABA injection) of the neuronal population of the ganglion(a) related to the injected segment(s). While these observations are consistent with the idea that a fraction of large primary afferents use glu and/or asp as neurotransmitters the mechanism underlying selective labelling of spinal ganglion neurons by ^{3}H-GABA remains to be elucidated.

106.14 PIPECOLIC ACID: A NEUROMODULATOR OF MOUSE CNS? E. Giacobini, H. Nishio*, J. Ortiz* and M.d.C. Gutierrez, Lab. of Neuropsychopharmacology, Univ. of Conn., Storrs, CT 06268

The following results obtained in our laboratory suggest that the imino acid pipecolic acid (PA) may be selectively localized in neuronal populations of the mouse brain where it could act as a physiological modulator:

1. The identity of PA in the brain has been unambiguously established by mass spectrometric identification. Its endogenous levels in the adult mouse brain were found to be 18 + 4 nmoles/g (Schmidt-Glenewinkel et al., Neurochem.Res. 2:619, 1977).
2. PA is synthesized both in vitro and in vivo from lysine in brain, liver, kidney, heart and the large intestine of the adult mouse and chick. In addition, the embryonic brain in both species is able to synthesize PA from lysine in vitro (Nomura et al., Dev. Neurosci. 1:239, 1978).
3. PA is taken up in synaptosomes of mouse brain by a high affinity, temperature and Na+ dependent, ouabain sensitive mechanism (Nomura et al., Neurochem. Res. 5:1163, 1980).
4. PA is released by a Ca++ dependent mechanism from brain slices (Nomura et al., J. Neurochem. 33:803, 1979).
5. PA, when injected in tracer amounts intracarodically, is taken up in the brain with a BUI (Brain Uptake Index) of 3.9 which is within the low range of aminoacid transport. This uptake is saturable and its kinetics suggest the presence of two transport systems. The corresponding BUI for lysine, the PA's precursor, is 8.5 (Nishio and Giacobini, Neurochem.Res. 6, 1981).
6. Following pulse-injection of PA, i.p. or i.v., three features are most salient: its rapid accumulation in brain; its rapid secretion in urine, and the long-lasting steady levels of radioactivity maintained in brain. A significant decline of the percentage recovered as PA in brain and kidney following i.p. injection suggests cerebral metabolic activity. PA accumulates following pretreatment with probenecid.
7. Following intraventricular injections, high levels of PA are maintained in brain. The labeled compound is accumulated in four brain regions (neocortex, hippocampus, diencephalon and striatum) and slowly metabolized.
8. Accumulation of ^{3}H-PA following i.p. inject. is greater in new born than in adult mice.
9. A high affinity binding for ^{3}H-PA in whole brain homogenates, as well as in crude mitochondrial (P_2) preparations, has been detected in preliminary experiments. This suggests the presence of a specific binding site for PA in mouse brain.

106.15 SPONTANEOUS AND DEPOLARIZATION-INDUCED TURNOVER OF GABA IN RAT CORTICAL SLICES: EFFECT OF A GABA-T INHIBITOR. J.C. Szerb, Dept. Physiol. & Biophys., Dalhousie U., Halifax, N.S. B3H 4H7.

In a previous study (Szerb et al., J. Neurochem., in press) it was shown that when both the synthesis and metabolism of GABA was inhibited with amino-oxyacetic acid only 10% of endogenous GABA present in slices was in a compartment from which elevated K^+ induced release. To see the turnover of GABA both in the releasable and non-releasable compartments, slices were first incubated with [^{3}H]GABA then were superfused with Krebs containing 3 mMK^+ either in the absence of an inhibitor or starting after 15 min with 5 μM gabaculine (GCU), a specific GABA-T inhibitor. Endogenous GABA released or remaining in the slices was measured with HPLC which also separated [^{3}H]GABA from its labelled metabolites. In the absence of GCU the endogenous GABA content of the slices remained constant while the labelled GABA content declined to about 1/3 at the end of 60 min superfusion as compared to that found after 15 min. With GCU present endogenous GABA content increased by 65% over 45 min and [^{3}H]GABA content remained constant. In the absence of GCU metabolites were responsible for 90% of radioactivity released spontaneously and the release of metabolites was reduced by 80% by GCU without increasing the efflux of [^{3}H]GABA. No spontaneous release of endogenous GABA was detected. Depolarization with 50 mMK^+ caused a large efflux of endogenous GABA which was only 25% higher in the presence of GCU than in its absence. However 50 mMK^+ released 70% more [^{3}H]GABA in the presence than in the absence of GCU. The specific activity of GABA released during 25 min exposure to 50 mMK^+, declined by 75% both in the absence or presence of GCU, indicating a depolarization induced synthesis of releasable GABA. Results suggest a considerable rate of spontaneous turnover of all GABA compartments and a depolarization induced enhanced synthesis of GABA in the releasable compartments. Gabaculine, by inhibiting the metabolism of GABA, increased the total GABA content to a lesser extent than the size of the releasable compartment.

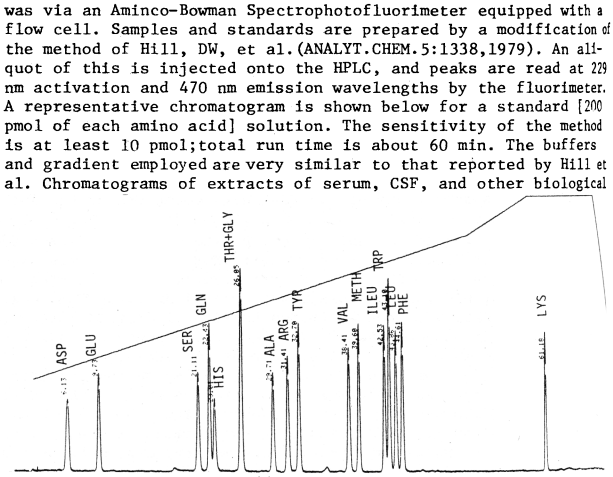
106.16 A SIMPLE, RAPID HPLC/FLUORESCENCE METHOD FOR MEASURING PICOMOLE QUANTITITES OF AMINO ACIDS IN PHYSIOLOGICAL SOLUTIONS. Madelyn Hirsch Fernstrom and John D. Fernstrom. M.I.T., Cambridge, MA 02139.

Recently, several reports have appeared concerning the measurement of amino acids using reversed-phase, liquid chromatography (HPLC) coupled with fluorescence detection. Amino acid samples are derivatized with ortho-phthalaldehyde (OPT) and then run over the HPLC. We have explored the utility of this method for routine analysis of amino acids in physiological solutions, and find the reliability and sensitivity to exceed that of conventional amino acid analyzers. The system we employ was obtained from Waters Associates (2 6000A pumps, a 720 Controller, & a 730 data analyzer; a 10 mm x 30 cm μBondapak C-18 reverse-phase column); post-column detection was via an Aminco-Bowman Spectrophotofluorimeter equipped with a flow cell. Samples and standards are prepared by a modification of the method of Hill, DW, et al. (ANALYT.CHEM. 5:1338, 1979). An aliquot of this is injected onto the HPLC, and peaks are read at 229 nm activation and 470 nm emission wavelengths by the fluorimeter. A representative chromatogram is shown below for a standard [200 pmol of each amino acid] solution. The sensitivity of the method is at least 10 pmol; total run time is about 60 min. The buffers and gradient employed are very similar to that reported by Hill et al. Chromatograms of extracts of serum, CSF, and other biological



fluids show the same excellent separation. For serum, we compared values from runs on the HPLC to those on a Beckman 119C Amino Acid analyzer for 15 amino acids, and found the data to be indistingusihable. These data, and those to be present d, show this method of analysis to be superior in many regards to that accomplished on a standard amino acid analyzer.

(Supported in part by a grant from the NIMH.)

106.17 DETERMINATION OF γ-AMINOBUTYRIC ACID IN WHOLE RAT BRAIN BY ELECTROREDUCTION FOLLOWING LIQUID CHROMATOGRAPHIC SEPARATION.
W. Lowry Caudill* and R. Mark Wightman. Department of Chemistry, Indiana University, Bloomington, IN 47405.

γ-Aminobutyric acid (GABA) has been recognized for many years as a neurotransmitter. However, measurements of its neuronal function have been hampered by the lack of a sensitive analytical method for its determination. In the past several years, amperometric detection with carbon electrodes following liquid chromatographic separation has become a widely accepted analytical method because of its high sensitivity, selectivity and low cost. We have developed a relatively simple microderivatization scheme which renders GABA electroactive. In basic solution, the derivatizing agent, 2,4,6-trinitrobenzenesulfonic acid, reacts rapidly with GABA to give the desired derivative in 100% yield. Following the quenching of the reaction at low pH and the introduction of trinitrophenyl-δ-aminovaleric acid as an internal standard, the mixture is extracted with toluene. The toluene fraction is extracted with an aqueous basic solution. This basic solution is then separated using C-18 reversed phase liquid chromatography and the derivatives are detected by reduction at -0.8 V vs. SCE with a pressure annealed pyrolytic graphite electrode. The technique has been applied to the analysis of whole rat brain samples. The method provides a routine and accurate analysis of the derivatized amine at picomole levels.

107.1 VASOPRESSIN LEVELS IN REAGGREGATE CULTURES OF THE DEVELOPING HYPOTHALAMUS AND PITUITARY. M.F.D. Notter*, C.D. Sladek, and D.M. Gash. Depts. of Anatomy, Center for Brain Research, and Neurology, Univ. of Rochester School of Medicine, Rochester, NY 14642.

Vasopressin released into culture media as well as vasopressin content of dispersed cell cultures taken from developing hypothalamus and pituitary tissue were measured by radioimmunoassay (RIA). The hypothalami and pituitaries, dissected from fetal 19 day postcoitus (dpc) and neonatal one-day-old Long Evans rats, were dissociated by a typsinization procedure. Dispersed cells were seeded into siliconized multiwelled tissue culture dishes containing Eagles minimum essential medium (medium supplemented with 0.6% glucose, .1% glutamine, 10% fetal calf serum, 100 μg/ml penicillin and 2.5 μg/ml fungizone) and rotated at 70 rpm in a humid CO_2 incubator. The cells reaggregated into spheroids, roughly 150 μm in diameter, within four hours. When media or homogenized cells from cultures containing only hypothalamus cells were examined for vasopressin by RIA after 4 days, vasopressin levels ranging up to 388 pg/10^6 cells were measured in the tissue and 2418 pg/ml in the media. Vasopressin was also present in cultures after eight to ten days, but the quantities measured were variable and tended to be lower than those measured in the four day cultures. When newborn hypothalamus was co-cultured with dispersed posterior pituitary cells, the amount of vasopressin in the reaggregates increased up to 6900 pg/10^6 cells in the tissue and approximately 3500 pg in the media. This same effect was seen after nine days of culture although less dramatically. The increase in vasopressin content of co-cultivated hypothalamus and posterior pituitary was not seen when neonatal anterior pituitary was substituted for posterior tissue nor when 19 dpc hypothalamus was co-cultured with 19 dpc pituitary tissue.

These data indicate that vasopressin containing neurons survive cell culture for at least nine days in vitro and that at a critical time in development the posterior pituitary may either promote survival of the neurons or stimulate secretion by them.
Supported by USPHS Grants NS 15109, AM-19761.

107.2 IMMUNOHISTOCHEMICAL ANALYSIS OF DISPERSED, HYPOTHALAMIC TRANSPLANTS. J. Schöler*, J.R. Sladek, Jr., M.F.D. Notter* and D.M. Gash (SPON: W.E. Armstrong). Depts. of Anatomy and Microbiology and Center for Brain Research, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

It has recently been shown that fetal hypothalamic tissue can survive transplantation into the third ventricle of a host animal. The present study was undertaken to determine the ability of dispersed hypothalamic neurons to survive transplantation and structurally integrate into the host brain. Hypothalamic tissue from 19 day, post-coital, Long Evans rats was dispersed with trypsin. Cells were counted with a hemocytometer and viability determined by .1% erythrocin dye exclusion. 500,000 viable hypothalamic cells were stereotaxically placed into the third ventricle of adult Brattleboro rats, homozygous for the diabetes insipidus trait. The hosts were allowed to survive for 21 to 60 days. Prior to tissue processing, the animals received 1mU of vasopressin (VP) in tannate oil per day for two days. The animals were then anesthetized and perfused through the ascending aorta with 4% paraformaldehyde in 0.01M PO_4 buffer. The brains were sectioned on a vibrating microtome and processed for light microscopic immunohistochemistry. Alternate 30μm free-floating sections were stained for neurophysin (provided by Dr. A.G. Robinson), oxytocin and VP (supplied by Dr. G. Nilaver). The respective antigenic sites were visualized with the peroxidase-anti-peroxidase technique.

Analysis of those animals in which the transplant could be located revealed that in each case the dispersed cells had reaggregated to form a large, viable clump of cells located either in the floor of the ventricle or juxtaposed to the ventricular walls. Sections stained for neurophysin revealed two populations of cells present within the reaggregated transplant. One cell population consisted of small neurophysin-positive neurons possibly parvicellular in nature; the other consisted of larger, magnocellular-type neurons. In each case, the neurons appeared normal and had processes extending throughout a large portion of the transplant. Studies are currently under way to determine what percentage of the neurophysin-positive neurons contain either VP or oxytocin. The present study indicates, however, that the third ventricle and its CSF provides a favorable milieu for transplanted hypothalamic neurons and demonstrates their ability to colonize within certain areas of the central nervous system.

107.3 LIGHT MICROSCOPIC IMMUNOCYTOCHEMICAL EVIDENCE SUGGESTING COUPLING OF HYPOTHALAMIC PEPTIDERGIC NEURONS. M.V. Sofroniew. Dept. of Anatomy, Ludwig-Maximilians University, Pettenkoferstr. 11, 8000 Munich 2, FRG.

Evidence in support of electrotonic transmission and coupling of neurons has now been observed in various areas of the mammalian central nervous system. Recently this evidence has been extended to magnocellular neurosecretory neurons (MNN's) of the rat hypothalamus by the observation of dye coupling and gap junctions occurring between such neurons (Andrews et al., Science 211, 1187). During the course of various light microscopic immunohistochemical studies on hypothalamic peptidergic neurons, in particular a morphological analysis of MNN's based on Golgi-like immunoperoxidase staining for vasopressin, oxytocin or neurophysin, we noted a number of neural configurations suggestive of the coupling of neurons. Although it is clear that light microscopic data alone cannot be taken as direct verification of coupling, these findings may provide information on the various 3-dimensional forms by which coupling may occur; information which may be difficult to obtain from ultrastructural studies relying largely on 2-dimensional analysis. Four types of contacts between neurons were observed which were considered possible substrates for coupling. The first three constituted dendro-dendritic, dendro-somatic and soma-somatic contacts occurring between MNN's via short interconnecting processes. These interconnecting processes generally arose as juxtaposed protuberations on both neurons which connected into single short extensions providing an uninterrupted (at the light microscopic level) transition between the neurons. In some cases several such connections appeared to be made between a single pair of neurons. Most frequent were dendro-dendritic, followed by dendro-somatic, followed by soma-somatic contacts of this nature. The fourth type of contact observed was soma-soma apposition between the perikarya of neurons. Since most perikarya did not appear to directly contact other perikarya, direct close apposition was a conspicuous well definable configuration, Apposition of this nature was identified between a number of pairs of MNN's, as well as between some chains of MNN's in certain magnocellular accessory groups. Soma-soma apposition was noted not only between neurons containing the same peptide, but also between neurons which contained two different peptides, i.e. somatostatin or neurophysin, stained different colors using two-color immunoperoxidase staining. Even though the light microscopic findings presented here cannot be taken as the direct demonstration of coupling of neurons, the findings may be useful in visualizing the various 3-dimensional forms by which coupling may occur, and as such warrant further study.

107.4 RECURRENT INHIBITION AND PHASIC BURSTING IN RAT PARAVENTRICULAR NEURONS: A CHALLENGE FROM THE HYPOTHALAMIC IN VITRO SLICE. Glenn I. Hatton. Neuroscience Program and Psychology Department, Michigan State University, East Lansing, MI, 48824.

It is not known by what mechanism the so-called "phasic bursting" patterns are generated in certain hypothalamic magnocellular neuropeptidergic cells (MNCs). Recurrent inhibition has been invoked to explain phasic bursting. Although there is evidence for recurrent inhibition in MNCs, it has never been reported for a phasic bursting cell. Thus, it was of interest to investigate the possibility that bursting patterns of activity might be displayed by MNCs independently of such inhibitory feedback. This was accomplished using the in vitro hypothalamic slice preparation in which all chemical synaptic transmission could be blocked. In order to be certain that chemical synaptic transmission was blocked, a monosynaptic pathway in the hippocampal slice was first monitored. Both hippocampal and hypothalamic slices were prepared (Brain Res. Bull., 1980, 5, 391 & 405) and placed side by side in an in vitro recording chamber. The field potential from Schaffer collateral stimulation was recorded in the CA1 region of the hippocampus. Blocking of this synaptic response was monitored while the medium bathing the slices was changed from one containing 2.4 mM Ca^{2+} and 1.3 mM Mg^{2+} to one with .05 mM Ca^{2+} and 18.7 mM Mg^{2+}. In some experiments this was reversed by changing back to a standard solution. When synaptic transmission was completely blocked in the hippocampal slice, recordings of spontaneous activity of MNCs in the paraventricular nucleus (PVN) were made in adjacent hypothalamic slices. Also, in some experiments the phasic bursting neuron was antidromically activated by extracellular electrical stimulation in order to monitor its presence or activity during the sometimes prolonged silent periods.

To date, 20 cells displaying phasic bursting activity have been recorded from 12 preparations in which synaptic transmission had been blocked. The activity patterns recorded from these cells are similar to those recorded in vivo, often consisting of bursts of 100-200 spikes and lasting 7-25 seconds. Nearly all the cells displaying this activity were located in the lateral subnucleus of the PVN. These results suggest that phasic bursting activity in MNCs is not generated by recurrent synaptic inhibition.

This research was supported by NIH grant NS 09140.

107.5 THE DISTRIBUTION AND CELLS OF ORIGIN OF SOME AFFERENT PROJECTIONS TO THE PARAVENTRICULAR AND SUPRAOPTIC NUCLEI IN THE RAT. P. E. SAWCHENKO* and L. W. SWANSON, The Salk Institute, La Jolla, California 92037.

Axonal transport and immunohistochemical techniques were used to clarify the organization of projections to the paraventricular (PVH) and supraoptic (SO) nuclei. Six rats received a 30 nl injection of the retrogradely-transported fluorescent tracer, true blue, centered in the PVH. The material was used to plot the distribution of retrogradely-labeled neurons, and to demonstrate simultaneously true blue and an antigen (Brain Res. 210:31, 1981), using antisera directed against dopamine-β-hydroxylase (DBH), serotonin, or ACTH (1-39). Then, the distribution of major inputs to the PVH and SO was charted, using the autoradiographic method. 20-40 nl of ^{3}H-amino acids was injected into each of the cell groups that were identified in the retrograde transport studies as projecting to the PVH. The parvocellular (pc) division of the PVH receives inputs from many sites in the brainstem, including DBH-positive neurons in the A1, A2 and A6 (locus coeruleus) catecholamine groups. Projections from the A1 and A2 groups end primarily in dorsal and medial parts of the pc division, while that arising from the locus coeruleus is restricted to the periventricular part. A light projection to most parts of the pc division arises from serotonin-stained cells in and near the dorsal and median raphe. The parabrachial nucleus, the bed nucleus of the stria terminalis and the subfornical organ all project substantially to most pc areas. Relatively light projections, primarily to the periventricular and medial pc zones, arise from nearby hypothalamic regions, including the lateral, medial, median and periventricular preoptic areas, the suprachiasmatic nucleus, the ventromedial nucleus and the posterior hypothalamic area. A dense projection to the periventricular, dorsal and medial pc areas arises from ACTH (1-39)-positive cells centered in the arcuate nucleus. Relatively few inputs to the magnocellular (mc) division of the PVH, and to the SO, were identified. A dense projection arising from DBH-positive neurons in the A1 catecholamine cell group is preferentially distributed to those mc areas of the PVH and SO in which vasopressin-containing cells are concentrated. The oxytocinergic parts of the PVH and SO receive inputs from midbrain serotonin-positive cells, and from ACTH (1-39)-stained neurons in and near the arcuate nucleus. Thusfar, only the subfornical organ appears to innervate both cell types, although this input was more dense over the vasopressinergic portions of the PVH and SO. These results indicate that limbic, hypothalamic and brainstem cell groups project to the PVH, where each appears to innervate discrete parts of the parvocellular division. Specificity was also clear in the inputs to the magnocellular parts of the PVH and SO, since each appears to terminate preferentially in regions where either oxytocin-or vasopressin-containing cells are concentrated. (We thank K.B. Helle, H. Steinbush, and S.A. Joseph for geneous supplies of antisera.)

107.7 ADRENALECTOMY INDUCES SPROUTING IN PROJECTIONS FROM THE PARAVENTRICULAR NUCLEUS TO THE MEDIAN EMINENCE OF THE RAT. A.J. Silverman, C. Moodhe*, and E.A. Zimmerman. Depts. of Anatomy and Neurology, Columbia Univ., P&S, New York, NY 10032.

In normal rat median eminence (ME), few immunoreactive vasopressin or neurophysin (NP) fibers are found in zona externa (ZE) by immunocytochemistry when compared to rhesus monkeys. It was previously reported that unilateral lesions (U_x) of the paraventricular nucleus (PVN) in monkey hypothalamus caused an ipsilateral loss of these ZE fibers, and in rats that bilateral PVN lesions (B_x) abolished the progressive visible reactivity in these fibers after bilateral adrenalectomy (ADX). The results of the next experiment prompted the studies reported: U_x of PVN followed by ADX for 2 weeks in rats did not result in significant ipsilateral ZE fiber loss suggesting two possibilities: either (a) the PVN-ME vasopressin-NP system in rat is not unilateral as in monkey, or (b) ADX and/or U_x causes sprouting to the opposite ZE. In the next group of animals, anterograde HRP-tracing from PVN was used to investigate this projection in intact animals. HRP was iontophoresed into PVN and visualized with the TMB procedure of Mesalum. Only pvl or pvm subnuclei (Armstrong et al., Neuroscience 5:1931, 1981) resulted in labeled terminals in ZE. Innervation of ZE was mostly unilateral with a small number of fibers just crossing midline. U_x of PVN 1-4 weeks preceding HRP into the intact PVN gave similar results. One animal surviving ADX, U_x and with correct placement of HRP showed bilateral innervation of ZE, suggesting sprouting. To further test this possibility, and to determine the time course of sprouting, rats were ADX for 2 weeks followed by U_x of PVN. Animals were killed 3-21 days post U_x and the brains processed for immunoperoxidase technique using antiserum to rat neurophysin. At 3 days post U_x NP fibers were numerous on the side of the intact PVN and few remained on the side of the U_x. At 6 and 21 days NP input to ZE was bilateral, although the side of U_x was less heavily innervated. Bilaterality was more prominent in rostral ME and infundibular stalk. These results demonstrate that the PVN-ME NP projection is normally unilateral in rat as in the rhesus monkey. These experiments suggest that unilateral denervation of the ZE is not sufficient to cause sprouting of contralateral NP-VP fibers. The additional stimulus of ADX, known to activate the VP neurons in PVN, is also involved in the sprouting process. In addition, therefore, to the known stimulatory effects of adrenal insufficiency on the synthesis of VP in this system, these experiments suggest an additional and separate effect on the ability of these cells to initiate sprouting. Supported by NIH grant AM20337; AJS is a recipient of an Irma T. Hirschl Career Scientist Award.

107.8 SUPRAOPTIC NEUROSECRETORY NEURONS: MODIFICATIONS OF EXCITABILITY BY ELECTRICAL STIMULATION OF LIMBIC AND SUBFORNICAL ORGAN AFFERENTS. L.P. Renaud, E. Arnauld*, M. Cirino*, B.S. Layton, S.Sgro* and Y.S. Siatitsas*. Division of Neurology, Montreal General Hospital and McGill University, Montreal, Canada.

The frequency of action potentials generated by magnocellular neurons of the neurohypophyseal system is an important determinant of the amount of hormone released at the level of the posterior pituitary. Investigation of synaptic pathways that alter the excitability of these neurosecretory neurons should assist the understanding of neural mechanisms that govern the release of neurohypophyseal hormones. We therefore examined the excitability of supraoptic neurohypophyseal (SON) neurons during electrical stimulation in several forebrain regions that provide afferent fibres to the supraoptic nucleus in the rat i.e. the cortico-medial or basal amygdala (AMYG), lateral septum (LS), hippocampus and subfornical organ (SFO).

Extracellular action potentials were recorded from antidromically identified SON neurons in urethane or pentobarbital anesthetized male Sprague-Dawley rats. Isolated stimulators delivered single current pulses (0.05msec, 0.1-0.6mA) at 1Hz or 10Hz to implanted bipolar electrodes. Excitability patterns based on frequency and poststimulus histograms were analyzed with a PDP 11/40 computer. Special attention was directed to 'phasic' SON neurons since these are deemed to be vasopressin secreting cells (cf Poulain et al, Proc. Roy. Soc. Lond.B. 196:367-384, 1977). Single or repetitive stimulation in AMYG and LS evoked a transient depression of excitability among more than 2/3 of active SON neurons. Among phasic SON neurons, bursts of repetitive stimuli applied during periods of activity shortened the duration of phasic discharges. In contrast, SFO stimulation evoked an increase in excitability for more than 50% of SON neurons. With phasic SON cells, repetitive SFO stimuli could trigger or prolong a phasic discharge. Tests conducted on adjacent SON cells indicated variability of responsiveness to the same stimulus.

These data suggest that limbic afferents to SON neurons in the rat serve to decrease their excitability and hence the release of neurohypophyseal hormones, while SFO afferents appear to exert a predominantly excitatory effect on SON cells and therefore to enhance the release of neurohypophyseal hormones. These actions on phasic or putative vasopressin-secreting SON neurons may indicate at least a part of the cellular basis for hormonal (vasopressin release) and behavioural (drinking) functions attributed to limbic brain regions and to the subfornical organ.

107.9 THE INFLUENCE OF ANGIOTENSIN II ON IDENTIFIED MAGNOCELLULAR NEURONS OF THE SUPRAOPTIC NUCLEUS. L. D. Mitchell & A.K.Johnson
Department of Psychology and Cardiovascular Center, University of Iowa, Iowa City, Iowa 52242

The supraoptic-hypophysial tract is a primary system for the synthesis and release of antidiuretic hormone (ADH). Angiotensin II (AII) has been shown to release ADH both when injected into the cerebral ventricles (IVT) or delivered intravenously (IV). The present studies were conducted to examine the effects of AII delivered by either route on the unit activity of SON magnocellular neurons.

Fourteen male albino rats were prepared with intracranial cannulae which insured delivery of drugs to the lateral ventricles, and with polyethylene catheters into the right jugular vein and femoral artery for systemic injections and arterial pressure recordings.

A transbuccal approach permitted visualization of the pituitary stalk, the cerebral arteries and the optic tracts. This allowed positioning of bipolar stimulating electrodes directly into the posterior pituitary and glass microelectrodes into the SON, without violating the ventricular-SON partition. Magnocellular neurons were identified by antidromic excitation and collision inhibition of action potentials.

Either 30ng of AII or 5ug of Saralasin (P113) in 10ul of 0.9% saline were delivered through the IVT cannulae.

In 7 identified cells, IVT AII produced increased firing in 6, and decreased firing in the seventh with latencies of between 4 and 40 sec. In 4 neurons, no change was observed. In 2 cases where P113 was given after AII, excitation was inhibited; in 4 cases where IVT P113 was given alone, firing was reduced to below basal levels with a latency of 2 to 10 sec.

In 6 neurons, pressor doses of AII (IV) produced an initial burst (2-20 sec) of firing followed by inhibition (2-4 min) while blood pressure was elevated.

Based on latency, the results indicate that IVT AII acts on a periventricular site to influence SON magnocellular neurons. Because P113 alone reduced the firing rate of identified cells, it is likely that in the anesthetized rat (urethane) there is a tonic influence of AII on the SON magnocellular neurons. Further more, although systemic AII may briefly excite SON neurosecretory cells, the sustained effect is inhibition which may be mediated via baroreceptor mechanisms.

107.10 MODULATION OF PARAVENTRICULAR UNIT ACTIVITY AND THE MILK EJECTION REFLEX BY POSTERIOR HYPOTHALAMIC AND PERIPHERAL MAMMARY NERVE STIMULATION. E. W. Haller* and J. B. Gearns* (SPON: E. K. Stauffer). Dept. of Physiol., Sch. of Med., Univ. of Minnesota, Duluth, MN 55812.

In view of the unit discharge pattern of oxytocinergic neurosecretory neurons when correlated with oxytocin secretion (and milk ejection), the question arises why oxytocin is not secreted from the neurohypophysis as a constant, elevated output under conditions of constant mammary receptor stimulation. The present experiments examine the possibility that the afferent input of the milk ejection reflex is modulated at the level of the posterior hypothalamus to account for the characteristic firing pattern of oxytocinergic neurons (J. B. Wakerley & D. W. Lincoln. J. Endocrinol. 57: 477, 1973) in relation to episodic oxytocin secretion. A stainless steel microelectrode (ME) (1-2 tip) and a concentric steel stimulating electrode (HSE) (0.3 mm tip, 0.3 mm exposed barrel) were placed stereotaxically on ipsilateral sides of the paraventricular nucleus (PVN) and posterior hypothalamus, respectively, of 5-10 day post-partum rats under urethane (1.3 g/kg b.w.) anesthesia. Contralateral mammary nerve stimulation was accomplished with bipolar Ag/AgCl electrodes (MSE); the nerve was looped over the electrode and kept moist by submerging in mineral oil. Trains of electrical pulses were applied to HSE (1-2 v, 10 Hz, 30 s, 0.5 s on/off) or MSE (5-20 v, 10 Hz, 30 s, 0.5 s on/off) either separately or simultaneously. Unit spike discharge rates and patterns recorded by ME were analyzed by computer program and correlated with mammary duct pressure and cortical EEG monitored during the experiment. Units responding to MSE stimulation were usually associated with a rise in milk duct pressure (96%). HSE stimulation per se inhibited PVN units or failed to elicit a unit response (79%). When MSE and HSE stimuli were applied simultaneously, PVN units displayed attenuated firing rates (61%) and milk duct pressure failed to rise (83%). Alternatively, unit firing patterns of some PVN units were altered without effect on their mean firing rates but reducing milk duct pressure nevertheless. Previous studies have indicated that the afferent path of the milk ejection reflex divides in two portions in the brain stem, but that both innervate PVN. Present experiments suggest that afferents coursing through posterior hypothalamus in close relation to mammillo-thalamic tract may serve a modulating inhibitory function in the milk ejection reflex. Supported by NIH HD13906.

107.11 METABOLIC RESPONSES TO SUCKLING IN POSTPARTUM LACTATING RATS. Theresa O. Allen, Judith M. Stern* and Norman T. Adler, Depts. of Psychology, Univ. Penn., Philadelphia, Pa. and Rutgers Univ., Piscataway, N.J.

In response to suckling by pups, lactating females are known to release pulses of oxytocin from the posterior pituitary and prolactin from the anterior pituitary. In order to investigate the central mediators of these systems, we used the (14C) deoxyglucose (2DG) method of metabolic mapping. All females were deprived of their pups and of food for 6 hours on the 5th or 6th day after parturition and assigned to one of three groups. Four suckled females were reunited with their pups and allowed to nurse during the incorporation period (45 min.) of 2DG. Three nonsuckled females were not reunited with pups during this period. Four postsuckled females were injected with 2DG after a bout of suckling had terminated. Females were killed, brains and pituitary glands were removed and processed for x-ray autoradiography. Sections were later stained with cresyl violet (brain) or aldehyde fuchsin(pituitary).

The data were analysed with a computerized image-processing system (UPenn-Drexel Autoradiography Project) which allowed precise alignment of the autoradiograph and the histology. The following anatomical areas were analysed: posterior pituitary, anterior pituitary, subdivisions of supraoptic and paraventricular nuclei, optic tract, hippocampal commissure, and corpus callosum. To make comparisons between animals, the data are expressed as a ratio of the concentration of 14C in a structure to that in white matter. The posterior pituitary is more active in both suckled ($P \leq 0.05$) and postsuckled ($P \leq 0.05$) females than in nonsuckled rats. This increase may reflect oxytocin release and restoration of ionic gradients (Mata,M. et al., J. Neurochem.1980 34, 213). The anterior pituitary is more active in suckled than in either nonsuckled($P \leq 0.005$) or postsuckled females ($P \leq 0.05$). This increase may be a consequence of depletion/transformation/repletion of prolactin during a bout of suckling. The subdivisions of the supraoptic(Sokol, H. et al., Endocrinol. 1976, 98, 1176) and paraventricular nuclei(Armstrong, W. et al.,Neurosci. 1980, 5, 1931) did not differ between suckled and nonsuckled females. In postsuckled females the dorsal and ventral parts of the supraoptic nuclei and the more posterior parts of the paraventricular nuclei were more active than in nonsuckled females. These increases may reflect synthesis of oxytocin and vasopressin in the cell bodies following a bout of suckling.

107.12 DOPAMINE SYNTHESIS IN THE POSTERIOR PITUITARY MAY BE REGULATED BY PLASMA CONCENTRATIONS OF SODIUM. R.H. Alper and K.E. Moore, Department of Pharmacology/Toxicology, Michigan State University East Lansing, MI 48824.

The in vivo rate of dopamine (DA) synthesis in selected regions of the rat brain was estimated by measuring the rate of accumulation of DOPA 30 min after the administration of a decarboxylase inhibitor (NSD 1015, 100 mg/kg, i.p.). Water deprivation for up to 5 days had no effect on the rate of DA synthesis in the striatum or median eminence, which contain terminals of nigrostriatal and tuberoinfundibular neurons, respectively. On the other hand, water deprivation caused a gradual increase in the rate of DA synthesis in the posterior pituitary, which contains the terminals of tuberohypophyseal neurons; the increase attained statistical significance ($p<0.01$) by 72 hr. Increases in plasma sodium concentrations and hematocrit preceeded the change in DOPA accumulation; they were significantly elevated by 24 hr and increased progressively with time as water deprivation was continued.

In rats deprived of water for 3 days the increased DOPA accumulation in the posterior pituitary and the increased plasma sodium concentration returned to control values within 3 hr after allowing the animals access to water; the hematocrit did not return to control until 24-48 hr later. When rats deprived of water for 3 days were given access to 2% NaCl the hematocrit returned to control values within 48 hr while the rate of DA synthesis in the posterior pituitary and the sodium concentration in the plasma remained elevated.

An injection of hypertonic saline (15% of NaCl, 5 ml/kg) caused a marked but brief (less than 2 hr) increase in the plasma sodium concentration but did not alter the hematocrit. In these animals the rate of DOPA accumulation in the posterior pituitary was increased 24 hr later. Thus, the injection of hypertonic saline causes a brief pulse of increased plasma sodium which apparently triggers a delayed increase in DA synthesis in the terminals of tuberohypophyseal neurons.

The results suggest that in rats subjected to dehydration, rehydration or hypertonic saline injections there is a relationship between changes in DOPA accumulation in the posterior pituitary and the sodium concentration in the plasma, but not with changes in the hematocrit. Thus, the activity of tuberohypophyseal DA neurons appears to be regulated, in part, by activation of sodium but not of volume receptors. (Supported by USPHS Grant NS 09174 and 15911).

107.13 BRAIN STEM PROJECTIONS TO NEURONS OF THE CAUDAL NEUROSECRETORY SYSTEM: HRP TRACER STUDIES. J.P. O'Brien* & R.M. Kriebel* (SPON: J. Wells). Department of Anatomy & Neurobiology, The University of Vermont, College of Medicine, Burlington, Vermont 05405.

The caudal neurosecretory system of P. sphenops(molly) is an isolated population of neurosecretory cells located in the caudal most aspect of the spinal cord. From our earlier studies it was suggested that the caudal system provided a suitable structure in which to study the synaptic control of neurosecretory processes. Morphological and electrophysiological studies have shown that caudal neurosecretory system neurons of fishes receive synaptic input from descending spinal projections. Previously, we have shown several axon terminal types forming axosomatic and axodendritic synapses with the neurosecretory cells in the caudal system. In this study HRP tracer techniques were used to determine the source of the descending spinal cord projections. By determining the source of the synaptic input we may begin to determine possible neurochemical pathways that are involved in synaptic control of these neurosecretory cells and to elucidate how this unique piscine caudal neuroendocrine system functions in concert with cranial neuroendocrine systems. Animals were anesthetized with MS222 and the spinal cord exposed through small lateral incisions. HRP-polyacrylamide implants (15% HRP) were inserted into the spinal cord. Implants were placed at various spinal cord levels in twenty fish, each fish receiving only one implant. Animals survived for 60 hrs; tissue fixed in 2.5% glutaraldehyde, 2% paraformaldehyde in phosphate buffer, transversely and parasagittally sectioned at 50µ, and processed by the TMB technique of Mesulam. All sections were counterstained with a Nissl stain. Using light and darkfield microscopy axons containing HRP were traced cranially in the spinal cord. There appeared to be no specific orientation within the spinal cord of these descending axons, but most were located in ventral funiculi. In the brain stem two groups of neurons were observed containing HRP granules. At mid-medulla levels cells were seen bilaterally in a ventrolateral location. In other species, medullary cells at this location were identified as catecholaminergic. At approximately the junction of the diencephalon and midbrain, just below the subependyma, a second group of cells was found containing HRP granules. These cells were also bilaterally observed and were close to the midline. Our preliminary ultrastructural studies suggest that these cells are peptidergic. Studies are in progress to examine the proposal that caudal neurosecretory cells receive both peptidergic and catecholaminergic descending synaptic input. (Supported by PHS 5429-19-4).

107.14 MATURATION OF NEURONAL PROJECTIONS AND ULTRASTRUCTURE OF THE GOLDFISH PREOPTIC NUCLEUS. W.A. Gregory and C.D. Tweedle. Dept. of Anatomy, Michigan State University, East Lansing, MI. 48824

Recent evidence has shown the continuation of neurogenesis in certain CNS regions and substantial increases in gross brain size throughout the lives of fishes. The preoptic nucleus was studied to observe the development of a neurosecretory system. This nucleus begins rostroventrally with small subependymally located neurons. A spatially graded increase in cell size has led to ill-defined terminology for subdivisions (e.g. parvocellular, magnocellular). Several workers report that cells of all sizes in all regions can contain the same hormones. Using the retrograde transport of HRP we have reported that neurons in the rostralmost as well as more caudal portions of the nucleus project to the pituitary in small (2-8g) fish. Some cells in these regions, as well as those further caudad cells were shown to project to the spinal cord. Findings for fish up to 75g are similar, with correspondingly placed cells larger in larger fish. Also, the most caudal neurons which were only shown to project to the cord in small fish project to the pituitary as well in larger fish (whether via collaterals or separate cells is undetermined). The positional and maturational transition from small to large neurosecretory cells was examined ultrastructurally in the preoptic region of various sized fishes by sectioning each throughout its rostrocaudal extent. Some fish had previously received HRP IP injections or HRP applied to the transected spinal cord to label populations of preoptic neurons. Evidence to date supports a gradual transition in ultrastructure with variation in either cell position or body weight. Morphological variation may be related to the cells' degree of hormone synthesis and release and the requirement for total hormone release as influenced by body size. The most rostral cells were densely packed, with extensive neuron-neuron appositions. Spherical nuclei were surrounded by a thin rim of cytoplasm with a rudimentary complement of organelles (small profiles of rough ER and Golgi (G), and no dense core vesicles (DCVs)). Slightly caudad cells had small stacks of rough ER and an occasional DCV. Neuronal form gradually transformed, yielding a cell rich in cytoplasmic organelles typical of neurosecretory cells (extensive G, large stacks of rough ER, and many DCVs and lysosomes). Some "magnocellular" cells had diameters < 10µm in small (2g) fish. Extensive neuronal appositions were still seen caudally, but neuropil was more evident between neurons. Richer cytoplasm was seen in corresponding larger cells of larger fish. The more caudal and largest cells of large fish had extremely invaginated nuclei, while other preoptic neurons of these or smaller fish had spherical nuclei.

107.15 LIGHT AND EM LOCALIZATION OF HRP-INJECTED, PHYSIOLOGICALLY IDENTIFIED MGC NEUROENDOCRINE CELLS IN GOLDFISH PREOPTIC NUCLEUS. T.A. Reaves, Jr., R. Cumming*and J.N. Hayward. H. Houston Merritt Electron Microscopy Lab., Dept. Neurology and Neurobiology Program, Univ. North Carolina, Chapel Hill, N.C. 27514.

By intracellular recording, cell marking with fluorescent dyes combined with immunocytochemistry, we described three chemical magnocellular (MgC) neuroendocrine cell types in the goldfish preoptic nucleus (NPO; JCN 193:777 '80). To further characterize the structure and connections of these physiologically identified NPO neurons, we report here on intracellular horseradish peroxidase (HRP) injection for light and electron microscopic analysis.

We recorded intracellularly from adult goldfish (Carassius auratus) pituitary-antidromically identified NPO neurons using 3% HRP-filled glass micropipettes. We injected HRP into identified cells with 5-10 nA cationic current for 30-180 sec, then vibratome sectioned the fixed brain at 50-100 uM. We processed the hypothalami with either DAB or TMB for light or EM study.

By light microscopy the HRP-filled MgC resembled Golgi impregnated neurons with a greater complexity of processes than found previously with fluorescent dye-marking. Densely labeled axons and dendrites projected to several sites: 1) to other NPO neurons; 2) to small blood vessels and capillaries; 3) to the third ventricular ependyma; 4) to fiber tracts in the preopticohypophysial tract, in the lateral forebrain bundle, in the medial forebrain bundle and others. We occasionally observed a lightly labeled large perikarya lying adjacent to a heavily labeled MgC, suggesting cell-to-cell connections.

Electron microscopic examination of these MgC showed a dense HRP-reaction product in perikarya and processes. Heavily labeled perikarya reveal elaborate networks of endoplasmic reticulum, somal appendages or spines, axosomatic contacts from unlabeled neurons and close somal apposition of unlabeled profiles or rarely a large adjacent lightly labeled perikarya. Most HRP-labeled perikarya and processes are separated from brain capillary endothelium by a thin glial sheath. HRP-labeled dendrites show heavily labeled spines or appendages and have axodendritic contacts from unlabeled neurons. HRP-labeled axons contact unlabeled perikarya, axons and dendrites.

These results demonstrate that MgC neuroendocrine cells in goldfish NPO have complex connections to other neurons, to brain capillaries, to ventricular ependyma and to the pituitary. We conclude that these data support non-endocrine as well as endocrine functions for MgC neurons. (Supported by NIH Grant NS-13411 and a Neurobiology Fellowship to R.C.)

107.16 NEURAL INNERVATION AND CONTROL OF THE TESTES: A ROLE FOR THE PARAVENTRICULAR NUCLEUS? D.M. Nance. Dept. of Anatomy, Fac. Med., Dalhousie University, Halifax, Nova Scotia, B3H 4H7.

Hemiorchidectomy of prepubertal male rats produces a selective increase in serum FSH with little or no change in serum LH levels. Previously, we found that unilateral hypothalamic knife cuts prevent this rise in serum FSH following hemiorchidectomy on the ipsilateral, but not the contralateral side (Neurosci. Abst. 189.8, 1980). This endocrine difference between ipsi- and contralateral hemi-castrated rats with identical brain surgeries can only be accounted for by postulating that FSH release is, in part, under direct neural control.

Using the fluorescent tracer Bisbenzimide (Bb), cell bodies providing afferent nerves to the testes were identified in dorsal root ganglions (DRG) T_{12} - L_4. All labelled cells were ipsilateral and the L_2 DRG generally showed the largest number of labelled neurons. Efferent nerves showed a similar spinal distribution and cell bodies were localized in lamina IX in the anterior horn of the spinal cord. Bilateral thoracolumbar cord injections of Bb produced extensive retrograde labelling of neurons in the paraventricular nucleus (PVN) of the hypothalamus. Labelled neurons were also localized in a lateral and posterior direction with respect to the PVN. Unilateral retrochiasmatic knife cuts (1.5 mm radius) located anterolateral to the PVN dramatically reduced or eliminated the labelling of PVN neurons on the ipsilateral side following bilateral Bb injections into the thoracolumbar cord. However, labelled neurons were still present lateral to the knife cuts. Thus, PVN neurons innervating the thoracolumbar cord project primarily in a lateral and somewhat posterior direction. These results provide direct evidence on afferent and efferent innervation of the testes and further suggest that the PVN may be involved in the endocrine response to hemi-castration. Research supported by MRC Grant # MA 6956.

107.17 VASOPRESSIN: A REQUIREMENT FOR ENDOTOXIN-INDUCED FEVER IN THE BRATTLEBORO RAT. P.C. Eagan*, W.L. Veale and K.E. Cooper. Department of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

The Brattleboro (DI) rat, a genetic mutant of the Long Evans strain, lacks the ability to synthesize the neuropeptide arginine vasopressin (AVP). The DI rat does not develop fever in response to bacterial endotoxin. These experiments were done to examine the possibility that the absence of AVP is the cause of this lack of a febrile response.

Male, DI rats (300 - 350 gm), which are homozygous recessive for the genetic mutant, were used in these experiments. Stainless steel guide cannulae were implanted stereotaxically into the brains of each animal and were directed towards the lateral cerebral ventricles. The post-operative recovery period was seven days. Colonic temperature was measured continuously using a thermistor probe inserted 9 cm into the rectum and taped to the base of the tail. Colonic temperatures were recorded for two hours prior to each injection and for three hours following. On Day 1, each animal received an injection into a lateral cerebral ventricle of 1 µg of the bacterial pyrogen derived from Salmonella abortus equi (SAEP). The volume injected centrally was 10.0 µl and the vehicle used was pyrogen-free sterile saline. No significant change in body temperature was observed during the three hours following injection, the time during which the fever would be expected to be at its peak. The following day (Day 2), each animal received a subcutaneous injection of 1.0 Units of AVP (Pitressin) in 0.5 ml of sterile oil suspension. Thirty minutes later, 1 µg of SAEP was injected intraventricularly. During the three hours following SAEP administration, no significant change in body temperature had occurred. This procedure was repeated on Days 3 and 4. On Day 3, the increase in colonic temperature was 0.51 ± 0.21°C, and on Day 4, the rats developed a fever of 1.15 ± 0.20°C during the three hours following SAEP. On Days 5, 6, and 7, the animals received 1 µg of SAEP, but the AVP injection was replaced by 0.5 ml of sterile oil subcutaneously. The febrile response on Day 5 was reduced (0.59 ± 0.12°C) and no significant change in body temperature occurred on Days 6 and 7.

The appearance and absence of the febrile response in the DI rat corresponds to the gradual rise and fall in circulating levels of AVP produced by the subcutaneous injections of the peptide on Days 2, 3, and 4. These results suggest that AVP must be present in the body to produce endotoxin fever in the DI rat.

This research is supported by the MRC of Canada. P.C.E. is supported by the AHFMR.

107.18 CENTRAL SEROTONERGIC CONTROL OF SODIUM EXCRETION. J.M. Stein, R.W. Lind, and A.K. Johnson. Department of Psychology and the Cardiovascular Center, University of Iowa, Iowa City, IA 52242.

Our understanding of the CNS neurochemical control of body sodium balance is still developing. Experiments involving central cholinergic and catecholaminergic stimulation have implicated these neurotransmitters in the control of sodium excretion ($U_{Na}V$) and vasopressin release. The present studies indicate a serotonergic (5-HT) component in the central control of sodium excretion.

We have previously reported (Stein, Lind, & Johnson, Neurosci. Abst. 6:228, 1980) that peripherally applied p-chloroamphetamine (PCA) (2.0-10.0 mg/kg) produces a natriuresis in the rat. Since this natriuresis was also found following intraventricular (IVT) infusions of 200-600 µg of PCA, some component of this effect is likely to be centrally mediated. The following experiments were performed to investigate this phenomenon further.

In Experiment 1, rats were implanted with intraventricular cannulae, femoral arterial and venous catheters, and urinary bladder catheters. A hydrating solution (10mM NaCl, 4mM $NaHCO_3$, 130mM Glucose) was continuously infused (0.2 ml/min) into the femoral vein during the experiment. Following a 2-3 hr equilibration period, the unanaesthetized rats were administered PCA (400 µg) intraventricularly with or without pretreatment with the serotonin reuptake blocker, fluoxetine (10 mg/kg, ip). The increased $U_{Na}V$ seen following PCA was totally abolished by fluoxetine. The antidiuretic and acute hypertensive actions of IVT PCA were unaffected or enhanced by fluoxetine pretreatment. Since fluoxetine treated rats could still show a natriuresis following IVT angiotensin II, a direct effect of fluoxetine on the kidney was unlikely. PCA has been shown to release 5-HT from serotonergic nerve terminals and this action is inhibited by 5-HT reuptake blockers (Ross & Kelder, Acta Physiol. Scand. 99:27-36, 1977). It appears that increases in synaptic 5-HT concentrations are necessary for the PCA induced natriuresis to be seen.

In Experiment II, rats were similarly implanted but administered 5-HT (0,1,5,20 or 100 µg) IVT. Dose dependent natriuretic responses were seen. Small (0-20 mmHg) increases in blood pressure and antidiuretic responses were observed at the highest doses tested.

Taken together, these findings suggest that stimulation of central 5-HT receptors increase sodium excretion independent of blood pressure elevation and antidiuretic responses.

107.19 PSYCHOPHARMACOLOGICAL ACTION OF BETA 2 STIMULANTS AGENTS AND VASOPRESSIN. B. Delbarre, G. Delbarre, O. Christin *. Lab. Chir. Exp., Fac. de Méd., 37032 Tours Cedex, France.

Pharmacological (FRANCES H.J. and al., J. Pharm., Paris, 1978 9,1-25 - B. DELBARRE and al., Mol. Biol. Pharmacol. of Cyclic Nucleot., 1978), and clinical studies (WIDLOCHER and al., Lancet 1977, 767) suggest that beta adrenergic agents have antidepressant properties. The precise mechanism of their antidepressant action remains to be elucitated. It is known that beta sympathomimetic amine : isoprenaline stimulates the renin angiotensin system and also vasopressin (VP) release (W. KNEPEL ans al., J. Card. Pharm., 1980, 2, 815).
GOLD P.W. and al., Lancet, 1978, 1233, makes this peptide (VP) a suitable candidate for involvement in complex behavioural syndromes. But no pharmacological data are available on this subject.
To investigate this action, we have used the antagonism to reserpine induced hypothermia in mice. The drugs were administered 4 hours after reserpine. Intraventricularly (IVL), lysine VP (SANDOZ) 0,01 to 0,1 U/mouse and arginine VP (SIGMA) 0,01 to 0,1 U prevent hypothermia induced by reserpine. Intraperitoneal (IP) 5 to 50 U/kg of lysine and arginine VP are ineffective. Angiotensin II (SIGMA) IVL 0,01 to 2 µg/kg/mouse and 5 to 20 µg/kg IP is ineffective. Drugs known to release VP from hypophysis, histamine (1 to 10 µg/kg/mouse),dimaprit (1 to 10 µg/kg/mouse), Db C.AMP (20 to 100 µg/kg/mouse), met.enkephalin (1 to 20 µg/kg/mouse) have no action.
These results suggest that beta 2 stimulant agent act on VP located in brain. Indeed, recently, S.M. GLICK (Lif. Sci., 1980, 27, 1103) found VP in amygdala, septum, thalamus and striatum of rat brain.
F. HIRATA and al. (Proc. Nat. Acad. Sci., 1979, 76, 6, 2640) reported that stimulation of the beta adrenergic receptor increases phospholipid methylation. To test this hypothesis, we have used a prostaglandin synthetase inhibitor : lysine acetylsalicylate. This drug IVL (50 µg/kg/mouse) does not prevent reserpine induced hypothermia, but increases the action of salbutamol (1 mg/kg i.p.) if administered 15 min. before.
It may be suggested that beta 2 stimulant agent exerts its effect in brain through a adenylcyclase system in connection with metabolism of phospholipids and arachidonic acid.

107.20 MECHANISM OF ANTIDIURETIC EFFECT OF BETA ADRENERGIC STIMULATION. G. Delbarre, B. Delbarre. Lab. Chir. Exp., Fac. de Méd., 37032 Tours Cedex, France.

It is considerable amount of experimental data which suggest that the adrenergic system is involved in the control of water metabolism. The effect of vasopressin (VP) appears to be mediated by adenylcyclase, an enzyme which in several tissues has been shown to be activated by beta adrenergic stimulation. Further support to this hypothesis is derived from studies in the rat, and cat which have demonstrated that beta adrenergic stimulation with intravenous isoproterenol (ISO) is associated with an antidiuretic response. The mechanism responsible for ISO antidiuresis is not clear. Data suggest that the antidiuretic effect of ISO is due to a direct action at the renal tubule rather than to the release of ADH. J. LEVI and al. (Am. J. Phys. 1971, 221-6, 1728) have demonstrated that ISO causes an antidiuresis by using the Brattleboro strain of rats which have no circulating or stored VP. ISO exerts its effect through the stimulation of beta adrenergic receptor in the renal tubule since the beta adrenergic antagonist propranolol abolished this effect. Recently, F. HIRATA and al. (Proc. Nat. Acad. Sci., 1979 76, 6, 2640) found that stimulation of the beta adrenergic receptor increases phospholipid methylation.
To investigate the action of a beta 2 stimulant agent, we have used salbutamol.
To investigate the enhancement of phospholipid methylation by stimulation of beta 2 receptor, we have used indomethacin, a prostaglandin synthetase inhibitor. In the normal rats, indomethacin (5 mg/kg per os), salbutamol (5 mg/kg i.p.) have no action on the diuresis. In contrast, in association the decrease of diuresis is significant. In the Brattleboro, indomethacin (5 mg/kg per os), salbutamol (0,1 mg/kg i.p.) decrease diuresis and in association have a more pronounced effect.
These results suggests that there is an interaction between stimulation of the beta adrenergic receptor and phospholipid methylation. Indeed, blockade of prostaglandin synthesis by indomethacin increases action of beta 2 stimulant : salbutamol. Moreover, the different action in Brattleboro and normal rats may be explained by the fact that Brattleboro have a modification of prostaglandin synthesis (WALKER L.A. and al., Am. J. Physiol., 1978, 4, 3, F. 180.

108.1 THE EFFECT OF α-MSH ON THE IN VIVO AND IN VITRO RELEASE OF PROLACTIN AND LH IN THE RAT. O. Khorram* and S.M. McCann. Department of Physiology, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

The neurointermediate lobe tridecapeptide, α-MSH, has been localized throughout the brain, with the hypophysiotropic area of the hypothalamus containing some of the highest levels (O'Donohue et al., Brain Research 17: 101, 1979; Oliver and Porter, Endocrinology 102: 697, 1978). This finding along with its detection in the portal plasma of the rat suggests that α-MSH may act as a modulator of anterior pituitary function (Oliver et al., Endocrinology 101: 598, 1977). The following study was conducted to examine this hypothesis in relation to the secretion of LH and prolactin. Long-term ovariectomized (OVX) rats bearing chronically implanted third ventricular cannulae were employed. Blood was withdrawn from jugular cannulae in unanesthetized freely moving animals before and after intraventricular (IVT) injection of 2 µl of 0.9% NaCl, 100 nanograms or 2 micrograms of α-MSH dissolved in saline. No effect on plasma LH and prolactin levels was seen following injection of saline or the lower dose of MSH. The higher dose of α-MSH inhibited the release of prolactin and LH within ten minutes following its injection as indicated by a lowering of plasma levels of the hormones. The 2 µg dose was also effective in inhibiting prolactin release in OVX rats primed 72 hours earlier with 50 µg of estradiol benzoate (s.c.), although LH release was not affected in these animals. The inhibitory effect of α-MSH on prolactin release could be blocked by the intravenous (i.v.) infusion of the dopamine receptor blocker, spiroperidol (.1 mg/kg body wt.), 1 hour prior to the IVT injection of α-MSH. Direct i.v. injection of 5 µg α-MSH in 0.9% NaCl slightly inhibited LH release in OVX rats one hour after its injection while prolactin release was unaffected. Hemipituitaries from male and OVX female rats were incubated with various doses of α-MSH. The secretion of neither LH nor prolactin was affected in this system. In conclusion, we have demonstrated that IVT injection of α-MSH inhibits basal and stimulated prolactin release possibly via a dopaminergic mechanism. α-MSH also inhibits the release of LH; this effect was blocked by estrogen. The failure of α-MSH to affect the release of LH or prolactin in vitro implicates a central neural site of action for this melantropic peptide. Supported by NIH Grants AM-10073 and HD-09988 and the Ford Foundation.

108.2 MARKED CHANGES OF SOMATOSTATIN CONTENT IN DIFFERENT HYPOTHALAMIC AREAS OF THE RAT DURING PROESTROUS AND THEIR INVERSE RELATION TO SERUM PROLACTIN U.A.Knuth*,G.S. Sikand*,F.Casanueva*,V.Havlicek and H.G.Friesen* Deparment of Physiology, University of Manitoba, Winnipeg, Manitoba R3E 0W3

To investigate physiological changes in Somatostatin content of the hypothalamus on day of proestrous groups of 10 rats were decapitated every two hours from 8.00 to 18.00. The heads were subjected to microwave irradiation to prevent degradation of peptides. Anterior pituitary (13.3±0.33mg) and median eminence (0.53±0.33mg) were removed. Punch biopsies were obtained from the anterior (12.9±0.33mg) and posterior hypothalamus area (19.7±0.27mg) and the region of the arcuate nucleus (2.9±0.11mg). All samples were homogenized in 0.1N acetic acid by an ultrasound homogenizer and boiled for 10min. Somatostatin was measured by a specific RIA and is expressed as µg/g of tissue. Serum prolactin (ng/ml) was determined in samples obtained from trunk blood. The following table gives means and SEM of tissue concentration of Somatostatin and serum prolactin. Significant differences from the 8.00 values are indicated by *(p=0.01) and **(p=0.001). These values are derived by a SCHEFFE test after an analysis of variance was performed, which was highly significant for all areas except the median eminence.

daytime	8.00	10.00	12.00	14.00	16.00	18.00
pituitary	2.6 (0.93)	0.80 (0.80)	1.09 (0.24)	0.18 (0.02)	0.68 (0.27)	0.18 (0.18)
anterior hypothal.	10.9 (2.76)	7.63 (1.07)	5.28 (0.65)	0.87* (0.25)	2.12* (0.84)	0.53** (0.54)
posterior hypothal.	4.3 (1.00)	3.77 (0.55)	2.35 (0.48)	0.21** (0.04)	1.46 (0.65)	0.37* (0.11)
arcuate nucleus	20.9 (3.69)	13.28 (1.79)	20.11 (3.14)	7.07 (1.34)	12.14 (3.34)	9.86 (1.27)
median eminence	314 (34.1)	316 (94.1)	273 (44.5)	342 (30.6)	184 (20.0)	220 (13.4)
serum prolactin	9.6 (1.07)	23.3 (1o.6)	52.2* (18.9)	732** (169.)	834** (119.)	493** (33.6)

Somatostatin in anterior and posterior hypothalamus and arcuate nucleus was inversely correlated with prolactin levels (r=-.45, -.42 and -.35, respectively).

108.3 STUDIES OF PROLACTIN-RELEASING ACTIVITY IN PLASMA AND HYPOTHALAMIC EXTRACTS OF MAMMALIAN AND AVIAN SPECIES. M. Hochstrasser*, L-Y. Huang* and J. Rabii (SPON: C.H. Page). Department of Physiology and the Bureau of Biological Research, Rutgers University, New Brunswick, N.J. 08903.

It has become established that prolactin secretion is under tonic hypothalamic inhibition in mammalian species, whereas in birds, the influence of the hypothalamus appears to be primarily stimulatory. As prolactin-releasing activity (PRA) has been demonstrated in human and rat plasma, we undertook to examine the plasma of an avian species for similar activity. Young male domestic fowl (8-week-old) of the White Leghorn strain and adult male rats of the Sprague-Dawley strain were used in this study. The PRA of various extracts was tested in in vitro dispersed pituitary cell cultures. Both chicken and rat prolactin were measured by their respective radioimmunoassays. A dose-dependant PRA was shown to exist in methanol extracts of both chicken and rat plasma. Inter-species tests indicated that plasma extract from either rats or chickens was effective in inducing prolactin release from cell cultures of the opposite species. Chicken hypothalamic extract was markedly effective in releasing chicken prolactin both in vitro and in vivo. Chicken hypothalamic extract, however, was not as effective in releasing in vitro rat prolactin as it was chicken prolactin. The avian plasma PRA was further characterized by a number of physical tests. Using a cascade ultrafiltration experiment it was shown that the circulating PRA had a molecular weight between 1,000 and 10,000. Furthermore, the reconstituted extract was heated to 100°C for 10 minutes which showed that the PRA was only partially heat-stable. Finally, the reconstituted plasma extract was subjected to trypsin digestion and was observed to be resistent to proteolysis. In a separate study the PRA of plasma from young birds was compared with that from older animals (10-month-old). It was observed that the young birds had a significantly higher plasma PRA than the adults. These results suggest the presence of PRA in plasma of birds in larger apparent levels than the PRA of mammalian plasma. Furthermore, younger birds with high circulating prolactin levels have higher PRA than old birds with a low secretory rate of prolactin. Finally, this plasma PRA appears not to be species specific. (Supported by the Bureau of Biological Research)

108.4 TUBEROINFUNDIBULAR DOPAMINE NEURONS IN THE LACTATING RAT ARE NOT RESPONSIVE TO INCREASED PROLACTIN CONCENTRATIONS. K.T. Demarest, D.W. McKay*, G.D. Riegle* and K.E. Moore. Michigan State University, East Lansing, MI 48824.

The results of previous studies have demonstrated that tuberoinfundibular dopamine (TIDA) neurons are activated during periods of increased serum concentrations of prolactin (see Fed. Proc. 39: 2912, 1980). It was thus unexpected to observe that the increased release of prolactin during lactation was associated with decreased TIDA neuronal activity compared to values observed during diestrus. TIDA neuronal activity was estimated by the rate of DOPA accumulation in the median eminence 30 min following NSD 1015 (100 mg/kg, ip) and expressed as ng DOPA/mg protein/30 min. Serum prolactin was continuously elevated in lactating rats (Day 12 postpartum) in the presence of their pups (580±79 ng/ml); 4 hr following pup removal prolactin decreased (39±6 ng/ml) to values observed during diestrus and remained suppressed for at least 144 hr. DOPA accumulation in the median eminence of lactating rats in the presence of pups was significantly lower (7.0±0.8) than that observed during diestrus (15.7±0.9). In addition, the decrease in serum prolactin induced by pup removal was not associated with an increase in TIDA neuronal activity, but rather DOPA accumulation in the median eminence remained suppressed for at least 144 hr. It would appear the TIDA neurons are inhibited during lactation to allow serum prolactin to increase. Studies were undertaken to determine if TIDA neurons in the lactating rats are still responsive to prolactin. Lactating (Day 6-8 postpartum) and regularly cycling rats were implanted with cannula guides in the lateral cerebroventricle 4-7 days prior to sacrifice. Rat prolactin (RP-2-B; 10 µg/10 µl) or 0.9% saline vehicle was administered via intraventricular (icv) infusion 12 hr prior to sacrifice in 1) rats during diestrus, 2) lactating rats with pups and 3) lactating rats which had pups removed 12 hr prior to prolactin administration. Rates of DOPA accumulation in the median eminence of these rats were:

	Diestrus	Lactating (pups)	Lactating (no pups)
Vehicle	15.7±1.6	9.7±0.8	11.6±1.6
Prolactin	22.9±1.9*	11.0±0.8	11.9±1.4

DOPA accumulation in the median eminence of diestrus rats was significantly increased by the icv administration of prolactin. On the other hand, icv prolactin administration had no effect on DOPA accumulation in the median eminence of either of the groups of lactating rats. These results indicate that the prolactin feedback mechanism that normally activates TIDA neurons does not operate in the lactating rat. (Supported by NS09174 and a MSU-COM Research grant.)

108.5 HYPOTHALAMIC LHRH IN OVARIECTOMIZED RATS FOLLOWING IMMEDIATE OR DELAYED ESTROGEN TREATMENT: ANALYSIS BY RADIOIMMUNOASSAY (RIA) AND IMMUNOCYTOCHEMISTRY(ICC). D. A. Damassa*, J. C. King, and K. Elkind-Hirsch. Dept. of Anatomy, Tufts Med. Sch., Boston, MA.

To assess the influence of gonadal steroids on the form, quantity and distribution of LHRH within the hypothalamus, LHRH immunoreactivity was examined by RIA and ICC using characterized antisera. Female rats (CD) exhibiting regular estrous cycles were ovariectomized(ovxed) 2 days after vaginal estrus, and implanted with Silastic capsules (3.18mm o.d. X 1.57mm i.d. x 3 mm l) containing estradiol (E2):cholesterol (1:1) either at the time of ovariectomy (ovx) or 3 weeks after ovx. Control ovxed animals received empty capsules. One day or 2 weeks after implantation of the capsules, blood was collected by decapitation. The preoptic-hypothalamus was dissected into anterior (AH) and posterior(PH) regions, homogenized in cold 2N acetic acid, lyophilized and stored at -20°C. LHRH was assessed by RIA using antisera which require the entire decapeptide (TN-R42), the interior sequence(AA-743), or the C-terminal sequence(IJ-29) for high affinity binding. Each group consisted of at least 5 animals and results were analyzed using a 1-way ANOVA. All three antisera yielded the same results for LHRH immunoreactivity in the PH, therefore, only results with TN-R42 are shown. Animals ovxed and implanted immediately with E2 capsules had a high PH LHRH content(D-1: 4.14 ± .41 ng/region X ± SE, or D-14: 4.92 ± .30 ng/region) and low serum LH levels (D-1:37 ± 7 ng/ml RP-1 or D-14: 64 ± 23). Three weeks after ovx, PH LHRH was reduced to 2.24 ± .24 ng/region (ovx ctl) and was not increased by one day of E2 treatment (D-1: 2.48 ± .41 ng/ region) although serum LH was significantly reduced (ovx ctl: 636 ± 67 ng/ml vs D-1:320 ± 40). Two weeks of E2 treatment partially reversed the castration-induced changes in PH LHRH (3.76 ± .48 ng/region) and LH. In contrast to the PH, no differences in LHRH content of the AH were found following ovx or after immediate or delayed E2 therapy. LHRH immunoreactivity of the AH with IJ-29 was significantly lower than that measured with either AA-743 or TN-R42 for all treatment groups. To correlate RIA and ICC data, female rats were ovxed, treated with E2 as described above, and then perfused under Nembutal anesthesia. Fixed brains were removed, Vibratome sectioned (50μ) and incubated with antisera IJ-29 or AA-743 in the PAP technique. Immunoreactive LHRH in the PH was localized in the median eminence and the amount of reaction product correlated well with RIA values. (Supported by Grants HD 14356 to DAD and HD00352 and HD14092 to JCK).

108.6 EXPOSURE TO FEMALE ODOR ALTERS LEVELS OF LUTEINIZING HORMONE-RELEASING HORMONE AND LUTEINIZING HORMONE IN THE MALE GOLDEN HAMSTER. Heidi S. Phillips*, Fred L. Jackson*, and Beng T. Ho (SPON: P. Kralik). University of Texas Graduate School of Biomedical Sciences and Texas Research Institute of Mental Sciences, Houston, Texas 77030.

The odor of female hamster vaginal discharge elicits in male hamsters behavioral and endocrine responses which resemble the effects of systemically administered luteinizing hormone-releasing hormone (LHRH). The presence of LHRH-like immunoreactivity in olfactory pathways of the golden hamster suggests that LHRH may facilitate behavioral or endocrine responses to olfactory stimuli. The present study examined the effects in male hamsters of female odor on regional LHRH content and serum luteinizing hormone (LH) levels. Responses to female hamster vaginal discharge were compared to those elicited by peanut oil, an attractive but sexually neutral substance.

Sexually naive male golden hamsters were transferred from home colony cages into individual cages one hour prior to olfactory exposure. Cotton swabs saturated with female hamster vaginal discharge or peanut oil were placed in each cage and animals were decapitated at intervals from 2 to 45 minutes later. Acid extracts of hypothalamus, olfactory bulbs, and amygdala were prepared from each animal and assayed individually for LHRH by radioimmunoassay. Serum LH was also determined by radioimmunoassay.

Exposure to female odor transiently elevated serum LH, while peanut oil exposure produced no significant change. Serum LH was elevated threefold in female odor-treated animals vs. peanut oil-treated animals at 6 minutes post-exposure. By 12 minutes LH values did not differ between the two groups. Hypothalamic LHRH varied in an inverse manner with serum LH. Female odor decreased hypothalamic LHRH while peanut oil had no effect. Preliminary results indicate that LHRH in olfactory bulbs and amygdala does not respond differentially to the two odors investigated. The LHRH pattern observed in these extrahypothalamic sites following exposure to both odorous substances may be either a non-specific reaction to novel stimuli or a specific reaction to attractive olfactory stimuli. The results of this study demonstrate that in sexually naive male hamsters, female odor causes a decrease in hypothalamic LHRH and a concommitent increase in serum LH that is not produced by another novel, attractive odor.

108.7 THE EFFECT OF N-METHYL ASPARTIC ACID (NMA) AND MONOSODIUM GLUTAMATE (MSG) ON PLASMA LH LEVELS IN THE OVARIECTOMIZED ESTROGEN-PROGESTERONE PRIMED RAT. A.J. Carrillo and O. Alcantara*, Department of Anatomy, The University of Texas Health Science Center at San Antonio, San Antonio, Texas, 78284.

There exists considerable evidence that NMA stimulates the release of LH in male rats (Shainker & Cicero, Br. Res. 184:425, 1980). The present study was designed to examine the effect of NMA and MSG on LH release in the female rat. Adult female rats were ovariectomized; 4-6 weeks later they were anesthetized with ether and an i.v. cannula was permanently implanted into the jugular vein. At the same time the rats were injected (s.c.) with 50μg of estradiol benzoate (EB) and 25mg of progesterone (P). Three days after steroid priming the animals were injected subcutaneously or intravenously with NMA (25mg/kg) and MSG (1g/kg) dissolved in PBS or with PBS alone. Blood samples were obtained through the i.v. cannula from the freely moving awake rat at 0, 7.5, 15, 30, 45, and 60 min. post injection for plasma LH determination (RIA-NIAMDD). For comparison, intact 25 day old male rats were also injected (s.c.) with the same dosages of NMA and MSG as the females and decapitated 7.5 minutes post injection and trunk blood collected for plasma LH and FSH determination. A PBS injected and intact group served as controls. Subcutaneous injection of NMA and MSG in adult female rats had no significant effect on plasma LH levels when compared to the PBS group. In the 25 day old rats s.c. injection of NMA resulted in a significant ($p<0.01$) elevation of plasma LH but not FSH when compared to controls. MSG had no significant effect on gonadotropin secretion. Intravenous injection of NMA and MSG to ovariectomized EB-P primed rats resulted in a significant ($p<0.01$) elevation of plasma LH levels when compared to the PBS group. NMA injection produced a much greater ($p<0.05$) rise in plasma LH levels than MSG. Incubation of hemipituitaries from ovariectomized EB-P treated rats in medium 199 with NMA (5.0×10^{-3}M) resulted in a significantly ($p<0.05$) greater amount of LH released into the medium when compared to hemipituitaries in medium 199 alone. These data suggest that NMA is a more powerful stimulator of LH release than MSG in the young male as well as the adult female; however, NMA may in part stimulate the release of LH by acting directly on the pituitary gland. (Supported by USPHS Grant NS 14581 and 15454.)

108.8 FSH-RELEASING ACTIVITY IN THE POSTERIOR PORTION OF THE RAT MEDIAN EMINENCE. H. Mizunuma*, W.K. Samson*, M.D. Lumpkin* and S.M. McCann (SPON: M. Kaufman). Department of Physiology, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

Immunohistochemical studies have shown that LHRH nerve terminals are predominantly localized in the rostral portion of the median eminence (ME) in every species examined thus far. That these terminals are involved mainly in stimulating LH release from the pituitary gland has been confirmed by studies from our laboratory (Ojeda et al., 1977), in which greater LH than FSH release was observed after implantation of prostaglandin E_2 into this area of the rat brain. Furthermore, greater FSH than LH release followed implantation of the prostaglandin into the posterior portion of the ME suggesting the possibility that these implants released FSH-releasing factor. To test this hypothesis, the anterior half of the ME (aME) and the posterior half of the ME (pME) were removed separately from adult male rats and extracted in 0.2 N acetic acid. The content of immunoreactive (IR)-LHRH in the extracts was almost twice as high in the aME as in the pME (1942 pg/5 aME and 1038 pg/5 pME, respectively) in agreement with the immunohistochemical studies. IR-LH and FSH-releasing activities were measured in an in vitro incubation in which 8 hemipituitaries from adult male rats were incubated for 6 h at a dose of 5 tissue equivalents. The results were expressed as LH or FSH release (ng RP-1/ml/mg anterior pituitary wet weight). LH-releasing activity of the aME was 233.6 ± 11.3 which was significantly greater than that of the pME (179.8 ± 13.5) ($P<0.05$), whereas there were no differences in FSH-releasing activity (56.4 ± 3.5 and 57.5 ± 2.6). A significant dose-related increase in FSH release was noted in this system when 1 and 2 ng of synthetic LHRH were tested which indicates that the assay was sensitive to different amounts of LHRH with regard to FSH-releasing action. Therefore, the results demonstrate that the pME has greater FSH-releasing activity than can be accounted for by the LHRH content. The additional FSH-releasing activity is presumably due to a distinct FSH-releasing factor. Supported by NIH Grants AM-10073 and HD-09988 and the Ford Foundation.

108.9 SYNAPTIC MECHANISMS MEDIATING COPULATION-INDUCED OVULATION IN THE RAT. R.E. Leipheimer*, T.P. Condon* and J.J. Curry, Dept. of Physiology, The Ohio State Univ., Columbus, OH. 43210

The synaptic mechanisms involved in mediating copulation induced ovulation (CIO) in rats have never been specifically investigated. The present experiments were designed to: (1) investigate protocols influencing CIO in pentobarbital-blocked proestrus rats; and (2) investigate synaptic mechanisms involved in mediation of CIO by the administration of synaptic blocking agents. Only rats demonstrating two consecutive 4 day estrus cycles were used for these experiments. Rats were given an ovulation blocking dose of pentobarbital (35 mg/kg)ip at 1200 hrs on proestrus. That evening one of the following procedures was utilized to induce ovulation: limited mating (maximum of 30 mounts), all night mating, or glass rod stimulation of the vagina and cervix (2 or 5 min). Rats were examined the following morning for the presence of tubal ova. Results of this experiment demonstrated that all night mating was the most successful procedure utilized, and resulted in 100% ovulation in rats that mated. Glass rod stimulation was somewhat effective (25-50% ovulation), while limited mating was ineffective (0% ovulation). The next experiment examined neural synaptic mechanisms involved in mediating CIO. Pentobarbital-blocked proestrus rats were given a sc injection of one of the following synaptic blocking agents at 1700 hrs: phenoxybenzamine (20 mg/kg); propranolol (20 mg/kg); pimozide (2 mg/kg); methysergide (100 mg/kg) or atropine (70 mg/100g). Females were placed with males between 2000 and 2100 hrs and were allowed to mate all night. Females were separated from males at 0900 hrs, and presence of spermatozoa in the vaginal smears was taken as evidence of mating. Oviducts were subsequently removed and examined for presence of tubal ova. Results showed that administration of phenoxybenzamine, propranolol or pimozide did not interfere with CIO. Methysergide treatment was found to completely block CIO. Also, LHRH (200 ng) administration to methysergide treated rats resulted in ovulation. Atropine administration resulted in a loss of mating behavior and therefore, those animals did not ovulate. In addition, atropine also blocked glass rod induced ovulation. In summary, methysergide treatment completely blocked CIO, suggesting that serotonin may be important in mediating this response. And because LHRH administration to methysergide treated rats resulted in ovulation, a CNS site of action for methysergide was indicated. Because atropine administration blocked mating behavior and glass rod induced ovulation, acetylcholine was implicated to be important in the mediation of mating behavior and reflex ovulation.

108.10 THE LHRH NEURONAL SYSTEM IN FEMALE RATS: RELATION TO THE MEDIAL PREOPTIC NUCLEUS (MPN). Ei Terasawa and Gary A. Davis* Wis. Reg. Primate Research Ctr., Univ. of Wis., Madison, WI. 53706

Previously we have reported that in the preoptic and suprachiasmatic regions small lesions restricted to the MPN and the immediately adjacent area are effective to block spontaneous ovulation, to induce persistent vaginal estrus, and to abolish the progesterone-induced LH surge in female rats. Since the MPN is located immediately caudal to the organum vasculosum laminae terminalis (OVLT) where LHRH fibers are reported to be dense, these effects of MPN lesions may be due to interruption of the LHRH neuronal system whose axonal endings terminate in the median eminence (ME). In the present experiments LHRH neurons were immunocytochemically stained in spontaneous and MPN lesion-induced persistent estrous rats, as well as in intact proestrous and metestrous rats using Arimura's anti-LHRH (No. 734) and Sternberger-Meyer's peroxidase-antiperoxidase complex. Anesthetized animals were perfused with saline and Zamboni's fixative, and brains were cut on a Vibratome at 50 µm. Alternate sections were serially taken for immunocytochemical staining and for cresyl violet. The results were as follows: 1) Cell bodies of the LHRH neurons were found in small numbers in the area surrounding the OVLT and also in the preoptic area, diagonal bundle and septum. The distribution density of cell bodies in the MPN region was similar to that in the other preoptic regions, and the immunoreactive cells were located mostly in the lateral margins of the MPN or immediately lateral to the MPN. 2) More LHRH cells were found in proestrous than in metestrous rats, and in persistent estrous (both spontaneous and MPN lesion-induced) rats than in proestrous rats. 3) LHRH fibers were most concentrated in the ME, OVLT and ventromedial part of the arcuate nucleus (ARC). In the MPN some fibers were observed running along the ventricle or transverse to it, but there were more fibers in the area ventrolateral to the MPN. However, the fiber density of the MPN region was far less than that in the OVLT. 4) More fibers were found in the OVLT, ME and ARC in spontaneous persistent estrous rats than in any other animals. In MPN lesion-induced persistent estrous rats there were more fibers in the OVLT (rostral to lesions) and in the ARC than in those regions of proestrous rats, while in the ME the density seemed to be similar to that in proestrus animals.

LHRH staining, then, does not appear to be diminished in animals with MPN lesions, in spite of the fact that these lesions severely disrupt the phasic release of LH. These results do not support the idea that the effects of MPN lesions are due to a deficiency in the LHRH system, but are consistent with the possibility that this nucleus is critical for triggering LHRH release. (Supported by NIH grants RR00167, HD11355 and HD15433).

108.11 THE ENKEPHALIN ANALOG FK 33-824 POTENTLY INHIBITS LH SECRETION IN GONADECTOMIZED IMMATURE RATS. R. Bhanot* and M. Wilkinson. Dept. Physiol. Biophys. and Obst. Gynecol., Fac. Med., Dalhousie University, Halifax, NS, Canada B3H 4H7.

Endogenous opiates are implicated in the regulation of gonadotropin secretion in man and in laboratory animals and may also exert an important influence during development (Blank et al. Science 203 1129 (79). We have sought to probe a hypothalamic involvement of opiates in sexual maturation with the aid of the synthetic enkephalin FK 33-824 (FK) which potently inhibits LH in man and which does not cross the blood-brain barrier (Grossman et al., Clin. Endocr. 14 41 (81).

In female rats (26 days; 48h post-ovx) FK completely inhibits the post-ovx elevation in LH (347±78 ng/ml to 29±4 ng/ml, $p<0.005$; 1 mg/kg). Approximately 50% inhibition was observed with a 10-fold lower dose. Comparable results were obtained with male rats of the same age. A 1.0 mg/kg of FK reduced post-ovx serum FSH levels of immature female rats (26 days) from 1317±64 ng/ml to 1108±35 ng/ml. This response of FSH contrasts strongly with that of LH in that the analog did not bring FSH levels to those in intact animals (192±28 ng/ml). However, we have found naloxone to increase FSH levels in both ovx and intact immature animals. The effects of FK on gonadotropin release could be prevented by simultaneous injection of naloxone (0.5 mg/kg).

Opiate regulation of gonadotropin secretion does not appear to occur directly at the pituitary gland. Pituitary halves from immature male rats pre-incubated with FK (2h; 10^{-10} - 10^{-6} M) responded normally, in terms of LH release, to GnRH (1.7×10^{-9} M). Similarly, naloxone (10^{-6} M) failed to modify either LH or FSH release from hemipituitaries of ovx or intact immature rats.

In view of the profound effects exerted by FK on LH secretion we have investigated the influence of daily FK or naloxone injections (1 mg/kg; from day 24) on the timing of vaginal opening (V.O.) in immature female rats. Neither drug had any effect on the age at V.O., body weight, ovarian or uterine weight or number of ova released at first ovulation when compared with age-matched vehicle-treated controls. Similar experiments with a regimen of increasing daily dosages (1-4 mg/kg FK or naloxone) also had no effect on puberty.

Although our studies with FK and naloxone provide further evidence of an opiate component in the control of gonadotropin secretion in immature rats, they failed to reveal opiate involvement in sexual maturation. More recently however, we have observed age-related decreases in the ability of FK to suppress LH secretion in maturing gonadectomized rats. (Supported by MRC grant to M.W.).

108.12 COMPARISON OF MORPHINE'S EFFECT ON UNIT ACTIVITY IN THE VENTROMEDIAL NUCLEUS (VMN) FOLLOWING SYSTEMIC OR INTRACRANIAL ADMINISTRATION. J.M. Lakoski and G.F. Gebhart. Department of Pharmacology, University of Iowa, Iowa City, Iow 52242.

The extensive anatomical interconnections of extrahypothalamic areas to the VMN have been demonstrated to modulate the secretion of luteinizing hormone (LH). Extrahypothalamic areas, including the amygdala (AMYG) and the periaqueductal central gray (PAG), have also been demonstrated to mediate the morphine-induced depression of LH. We have further investigated the role of the AMYG and PAG by comparing the effects of systemic vs intracranial administration of morphine (MOR) on single unit extracellular activity in the VMN. Unit activity in the VMN (7.8-8.4 mm ventral to the dura) was recorded in urethane-anesthetized (1.5 gm/kg, ip) adult male Sprague Dawley rats using conventional electrophysiological techniques; only one unit per animal was tested for responses to morphine administration and all sites were subsequently confirmed histologically. Opiate sensitive units (n=33, 72% of units tested) were identified in intact and chronically castrated animals; castration resulted in a significant enhancement of spontaneous unit activity compared with intact animals (4.6 ± 0.5 and 2.9 ± 0.4 spikes/sec, respectively). MOR SO_4 administered iv in log intervals produced a marked decrease in firing (> 75%) with cumulative doses (as MOR base) ranging from 0.8-6.4 mg/kg ($\bar{X}$ = 3.2 mg/kg). Naloxone administered in log intervals (0.4-.16 mg/kg) reliably reversed the MOR-induced depression of firing. The stereospecificity of this response was confirmed by the inability of dextorphan (cumulative dose to 1.6 mg/kg iv) to alter VMN activity. In animals previously prepared with cannulae implanted bilaterally in the AMYG or PAG, microinjection of MOR (5.0 µg/0.5 µl CSF/site) also produced a significant inhibition of unit activity in the VMN; this depression was reversed by the systemic administration of naloxone. Microinjection of dextorphan (5.0 µg/0.5 µl CSF/site) into these sites failed to alter unit activity in the VMN. The time course of maximal depression of firing induced by MOR differed depending on the route of drug administration. Thus, these data demonstrate the ability of morphine to influence the neuronal activity of the VMN whether administered systemically or intracranially into discrete extrahypothalamic sites. These data also provide further insight into the mechanism whereby extrahypothalamic sites, such as the AMYG and PAG, with demonstrated high levels of specific opiate receptor binding and known interconnections with the hypothalamus may mediate the morphine-induced depression of LH.

108.13 ESTROGEN ELICITS LH AND FSH SURGES IN ACYCLIC FEMALE RATS BEARING PROLACTIN(PRL)/GROWTH HORMONE(GH)-SECRETING TUMORS.
Thomas E. Nass*, John K.H. Lu* and Howard L. Judd* (SPON: P.C.K. Leung). Depts of Obstetrics/Gynecology and Anatomy and Lab of Neuroendocrinology, Brain Res Institute, University of California Los Angeles School of Medicine, Los Angeles, CA 90024.

Subcutaneous(sc) transplantation of PRL/GH-secreting tumors (Furth,MtT.W15) into regularly cyclic female rats results in a rapid cessation of estrous cycles associated with persistent diestrous vaginal smears. To date, the mechanisms by which abnormal secretion of PRL and/or GH inhibit normal reproductive cycles are unknown. The present study was undertaken to determine if the stimulatory feedback action of estrogen on gonadotropin secretion is present in acyclic female rats (Wistar) bearing MtT.W15 tumors. Blood samples were obtained before and after the tumor transplantation at 2-3 day intervals for about one month, and sera were assayed for FSH, LH and PRL concs. by RIAs. Tumor transplantation resulted in a large increase in PRL secretion within 5-10 days and a cessation of estrous cyclicity. However, serum concs. of both LH and FSH during the prolonged acyclic state were comparable to basal values in regularly cyclic females. After a chronic (8 wks) elevation of circulating PRL, 5 acyclic females were each injected sc with 20 μg estradiol benzoate(EB) at 1230h. On the following day all animals showed significant increases in serum LH (893 ± 71 vs 65 ± 6 ng/ml, mean ± SEM, $p<0.01$) and FSH (1471 ± 377 vs 239 ± 17 ng/ml, $p<0.01$) at 1700h. A second injection of EB 4 days later also elicited LH and FSH surges. In a second group (n=5) of acyclic females bearing MtT.W15 tumors for 3 wks, a priming dose of 1 μg EB was followed 21h later by a 50 μg EB injection. EB administration resulted in significant increases in both serum LH (303 ± 142 vs 57 ± 7 ng/ml, $p<0.05$) and FSH (574 ±138 vs 254 ± 34 ng/ml, $p<0.05$) between 1600 -1800h on the next day. Similarly, a second test with EB administration 9 days later also induced both LH and FSH surges. These results demonstrate that, in the presence of high circulating PRL/GH, acyclic female rats maintained normal basal secretion of LH and FSH and responded to estrogen administration by increasing gonadotropin release. These findings provide evidence that the stimulatory feedback mechanism of estrogen on gonadotropin secretion is present, but not functioning, in female rats during the acyclic state associated with high circulating concs. of PRL/GH, and suggest that the cessation of estrous cyclicity may be related to a lack of estrogen stimulation to the central nervous system (Supported in part by NIH research grants AG01512 and CA23093).

108.14 ULTRASTRUCTURAL CHANGES IN LH GONADOTROPES EFFECTED BY ETHANOL AND VITAMIN A INTERACTION. J.P.Hagedoorn*, G.G.Gordon* and Ch.S.Lieber*(SPON: A.B.Rothballer). Depts.of Anat.,Medicine,New York Med.College, Valhalla,N.Y.,10595;Alc.Res.Treatm.Center,V.A.Med. Center,Bronx,N.Y.,10468,Mt.SinaiSchool of Medicine, New York,N.Y.,10029.

Young male Sprague-Dawley rats were pair-fed liquid isocaloric diets in which 36% of the carbohydrate caloric intake was substituted by ethanol. Each diet was either Vitamin A replete- or deficient (100 grams/day, resp. 0.33 grams/day). Dietary treatment lasted 70 days.At sacrifice bloodsamples were taken for serum analysis of testosterone and luteinizing hormone. Testes, hypophysis and hypothalamus were resected and routinely fixed, dehydrated and embedded in Epon for ultrastructural examination. The LH producing cells of the adenohypophysisshowed a marked reduction in granular contents,extensive vacualization, lamellar formation and abundant RER in cisternal profiles in the ethanol-fed Vitamin A deficient animal when compared to the ethanol-fed Vitamin A replete rat. Mere Vitamin A deficiency without alcohol treatment did not significantly affect the secretory granular contents of the LH gonadotropes when compared to these pituitary cells of the Vitamin A replete rats. Low serum testosterone levels of the alcohol-fed Vitamin A deficient animals was consistent with impaired spermatogenesis, as observed on ultrastructural analysis of the seminiferous tubules. Our data show morphologically, that the hypogonadal effects of alcohol, intensified by Vitamin A deficiency are concomitant with a diminished granule maturation in the LH cell of the anterior pituitary gland. High Vitamin A supplements will minimize these endocrine effects of alcohol on the hypophyseal-gonadal axis.

108.15 SELECTIVE ENDOCRINE EFFECTS ON IN VIVO TRYPTOPHAN HYDROXYLASE ACTIVITY AND SEROTONIN LEVELS IN DISCRETE RAT BRAIN NUCLEI.
J. B. Long*, W. W. Youngblood*, and J. S. Kizer* (SPON: G. H. Greeley). Biol. Sci. Res. Ctr., Depts. of Medicine and Pharmacology, Univ. of N. C. Sch. of Medicine, Chapel Hill, N. C. 27514.

To identify endocrine-responsive serotonergic neurons in the rat brain, in vivo tryptophan hydroxylase activities (THA) and serotonin (5HT) levels were measured in discrete brain nuclei after gonadectomy (2 wks.), adrenalectomy (10 days), or administration (4 wks.) of propylthiouracil (PTU) to male rats. THA was determined by measurement of the accumulation of 5 hydroxytryptophan (5HTP) following L-aromatic amino acid decarboxylase inhibition by Ro4-4602/1. 5HTP and 5HT were separated by liquid cation exchange and subsequently measured by a sensitive radioenzymatic assay. This procedure is specific and sensitive to 10 pg of 5HTP or 5HT. 5HTP accumulation and 5HT levels were measured in the lateral septal nucleus (LS), suprachiasmatic nucleus (SCN), anterior hypothalamic nucleus (AH), median eminence (ME), central amygdaloid nucleus (AG), dorsal raphe nucleus (DR), and central superior nucleus of the raphe (NCS) following endocrine manipulations. Gonadectomy significantly ($p<0.05$) decreased THA in the SCN, DR, and NCS by 19.2, 18.4, and 11.7% respectively but was without effect on the THA of other nuclei examined. 5HT levels in all nuclei were unchanged following gonadectomy. Administration of testosterone propionate (500 ug/kg b.wt., s.c. daily) for 6 days to gonadectomized males did not reverse the gonadectomy-induced decrease in THA in the SCN, DR, and NCS, but did significantly decrease THA in the LS and AG. Adrenalectomy significantly increased THA in the ME by 58.5% and the NCS by 34.7%. while significantly increasing 5HT levels in the ME by 35.2%. Administration of corticosterone (2.5 mg/animal, s.c. daily) for 4 days to adrenalectomized rats did not reverse these increases. PTU administration (0.05% in drinking water) significantly decreased THA in the SCN by 15.5% and NCS by 16.1%, while significantly increasing 5HT levels in the LS, AH, AG, and DR by 28.3, 19.6, 26.0, and 25.7% respectively. These findings indicate the presence of CNS serotonergic neurons which selectively respond to altered endocrine states, and also demonstrate a dissociation of the effects of altered endocrine states on 5HTP synthesis and 5HT levels measured in these nuclei.

108.16 VALIDATION OF A PERIFUSION SYSTEM FOR AUTOMATED PULSATILE DELIVERY OF HORMONES TO PITUITARY CELLS.
Jeanne E. Martin, George J. O'Neil*, and Carol Sattler*, Departments of Pharmacology and Ob.-Gyn., Washington U. Med. Sch., St. Louis, MO 63110.

A perifusion system has been developed for automated, long-term pulsatile delivery of hormones to dispersed anterior pituitary cells. Rat anterior pituitary glands are dissociated with collagenase and hyaluronidase and incubated overnight. The next day, the cells are washed once and placed into perifusion chambers. The chambers are 25-mm stainless steel Swinnex filter holders with luer fittings (Millipore) modified by the addition of a second inlet (for LHRH) oblique to the central inlet (for basal medium). Each chamber contains a stainless steel screen supporting cellulose acetate and glass fiber filters which retain the cells. The medium is MEM with Hank's salts and contains 25 mM HEPES, 14 mM glucose and antibiotic-antimycotic (HMEM). HMEM is supplemented with 10% newborn calf serum (NBCS-HMEM) for basal perifusion and with 1% BSA for LHRH medium and the corresponding control. Media are delivered from reservoirs at 0°C through the chambers by 2 peristaltic pumps regulated by timers to operate alternately. Both pulse length and pulse interval can be varied over a wide range. With the use of multi-head pumps, 4 chambers can be perifused simultaneously.

Cells ($4-5x10^6$/chamber) obtained from castrated female rats were perifused (0.2 ml/min) with NBCS-HMEM for 110/120 min and with LHRH (0.1-100 nM) or control medium for 10/120 min for up to 48h. Ten-min effluent fractions were collected with the use of a multi-channel fraction collector. LH concentrations were measured by RIA. Medium LH rapidly declined within several fractions to 50-200 ng/ml and, in the controls, remained at this level for the duration of the experiment. Pulsatile LHRH at all concentrations produced discreet peaks of LH which returned to the control level between pulses. Peak magnitude was dose-related and maximal by 10 nM LHRH. Pulsatile release continued for at least 48h. At the end of perifusion, both LHRH-treated and control cells responded robustly and equivalently to 1 μM LHRH. This finding indicates that the control cells were still viable and responsive and the LHRH-treated cells apparently were neither highly sensitized nor de-sensitized by pulsatile exposure to LHRH. The simplicity, ease of operation, and relative inexpense of this automated perifusion system make it a useful technique for study of long-term pulsatile treatment of cells with hormones or other agents. (Supported by NIH Grant HD-11854.)

108.17 STRESSORS ELEVATE PITUITARY CYCLIC AMP IN THE RAT. G.J. Kant, B.N. Bunnell, R.H. Lenox, L.L. Pennington*, D.R. Collins*, E.H. Mougey* and J.L. Meyerhoff. Dept. Med. Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20012 and Dept. Psychiatry, Univ. of Vermont, Burlington VT 05405.

Cyclic AMP may be involved in the release or synthesis of pituitary hormones. Incubation of pituitaries in vitro with cyclic AMP analogues increases the release of hormones into the medium and various neurotransmitters and releasing factors have been reported to increase pituitary cyclic AMP levels in vitro. In previous studies we have found that pituitary cyclic AMP levels in vivo are responsive to dopaminergic, cholinergic, and adrenergic agonists and that immobilization also increases pituitary cyclic AMP. We hypothesized that other stressors might also increase pituitary cyclic AMP in vivo, possibly by central release of neurotransmitters or releasing factors into the pituitary through the portal circulation. Pituitary cyclic AMP could then link stress-activated central circuits with pituitary hormonal output.

Male rats were handled for two weeks prior to the experiment to minimize non-specific stress effects. Six stressors (cold, forced running, saline injection (i.p.), formalin injection (s.c.), immobilization and electric foot shock) were tested. Six animals were sacrificed for each stressor at each of three time points (15, 30 and 60 minute stress duration). In addition 12 control "non-stressed" rats were sacrificed immediately upon removal from the home cage.

All animals were sacrificed by high-power microwave irradiation for 5 sec. Plasma prolactin, corticosterone, and growth hormone and pituitary cyclic AMP were measured by radioimmunoassays.

All stressors except saline increased pituitary cyclic AMP, prolactin and corticosterone; growth hormone was variable but generally decreased in the stress groups. Pituitary cyclic AMP levels after each stressor are given below in pmoles cyclic AMP/mg wet weight ± S.E.M.: control levels were 1.06±.09.

STRESSOR	15 MIN	30 MIN	60 MIN
saline (i.p.)	1.01 ± .06	1.01 ± .05	.86 ± .11
cold	1.33 ± .20	1.78 ± .51	1.63 ± .18
running	1.55 ± .23	4.12 ± 2.71	2.73 ± .55
formalin s.c.	6.96 ± 2.58	5.42 ± 1.34	3.36 ± .62
immobilization	5.12 ± 1.40	5.50 ± 1.56	3.25 ± .57
shock	10.08 ± 2.31	13.61 ± 3.23	10.17 ± 2.04

Prolactin levels increased 60 fold from the least stressed to the most stressed (shock) groups, the more moderate stressors produced intermediate prolactin levels. Corticosterone levels were roughly 5 times higher in all stress groups compared to controls.

108.18 PAIN STIMULI MODIFY THE ACTH RESPONSE TO HEMORRHAGE. D.A. Bereiter, P.M. Plotsky and D.S. Gann. Division of Biology and Medicine, Brown Univ., RI Hospital, Providence, RI 02902.

To assess the interaction of pain and blood loss on the activation of the release of ACTH, acutely prepared cats were hemorrhaged (H) in the presence or absence of tooth pulp (TP) stimulation. Adult cats of either sex were anesthetized with α-chloralose/urethane (40/200 mg/kg, iv). Catheters were placed in the inferior vena cava above the liver for blood sampling, in the descending aorta for monitoring blood pressure and heart rate, and in the femoral artery for hemorrhaging. A bipolar electrode was positioned in the upper incisor for TP stimulation (100-500 μA, 0.2 msec, 3Hz). Stimulations lasted 3 min for TP, and 10 ml/kg of blood was withdrawn over 1 min and reinfused at 3 min for H. Each cat received H, H + TP and TP in a randomized sequence over a 6 h period.

Table I. Mean % Change in ACTH from baseline

	During Stimulation	Post Stim. (+ 2 min)	Post Stim. (+ 7 min)	Post Stim. (+ 12 min)
H alone	+ 0.8	+ 68.0	+ 31.6	- 0.8
H + TP	+ 47.5	+ 332.6	+ 100.9	+ 221.7
TP alone	- 10.4	- 32.2	- 34.9	- 28.9

As shown in Table I, H alone led to a small transient increase in ACTH by 2 min post H. TP alone led to a decrease in ACTH in all cats (n = 5) over the entire sampling period ($P<.01$). In contrast, H + TP led to a larger and more sustained increase in ACTH (interaction, $P<0.05$) relative to either H or TP alone. The apparent facilitation of TP on the ACTH response to H could not be accounted for by a difference in the hemodynamic response, since changes in mean blood pressure and heart rate to H and H + TP were equivalent. Furthermore, H and H + TP led to equivalent increases in plasma glucose and osmolality. Clearly, these results suggest that H and TP do not activate separate afferent neural pathways for the release of ACTH, but must interact at some common neural loci proximal to the site of CRF release. Preliminary neurophysiological experiments suggest that such interaction may exist at the brain stem level.

(Supported in part by grant AM 26831 from the NIH).

108.19 *IDENTIFICATION OF THE "TUBEROINFUNDIBULAR" SYSTEM OF THE RAT* USING IMMUNOHISTOCHEMICAL LOCALIZATION OF RETROGRADELY TRANSPORTED WHEAT GERM AGGLUTININ(WGA). R.M. Lechan, J.L. Nestler and S. Jacobson*(SPON:S. Reichlin). Endocrine Div. and Dept. of Anatomy, Tufts-New England Medical Center, Boston, MA 02111

The median eminence (ME) of the hypothalamus is an important neurovascular structure which has a critical role in the neuroendocrine regulation of the anterior pituitary gland. To determine the origin of neuronal cell bodies which project to the ME, we extend our previous observations which employed HRP (Lechan et al, Brain Res.,195,13,'80) by using the more sensitive retrograde marker protein, WGA.

The ME of adult, male, albino, CD rats was exposed by the retropharyngeal approach and under the dissecting microscope, WGA was injected into the ME (0.5-1.5 ul of a 5% soln. dissolved in TBS, pH 8.1). In other animals, WGA was suspended in poly(vinyl alcohol) (PVA), adopting methods described by Dr. M. Moskowitz (Brain Res., in press), and allowed to diffuse into the ME after being applied directly to its surface. After survival times of 18-24 hrs., the animals were perfused through the aorta with Bouin's soln. and the brains sectioned coronally at 60 u on a vibratome. The resulting free floating tissue sections were incubated for 24 hrs. with antiserum to WGA (E-Y Lab.,Inc.) at a titre of 1:800, diluted in TBS containing 0.3% Triton X-100. Following the peroxidase-antiperoxidase technique, the final reaction product was developed with 0.05% DAB and 0.01% H_2O_2.

Retrogradely transported WGA was present in bipolar and multipolar perikarya in the dorsal and lateral portions of the arcuate nucleus, the periventricular nucleus and the parvocellular division of the paraventricular nucleus, excluding the dorsal and lateral subdivisions and portions of the medial subdivision. Unipolar and bipolar cells were also labeled in the medial preoptic nucleus, lamina terminalis, diagonal band of Broca and medial septum. Fewer immunoreactive cells were identified in the dorsomedial nucleus, anterior hypothalamus, and in the nucleus ambiguus of the brain stem. Even with this more sensitive technique, however, we failed to identify any neuronal input from the amygdala and detected only rare cells in the ventromedial and suprachiasmatic nuclei. Reaction product within magnocellular nuclei of the hypothalamic-hypophysial system was apparent after WGA injections but reduced in the supraoptic nucleus, accessory magnocellular nuclei and portions of the paraventricular nucleus, when allowed to diffuse into the ME from the PVA-suspension.

These results confirm many of our earlier observations but also identify projections to the ME from neurons outside of the hypothalamus and indicate that the concept of a "tuberoinfundibular" system must be expanded.

108.20 PULSATILE SECRETION OF LH IN MALE RATS: VARIATION WITHIN AND AMONG INDIVIDUALS. Gary B. Ellis* and Claude Desjardins* (SPON: R.V.Smith). Institute of Reproductive Biology, Dept. of Zoology, University of Texas, Austin, Texas, 78712.

In examining moment-to-moment changes in circulating LH levels in individual male rats [Biol. Reprod., 24(Suppl.1)], we observed a spectrum of hormonal profiles among individuals in the population. Most male rats exhibited well-defined episodes of LH release, typically characterized by a 5-7 fold increase in plasma LH levels within a 5-minute interval and a decline through the next 60-75 minutes. These LH pulses occurred singly or in sequences of 2 or 3. Other males exhibited less-well-defined episodes of LH secretion, or highly variable LH levels with no apparent pulses. No distinct day/night distribution of secretory bouts was seen, regardless of the pattern of LH release. In the present study, we expand our perspective of episodic hormone secretion and the diversity among individual hormonal profiles by evaluating the pattern of LH secretion of a single animal at different times.

Each of four rats (age 29 weeks; 595-697 g) was fitted with an indwelling atrial cannula, and loosely tethered to a valve mounted outside of his cage. Blood was withdrawn every 5 minutes for 8 hours (96 samples @ 0.2 ml), on three occasions (at 5, 10, and 15 days post-cannulation). Withdrawn blood was replaced by a mixture containing 45% rat red blood cells and 2.5% human plasma proteins in Krebs-Ringer solution. Blood sampling was completed during the light portion of an LD 14:10 photoperiod. Rats appeared unperturbed during the sampling period, eating and drinking on occasion.

Unambiguous episodes of LH secretion, as defined above, occurred in all animals. During 8-hour sampling periods, rats exhibited from 0 to 6 distinct pulses. When sequences of 2-4 pulses occurred, they were often regularly spaced at intervals of 65-85 minutes. Within a particular animal, on different days, LH pulses varied in number; amplitude; and timing, relative to adjacent pulses and to absolute clock time. Thus, a particular LH secretory profile did not serve as a consistent hormonal "signature" for an individual rat.

Discrete, short-term pulses in LH release are now recognized as a fundamental aspect of the pattern of tonic LH secretion in normal male rats. The inter-individual variation in the degree and nature of pulsatile LH activity is most likely a manifestation of the considerable intra-individual variation through time.

SYMPOSIUM

109 CELLULAR MECHANISMS OF EPILEPTOGENESIS. D.A. Prince (Chairman; Stanford), R. Wong (Louisiana State Univ.), W. Crill (Univ. of Washington, R.A. Nicoll (UCSF), E. Dudek (Tulane).

A complex array of neuronal events interact to produce epileptogenesis and the contribution of each of these may vary in different neuronal populations.

1) Voltage-dependent slow depolarizations and burst generation: In hippocampal pyramidal neurons (HPCs) and dentate granule cells (GCs) the degree of involvement in convulsant-induced epileptiform discharge is related to the capacity to generate intrinsic Ca^{++} dependent slow depolarizations and bursts. CA3 HPCs tend to burst normally, and also serve as pacemakers during epileptogenesis, while GCs have poorly developed voltage-dependent depolarizations and are only minimally involved in epileptogenesis in vitro. In spinal motoneurones prolonged depolarizations produced by penicillin are associated with enhancement of a persistent inward current, probably carried by Ca^{++}, and a decrease in outward current due to a depolarizing shift in E_K, perhaps related to the significant increases in $[K^+]_o$ that occur during epileptogenesis. Voltage-dependent conductances for K^+ and probably Ca^{++} in HPCs are under control of neuromodulatory substances such as ACh and norepinephrine, which act tonically to influence baseline membrane properties and burst generation.

2) Disinhibition: GABA-mediated chloride dependent IPSPs normally suppress intrinsic burst firing in hippocampal pyramidal somata and dendrites. GABA antagonists block IPSPs, lengthen EPSPs, and lead to intrinsic spontaneous depolarizations and bursts which increase neuronal output and excitatory synaptic coupling between neurons. A Ca^{++} activated K^+ conductance also functions as an inhibitory event in HPCs. Orthodromically evoked EPSPs are followed by a GABA-mediated IPSP and a longer duration hyperpolarization due to increased gK, presumably a consequence of Ca^{++} entry during the EPSP. The latter hyperpolarization, which is increased as IPSPs are blocked and bursts develop, serves to limit burst duration and frequency. Blockade of this event can lead to prolonged depolarization and repetitive firing.

3) Enhanced EPSPs: These serve to trigger intrinsic bursts, synchronize aggregates of neurons, and, in some instances (e.g., neocortical neurons), contribute significantly to the slow envelope of depolarization shifts during epileptogenesis. Although chemical synaptic coupling is a major event underlying intercellular synchronization during epileptogenesis, anatomic and physiologic evidence shows that some hippocampal and neocortical neurons are electrotonically coupled. This may contribute in part to the neuronal synchrony observed during epileptogenesis.

WORKSHOP

110 QUANTITATIVE MICROSCOPY: THEORY, METHODS AND APPLICATIONS. L.M. Smith (Chairman; Brown Univ.), E.E. Underwood* (Georgia Inst. Tech.), J.J.Norden (Vanderbilt Univ.), E.R. Macagno (Columbia Univ.), M.M. Salpeter (Cornell Univ.).

The last few years have witnessed a dramatic increase in the number of quantitative morphological studies of neural systems. This workshop is intended to help Neuroscientists become aware of---and be able to use---powerful, yet mathematically simple methods of analyzing quantitative and structural information from light and E.M. images.

Dr. Underwood will begin the workshop by giving a brief history of the field of stereology, the three-dimensional interpretation of two-dimensional images. He will present the basic definitions and equations used in stereology and morphometry and explain how these are used to estimate the proportion of some volume of tissue occupied by some element, the number of some element in a volume of tissue, and the real size distribution of microscopic profiles.

Dr. Norden will then demonstrate how to use planimetry and point counting methods to estimate volumetric density of neurons and nuclei from light images. She will illustrate how such techniques can be used to measure changes in both the number and size distribution of neurons in the presence of tissue volume changes following denervation. Possible applications of these methods to histo- and immunocytochemical studies will be presented.

Dr. Smith will discuss stereological methods used to extract quantitative and structural information from E.M. images. Topics such as sampling procedures, sources of experimental bias, estimates of profile size, shape and volume fraction, and semi-automatic image analyzers will be covered. She will demonstrate how to calculate the number of synapses and boutons in a volume of normal and denervated nervous tissue.

Dr. Macagno will discuss computer graphics techniques developed in the past decade which can be applied to the analysis of serially sectioned tissue. Such techniques are used for the reconstruction in three dimensions of individual neurons and neuronal assemblies. These methods allow the visualization of the complexity of neuronal branching patterns and the determination of the distribution of contacts among neurons.

Dr. Salpeter will discuss how the limited resolution of E.M. autoradiography can cause problems in localizing sources of radioactivity in tissues with complex geometry. Examples will be given, and the statistical procedures for solving problems will be illustrated.

Handouts with guidelines for the practical application of each of these methods will be provided.

111.1 CALCIUM INDEPENDENT RELEASE OF GABA FROM ISOLATED HORIZONTAL CELLS OF THE TOAD RETINA. E. A. Schwartz* (SPON: V. Holcombe). Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637.

When toad (Bufo marinus) retinae were incubated first with veratrine, then with antibodies that reacted with the outer segments of photoreceptors, and finally with complement, horizontal cells survived and most other neurons died. This preparation of "isolated" horizontal cells accumulated radioactive GABA from the incubation medium. The subsequent release of radioactive GABA could then be measured. The efflux of GABA was increased by depolarization or by adding GABA to the external medium. An increase in GABA efflux produced by an elevated potassium concentration (41.5 mM) was unaffected when calcium in the external medium was replaced with cobalt and when sodium was replaced with either choline or lithium. An increase in GABA efflux produced by glutamate (100 μM) was unaffected when calcium was replaced with cobalt and when sodium was replaced with lithium, but was inhibited when sodium was replaced with choline. An increase in GABA efflux produced by external GABA (100 μM) was unaffected when calcium was replaced with cobalt but required sodium; neither choline nor lithium would substitute for sodium. After a high concentration of GABA (2-20 mM) had produced a maximal increase in GABA efflux, the addition of glutamate (2 mM) produced no further effect. Conversely, after a high concentration of glutamate (2-20 mM) had produced a maximal increase in efflux, the addition of external GABA (2 mM) produced only a small further increase. Superfusing with either 2 mM glutamate, or 2 mM GABA, or 2 mM glutamate + 2 mM GABA each increased efflux approximately ten fold. These results could occur if GABA efflux were mediated by a carrier system which could be activated by either depolarization or homoexchange.

(Supported in part by NIH grant EY-02440.)

111.2 A NEW APPROACH TO MEASURING THE TURNOVER RATE OF GABA C. M. Forchetti* and J. L. Meek. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Measurement of GABA turnover in rat brain has proven difficult whether using pharmacological blockade of synthesis or degradation or isotopic incorporation methods. Approaches involving peripheral injection of drugs to block GABA synthesis or breakdown have met with limited success: some drugs (isoniazid) are convulsants, others (aminooxyacetic acid) affect both the synthesis and breakdown of GABA, while the action of certain specific drugs (γ-vinyl GABA) is slow in onset, making it impossible to determine initial rates for accurate estimation of GABA turnover. In studying GABA in the median raphe (MR) and substantia nigra (SN), we made stereotaxic injections into the MR or SN of isoniazid (50μg) to block glutamate decarboxylase or gabaculine (80 ng) to block GABA-transaminase. The method provides a rapid onset of inhibition and a high local concentration of drugs without producing convulsions or sedation. The drugs were injected in 1 μl of saline during 5 min. The GABA content was measured by HPLC in tissue punched from frozen 400 μm sections.

Isoniazid injection caused a decrease in GABA content of the median raphe that was rapid in onset (30% decrease by 7 min) but not exponential and short in duration (the content returned to near control values by 90 min). The difficulty in achieving a prolonged inhibition of GAD and the high concentraton of isoniazid required (50 mg/ml) limits the usefulness of this approach.

Gabaculine induced an increase in GABA content that was rapid in onset and linear for 60-90 min, and reached a content 5 times that of controls by 8 hr. The estimated rates of turnover were 37 and 60 nmol/mg prot/hr in the MR and SN, respectively. These turnover rates may be low if the accumulated GABA can affect its own synthesis. To establish if the GABA accumulation reflects turnover, we destroyed the major GABA-ergic input to the SN by hemitransections. The nigral content of GABA decreased by 80% 7 days after surgery; the gabaculine induced GABA accumulation was also decreased by 80%. In the median raphe, we examined if local injection of substance P (4μg) would affect GABA turnover. Substance P increased the gabaculine induced accumulation of GABA by 30%.

In summary, GABA turnover can be estimated by measuring the initial rate of accumulation of GABA after local injection of the GABA-transaminase inhibitor gabaculine. This approach has the advantage of linearity in initial rates, low toxicity, and apparently high specificity.

111.3 DECREASE OF GLUTAMATE DECARBOXYLASE IN VENTRAL GLOBUS PALLIDUS AFTER ELECTROLYTIC LESIONS OF THE NUCLEUS ACCUMBENS. G. T. Murata*, L. L. Butcher, and P. H. Kelly. (Spon: D.F. Lindsley). Dept. of Physiology and Biophysics, University of Southern California Sch. Med., Los Angeles, CA 90033, and (L.L.B.)Dept. Psychology, UCLA, Los Angeles, CA 90024.

The main efferent projections of the nucleus accumbens are to the substantia nigra and a subcommissural region which has been termed "ventral globus pallidus" (Heimer & Wilson, 1975; Nauta, Smith, Faull, & Domesick, 1978). There also appear to be sparser projections to parts of the globus pallidus itself and to the ventral tegmental area. We have investigated if these projections are cholinergic or GABA-ergic by examining if lesions of the nucleus accumbens result in decreases of the neurotransmitter-synthesizing enzymes, choline acetyltransferase (ChAT) and glutamate decarboxylase (GAD), in these regions.

Unilateral electrolytic lesions of the nucleus accumbens were made in adult Sprague-Dawley rats. Seven to nine days later the rats were killed by decapitation and their brains frozen and sectioned in a cryostat. Fifty micron sections were taken for verification of lesion sites and 200-300 micron sections for dissections of globus pallidus, ventral globus pallidus, substantia nigra, and ventral tegmental area. On the lesioned side GAD was reduced to 75 + 11% of control ($p<0.05$) in the ventral globus pallidus. Smaller decreases in the globus pallidus proper (by 13%) and ventral tegmentum (by 6%) were not statistically significant. GAD was unchanged in the substantia nigra. ChAT was not significantly altered in any of the regions studied. These results suggest that at least some of the neurons whose axons project from the nucleus accumbens to the ventral globus pallidus use GABA as a transmitter. (Supported by USPHS grants NS 16175 (to P.H.K.) and NS 10928 (to L.L.B.).

111.4 THE CHOLINERGIC SYSTEM AND THE ANTINOCICEPTIVE EFFECT OF GABA AGONISTS. D.A. Kendall,* M. Browner* and S.J. Enna. Depts. Pharmacology and Neurobiology, Univ. Texas Med. Sch., Houston, Texas 77025.

The antinociceptive action of three classes of GABA agonists was examined in mice using hot-plate and tail-immersion tests. A significant increase in reaction time was noted in the hot-plate test following treatment with the direct-acting GABA receptor agonists, kojic amine or THIP, with γ-vinyl GABA, an inhibitor of GABA degradation, or with nipecotic acid ethyl ester, an inhibitor of high affinity GABA transport. Studies with naloxone indicated that the increase in pain threshold was not mediated through the brain opiate system. However, it was possible to reverse the antinociceptive effect of these drugs with atropine, a cholinergic muscarinic receptor antagonist. Receptor binding experiments indicated that, except for the ethyl ester of nipecotic acid, the GABA agonists had little affinity for the cholinergic muscarinic receptor site. In addition, atropine, at a dose that completely blocked the antinociceptive action of kojic amine, was unable to attenuate the sedative effects of this drug. These findings suggest that, regardless of their mechanism, all classes of GABA agonists are capable of inducing an antinociceptive response in mice and that this action is apparantly secondary to a GABA-mediated increase in brain cholinergic function. The discovery that the sedative and antinociceptive effects are functionally unrelated indicates that it may be possible to develop nonsedating antinociceptive GABA agonists. (Supported in part by USPHS grants NS-13803 and NS-00335).

111.5 A STUDY OF PLASMA ASPARTIC ACID LEVELS AND PATHOLOGY IN THE ARCUATE NUCLEUS FOLLOWING ASPARTAME AND SODIUM ASPARTATE ADMINISTRATION. E. W. Powell, Terry Sims, Jean Linebarger* and Bradley Diner*. Departments of Anatomy and Pathology, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

The arcuate nucleus is susceptible to damage when exogenous aspartic acid is administered in high doses to neonatal mice (Olney et al, 1971). Utilizing light microscopic and electron-microscopic examinations and enzymatic biochemical determinations, this study correlates the increase in aspartic acid plasma levels with damage of the arcuate nucleus following the administration of oral doses of L-aspartyl-L-phenylalanine methyl ester (aspartame) and subcutaneous injections of sodium aspartate. Plasma aspartic acid concentrations were measured in 6 to 8 day old mice following oral doses of physiological saline, 2 mg/gm (body weight), 3 mg/gm of aspartame and .5 mg/gm subcutaneous injections of sodium aspartate. Following an oral 2 mg/gm dose of aspartame, plasma aspartic acid levels had a mean peak value of 0.80 ± .10 (SEM) μ mol/ml at 1 hour as compared to a control value of .05 ± .004 μ mol/ml. No pathology was observed in the arcuate nucleus in animals orally dosed with 2 mg/gm aspartame. However, oral doses of 3 mg/gm aspartame and subcutaneous injections of 0.5 mg/gm sodium aspartate resulted in a similar degree of frank neuronal death in all of the brains examined. In subjects treated with 3 mg/gm of aspartame, the aspartic acid plasma levels reached a mean peak value of .65 ± .11 μ mol/ml at one hour post gavage; however, they remained elevated above the levels of the 2 mg/gm dose subjects between the 2nd and 6th hour post gavage intervals. The fact that the plasma concentration peak at 1 hour post gavage was lower for the 3 mg/gm dose than it was for the 2 mg/gm dose may have been due to physical factors associated with a larger bolus of aspartame. Following subcutaneous injections of 0.5 mg/gm of sodium aspartate, plasma aspartic acid levels reached a mean value of 3.9 ± .98 μ mol/ml in five minutes and fell to 3.0 ± .36 μ mol/ml at the next interval sampled at 15 minutes.

These results suggest that the duration of elevated plasma aspartic acid levels as well as the peak concentration determines whether pathology will occur in the arcuate nucleus of the 6 to 8 day old mouse. These results show that following subcutaneous injections of aspartic acid, the plasma must be sampled within 5 minutes in order to determine the peak plasma amino acid values.

111.6 EXCITATORY AMINO ACID RECEPTOR MEDIATED RELEASE OF ^{3}H-ACETYLCHOLINE FROM STRIATAL SLICES OF THE RAT : MAGNESIUM SENSITIVITY AND PHARMACOLOGICAL CHARACTERISTICS. Bernard Scatton and John Lehmann Synthélabo-L.E.R.S., Biology Department, 92220 Bagneux, France.

Application of L-glutamate, L-aspartate and excitatory amino acid receptor agonists to superfused striatal slices previously incubated with ^{3}H-choline evoked the release of ^{3}H-acetylcholine (ACh). In medium containing magnesium (1.2 mM), application of L-glutamate, L-aspartate, kainate, ibotenate, N-methyl-DL-aspartate (NMA), L-cysteate, quisqualate, and the recently developed glutamate agonist RS-α-amino-3-hydroxy-5-methyl-4-isoazolepropionic acid (AMPA) (0.1 mM to 1 mM) produced an increase in the efflux of ^{3}H-ACh which was abolished by removal of calcium from the medium. Under these conditions, the maximal effects and potencies of agonists were similar.

However, when magnesium was removed from the medium, a six-fold increase in the release evoked by application of L-glutamate was observed. Removal of magnesium also potentiated the response elicited by NMA, L-aspartate, AMPA, ibotenate, and L-cysteate, but not that elicited by kainate and quisqualate. In the absence of magnesium, the excitatory amino acid agonists assumed a clear rank order of potency :

NMA > ibotenate > AMPA = L-glutamate ≥ L-aspartate > L-cysteate

> kainate = quisqualate

In magnesium free medium, both DL-2-amino-4-phosphonobutyrate (APB) and glutamate diethylester (GDEE) were capable of completely blocking the release of ^{3}H-ACh evoked by L-glutamate, APB being significantly more potent than GDEE. In contrast, DL-α-amino adipate was almost totally inactive. APB was also capable of completely blocking the release of ^{3}H-ACh evoked by L-aspartate, kainate, quisqualate and L-cysteate.

The concentrations of excitatory amino acid receptor agonists found to be effective in eliciting release of ^{3}H-ACh are similar to those effective in electrophysiological studies. Striatal cholinergic neurons are thought to receive a direct excitatory amino acid input from the cerebral cortex. The excitatory amino acid receptor thought to mediate this action has been characterized by measuring the release of ^{3}H-ACh from striatal slices. This represents a simple model to study the direct action of amino acid neurotransmitters on a population of neurochemically defined target cells and their biological response.

111.7 STRYCHNINE: BRAINSTEM AND SPINAL CORD MEDIATION OF EXCITATORY EFFECTS ON ACOUSTIC STARTLE. J.H. Kehne*, D.W. Gallager, and M. Davis. Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508

The acoustic startle response has proven to be a sensitive measure for evaluating the effects of drugs on behavioral reactivity to sensory stimulation. In the present study, the effects of the glycine antagonist strychnine (STRY) were measured on acoustic startle. STRY (0.25 - 2.0 mg/kg, i.p.) produced a powerful, dose-dependent increase in startle amplitude that reached its greatest magnitude within 10-15 minutes after injection. These doses did not produce convulsions or behavioral activation and did not increase movement in the absence of startle stimuli. Furthermore, enhanced startle amplitude does not appear to be a general property of convulsant drugs, since i.p. administration of picrotoxin, a GABA antagonist, produces a dose-dependent inhibition of acoustic startle.

In an attempt to localize the site of action of this excitatory STRY effect, rats were implanted with catheters in the lumbar region of the spinal cord (intrathecal implantation), in the cisterna magna, or in the lateral ventricle. One to two days later they were tested for startle after microinjections of STRY. Dose-dependent excitatory effects on acoustic startle were found when STRY was injected onto the spinal cord (3.1 - 12.5 μg) or into the cisterna magna (6.2 - 25 μg), whereas infusion into the lateral ventricle produced a dose-dependent inhibition (6.2 - 25 μg). The excitatory effects were not attributable to convulsions or behavioral excitation. The maximal increases produced by 25 μg STRY intracisternally (144%) and 6.2 μg intrathecally (164%) were approximately equivalent to the peak effect seen following systemic administration (160%).

Thus, the excitatory effect produced by systemic injection of STRY can be attributed to its action in the spinal cord and brainstem. These results are consistent with studies suggesting that glycine neurons and receptors are primarily localized in the caudal regions of the central nervous system.

The inhibitory effect of intraventricularly-administered STRY was somewhat surprising, since there is little evidence for glycine or glycine receptors in the forebrain. However, high concentrations of STRY have been reported to have GABA antagonist properties. Since intraventricular injection of picrotoxin produces a potent inhibition of startle, it is possible that the inhibition accompanying intraventricular STRY infusion resulted from a blockade of GABA receptors.

The present results suggest that glycine exerts a tonic inhibitory effect on acoustic startle. The possible relation of such a system to phenomena that involve reduction in startle amplitude (e.g., habituation, pre-pulse inhibition) is discussed.

111.8 EXCITATORY AMINO ACIDS EVOKE A VOLTAGE-DEPENDENT DECREASE IN THE CONDUCTANCE OF CULTURED MURINE NEURONS. John F. MacDonald and J. Martin Wojtowicz. Playfair Neuroscience Unit, Dept. Pharmacology, U. of Toronto, Toronto, Ont. M5T 2S8.

Neurons derived from foetal mouse spinal cord or brain were grown, dissociated, in tissue culture. Intracellular recordings were then performed with either a single or with two independent microelectrodes (3M KCl). Membrane conductance (G) was assayed by passing: 1) constant current pulses via the recording electrode 2) constant current pulses via a second graphite shielded electrode 3) constant voltage pulses during a single electrode voltage-clamp 4) constant voltage pulses during a conventional two electrode voltage-clamp. Results were qualitatively similar with each method of measurement. Drugs were applied by pressure microperfusion or by microiontophoresis. In addition TTX (1 to 3 μM) was added to the bathing medium (Hank's) in order to block TTX-sensitive action potentials and to prevent synaptically mediated intercellular effects of excitatory amino acids. L-glutamic, L-aspartic, DL-homocysteic and N-methyl-D-aspartic acids (but not Kainic acid) depolarized neurons from resting values in association with a decrease in G (inward current). However, when membrane potential was lowered towards 0 mV by steady-state current injection this decrease gradually converted to a net increase in G. A distinct reversal potential (-10 mV) could be attributed to this increase in G whereas a second reversal potential (-80 to -85 mV) was linked to the decrease. The decrease of G was therefore likely due to a reduction of G_{K+} and is similar to the reported action of DL-homocysteic acid on in vivo cat motoneurons (Engberg, et al, J. Physiol. 288:227-261, 1979). Extracellular applications of G_{K+} blockers such as TEA, 4-aminopyridine, Co^{2+} Mn^{2+}, Cd^{2+}, Mg^{2+} and EGTA were unable to mimic this decrease of G. In addition, acetylcholine (up to 5 mM) was unable to evoke such a decrease. Ba^{2+} (5 mM) consistently decreased G but the voltage-dependency differed in that the magnitude of the decrease was augemented with depolarization rather than diminished as was seen with excitatory amino acids. These results demonstrate that excitatory amino acids both decrease and increase G of cultured neurons. The decrease is likely due to reduction of a resting G_{K+} distinct from that underlying delayed rectification or an analogous M-current reported in sympathetic neurons (Constanti, et al., Brain Res. 206:244-250, 1981). (supported by the MRC of Canada and by the Dystonia Research Foundation).

111.9 THE ACTION OF GLUTAMATE ON CA1 PYRAMIDAL NEURONS. J. J. Hablitz and I. A. Langmoen*. Sect. of Neurophysiology, Dept. of Neurology, Baylor College of Medicine, Houston, TX 77030.

Iontophoretically applied glutamate (glu) is a potent excitant of hippocampal CA1 pyramidal neurons. We used the guinea-pig in vitro hippocampal-slice preparation to investigate the mechanism by which glutamate excites these neurons. Intracellular recordings were obtained from CA1 pyramids while glu (1 M, pH = 8) was iontophoresed onto the proximal apical dendrites.

Glu reliably depolarized and excited all neurons tested. The glu response was highly localized (±15 μM) and dose dependent. Two types of response were seen. The most typical, occurring in 85% of cells, was characterized by a steadily increasing cellular firing, superimposed on a depolarization that seldom exceeded 20 mV. The other, obtained with increased glutamate doses, was a large depolarization that reached a plateau 35-45 mV positive to rest. The limiting slope of log-log dose-response curves for the first type of response varied from 1.5 to 5.0, indicating that more than one glu molecule was involved in the response. The depolarization and cellular firing induced by moderate glu-ejection currents (10-40 nA) showed no appreciable desensitization during 30-sec applications.

The effect of glu on input resistance (R_{in}), as measured by 100-300 msec hyperpolarizing-current pulses, was dose dependent. Small doses of glu produced either no change or an apparent increase in R_{in}. With larger doses, R_{in} invariably decreased. Increases in R_{in} were observed also with passive depolarization of the membrane. This suggested that the increase in R_{in} seen with glu resulted from conductance changes after the depolarization instead of a direct effect of glu. To study the direct effect of glu on R_{in}, we used slices in which all regenerative activity had been blocked by bath application of TTX (1 μg/ml) and $MnCl_2$ (4 mM). Here, glu produced a dose-dependent depolarization and decrease in R_{in}.

The glu-response amplitude was membrane-potential dependent and had a reversal potential (E_{glu}) near 0 mV (Langmoen and Hablitz, Neurosci. Lett., 1980, 23:61), suggesting that Na ions play a prominent role in producing the glu depolarization. Replacement of 75% of the $[Na]_o$ with TRIS reduced the slope of the glu dose-response curve, decreased the maximum response, and shifted E_{glu} to -38 mV.

We suggest that glu increases the permeability of the postsynaptic membrane primarily to sodium. Because E_{glu} in normal saline is close to 0 mV, the inward Na^+ current must be contaminated by an outward current that most likely is carried by K^+, since Cl^- injection does not alter the glu response.

(Supported by NIH grants NS 11535 and NS 15772.)

111.10 RESPONSE OF HIPPOCAMPAL SYNAPTIC FIELDS TO ANALOGUES OF ACIDIC AMINO ACIDS. J. F. Koerner* and C. W. Cotman (SPON: R. L. Purple). Dept. of Biochemistry, Univ. of Minnesota, Minneapolis, MN 55455, and Dept. of Psychobiology, Univ. of California, Irvine, CA 92717.

Analogues of the putative excitatory transmitters aspartic acid and glutamic acid were tested for antagonism against stimulus-evoked activation of Schaffer collateral-CA1 pyramidal cell synapses and perforant path-granule cell synapses in slices of rat hippocampus. Responses to the analogues, applied via the superfusing medium, were measured by their effects on the extracellular synaptic field potential. Compounds examined included higher homologues of D- and L-α-aminodicarboxylic acids, diaminodicarboxylic acids, phosphonate analogues of acidic amino acids, γ-D-glutamylglycine, and cis-2,3-piperidine dicarboxylic acid. Many of the compounds were chosen for their potent antagonism for the N-methyl-D-aspartate receptor of the dorsal-ventral root excitatory pathway of the spinal cord. Against Schaffer-CA1 pyramidal cell synapses, all analogues showed relatively low and similar potency with less than 15% inhibition at 0.5 mM and at least 40% inhibition at 5 mM. Most also evoked extracellular responses, including population spikes, abnormally prolonged times of inhibition and recovery, and anomalous dose-response curves, attributable to weak agonist responses of CA1 pyramidal cells. Thus for this synaptic field there are presently no known potent antagonists, and no conclusions can be drawn about this postsynaptic receptor from structure-function relationships, such as it being aspartate- or glutamate-preferring, or with specificity for L- versus D-amino acids. These results strongly contrast with those obtained for perforant path-granule cell synapses. In particular, the portion of the perforant path derived from the lateral entorhinal cortex is selectively inhibited by micromolar L-2-amino-4-phosphonobutyric acid, a structural analogue of L-glutamic acid. (Koerner, J.F., and Cotman, C.W., Brain Res., 217: in press). The extracellular responses of this pathway to this drug are those expected for inhibition by a pure antagonist. The hippocampal data also contrast with the responses documented by others for the dorsal-ventral root excitatory pathway of the spinal cord (Watkins, J.C. and Evans, R.H., Annu. Rev. Pharmacol. Toxicol., 21:165, 1981). In that system, the higher homologues tested were the most potent antagonists, and the D-isomers were more potent than the L-isomers. Thus these three excitatory pathways of the CNS each show a unique pattern of pharmacological response to this series of drugs. (Supported by NIH grants NS 08957 and MH 19691 and the Minnesota Medical Foundation).

111.11 PHOSPHOLIPID METHYLATION, A POSSIBLE MOLECULAR EVENT INVOLVED IN THE ACTION OF BENZODIAZEPINES. G. Toffano, G. Calderini*, A. Leon* and A. Battistella*. Dpt. of Biochemistry, Fidia Research Laboratories, Abano Terme, Italy.

The participation of postsynaptic GABAergic mechanisms in the action of benzodiazepines has been evidentiated by electrophysiological, pharmacological, biochemical, histological and behavioural observations. However the intimate molecular mechanisms by which benzodiazepines facilitate GABAergic transmission is still hidden in the complexity of GABA receptor.This supramolecular unit includes CL^- channel GABA recognition sites, endogenous GABA binding modulator (s), benzodiazepine recognition sites and putative ligand(s) for the benzodiazepine receptor sites (for a review see Costa, E. and Guidotti, A., Ann. Rev. Pharmacol., 19:531-545, 1979).

Recently it has been reported that benzodiazepines increase membrane fluidification and phospholipid methylation in C_6 glioma cells, which however contain benzodiazepine recognition sites of "peripheral-type" (Strittmatter et al., Nature, 282:857-859, 1979). As phospholipid methylation alters a variety of membrane functions (Hirata, F. and Axelrod, J., Science, 209:1082-1090, 1980) we investigated whether also the stimulation of benzodiazepine recognition sites of "central-type" enhances phospholipid methylation. Crude synaptic plasma membranes from rat cerebellum were incubated with 0.7 μM [^{3}H]-S-adenosylmethionine ([^{3}H] -SAM) in the absence or presence of 10^{-7} M diazepam.

The incorporation of [^{3}H]-methyl-group into phospholipidic fraction increases in the presence of Diazepam and conversely the binding of [^{3}H]-Diazepam is enhanced in membrane preparation preincubated with SAM. The effect is dose dependent. On the other hand in fresh membrane preparation the addition of the methyl donor produces a significant decrease of the KD for [^{3}H]-GABA binding (from 130 to 40 nM).

From these data, one could infer that the occupancy of benzodiazepine recognition sites stimulates phospholipid methylation, and that, in turn, increased membrane fluidity allows for a change of GABA receptor responsiveness.

111.12 DEPLETION OF GABA AND SEIZURES PRODUCED BY ISONIAZID AFTER IRREVERSIBLE INHIBITION OF GABA-TRANSAMINASE. R.F. Keating* and K. Gale (SPON: A. Raines), Department of Pharmacology, Georgetown University, Schools of Medicine and Dentistry, Washington, D.C., 20007.

The rate of decline in GABA after inhibition of GABA synthesis (by isoniazid, INH) was measured in several brain regions of rats which had been pretreated with gamma-vinyl-GABA (GVG), an irreversible inhibitor of GABA-transaminase (GABA-T). After GVG alone (1800 mg/kg i.p.), GABA-T activity was inhibited by 80-85%. GABA levels reached a plateau by 12 hr, remaining constant (3-4 fold over control) beyond 18hr. In rats which were treated with GVG, (1800 mg/kg i.p.) 12 hr before, INH (600 mg/kg i.p.) caused a net decrease in GABA at 45 min which was equivalent to the decrease observed in controls receiving INH alone. To determine the rate of decline in GABA after INH, rats which had been pretreated (12 hr) with GVG were killed at 20, 45, 70, 90, and 120 min after INH. The rate of decline after INH was highest in superior colliculus and substantia nigra (50-60 nmol/mg prot/hr) and lowest in cerebellar cortex and caudate nucleus (20 nmol/mg prot/hr). These rates were found to be similar to those obtained in control rats treated with INH alone (20 and 45 min before killing). In rats receiving GVG + INH, seizures were frequently observed after a latency of 45 min following INH.

The direct intracerebral microinjection of GVG (10ug into superior colliculus and 5ug into substantia nigra) resulted in a virtually complete (> 95%) inhibition of GABA-T and a significantly greater elevation of GABA than had been observed after systemic treatment. Under these conditions, there was a significant attenuation of the decline in GABA induced by systemic INH.

These data indicate that a normal rate of elimination of GABA can be maintained despite marked irreversible inhibition of GABA-T. We have previously demonstrated that the elevation of GABA measured 12 hr after GVG was associated with compartments other than nerve terminals. The decline in GABA induced by INH 12 hr after GVG, may therefore be due to depletion of nerve-terminal GABA. On the other hand, direct application of GVG into brain results in a rapid increase in nerve-terminal associated GABA and prevents the depletion of GABA induced by INH. Nerve terminals may therefore represent a critical site for the degradation of GABA in circumstances in which there is less than complete inhibition of GABA-T.

112.1 MICROIONTOPHORETIC APPLICATION OF 5HT BLOCKS RESPONSES TO NOXIOUS STIMULI IN SINGLE UNITS IN THE PARAFASCICULARIS OF THE RAT. E. Andersen and N. Dafny, University of Texas Health Science Center, Dept. of Neurobiology and Anatomy, Houston, TX.

The raphe nuclei of the midbrain are known to be involved in a pain modulation system. They contain a high consentration of serotonergic (5HT) cell bodies and pharmacological manipulation of 5HT has been shown to alter the effects of morphine and other types of analgesia. Electrical stimulation of the raphe/central grey region causes behavioral analgesia and causes changes in neurons in the spinal cord which respond to noxious stimuli. Noxious stimuli cause changes in many forebrain structures as well, and it is likely that the raphe nuclei and 5HT modify responses to pain not only in the spinal cord, but in other specific areas of the CNS.

Our laboratory has previously shown that an intralaminar thalamic nucleus of the rat (parafascicularis, PF) like similar nuclei in other species, is particularly responsive to noxious stimuli. Furthermore, electrical stimulation of the dorsal raphe nucleus (DR) blocks the increase in firing rates caused by noxious stimuli in single units of the PF.

In order to test 5HT as a possible neurotransmitter in this system, 5HT was microiontophoresed directly onto spontaneously active units in the PF of urethane-anesthetised rats. Doses of 20, 50, and 80 nAmps were given for two minutes each with recovery periods between each dose. 5HT caused a decrease in the firing rates of spontanouesly active neurons in a dose dependent manner. Noxious tail pinch, in contrast, increased firing rates. The application of 5HT onto units excited by tail pinch caused a decrease in firing rates.

Microiontophoretically applied 5HT therefore has a similar effect as DR stimulation in inhibiting the response of PF neurons to noxious stimuli. This indicates that 5HT may be a neurotransmitter used by the DR in a direct, ascending pathway to the PF whose function is to modify responses to painful input at this central level.

112.2 DOES NORADRENALINE MEDIATE THE MODULATORY EFFECTS OF THE LOCUS COERULEUS ON LUMBAR DORSAL HORN INTERNEURONS? J. Franck, C. J. Hodge, Jr., A. Apkarian, R. Stevens, G. Peca-Vogelsang, and J. Wisnicki. Dept. of Neurosurgery, Upstate Medical Center, Syracuse NY 13210.

Stimulation of the locus coeruleus (LC) results in potent inhibition of responses of lumbar lamina IV and V neurons to peripheral stimulation. Since LC is rich in noradrenaline (NA) containing neurons, and since noradrenergic projections from the brain stem to the spinal cord have been implicated in spinal cord antinociception, it has been proposed that NA is the principal mediator of direct coeruleo-spinal modulatory effects. We report anatomical and physiological evidence to the contrary.

Evan's Blue (EB) was injected into the lumbar spinal cord of cats. After 3 days, fluorescent microscopy was used to examine the brain stem, which had been processed with glyoxylic acid. This allowed identification of cells containing retrogradely transported EB as well as cells containing catecholamines (CA). Most of the cells in LC that project to the lumbar cord do not contain NA.

Responses of lumbar lamina IV and V cells, activated by either peripheral innocuous or noxious stimuli, were studied in cats. Stimulation of the dorsolateral pons with monopolar electrodes was used to locate points where stimulation was effective in inhibiting the responses of lumbar dorsal horn cells to somatic stimulation. The minimal stimulation thresholds (10 uA) for inhibition were in LC. The latency to initial inhibition of lumbar unit responses following LC stimulation was 30-50 msec. This data implies that the conduction velocity is at least 10 m/sec., which is faster than any reported conduction velocity for central NA containing neurons.

After IV or direct topical cord administration of phenoxybenzamine, an alpha-blocker, or propranolol, a beta-blocker, potent dorsal horn inhibition could still be evoked at low thresholds (less than 50 uA). Intrathecal 6-hydroxydopamine was used to induce depletion of lumbar cord NA. Adequate depletion was confirmed by fluorescent microscopy and chromatography. There was no apparent difference between these cats and untreated cats in either the electrical thresholds or loci of stimulation capable of causing lumbar dorsal horn cell inhibition.

We conclude that the coeruleo-spinal inhibition is not principally mediated by NA-containing LC neurons that project to lumbar spinal cord.

112.3 SERUM MORPHINE LEVELS DURING SUPPRESSION OF DORSAL HORN WDR NEURONS BY SPINALLY ADMINISTERED MORPHINE. J.G. Collins, J. Bach*, E. Homma*, L.M. Kitahata, Dept. Anesthesiol. and Dept. Lab. Medicine, Yale Univ. Sch. Med., New Haven, CT. 06510

The peridural administration of opioids can produce profound analgesia in both man and experimental animals. We have recently demonstrated that the spinal administration of morphine causes a dose dependent, partially naloxone reversible suppression of WDR neurons in the dorsal horn of the spinal cord. The use of spinal narcotic analgesia raises a question as to the degree of systemic uptake of the drug. Systemic uptake could explain part or all of the analgesia and/or neurophysiological effects seen following spinal morphine administration. The present study was carried out in order to determine serum morphine levels at the time of suppression of neuronal activity in the dorsal horn of the spinal cord following the spinal administration of morphine.

Cats, ranging in weight from 2.5 to 5.0 kg, were prepared for electrophysiological recording as previously described.[1] Blood samples were drawn prior to surgical preparation of the animal (to control for possible release of endogenous opioids during surgery), prior to drug administration and 10, 20, and 30 min after the spinal administration of morphine (0.1 or 0.25 mg.). Samples were centrifuged and serum was separated and frozen until assayed. Morphine levels were determined using a commercially available RIA Kit (Roche Diagnostics "Abuscreen") calibrated with morphine standards prepared in cat serum. The assay detects both free morphine and morphine glucuronide. No other drugs administered to the animals were known to react with the assay.

Both time and dose response effects were seen following the spinal administration of morphine. At the time of maximum suppression of neuronal activity (30 min.) the average serum levels following 0.25 mg of spinally administered morphine were below 20 ng/ml. The 0.1 mg dose of morphine produced even lower serum levels.

The present study indicates that there is systemic uptake following the spinal administration of morphine but that the serum levels are relatively low at the time of maximum neuronal suppression. They are much lower than the levels reported in humans at the time of adequate analgesia (50 ng/ml)[2]. Studies are being conducted to determine the serum levels of free morphine at the 30 min. time point.

112.4 SPINAL MORPHINE ADMINISTRATION SUPPRESSES NOXIOUSLY EVOKED ACTIVITY OF DORSAL HORN WDR NEURONS. E. Homma*, J.G. Collins, L.M. Kitahata, Dept. of Anesthesiol., Yale Univ. Sch. of Med., New Haven, CT. 06510

Studies of the neuropharmacology and neurophysiology of the spinal cord have led to an appreciation of the importance of spinal sites in the production of analgesia. Such studies are responsible for the present interest in the technique of spinal narcotic analgesia, a technique which has been shown to produce profound analgesia in both man and experimental animals. The present study was carried out in order to determine if the spinal administration of morphine is capable of producing a dose dependent, naloxone reversible suppression of noxiously evoked activity of wide dynamic range neurons in the dorsal horn of the spinal cord.

Extracellular single unit recordings were obtained from physiologically identified wide dynamic range neurons in decerebrate, spinal cord transected (L-1) cats. The animals had been surgically prepared (tracheal, carotid artery, jugular vein cannulation and lumbar laminectomiy L-7, L-4) under halothane, nitrous oxide-oxygen anesthesia but at least 4 hours passed between the end of anesthetic administration and the start of drug studies. Physiologic parameters were monitored and maintained within normal limits. Spontaneous and stimulus driven activity (radiant heat stimulus of 51°C, 8 sec. on the peripheral receptive field located on the footpad of the hindpaw) were studied both during the control situation and following the spinal administration of either 0.1 or 0.25 mg of morphine.

Although 0.1 mg of spinally administered morphine was found to produce small reductions in both stimulus driven and spontaneous activity, 0.25 mg produced a significant reduction in both stimulus driven and spontaneous activity with stimulus driven activity being suppressed to a greater extent. The spinal administration of naloxone (0.2 or 0.4 mg) produced some reversal of the spinal morphine effect on the WDR neuronal activity. Subsequent intravenous administration of 0.2 or 0.4 mg of naloxone produced further reversal of the narcotic effect. Complete naloxone reversal was not seen.

This, to the authors knowledge, is the first report of the ability of spinally administered narcotics to block neuronal activity elicited by noxious stimuli at the periphery. It is further evidence to support both the importance of spinal sites for the production of analgesia and the ability of spinally administered narcotics to block the afferent input of information following the presentation of a noxious stimulus at the periphery. (Supported by NIH Grant NS-09871)

112.5 NORADRENERGIC UPTAKE BLOCKERS ANTAGONIZE TONIC DESCENDING INHIBITION OF CAT SPINAL CORD NOCICEPTOR-DRIVEN NEURONES. P.J. Soja* and J.G. Sinclair. Div. of Pharmacology & Toxicology, Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C. V6T 1W5 Canada

The biogenic amines noradrenaline (NA) and serotonin (5-HT) have been implicated in antinociception and inhibition of spinal cord nociceptor-driven neurones by stimulation of certain brainstem nuclei. Furthermore it has been suggested that opiates produce analgesia in part by activating (a) descending NA and/or 5-HT pathway(s). However it is not known what synaptic transmitter(s) is (are) involved in mediating the powerful tonic descending inhibition of nociceptor-driven neurones from supraspinal structures. Recent studies (Soja and Sinclair, Brain Res. 199: 225-230, 1980 and Griersmith et al., Brain Res. 204: 147-158, 1981) have failed to implicate 5-HT in tonic descending inhibition. Therefore the present experiments were initiated to determine whether NA is involved in this tonic inhibitory impingement. In chloralose-anaesthetized cats a thermoelectric cooling device positioned at the L_1 spinal cord segment was employed to reversibly cold block the cord. Extracellular unit activity was recorded from wide-dynamic-range (WDR) neurones in the lumbar cord. Noxious radiant heat (with feedback control, 47-55°C, 10-15 s, 2 min intervals) was used to activate these units. The degree of tonic inhibition, as judged by comparing the noxious heat-evoked response in the normal vs. cold blocked state of the spinal cord, was determined for each neurone. With the cord in the normal state nisoxetine (6 mg/kg i.v.), a specific NA uptake blocker, enhanced the noxious heat evoked unit responses in 5 animals and decreased them in one. Desipramine (6 mg/kg i.v.) produced similar results on 6 other WDR neurones. Only one cell was tested per animal. Responses obtained during the cold block state after the drugs were administered were the same as those obtained in the control cold block state suggesting that these agents did not affect primary afferent input of these cells. This also implies that these agents did not exert their effects directly on the recorded cells but rather were dependent on the tonic descending inhibition. If NA mediates tonic descending inhibition then these agents which enhance NA synaptic activity should have decreased the heat evoked responses in the cells tested. However the results suggest that a noradrenergic system participates in antagonizing the tonic descending inhibition of spinal cord nociceptor-driven neurones.

112.6 THE ROLE OF ACETYLCHOLINE IN INTERACTION BETWEEN THE PERIAQUEDUCTAL GRAY AND NUCLEUS RAPHE MAGNUS. M.M. Behbehani and C.E. Mack*. U. Cincinnati Coll. of Med., Dept. of Physiol., Cincinnati, OH 45267

The involvement of the nucleus raphe magnus (NRM) in inhibition of pain has been clearly established. Physiological and anatomical methods have shown that the NRM receives diverse afferents from all regions of the brain. Of particular importance are the afferents from the periaqueductal gray (PAG). Although the afferents to the NRM have been studied by histochemical methods, the neurotransmitter(s) involved in activation of NRM cells is not known. The experiments reported here were designed to examine the role of acetylcholine in the function of NRM neurons and to determine whether this neurotransmitter is the one which mediates the excitation of NRM neurons by the PAG. Rats were anesthetized with 1.2 g/kg of urethane; after relevant surgical procedures, a monopolar stimulating electrode was placed in the central part of the PAG. A glass recording electrode filled with pontamine blue and glued to a 5-barrel electrode was used to record single unit activity of the NRM Ach (500mM), scopolamine (200mM) and gallamine (200mM) were used in these experiments. One electrode filled with 3M NaCl was used as a balance electrode. The pH of the drugs ranged between 4.5 and 5.5. Of the 53 cells tested that responded to PAG stimulation, 36 responded by excitation and 13 by inhibition. For each cell, after the response to PAG stimulation before and after scopolamine application was determined, the response to iontophoretically applied Ach (80-130 nA, 10 or 20 seconds) was examined. Of the 53 cells, 33 were excited, one was inhibited and 21 did not respond to Ach. In order to determine the type of Ach receptor present in the NRM, the effect of muscarinic and nicotinic antagonists were examined. Of the 32 cells tested, application of scopolamine for 1 minute totally or partially blocked the response to Ach in 18 cells and in 14 cells Ach response was not affected by scopolamine. Response to gallamine was tested in 15 cells. In 11 cells, gallamine alone caused a significant increase in the firing rate of the cells. The response to Ach was not affected by gallamine in any cells. A strong correlation between excitatory response to PAG stimulation and to Ach was observed. However, since a large number of cells were excited by Ach but inhibited by PAG stimulation, the fact that several cells excited by PAG did not respond to Ach and the observation that the response to PAG stimulation could not be blocked by scopolamine provide evidence that Ach is not the transmitter that mediates the interaction between the PAG and the NRM. The fact that the response to Ach could be reversed by scopolamine and not by gallamine indicates that the Ach receptor present in the NRM is muscarinic. Supported by NIDA DA02282.

112.7 SIMULTANEOUS SUPPRESSION OF PAIN, ARTERIAL BLOOD PRESSURE AND HEART RATE BY CLONIDINE IN THE CAT: LACK OF OPIATE RECEPTOR INVOLVEMENT. Samuel H.H. Chan and Yih-Huey Chen. Dept. of Life Sciences, Indiana State University, Terre Haute, IN 47809.

There are recent evidences that implicated an inter-relationship between the regulation of pain and blood pressure. For example, pain threshold appears to be elevated in hypertensive animals or patients. The antihypertensive agent clonidine is now also known to be antinociceptive, and the analgesic action of this imidazoline compound is potentiated by morphine. Furthermore, cross-tolerance exists between clonidine and the opiate in the production of pain suppression. In light of these findings, the present study was carried out to investigate the simultaneous effects of clonidine on pain, arterial blood pressure (ABP) and heart rate (HR), as well as the possible involvement of opiate receptors in these processes.

Experiments were performed on adult cats that were anesthetized with α-chloralose and urethane (40 and 350 mg/kg, i.p.). The jaw-opening reflex (JOR), quantified as the averaged EMG signals recorded from the digastric muscle in response to dental-pulp stimulation, was taken as the experimental pain index. It was monitored alongside the ABP and HR throughout the experiment. Drugs were administered via a cannulated vertebral artery.

Intravertebral injection of clonidine (2, 4 and 10 μg/kg) induced a dose-dependent suppression of the JOR, ABP and HR. The degree of analgesia induced by any dose, however, was greater than the elicited hypotension or bradycardia. Such clonidine-promoted antinociceptive, vasodepressive and cardioinhibitory effects were not reversed by a subsequent injection of naloxone (0.2, 0.4 and 1.0 mg/kg), an opiate antagonist.

Reversal of the drug-administration sequence produced similar results. Initial injection of naloxone did not result in any significant changes in the JOR, ABP and HR. However, clonidine that followed still elicited appreciable analgesia, hypotension and bradycardia, the degrees of which were comparable to those observed in the previous series.

These data demonstrated that in addition to its hypotensive and cardioinhibitory effects, clonidine also possesses an antinociceptive action. However, there appears to be a dose-difference in the production of analgesia, vasodepression and bradycardia by the imidazoline compound. Furthermore, the failure of naloxone to reverse the clonidine effects implicated that it is unlikely for the opiate receptors to be involved in these pain and cardiovascular suppressive processes.

WITHDRAWN

112.9 EFFECT OF N. RAPHE ALATUS (NRA) & PERIAQUEDUCTAL GRAY (PAG) LESIONS ON FOOTSHOCK INDUCED ANALGESIA (FSIA) & CLASSICALLY CONDITIONED ANALGESIA. L.R. Watkins*, E.G. Young*, I.B. Kinscheck* & D.J. Mayer. Dept. of Physiology, MCV/VCU, Richmond, VA 23298.

It has recently been shown that front paw FSIA & classically conditioned analgesia involve endogenous opiates since they are antagonized by systemic naloxone, spinal naloxone & morphine tolerance. In contrast, hind paw FSIA involves non-opiate systems for it fails to be reduced by these manipulations. Each of these phenomena appears to be neurally mediated since none are attenuated by hypophysectomy or adrenalectomy. In addition, all are dependent upon activation of supraspinal sites which inhibit pain via descending pathways in the dorsolateral funiculus of the spinal cord.

A major source of these descending axons is the NRA, which consists of the combined cell populations of the n. raphe magnus (NRM) & the n. reticularis paragigantocellularis (NRPgc). This area has previously been implicated in morphine analgesia (MA) & stimulation-produced analgesia (Br Res, 181:1, 1980). NRA, NRM & NRPgc are also involved in front paw FSIA. When rats are exposed to 90 sec front paw shock, the resultant analgesia (as measured by the tail flick test) is greatly reduced in NRA, NRM & NRPgc lesioned animals compared to sham operated controls. When these rats were tested for both systemic MA and front paw FSIA, a highly significant correlation was found between lesion-induced reductions in both forms of opiate analgesia. Preliminary studies indicate that at least NRPgc is involved in classically conditioned (opiate) analgesia. Using the non-electrified grid as the conditioned stimulus (CS), 90 sec hind paw shock as the unconditioned stimulus (UCS) & analgesia as the unconditioned response, 3 CS-UCS pairings result in analgesia being produced following exposure to the CS alone. This classically conditioned analgesia was reduced in rats with NRPgc lesions. In contrast, non-opiate FSIA produced by 90 sec hind paw shock is not blocked by these lesions. These results provide the first anatomical evidence that opiate & non-opiate analgesia may be mediated by independent supraspinal systems.

In addition, the effects of rostral & caudal PAG lesions were tested for FSIA & classically conditioned analgesia. Neither lesion had any effect on front paw FSIA or hind paw FSIA. However, caudal lesions reduced classically conditioned analgesia. Since the PAG has been implicated in affect, the observations that PAG lesions and librium both reduce classically condtioned analgesia suggests that an affective state, such as fear, is involved. This research was supported by Grant DA-00576 to DJM.

112.10 NON-ENDORPHINERGIC PATHWAYS SUPPRESS PAIN IN HUMANS. J.B. WALKER* AND R.L. KATZ (SPON: M.H. CHASE). Department of Anesthesiology, UCLA School of Medicine, Los Angeles, California 90024.

Subcutaneous electrical stimulation (20HZ) of median, radial, and saphenous nerves produces prolonged analgesia. This effect of subcutaneous nerve stimulation (SCNS) is not mediated by opiate receptors (1) there is no cross-tolerance with opiates, and SCNS suppresses pain in patients who have received chronic administration and meperidine every two hours for months (2) patients unresponsive to morphine benefit from SCNS (3) there is no tolerance to SCNS, and (4) SCNS, can be administered with oral analgesics (both opiate and non-opiate) to increase patient comfort. These observations suggest that non-endorphinergic pathways produce powerful analgesia.

Although the mode of SCNS is unknown, it decreases the excitability of spinal reflexes. In a double blind study, SCNS suppresses clonus in spastic patients for three hours. The effect is contralateral so that each patient can serve as his own control. Suppression is not mediated by opiate receptors because it is not mimicked by opiates nor is it naloxone-reversible. The neurochemical basis for long duration of SCNS-induced alterations in neural excitability are currently under investigation.

112.11 DIFFERENTIAL EFFECTS OF FENTANYL AND DIAZEPAM ON PAIN SENSATIONS AND PSYCHOPHYSICAL PERFORMANCE. R.H. Gracely*, P.J. Wolskee*, W.R. Deeter* and R. Dubner (SPON: R. Dionne). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Functional measurement divides psychophysical assessment into perceptual, cognitive-integrative and response stages. This technique requires subjects to integrate pairs of stimuli from two independent stimulus sets. In this study, subjects rated both pain produced by electrical stimulation of the tooth pulp and pain symbolized by a word. This procedure produces measures of each stimulus set and a measure of cognitive integration performance. Eighty-two subjects were presented all possible pairs of 5 tooth pulp stimuli (a blank and 4 current intensities ranging from pain threshold to pain tolerance) and 5 verbal descriptors of pain intensity (no sensation, weak, moderate, strong, very intense). Subjects used a 15 point category scale to rate the average of the pain intensity experienced and the pain symbolized by the descriptor. The 25 pairs were presented twice in random order before and after the double blind intravenous administration of 1) 0.66 mg/kg diazepam or saline placebo, followed immediately by 2) 0.001 mg/kg fentanyl or saline placebo. Seven subjects could not perform the task and were excluded from the analysis. Two-way analyses of variance (fentanyl effect X diazepam effect) assessed the effects of the drugs on the two stimulus sets and on a nonparametric index of integration error. The intensity of the tooth pulp sensations was reduced significantly after fentanyl in comparison to placebo ($F(1,64)=8.79$, $p<.005$). Diazepam had no effect. The magnitude of pain intensity implied by the verbal descriptors was not altered by either drug. The ability to perform the stimulus integration task was reduced significantly by diazepam in comparison to placebo ($F(1,64)=7.63$, $p<.01$) and not altered by fentanyl. Significant interactions were not observed for any analysis.

These results show that pain perception was altered only by fentanyl, that stimulus integration was altered only by diazepam, and that the use of the category scales and the meanings of the words were not altered by either drug. These findings suggest that most subjects can perform an integration task involving physical sensations and words and that functional measurement techniques can distinguish between the effects of pharmacological manipulations on pain sensations and psychophysical performance.

112.12 SIMULTANEOUS RECORDINGS FROM HUMANS OF PAIN SENSATION AND NOCICEPTOR ACTIVITY BEFORE AND AFTER CUTANEOUS HYPERALGESIA C.J. Robinson, H.E. Torebjork* and R.H. LaMotte. Dept. of Anesthesiology, Yale Univ. Med. Schl., New Haven, Ct. 06510

Our aim was to study the functional relationship between pain sensations and activity in single cutaneous nociceptors. Brief heat stimuli of 38 to 51^{0}C were delivered to the foot or leg before and at varying intervals of time after a conditioning stimulus (CS) of prolonged noxious heat. Fourteen humans, each of whom gave informed consent to an approved protocol, made continuous ratings of the magnitude of pain sensations evoked by the heat stimuli. Simultaneously, percutaneous recordings were made of the evoked responses of single C-fiber polymodal nociceptive afferents in the common peroneal nerve.

Prior to the CS, the magnitude of neuronal response (NR), defined as the number of impulses evoked by each stimulus, increased linearly with stimulus temperature. In contrast, the magnitude ratings (MRs) of pain increased as a positively accelerating function of temperature. Following the CS, threshold temperatures required to evoke a minimal MR or NR were initially elevated. But, by 10 minutes after the CS, MR thresholds of most subjects were lower than pre-CS values (hyperalgesia) as were the NR thresholds of about half of the nociceptors (sensitization).

The correlation between each subject's MRs and the NRs of the nociceptor under study was weak. This relation between the MR and NR was monotonic but nonlinear before the CS; and typically nonmonotonic after the CS due to a saturation of the NR at the higher temperatures. In contrast, a closer correlation,and one with a greater degree of linearity,was obtained between pain sensation and nociceptor response when the MRs of each subject were related to the average NRs of all nociceptors studied. These observations indicate that the central summation of activity across the population of active nociceptors is an important determinant of the magnitude of pain sensation in man.

(Supported by NIH Grant NS14624)

113.1 ACTIVITY OF DOPAMINE-CONTAINING SUBSTANTIA NIGRA UNITS IN FREELY MOVING CATS. Michael E. Trulson, Donald W. Preussler and Gailyn A. Howell. Dept. Psychol., Univ. of Texas at Dallas, P.O. Box 688, Richardson, TX 75080.

Fluorescence histochemical mapping studies have revealed that the substantia nigra is densely populated with dopamine-containing neuronal perikarya. These neurons diffusely innervate the striatum, which is intimately involved in the control of movement. The nigral-striatal dopamine system is so diffuse, in fact, that it has been estimated that each dopamine neuron gives rise to approximately 500,000 synaptic contacts in the striatum, and that virtually every neuron in the striatum receives a dopaminergic input (Anden et al, Acta Physiol. Scand. 67: 306-312, 1966). While the anatomy of the nigral-striatal dopamine system has been well-described, the physiological role of this system remains unknown, despite intensive research efforts involving pharmacological and electrophysiological techniques. Although these latter studies have greatly increased our knowledge of the nigral-striatal system, one common disadvantage of these previous studies is the fact that they were carried out in animals that were immobilized and often anesthetized. Therefore, in the present study, we recorded the activity of dopamine-containing substantia nigra units in awake, freely moving cats. Nigral unit activity was recorded by means of movable 32 or 62 u dia insulated nichrome wires. Dopamine-containing nigral units were initially identified on-line by their unusually wide action potential (2-5 msec) and characteristic triphasic wave form (Guyenet and Aghajanian, Brain Res. 150: 69-84, 1978). This identity was later confirmed by the nearly total inhibition of unit activity by low doses of apomorphine (0.5 mg/kg, i.p.), and by subsequent histological analysis, i.e., all units were in the densely dopaminergic pars compacta of the substantia nigra. During quiet waking (i.e., no overt movement) nigral units displayed a slow, somewhat irregular activity ($\bar{X}$= 4.1 spikes/sec). Unit activity showed no significant change from quiet waking during slow-wave sleep ($\bar{X}$= 3.4 spikes/sec) or REM sleep ($\bar{X}$= 3.6 spikes/sec). These results are in sharp contrast to the other monoamine-containing neurons, since the activity of both serotonin- and norepinephrine-containing neurons have been shown to decrease dramatically during REM sleep. While nigral unit activity was somewhat higher during active waking ($\bar{X}$= 5.2 spikes/sec), i.e., when overt behaviors such as walking, grooming or eating were occurring, there was no apparent relationship to phasic movement. This is interesting in view of the fact that we have recently found that many striatal units show bursts of activity in relation to phasic movement (Trulson and Jacobs, Neuropharm. 18: 735-738, 1979). Therefore, dopamine-containing nigral units apparently exert some modulatory influence in the striatum, but are not involved in phasic changes in the activity of striatal neurons.

113.2 UNIT ACTIVITY OF DOPAMINERGIC NEURONS IN FREELY MOVING CATS. George F. Steinfels, James Heym, and Barry L. Jacobs. Prog. in Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

The role of brain dopamine in various behaviors and motor processes has been studied by a variety of methods. Single unit studies of dopamine-containing neurons in chloral hydrate anesthetized rats have contributed much to our understanding of this system. However, the use of anesthetized animals precludes studying, for example, sleep-waking behaviors or motor related functions. Thus, we have attempted to identify and characterize single unit activity of dopaminergic neurons in the substantia nigra (SN) in freely moving cats. Since the majority of previous single unit studies of dopamine neurons was conducted in chloral hydrate anesthetized rats, we initially conducted pilot studies which examined unit activity in the pars compacta of the SN in chloral hydrate anesthetized cats. These neurons in the cat shared several distinctive characteristics with known dopaminergic cells studied in chloral hydrate anesthetized rats: action potentials of long duration (2-4ms) relative to other neurons (< 2ms) in the area; firing in bursts with successive decreases in spike amplitudes; firing rates of 4-10 spikes/sec; and suppression by i.v. apomorphine. In a second series of studies, cats were prepared for chronic unit recordings as previously described (Brain Res. 163: 135-150, 1979). The coordinates for the area studied in the SN were A 3.0-6.0, L 1.8-3.8, and H (-)4.0-(-)6.0. Ninety cells were studied from 9 cats. Of these, 20 cells were found which had the following characteristics: action potential durations of 2-4ms; firing rates of 2-6 spikes/sec; single discharges along with periods of bursts which displayed successive decreases in spike amplitude. Initial observations indicate that the activity of these neurons is neither heavily state-dependent nor motor-related. Eight of the twenty cells were held long enough for pharmacologic manipulations to be performed. Apomorphine (0.35-1.0 mg/kg, i.p.) caused decreases in firing rates of 60-100%, whereas, haloperidol (0.5-0.75 mg/kg, i.p.) caused increases of 30-60% in firing rates. The remaining 70 cells had action potential durations of 0.5-2.0ms and firing rates of 5-40 spikes/sec. Their activity was often heavily motor-related. In 25 of these cells, administration of apomorphine (0.35-1.0 mg/kg, i.p.) caused either no change or an increase in firing rates. Therefore, based upon physiological and pharmacological evidence, the unit activity of neurons in the area of pars compacta in the freely moving cat is similar to that of known dopaminergic cells in anesthetized rats and cats. Thus, this study is the first to report recording from presumed dopaminergic neurons in freely moving animals. (Supported by NIMH Grant MH 23433).

113.3 DOPAMINERGIC UNIT ACTIVITY IN THE BEHAVING RAT. J.D. Miller, M.K. Sanghera and D.C. German. Depts. of Physiology and Psychiatry, Univ. of Texas Health Science Center, Dallas, TX. 75235.

Mesencephalic dopaminergic (DA) neurons have been implicated in a number of behavioral processes, including intracranial self-stimulation, attentional mechanisms, motoric function, and a variety of pathological states such as schizophrenia and Parkinsonism. Single DA cells have been recorded in the substantia nigra zona compacta (nucleus A9) and ventral tegmental area (nucleus A10) both in the anesthetized and paralyzed-unanesthetized rat. These cells have a characteristic long duration action potential (> 2 msec), and typically fire in bursts at a rather low rate (3-10 Hz). A number of investigators have studied nigral single unit activity in the awake behaving monkey and rat; however, it is not clear whether DA cells were among the units recorded. It is a matter of some importance to understand the function of DA neurons in the unanesthetized, behaving animal. The goal of the research reported here was to develop methods which would allow recording of DA cells in behaving rats. Male albino rats (Sprague-Dawley) between 225-275g were used in these experiments. The animals were operantly conditioned on either a DRL-10 sec or a classical conditioning task with chocolate milk as the reinforcer. A stainless steel recording well was stereotaxically positioned over the DA cell region and glass coated tungsten microelectrodes were driven into the DA cell region while the animals were performing the operant task. A total of 183 tracks were run in 19 awake, behaving rats; 105 of these tracks were run in A10 (< 1 mm from midline), and 78 in A9 (1-1.5 mm from midline). In four out of 96 tracks DA cells were observed. In these four tracks, six DA cells were found. These six cells were encountered in the classical conditioning task, in animals who were behaviorally inactive. In rats tested with low doses of haloperidol (HALO), however, 49 DA cells were observed in 87 tracks. The majority of the cells observed under HALO were found during classical conditioning. Histological examination of microlesions showed that recording sites were in DA cell regions in both untreated and HALO-treated animals. The DA cells exhibited long spike durations (> 2 msec) and typically exhibited a characteristic bursting firing pattern with spikes of decreasing amplitude. There was little relationship between cell firing pattern and performance of the operant tasks, although some few A10 units gave a burst of activity to the conditioning stimulus. These results suggest that the incidence of A10 and medial A9 DA neurons is reduced during active behavioral states, whereas when the animals are behaviorally calmed (e.g. with HALO) cell incidence is higher. (This research was supported by NIMH grant MH-27574).

113.4 NIGRAL DOPAMINERGIC NEURONS: SINGLE UNIT ACTIVITY IN THE AWAKE, UNRESTRAINED RAT. L. T. Meltzer* and B. S. Bunney. Depts. Psychiatry & Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510

Central dopamine (DA) systems have been implicated in the modulation or mediation of both natural and drug-induced behaviors. However, most of the evidence linking DA systems with behavior is indirect as the activity of DA systems has not been directly assessed at the same time that the behavior is occurring. To directly correlate the activity of DA systems with behavior, we have begun to record the extracellular single-unit activity of substantia nigra (SN) zona compacta (ZC) neurons in the awake, unrestrained rat.

For these experiments, a stainless steel sleeve was implanted on the skull of male rats (380-480 gm) above the SN and a microdrive and field-effect-transistor inserted into the sleeve. Cell activity was recorded through glass insulated tungsten electrodes (1 u tip diameter). Jugular vein cannulae for drug administration in the freely moving animal were also implanted. Recording was begun one week after surgery.

Abundant spontaneously active putative DA neurons were found. Three sets of criteria were used to determine that DA neurons were being recorded. (1) Neurophysiological characteristics: The putative DA neurons had action-potential characteristics identical to those of identified DA neurons in the anesthetized and paralyzed rat. These included a wide action-potential (3-4 msec duration), a notch in the initial positive phase, and often a bursting pattern with spikes of successively decreasing amplitude within the burst. As is true in the anesthetized preparation, these characteristics are different from those of non-DA neurons seen in brain regions adjacent to the ZC. Firing rates were between 1.0 and 4.5 spikes/second. (2) Pharmacological responsiveness: The activity of these putative DA neurons was decreased by the DA agonist apomorphine and increased by the DA antagonist haloperidol. In addition, there appears to be a population of these neurons that are tonically inhibited, since more appear to be firing after haloperidol treatment. (3) Histological verification: Following recording, current was passed through the electrode resulting in a small lesion at the recording site. Brains were processed for histology utilizing both thionin staining and catecholamine fluorescence techniques. Recording sites of putative DA cells were histologically verified to be within the ZC of the SN. In conclusion, single unit recordings were obtained in the awake, unrestrained rat from neurons in the ZC of the SN. They had neurophysiological characteristics and pharmacological responses similar to identified DA neurons and, therefore, are presumed to be dopaminergic. 113.5 UNIT ACTIVITY OF MEDULLARY SEROTONIN-CONTAINING NEURONS IN FREELY MOVING CATS. James Heym, Geroge F. Steinfels and Barry L. Jacobs. Prog. in Neurosci., Dept. of Psychol., Princeton Univ., Princeton NJ 08544.

A great deal has been learned about the activity of serotonin-containing neurons in the dorsal raphe nucleus (DRN), and the factors influencing the discharge rate of these cells. On the other hand, little is known about the activity of serotonergic neurons in raphe nuclei other than the DRN. Nucleus raphe pallidus (NRP), on the midline of the medulla, contains a relatively high proportion of serotonin-containing neurons. The present study examined the activity of serotonergic and non-serotonergic cells in the region of the NRP in adult freely moving cats. Single unit activity was recorded utilizing a methodology previously described in detail (Brain Res.: 163, 135-150, 1979). Briefly, movable electrode bundles consisting of 32 and 62μ diameter, insulated, nichrome wires were implanted 2 mm above the NRP at an angle 15° posterior to vertical. Stereotaxic coordinates for the NRP target were P -10.0, L 0.0, H -9.5. Electrodes were also implanted for recording the EEG, EOG, and dorsal neck EMG. Serotonergic neurons were initially identified on-line by their slow and regular spontaneous activity which was similar to that previously reported for serotonergic cells in the DRN. Discharge rates of medullary serotonergic neurons were highest during waking (4.3 ± 0.5 spikes/sec, mean ± sem, n = 12), decreased somewhat during slow wave sleep (3.3 ± 0.5 spikes/sec), and were slowest during REM sleep (0.8 ± 0.3 spikes/sec). These cells responded to administration of the specific serotonin agonist 5-methoxy-N, N-dimethyltryptamine (5-MeoDMT, 250 μg/kg i.m.) with a mean decrease in activity of approximately 80%. Despite these general similarities to serotonergic neurons of the DRN, the activity of medullary raphe neurons also showed some marked differences. The mean discharge rate of medullary serotonergic neurons was higher across all behavioral states and the activity of these neurons was not as strongly related to behavioral state or arousal. In addition, the activity of medullary serotonergic neurons was unaffected by auditory or visual stimuli, appeared unrelated to EEG spindles, and was less responsive to systemic administration of 5-MeoDMT. Control cells recorded from the NRP region had more irregular spontaneous activities, often firing with high frequency bursts, did not exhibit their slowest firing rate during REM sleep, and did not show a large decrease in activity after 5-MeoDMT. These initial data indicate that the activity of serotonergic neurons in the medulla bear strong similarities to identified serotonergic neurons in the DRN of the midbrain. However, clear differences also exist which may relate to functional distinctions.

113.6 RAPHE UNIT DISCHARGE IN FREELY MOVING CATS: DEPENDENCE ON CENTRAL MOTOR ACTIVITY. Barry L. Jacobs, George F. Steinfels and James Heym. Prog. in Neurosci., Dept. Psychol., Princeton Univ., Princeton, N.J. 08544.

We have previously reported that the activity of serotonergic (raphe) neurons in freely moving cats is grossly correlated with the level of behavioral arousal, or tonic motor activity (Brain Res. 163: 135-150, 1979). Neurons within the dorsal raphe nucleus of the cat discharge at a high level (approx. 3-4 spikes/sec) during active waking or arousal, and display a monotonic decrease in activity in conjunction with decreasing levels of behavioral arousal or tonic motor activity, becoming virtually silent (approx. 0.1 spikes/sec) during REM sleep. In a subsequent study (Soc. Neurosci. Abst. 6: 235, 1980; Brain Res., in press), we found that this decrease during REM sleep was primarily attributable to the profound atonia that characterizes this state. Cats with bilateral lesions in the pontine tegmentum display REM sleep without atonia. During these REM sleep periods, the discharge rate of raphe neurons in those animals displaying the greatest amount of motor activity was only 40% below that seen in these neurons during waking. The present series of studies continues this analysis, employing two different approaches. Unilateral injections of the cholinomimetic agent, carbachol (6 μg/0.37 μl), into the pontine tegmentum (P -4.0, L 2.0, H -6.0) of cats produces complete antigravity muscle atonia within 4-20 min. During these periods of drug-induced atonia, the activity of serotonergic neurons within the dorsal raphe nucleus was almost completely suppressed, in spite of the fact that the animals were unambiguously awake and responsive (see Brain Res. 163: 135-150, 1979 for complete details of the unit recording procedure). On some occasions the carbachol injections did not produce atonia, and in these cases no decrease in raphe unit activity was observed. To distinguish between central and peripheral induced atonia, we administered intravenous injections of succinylcholine, a peripherally acting paralytic agent, to cats that were artificially respirated. In this case, in spite of atonia to the point of depressing natural respiration, there was no effect upon raphe unit activity. Finally, we administered high doses of either a centrally acting muscle relaxant (mephenesin 50-200 mg/kg i.p.) or a peripherally acting muscle relaxant (dantrolene 100 mg/kg i.p.). Confirming our previous results, a large decrease in raphe unit activity was seen following the mephenesin-induced atonia, whereas no change in unit activity accompanied the dantrolene-induced atonia. In conclusion, the results of the present experiments, taken in conjunction with our previous data, indicate that the discharge of serotonergic neurons in the dorsal raphe nucleus is heavily dependent on central motor activity.

113.7 AN ANALYSIS OF NEURONAL ELEMENTS WITHIN THE NUCLEUS MEDIANUS RAPHE AND BEHAVIOR. K.E. Asin and H.C. Fibiger. Dept. Neurol. Sci, Univ. British Columbia, Vancouver, B.C. V6T 1W5.

In past years, we (Asin et al. Neur.Absts. 2-6; Wirtshafter et al. Neur.Absts. 5-6) have demonstrated that electrolytic lesions of the median nucleus of the raphe (MR) produce behavioral changes which may be likened to those seen following damage to certain limbic structures-the septum and hippocampus, in particular. Although these data support limbic-midbrain interactions in behavior, the question arises as to which neuronal elements within or near the MR produce the behaviors described, since this area of the midbrain tegmentum contains both serotonergic (5HT) and non-5HT cell bodies, as well as fibers of passage. This study sought to clarify which elements, when damaged, lead to the behavioral changes seen following electrolytic MR lesions.

Six groups of rats, matched for body weight, were operated. Following pretreatment with desmethylimipramine, one group received an intra-MR injection of 5,7-dihydroxytryptamine (DHT) and another group received a vehicle injection. Another group of rats was given an intra-MR injection of ibotinic acid (IBO)(which destroys cell bodies) and another group received the vehicle. The final groups were either sham operated or were given an electrolytic lesion of the MR (ELEC).

During the two week post-operative recovery period, DHT and IBO rats lost equivalent amounts of weight which were greater than that lost by controls, but the ELEC group surpassed all others in terms of the duration of weight loss; the body weight of this group remained depressed throughout the two weeks.

When tested in the open field, the IBO group was more active than both the controls and DHT's, but their hyperactivity was far less than that shown by ELEC rats. Also, both DHT and controls showed significant spontaneous alternation in a T maze, whereas IBO injection reduced alternation but failed to produce the perseveration shown by ELEC's. In photocell cages, both IBO and ELEC groups were hyperactive prior to and following an injection of 1 mg/kg d-amphetamine.

Finally, all rats were trained on a T-maze learned alternation task. The behavior of DHT and control groups was equivalent; although IBO rats were impaired on the task, they did not perform as poorly as ELEC rats.

These results suggest that the destruction of 5HT elements within the MR are not responsible for many of the effects pro produced by electrolytic damage to the nucleus. However, the destruction of non-5HT cell bodies and, especially, fibers of passage, does produce patterns of behavior similar to those seen following destruction of certain limbic nuclei. (KEA is supported by Post-doc. Fellowship #1 F32 NS06399-01 from NINCDS.)

113.8 EVIDENCE FOR DOPAMINERGIC INVOLVEMENT IN THE HYPERACTIVITY PRODUCED BY ELECTROLYTIC MEDIAN RAPHE LESIONS. D. Wirtshafter and K.E. Asin. Dept.Psychology, University of Illinois at Chicago Circle, Chicago, Il 60680 and Kinsmen Laboratory of Neurological Research, University of British Columbia,Vancouver, B.C., Canada.

It is well known that electrolytic lesions of the median raphe nucleus produce a dramatic increase in locomotor activity which must reflect the release of other structures from some sort of inhibitory influence. In an attempt to identify which neural systems might play a role in raphe lesion-induced hyperactivity, the current study examined the effects of several drugs on photocell cage activity in animals with median raphe lesions. All testing was conducted 6 to 8 weeks after surgery.

Haloperidol (0.15,0.30 mg/kg) produced a dose dependent decrease in the activity of both lesioned and sham operated control animals. The reduction was significantly larger in lesioned than in control rats with the effect that, at a dose of 0.3 mg/kg, activity in the two groups was indistinguishable. This result suggests that dopaminergic mechanisms play some role in lesion-induced hyperactivity. In contrast, the α-adrenergic antagonist phenoxybenzamine (20 mg/kg) produced a parallel reduction in the activity of lesioned and control rats. In intact animals phenoxybenzamine depressed activity to about the same extent as did haloperidol (0.15 mg/kg), but it was much less effective than haloperidol in lesioned animals. These results suggest that α-adrenergic mechanisms do not play an important role in raphe lesion-induced hyperactivity. Naloxone (1,10 mg/kg) was without effect on activity in either group. The GABA antagonist picrotoxin (1,2 mg/kg) reduced activity in both lesioned and sham operated rats, but was unable to eliminate the relative hyperactivity of the lesioned subjects.

In order to investigate whether dopaminergic mechanisms play a causal or merely a permissive role in the hyperactivity, control and lesioned rats were injected with reserpine (2.5mg/kg) and 6 hours later activity in response to apomorphine (0.5mg/kg) was measured. If the role of dopamine in hyperactivity was merely permissive, one would expect that lesioned animals would show a larger locomotor response to apomorphine than controls. In fact, the opposite pattern of results was obtained with lesioned animals tending to show a smaller response than shams. The simplest explanation of these findings is that median raphe lesions produce an increase in dopamine turnover which leads to both hyperactivity and to hyposensitivity of dopamine receptors. This possibility is in agreement with the results of studies showing increased dopamine turnover following raphe lesions.

113.9 NORADRENALINE, EXTINCTION, AND SPATIAL ALTERNATION LEARNING. M. Pisa, M.T. Martin-Iverson, and H.C. Fibiger. Div.Neurol.Sci., Dept. Psychiatry, Univ. British Columbia, Vancouver, B.C. V6T 1W5

It has been proposed (Mason, S.T. and Iversen, S.D., Brain Res. Rev. 1:107, 1979) that a deficit of selective attention could best account for the impairments of discrimination learning, discrimination reversal, and spatial alternation learning, and for the facilitation of nonreversal shift, of rats with 6-OHDA lesions of the dorsal noradrenergic bundle (DNB). However, we were recently unable to replicate any of these behavioral findings (Pisa, M. and Fibiger, H.C., Neurosci. Abstr. 6:724, 1980). The most robust behavioral effect of DNB lesions reported by Mason and his colleagues is resistance to extinction of continuously reinforced responses--the dorsal bundle extinction effect (DBEE). To evaluate whether our previous failure to replicate the impairment of spatial alternation learning resulted from an inability to produce behaviorally effective noradrenaline depletions--depletions, that is, sufficiently severe to induce the robust DBEE--we examined the behavior of 13 rats with bilateral injections of 6-OHDA (4 µg in 2 µl of ascorbate-saline solution) in the DNB during both extinction of continuously reinforced lever pressing and spatial alternation learning.

One month after surgery, the rats were magazine trained and then given 12 sessions of lever-pressing acquisition and three sessions of extinction, each session lasting 15 min. All 12 control rats learned to press the lever, three rats with lesions failed to do so. The remaining 10 rats with lesions did not differ from the controls in acquisition. Also, they did not perform significantly more responses than the controls in the extinction sessions; however, they took longer than the controls to reach the criterion of two minutes of no responding in the first extinction session. Some support was therefore found for a DBEE. The rats were then trained in a conventional T maze. After one session with five trials of spontaneous alternation, and one session of free exploration and adaptation to the food pellets, the rats were given daily sessions of five trials of food-reinforced, left-right alternation, with an intertrial interval of 15 sec spent outside the maze. After 22 such sessions, no significant difference in performance emerged among DNB-lesioned and control rats. Thus, DNB lesions that produced a DBEE failed to impair spatial alternation learning. Taken together with our previous study, these observations indicate that, although DNB lesions increase resistance to extinction according to one, albeit arbitrary criterion, there is at present no reliable behavioral evidence in direct support of Mason's attentional hypothesis.

113.10 EFFECTS OF DORSAL NORADRENERGIC BUNDLE LESIONS ON MEASURES OF CONFLICT, LEARNING AND LOCOMOTION. D.R. Britton, C. Ksir, and G. Koob. Behav. Neurobiol. Lab., The Salk Institute, La Jolla, CA 92138 and Department of Physiology, University of N.M., School of Medicine, Albuquerque, N.M. 87131

The dorsal noradrenergic bundle (DNB) has been implicated in a number of behavioral processes including learning locomotor activity and the expression of anxiety. We investigated evidence for such involvement in the rat. Male Sprague-Dawley albino rats were given bilateral 6-hydroxydopamine lesions to the dorsal bundle. These lesions resulted in substantial (90%) depletion of norepinephrine (NE) in cortex and hippocampus. There was also a significant decrease in NE in hypothalamus and caudate. Dopamine was decreased by 15% in caudate and not significantly effected in other regions.

Following a recovery period of 10-12 days animals were fasted for 24 hrs. and tested in an open field paradigm previously shown to be sensitive to anxiolytic drugs (Britton and Britton, Pharm., Biochem and Behav., in press). In this test, lesioned animals show behavior which is in the opposite direction of that produced by anxiolytic drugs. The lesioned group showed a significant decrease in the $\bar{x}$ amount of food eaten per approach to the food pedistal (located in the center of the novel open field) and a decrease in the total amount eaten during the 15 min. duration of the test. These measures have previously been shown to be increased in animals treated with anxiolytic drugs. Lesioned animals, fasted for 24 hr. and tested for food consumption in their home cages, ate the same amount as sham lesioned controls. The decreased food consumption and decreased amount eaten per approach to the food pedistal appear, therefore, to reflect an increased neophobia in lesioned animals. This is consistant with other reports of DNB lesion-induced neophobia (S. Mason, et. al., Physiol & Bhv, 1978) and does not support the hypothesis that anxiolytics act by decreasing forebrain NE functioning. These same animals were subsequently tested for acquisition and extinction in an operant task. Legioned animals showed no differences between the two groups in locomotor activity measured by photocell activation in single cages over a 2 hr. period.

113.11 ELECTROPHYSIOLOGICAL AND BEHAVIORAL EVIDENCE OF INTERACTION OF DOPAMINERGIC AND GUSTATORY PROJECTIONS TO THE AMYGDALA. G. J. Mogenson and M. Wu*. Dept. of Physiology, University of Western Ontario, London, Canada, N6A 5C1.

The amygdala receives gustatory afferents which have been implicated in taste-motivated behavior. Lesions of the amygdala alter the intake of salt solutions and change the preference for novel foods. The central nucleus of amygdala (CNA), which is the main target of taste afferents, also receives dopaminergic afferents. The present experiment was undertaken to study the possibility that these dopaminergic afferent fibers interact with taste afferents and contribute to taste-motivated behavior.

Extracellular single unit recordings were obtained from neurons in the CNA of rats anaesthetized with urethane using glass micropipettes filled with 0.5M sodium acetate. The effects of electrical stimulation of the pontine taste area (PTA) or the ventral tegmental area (VTA) which contain gustatory and dopaminergic neurons respectively, were investigated. 73% of the CNA neurons were affected by PTA stimulation and 51% by VTA stimulation, with 41% of CNA neurons receiving convergent inputs from PTA and VTA.

In two-bottle taste preference tests, the intracerebral injection of either apomorphine (DA agonist) or spiroperidol (DA blocker) into the CNA produced a significant increase in consumption of 1.5% NaCl solution with no change in water intake after overnight deprivation of water. The administration of procaine also significantly increased the consumption of 1.5% NaCl, but, with simultaneous injections of both apomorphine and spiroperidol the intake of water and 1.5% NaCl were the same as during control tests. As an additional control for anaesthetic or other non-specific effects of apomorphine and spiroperidol, these drugs were injected via chronic cannulae into the nucleus accumbens and locomotor activity measured in an open-field test. Locomotor activity was increased by injections of apomorphine into the nucleus accumbens but injecting spiroperidol along with apomorphine reduced this effect in a dose-related manner.

These observations suggest that the CNA receives converging dopaminergic afferents from VTA and gustatory afferents from PTA which may play a role in taste-motivated behavior.

113.12 **DIFFERENTIAL ANTAGONISM OF d-AMPHETAMINE EFFECTS ON MOTOR ACTIVITY AND AGONISTIC BEHAVIOR IN MICE.** **Klaus A. Miczek. Dept. Psychology, Tufts Univ., Medford, MA 02155.**

Catecholamines (CA) appear to be critically involved in motor activity as well as aggressive, defensive and flight behavior. An ethological and pharmacological analysis was performed to examine the effects of CA agonists and antagonists on several elements of fighting behavior and motor activities, as they were engendered in resident-intruder confrontations in mice. Resident mice typically show the attack pattern, whereas intruders react with escapes, defensive postures, and vocalizations. The drugs were administered i.p. either to the resident male Swiss-Webster mice or to the intruder. Videorecords of 5-min confrontations were viewed by experimenters who measured with the aid of a computerized data collection system frequency and temporal pattern of all essential acts, postures, displays and movements characteristic of attack, threat, pursuit, defense, flight, grooming as well as walking and rearing. d-Amphetamine (0.63-5 mg/kg) (1) decreased attack and threat behavior at the higher doses, (2) increased defensive postures, (3) left grooming and vocalizations unaltered, (4) increased monotonically walking. Haloperidol (0.125- 1 mg/kg), phenoxybenzamine (5-15 mg/kg), propranolol (10-20 mg/kg), and methysergide (1-30 mg/kg) decreased attacks and threats as part of their general activity-reducing effect; by contrast, escapes, defensive upright postures and vocalizations remained largely unaffected by these drugs, although walking and rearing were reduced. These results indicated that defensive and flight reactions are least affected by the CA drugs, whereas basic motor functions such as walking across the cage are very sensitive to these drugs. Combined administration of d-amphetamine and one of the antagonists showed that (1) the motor activity-enhancing effects of d-amphetamine were effectively blocked by haloperidol, phenoxybenzamine, propranolol, but not by methysergide, (2) the aggression-reducing effects of d-amphetamine were not antagonized, but intensified by haloperidol, phenoxybenzamine, propranolol and methysergide. These results suggest different CA mechanisms underlying motor activities and aggressive behavior. Peripheral effects of the antagonists may have masked central actions of the CA drugs and may have contributed to the behavioral effects.

114.1

WITHDRAWN

114.2 FUNCTION OF CHEMICALLY-MODIFIED ACETYLCHOLINE RECEPTOR. M. G. McNamee, J. W. Walker* and R. J. Lukas. Dept. of Biochem. and Biophys., Univ. of Calif. at Davis, Davis, CA 95616.

Chemical modification of membrane-bound Torpedo californica acetylcholine receptor by the disulfide reducing agent dithiothreitol has two major effects on receptor function: (1) it shifts the dose-response curve for carbamoylcholine-induced increases in $^{22}Na^{+}$ permeability to 10-fold higher concentrations, and (2) it decreases the binding affinity of the receptor for the same agonist about 6-fold. Despite the quantitative changes in agonist binding and flux response, dithiothreitol-treated membranes display all other functional properties expected of the receptor. The flux response is blocked by preincubation of the membranes with carbamoylcholine, a phenomenon known as desensitization. In parallel, the receptor undergoes a carbamoylcholine-induced shift from a low-affinity to a high-affinity binding state for the same agonist. All of the effects of dithiothreitol are reversed by the oxidizing agent 5,5'-dithiobis(2-nitrobenzoic acid). Alkylation of the membranes with N-ethylmaleimide after dithiothreitol reduction results in complete inhibition of the flux response, and the effect is not reversed by the reoxidation treatment. The N-ethylmaleimide also shifts the receptor into a very low-affinity binding state for carbamoylcholine that is shifted to only a slightly higher affinity by preincubation with carbamoylcholine. Prior to reduction, N-ethylmaleimide has no effect on receptor binding or flux properties. Detailed binding studies on membranes affinity alkylated at one-half of the agonist binding sites indicate that the α-neurotoxin binding site not occupied by the affinity label displays all the same properties as unlabeled membranes, including the dithiothreitol and N-ethylmaleimide effects. The results will be discussed in the context of several hypotheses previously proposed to account for the diverse effects of thio-group modifications on the acetylcholine receptor.

114.3 SULPHYDRYL MODIFICATION OF ACETYLCHOLINE RECEPTOR KINETICS, A. Steinacker and †D.C. Zuazaga, Biophysics, The Rockefeller University, New York, N.Y. 10021, †Lab. of Neurobiology, U. of Puerto Rico, San Juan, P.R. 00901.

Disulfide groups are known to be critical determinants of acetylcholine receptor (AChR) function. Treatment of the AChR of the intercostal muscle at the lizard neuromuscular junction with specific reagents which modify disulfide groups on the receptor molecule produces an increase in the decay time of miniature endplate current (mepc) which cannot be accounted for by changes in single channel open times as measured by noise fluctuations. The decay of the mepc and the noise spectra show only a single exponential. A small increase in rise time of the mepc is also seen. Control experiments using carbachol and an anticholinesterase were done to determine that the change in mepc decay was not due to an action on disulfide bonds of the endogenous cholinesterase. These data are interpreted in terms of a three-state kinetic model ($A + R \underset{k_2}{\overset{\alpha}{\rightleftharpoons}} AR \underset{\beta}{\overset{k_2}{\rightleftharpoons}} AR^*$) in which time spent in the intermediate bound but not open state of the receptors is increased. This could be due to an increase in affinity of the receptor brought about by chemical modification of the receptor. An affinity increase should be reflected in a change in β or k_2 of the three-state kinetic model Experiments under way are designed to determine these constants. Supported by Muscular Dystrophy Association and NIH NS15956 (AS) and NIH NS07464 (DC.Z.)

114.4 LOCATION OF THE ACETYLCHOLINE RECEPTOR KINASE IN THE POST-SYNAPTIC MEMBRANE. C.G. Davis*, D. Milfay*, I. Diamond, and A.S. Gordon. Dept. of Neurology, Univ. of Calif., San Francisco, CA 94143.

We have previously reported that the AChR is phosphorylated in situ by an endogenous protein kinase. This reaction is reversible; endogenous phosphatase activity dephosphorylates the AChR. The presence of such a rapid, reversible enzymatic system capable of mediating changes in the structure of the receptor protein suggests that it may play a role in receptor function. As a step in understanding the physiological significance of AChR phosphorylation, we have undertaken to determine whether the kinase is restricted to one side of the plasma membrane, and, if so, which side.

Sealed right-side-out membrane vesicles were prepared from Torpedo californica electroplax. Incubation of these vesicles with [γ-^{32}P]-ATP for one minute did not result in significant phosphorylation of AChR subunits. However, if the vesicles were lysed by hypoosmotic shock, phosphorylation of four bands of MW 36K, 40K, 60K and 65K was greatly enhanced. The degree of enhancement correlated with the strength of the osmotic shock. The possibility that the effect of hypoosmotic shock on phosphorylation might be due to solubilization of the kinase or its substrates was considered. To test this possibility, lysed vesicles were resealed before the addition of γ-^{32}P-ATP. Phosphorylation of the 4 bands was reduced by 70-85% as compared to that observed in untreated lysed vesicles. Furthermore, if lysed vesicles were centrifuged and the supernatant incubated with intact vesicles, no enhancement was observed. Together, these results strongly indicate that hypoosmotic shock increases phosphorylation by making ATP accessible to the inside of vesicles and not by release of kinase or substrate from the membranes.

Other methods of membrane lysis were also tested for effect on AChR phosphorylation. Triton X-100 at a concentration of .02% caused a significant increase in phosphorylation of the same four polypeptides. Digitonin, a detergent specific for cholesterol, had an identical effect at the same concentration.

Since no significant phosphorylation was observed in intact right-side-out vesicles, while three different methods of membrane lysis resulted in greatly increased phosphorylation of AChR subunits, it can be concluded that the AChR kinase is restricted to the cytoplasmic side of the post-synaptic membrane.

114.5 KINETICS OF HISTRIONICOTOXIN BINDING TO TORPEDO NICOTINIC POST-SYNAPTIC MEMBRANES. Dan C. Medynski* and Jonathan B. Cohen. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

Rapid-mixing and ultrafiltration techniques have been used to measure the kinetics of binding of [^{3}H]-perhydrohistrionicotoxin ([^{3}H]-HTX) to nicotinic post-synaptic membranes isolated from Torpedo electric tissue. In control experiments at 20°C, both in the absence of agonist and with acetylcholine (Ach) sites occupied by carbamylcholine (Carb), the equilibrium binding function (K_{eq} = 0.25 μM, 0.48 ± .09 sites per α-bungarotoxin site) was the same whether determined by ultrafiltration or ultracentrifugation and was also the same as that at 4°C in the presence of carb. Despite the identity of K_{eq} under these different conditions, the kinetic parameters defining that equilibrium binding indicate the existence of significant differences: 1) Kinetics of dissociation of [^{3}H]-HTX at equilibrium was measured as the rate of exchange for H_8-HTX or meproadifen. For ^{3}H-HTX concentrations resulting in occupancy of 2 to 80% of the binding sites, when Ach sites were occupied by agonist or antagonists, the dissociation kinetics were characterized by a single exponential ($T_{1/2}$ = 10 min at 20°C and 180 min at 4°C) for greater than 75% of the exchange reaction. 2) With Ach sites unoccupied at 20°C in the presence of 2-20 μM H_8-HTX, $T_{1/2}$ = 30 min. In the presence of meproadifen, the observed dissociation rate depended upon the meproadifen concentration, presumably because meproadifen binds to the Ach sites as well as to the anesthetic site. 3) When membranes were equilibrated at 20°C with [^{3}H]-HTX in the absence of cholinergic ligands and then exchange measured by the addition of non-radioactive anesthetic simultaneously with agonist, the rates were increased. For carb concentrations of 0,10, and 500 μM, the $T_{1/2}$'s were 30, 0.5, and 0.5 min respectively. This fact indicates that the occupied HTX site can be converted by agonist to a transient conformation characterized by rapid dissociation, a conformation distinct from that stabilized by HTX (-carb) or by carb at equilibrium. 4) Analysis of [^{3}H]-HTX association kinetics at 20°C in the absence of cholinergic ligands has provided evidence that the association reaction is limited by a slow conformational transition; however, there is no evidence of preferential binding to the 20% of the receptors which pre-exist in a conformation binding Ach with high affinity (Biochemistry 19:5354,1980). The parameters characterizing the kinetics of binding of HTX will be related to the known conformational transitions of the membrane-bound Torpedo receptor.

114.6 ACETYLCHOLINE RECEPTOR REGULATION IN THREE MAMMALIAN MUSCLE CELL LINES. Jeffrey Boone Miller* and Zach W. Hall. Dept. of Physiology, University of California, San Francisco, CA 94143

As one step in investigating the biochemical and genetic mechanisms underlying acetycholine receptor (AChR) metabolism in muscles, we have examined AChR clustering, degradation rate, and immunological properties in three muscle cell lines: BC_3H-1, derived from a mouse tumor and similar to smooth muscle; C_2, derived from adult mouse skeletal muscle; and L6, derived from rat skeletal muscle. All three lines can be induced to synthesize AChR, but only C_2 and L6 cells fuse to form myotubes.

The distribution of AChR labeled with ^{125}I-α-bungarotoxin (^{125}I-Butx) was examined by autoradiography. Clusters, which were similar to those reported on myotubes in primary cultures, were seen only on C_2 myotubes. The clusters had a longest dimension of 10-30μm, and were found as early as one day after fusion began, although they became more frequent on older myotubes.

Degradation of the ^{125}I-Butx labeled AChR on C_2 myotubes showed complex kinetics that could not be described by a single exponential. In addition, the halftime for degradation increased from 8h on day two in fusion medium to 15h on day four. Such complex AChR degradation kinetics have also been reported with cultured primary myotubes (1). The degradation rate of clustered AChR was measured by autoradiography and found to be no different than the degradation rate of the total AChR population. Thus, the complex kinetics of C_2 AChR degradation can not be explained by the presence of clustered and non-clustered AChRs - a conclusion reinforced by the finding that the AChRs in L6, which never cluster, have a similarly complex pattern of degradation. In contrast, BC_3H-1 AChRs have an 8h degradation halftime (2) which we found is unchanged by prolonged culture.

The immunological properties of AChRs in extracts were determined by precipitating ^{125}I-Butx-AChR complexes with a myasthenic serum that distinguishes junctional from extra-junctional receptors (EJR). The AChRs in each cell line were immunologically indistinguishable from EJR of the animal from which the cell line was derived.

Thus, in the three cell lines examined, the properties of AChRs in C_2 most closely resemble those seen in embryonic myotubes. C_2 cells may, therefore, serve as useful models in which to study the mechanisms regulating receptor distribution.

115.1 Granule Cell Behavior in Dissociated Cultures of Weaver (wv) Mutant Cerebellum. M. Willinger,* D. M. Margolis* and R. L. Sidman, Depts. of Neuropathology, Harvard Med. School, and Neuroscience, Children's Hospital Medical Center, Boston, MA 02115

The behaviors of granule cell neurons in dissociated monolayer cultures of cerebellum from seven-day-old normal (+/+), heterozygous weaver (+/wv) and homozygous weaver (wv/wv) mice were examined by phase contrast time lapse cinematography. The mixed cell population was plated at 1.5 x 10^4 cells/mm^2 onto poly-L-lysine-coated glass surfaces. The cell cultures were photographed between 20 and 60 hours in vitro at a rate of 2 - 6 frames per minute. We observe a mutant gene dose-dependent effect on the behavior of granule cell neurons in vitro. Neurite elongation proceeds in a noncontinuous fashion in normal cells. Neurite retraction is rarely observed. Cell body and intranuclear migration are each unidirectional. Cell death was rare. The features that distinguish +/wv cells from +/+ cells are the following: partial neurite retraction, reversal of migrational direction and moderate cell death. The most striking features of wv/wv granule cell behavior are: frequent neurite initiation followed by complete retraction, cell body and intranuclear migration in more than one direction, and a high percentage of cell death. Homozygous weaver neurites rarely exceeded 10 - 15 μm, and are different in morphology from +/+ and +/wv neurites. The growth cones are phase-dark and thick; the neuritic shafts are constantly active, bearing membrane blebs and microspikes.

Quantitation of both the percentage of cells having neurites of a given length class and of the exact lengths of neurites in fixed cultures showed a mutant gene dose-dependent impairment of neurite growth over the first week in vitro (Willinger, Margolis and Sidman, J. Supramol. Struc., 1981 in press). Preliminary quantitative analyses of the time-lapse films show a mutant gene effect on rates of growth cone elongation. The average rates of neurite growth are 196 μm/day for +/+ neurons and 5 μm/day for wv/wv neurons. The mean maximum rates of growth cone elongation are 938 and 339 μm/day for +/+ and wv/wv neurons, respectively.

In conclusion, the weaver mutant gene affects neurite outgrowth by impairing neurite elongation and maintenance, rather than neurite initiation. The effect is gene dose-dependent and probably represents, at least in part, the in vivo weaver phenotype.

115.2 THE RELATIONSHIP OF MELANIN DISTRIBUTION TO CELLULAR DEGENERATION IN THE DEVELOPING MAMMALIAN EYE. A.C. Strongin and R.W. Guillery. Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637.

Melanin appears early in the development of the mammalian eye cup, long before it can perform any of its known adult functions. Studies on individuals with abnormally low amounts of melanin in the retinal pigment epithelium show a chiasmatic misrouting of some retinofugal fibers; because a variety of genes may produce such abnormalities by a variety of cellular mechanisms, it seems likely that melanin itself is involved in producing the pathway abnormality. The appearance of melanin correlates temporally with the closure of the optic fissure. Silver and Hughes (J. Morph., 140:159, 1973) have shown that extensive cellular degeneration occurs normally in the region of the optic fissure while it is in the process of closure; however, no pigment cells near this region show any signs of degeneration. Melanin does not even appear in the region of the fissure until closure and associated degenerative changes are complete. This "avoidance" of a region of cellular degeneration by pigment cells has led to this study of the distribution of melanin as it relates to zones of degeneration throughout the eye cup and stalk in fetal hamsters, mice, ferrets, and humans.

Although melanin is not associated with degenerative changes near the fissure, there is a region, where the eye cup joins the dorsal stalk, which contains melanin that is closely related to degenerative changes within the melanocytes. Here, pigment granules form dense clusters which are associated with basophilic areas of cytoplasm. These clusters are most prominent for a short period when axons are invading the ventral part of the eye stalk. Electron microscopic observations thus far indicate that these clusters are lysosomal in nature; acid phosphatase studies in progress should clarify this problem. Because of its specific localization within the developing eye cup and stalk, and its close temporal relationship to axonal outgrowth, the degradation of melanin may have a significant role in the organization of retinofugal pathways, especially in the ordering of the chiasmatic course of the fibers. The above results are consistently found in all four species studied. Slightly more pigment degeneration is seen in the ferret and human, which do have relatively larger uncrossed retinofugal components than the hamster or mouse.

115.3 IMMUNOCYTOCHEMICAL IDENTIFICATION OF MACROPHAGES IN THE CORPUS CALLOSUM OF THE NEONATAL RAT. K.L. Valentino and E.G. Jones Dept. of Anatomy and Neurobiology and McDonnell Center for the Study of Higher Brain Functions, Washington University School of Medicine, St. Louis, Missouri 63110.

Cells identified as macrophages on morphological grounds have been seen in the fetal and neonatal rat corpus callosum, but definitive proof of their character and their origins remain unclear. We wished to determine whether phagocytic cells that invade the corpus callosum during its formation in the fetal brain were true macrophages and, thus, of nonneural origin. An immunocytochemical study was carried out using a monoclonal antibody specific for macrophage surface polypeptides, MAC-1 (Springer et al., Eur. J. Immunol. 9:301, 1979).

Brains of neonatal rats were fixed by perfusion with 4% formaldehyde and .01% glutaraldehyde. The brains were then frozen in liquid nitrogen and sections cut with a cryostat. Primary antibodies and controls included MAC-1, thy-1, S-100, rat IgG and normal rabbit serum. Secondary antibodies were fluorescein conjugated goat anti-rat IgG or F $(ab')_2$ fragments.

Specific staining of macrophages in and around the corpus callosum was seen with MAC-1, but also with control rat IgG, and with the secondary antibody alone, when the secondary antibody was the whole anti-rat IgG. No other cells in the brain were labelled. This pattern of staining is indicative of Fc receptor binding, itself indirect evidence that the cells are macrophages. Fc receptor binding could be eliminated by using F $(ab')_2$ fragments as the secondary antibody. This treatment results in specific staining of the cells with MAC-1. Though the phagocytic callosal cells, like macrophages elsewhere, are autofluorescent, this can be reduced to the red end of the spectrum by a pre-treatment with Evans blue. Thus, cells with a surface marker specific to macrophages have been identified in the developing rat brain.

Stained macrophages were found in the same locations as described in normal electron microscopic studies: in the corpus callosum dorsal to the lateral ventricle, in the cavum septi pellucidi and where the corpus callosum pierces the ventricular zone of the hemisphere. Staining with thy-1 was negative, as was staining with S-100 at early ages. The callosal macrophages stained with S-100 in older animals in which astrocytes were also stained. The staining of macrophages with S-100 may indicate phagocytosis of glial elements during formation of the corpus callosum. Whether the macrophages play any active role in guiding the callosal axons across the midline and towards their targets is still unclear.

115.4 **INHIBITION OF NEURITE EXTENSION BY FLUORODEOXYURIDINE IS AGE-DEPENDENT, DOSE DEPENDENT AND REVERSIBLE.** Vincent Argiro* and Mary Johnson (SPON: R.P. Bunge). Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Fluorodeoxyuridine (FdU) is used as an anti-mitotic agent in tissue culture studies and in cancer chemotherapy in humans. Its effect on post-mitotic cells such as neurons has not been extensively studied. In our studies of the kinetics of neurite growth of autonomic neurons in culture, we initially used FdU to suppress non-neuronal cell proliferation, but it became apparent that the drug had an inhibitory effect on neurite extension.

Explants of superior cervical ganglion were taken from rats ranging in age from embryonic day 15 (E15) to postnatal day 279 (P279), cultured on a fibrous collagen substrate and fed a medium containing serum, embryo extract and NGF. When included, the standard dose of FdU was 10^{-5} molar. Neurite lengths were determined by tracing the circumference of the neurite halo at 5-8 invervals over several weeks. Average neurite lengths and linear regression growth rates were calculated with the aid of a computerized morphometry system.

Age Dependence: The standard dose of FdU was given throughout the culturing period. The inhibitory effect is greatest for adult explants and embryonic explants and least for perinatal explants. At two weeks in culture the mean neurite lengths relative to untreated cultures were: E15-66%, E21-77%, P2-74%, P16-72%, P279-36%. At one week in culture the growth rates relative to untreated cultures were: E15-52%, E21-65%, P2-62%, P16-66%, P279-45%.

Dose Dependence: FdU doses were 10^{-6}, $3x10^{-6}$, 10^{-5}, $3x10^{-5}$, and 10^{-4} molar. E21 explants were minimally effected at all doses and throughout the culturing period. E18 explants were most affected after two weeks in culture. Growth rates ranged between 88% of control for the smallest dose and 49% for the largest dose at 12 days in culture; the dose curve was flat at about 80% at 3.6 days. The adult (P43) explants were most severely affected in the first few days of culture. Growth rates relative to controls ranged from 79% to 14% at 3.6 days, and from 100% to 72% at 12 days.

Reversibility: Cultures were either maintained on the control medium, maintained on the medium containing 10^{-5} molar FdU, fed control medium for three days and then fed FdU-containing medium, or fed FdU-containing medium for three days follwed by control medium. For all ages tested, cultures taken off the drug increased their growth rate and those placed on the drug after three days showed a delayed inhibition of growth.

115.5 PREFERRED AXON PATHS IN THE WING OF DROSOPHILA. Marjorie A. Murray‡ Margrit Schubiger‡ and John Palka. Dept. of Zoology, Univ. Washington, Seattle, WA 98195

The axons of sensory neurons in the transparent wings of Drosophila melanogaster can be seen clearly with methylene blue or silver staining. They normally form bundles which travel through particular veins to reach the base of the wing. We have used this system to test hypotheses about factors which establish the specific axon paths seen in adult tissue.

One plausible hypothesis is based on the observation that epidermal cells in the anterior and posterior regions of the wing form two discrete, non-intermingling populations which meet at a straight boundary just anterior to the fourth longitudinal vein (L4). We have asked, do the mechanisms (thus far unknown) which segregate the epidermal cells into two compartments also prevent the growth of axons from one compartment into the other?

In wild type flies all sensory axons develop in the anterior compartment, so axonal behavior at the compartment boundary cannot be studied. Hairy wing mutants, however, carry supernumerary receptors in both compartments. Their axons are observed to converge on vein L3 of the anterior compartment. This is true both for axons originating from receptor cells in the posterior compartment and for axons from supernumerary anterior receptors. Thus, the compartment boundary has no obvious influence on the paths taken by adult axons, but vein L3 appears to have some special properties.

Why is vein L3 so attractive to growing axons? Perhaps it carries pioneer axons such as have been seen during early development in a variety of insect appendages. Nerve strands have been described in everted wing discs of Drosophila as early as 6-9 hours after pupariation, long before the differentiation of adult sensory neurons (Waddington, C.H., J. Genet., 41:75-139, 1940). With Nomarski optics we have seen distinctive cells at the tips of the wings of somewhat older pupae, and are looking with transmission electron microscopy to determine whether these are indeed pioneer neurons. Our electron micrographs of the strands described by Waddington in the younger pupae, however, show that they are composed primarily of tracheae, and correlated observations with Nomarski optics reveal that tracheae run only in veins which will later carry nerves. If pioneer axons do not guide sensory fibers in the developing wing, other structures such as tracheae may act as guiding substrates.

115.6 MULTIPLE PIONEER NEURONS ESTABLISH (IN VIVO AND IN EMBRYO CULTURE) MAJOR NERVE TRUNKS FOLLOWED PREFERENTIALLY BY IDENTIFIED NEURONS. H. Keshishian and D. Bentley. Neurobiology Group and Zoology Dept. University of California, Berkeley, Ca. 94720.

The role of pioneer neurons in establishing the numbers and routes of peripheral nerve branches was examined in the metathoracic leg of embryonic grasshoppers, using Lucifer yellow dye-fills, silver impregnations and cobalt back-fills. It was previously shown that the first pioneer neuron cell-pair to originate in the leg, cells PN1, establish a stereotyped axonal trajectory that serves as the substrate for the axonal fasciculation and development of nerve 5b1 (Keshishian '80, Dev. Biol. 80, 388). It is now shown that a second pair of pioneer neurons, cells PN2, recapitulate in the tarsal and tibial segments of the leg the ontogeny and stereotyped axonal projection seen for the PN1 cell-pair in the tibia and femur. The PN2 cell-pair project their axons in a stereotyped route across the tibia with the characteristic cross-over morphology seen with the PN1 axons in the femur. The PN2 axons join the PN1 axons at the proximal femur, and they collectively project into the central nervous system.

Utilizing double staining methods, the two pioneer neuron cell-pairs were found to serve as the guidance substrate for subsequently differentiated afferent and efferent axons. Lucifer yellow dye-filled pioneer neuron axons were found running within silver impregnated nerve trunks, with the axons serving as a nucleus for axonal fasciculation. Thus, nerve 5b1 arises through the initial axonal projection of cells PN1 and nerve 5b2 through the projections of the PN2 cell pair.

The guidance preferences of identifiable neuronal projections were examined. A group of tarsal sensory neurons, the TC cells, establish their initial projection along the segmental apodeme (tendon) until their axons contact the PN2 axons. At that point the TC axons show a preference for the pioneer neurons over the apodeme for their subsequent guidance. Similar behavior was observed for axons of the femoral chordotonal organ. Other neurons, such as the SR1 (a putative femoral stretch receptor), used the pioneer axons as the sole guidance substrate from the site of axonogenesis to the CNS.

The axonal projections to the femoral and tibial muscle groups were observed to grow peripherally along the PN-established nerve trunks to the borders of their target muscles, where they diverged to form novel projections. Thus, these efferent projections are not established by axons that adopt the shortest available routes across the limb-bud.

In embryos cultured in vitro from the 30% to 40% stages of development, the pioneer neurons differentiated and established a normal axon trajectory to the CNS.

115.7 THE GROWTH CONES OF TWO IDENTIFIED SIBLING NEURONS DIVERGE AT A PARTICULAR CHOICE POINT DURING GRASSHOPPER EMBRYOGENESIS. Jonathan A. Raper and Corey S. Goodman. Dept. of Biol. Sci., Stanford University, Stanford, CA 94305

We have been studying the development of two identified neurons,'G' and 'C', during grasshopper embryogenesis. These identified interneurons are siblings that arise from an identified precursor cell, neuroblast 7-4. The cell bodies of G and C assume a characteristic and highly accessible position before axonogenesis. In most egg clusters G's cell body is slightly anterior and lateral to C's on the dorsal surface.

G initiates axonal outgrowth a few hours before C. G's growth cone traverses the posterior commissure, a pathway pioneered by descendants of the same neuroblast that produce G and C. Upon reaching the lateral edge of the contralateral neuropil, G's growth cone elongates anteriorly upon an anterior-posterior running axonal pathway. C's growth cone follows G across the commissure and elongates posteriorly along the same axonal pathway.

This pathway upon which G and C diverge is formed by the axons of three neurons. One axon originates from a cell body which is ipsilateral to the pathway and in the same ganglion of origin as G and C. Its process runs posteriorly. The other two axons originate from two adjacent cell bodies contralateral to the pathway in the next posterior ganglion from that containing G and C. Their processes run anteriorly.

Correlating the relative times of arrival and elongation of these identified axons in the lateral pathway suggests a working hypothesis whereby (i) G's growth cone recognizes and follows the anterior running axons originating in the next posterior ganglion; and (ii) C's growth cone recognizes and follows the posterior running axon originating in the same ganglion. We plan to test this 'guide fiber' hypothesis by determining if G and C can make their appropriate choices in the absence of any one of these identified axonal processes.

115.8 A MONOCLONAL ANTIBODY WHICH STAINS PIONEER NEURONS AND EARLY AXONAL PATHWAYS IN GRASSHOPER EMBRYOS. S. Chang*, R. Ho*, J.A. Raper and C.S. Goodman. (SPON: D. Edgington). Dept. of Biol. Sci., Stanford University, Stanford, CA 94305.

During the embryonic development of the grasshopper nervous system, growth cones of neurons make specific and stereotyped choices; the interactions of these cells with their environment is undoubtedly important to their further development. In an effort to identify the molecules which are mediating such interactions, we have made monoclonal antibodies to the grasshopper nervous system. The antibodies were produced by injecting mice with adult nervous tissue and screening successful hybridomas on 40% grasshopper embryos. One of the antibodies produced in this manner, designated I-5, may be recognizing an antigen which is important during embryogenesis. Staining of the embryo by I-5 first appears on the central and peripheral pioneers. The first cells to establish a particular axonal pathway are called pioneer neurons; their growth cones take stereotyped routes while navigating on the basement membrane. Later developing cells use the pioneer pathways to navigate upon. The pioneer cell bodies stain with the I-5 antibody shortly after their final cell division; subsequently, their growth cones and axonal processes stain. With time the cell body staining declines whereas the processes remain darkly stained. The antibody shows striking specificity. Of the central pioneers, certain ones consistently stain darker than others. Furthermore, many later developing axons do not stain at all. The antibody also selectively stains certain non-neuronal tissue. For example, a thin muscle over each segmental ganglion stains with the antibody, although muscles in general do not.

We are now investigating the molecular nature of the antigen which I-5 recognizes, and using the antibody in embryo cultures to ascertain the functional importance of the antigen.

(supported by the McKnight Foundation and the American Cancer Society)

115.9 MONOCLONAL ANTIBODIES REVEAL THE DEVELOPMENT OF PERIPHERAL PIONEER NEURONS AND AXONAL PATHWAYS IN GRASSHOPPER EMBRYOS. R. Ho*, S. Chang*, and C.S. Goodman. Dept. of Biol.Sci., Stanford University, Stanford, CA 94305

In grasshopper embryos, Bate(1976) and Keshishian(1980) described pairs of cells in the periphery, called peripheral pioneer neurons, which establish the first peripheral axonal pathways in the antennae and limb buds. The growth cones of the pioneers take a stereotyped pathway along the basement membrane on the inside of the ectoderm. We have been making monoclonal antibodies to the grasshopper nervous system. One of the antibodies,designated I-5, and described in detail in another abstract (Chang et al 1981),stains the peripheral and central pioneer neurons. The advantage of the monoclonal antibody technique is that all of the pioneer cells throughout the embryo can be reproducibly and reliably stained in whole mount preparations using an HRP conjugated second antibody. Furthermore, their relationship to other peripheral cells and to the peripherally growing axons of central neurons can also be seen.

The cell bodies of the pioneer neurons first stain with the I-5 antibody just after their final cell division; the antibody stains their growth cones and axons throughout their development. We have described pairs of peripheral pioneer neurons throughout the head, thorax, and abdomen including the antennae, mouth parts, limb buds, and body wall.

In the antennae, two pairs of distal pioneers establish the two axonal pathways in the antennae itself, however, there is another pair of pioneers at the base which first establishes the pathway from the base of the antennae to the CNS. At the same time, growth cones from central cells extend distally making other pathways toward the base of the antennae. A similar sequence occurs in the limb buds, with pairs of pioneers at the base establishing connections with the CNS and the distal pioneers establishing the pathway in the limb bud. Growth cones from central cells also contribute to these pathways. Thus, the peripheral pathways in the appendages and between the appendages and the CNS are established by a series of peripheral pioneers and central growth cones.

Because it is so easy and reliable to stain all of the pioneers with the I-5 antibody, we now plan to manipulate the pioneers and their environment in embryo culture in order to understand the mechanisms by which they establish their stereotyped pathways.

115.10 LACK OF EFFECT OF NERVE GROWTH FACTOR (NGF) AND NGF-ANTIBODIES INJECTED INTO THE CYTOPLASM OF TARGET CELLS. R. Heumann* and H. Thoenen (SPON: F. Hefti). Max-Planck-Institute for Psychiatry, Department of Neurochemistry, D-8033 Martinsried, FRG.

Nerve growth factor is taken up by the terminals of its target neurons by a selective, saturable mechanism and subsequently is transported retrogradely, in membrane-confined compartments, to the perikaryon where it evokes its characteristic biological effects. Previous electron-microscopic studies (quantitative autoradiography and histochemical localization of NGF covalently coupled to horseradish peroxidase) provided no evidence that NGF leaves the membrane-confined compartments. However, it could not be excluded that very small, but physiologically significant, quantities of NGF reach the cytoplasm and subsequently also the cell nucleus. Therefore, we studied the effect of NGF or of NGF-antibodies introduced directly into the cytoplasm of target cells. Loaded guinea pig erythrocyte-ghosts were fused with pheochromocytoma cells (PC12) or with neurons isolated from embryonic chick dorsal root ganglia. Taking into account the multiplicity of ghost to cell fusion and the degradation of injected ^{125}I-NGF in the cytoplasm, the quantity of intact NGF present at the end of the observation period exceeded by several fold that accumulated in the cells by receptor-mediated endocytosis when ^{125}I-NGF (100 ng/ml) was added to the culture medium. NGF injected into the target cells by means of erythrocyte ghosts distributed equally throughout the cytoplasm and the nuclear chromatin. However, it did not evoke the characteristic effects of fiber outgrowth or maintenance of survival observed when NGF is added to the culture medium and acts via plasma membrane receptors. Conversely, NGF-antibodies injected into the cytoplasm did not prevent the effects of NGF mediated by membrane receptors. It is concluded that cytoskeletal elements or the chromatin of the nucleus are not direct physiological targets of NGF and that both fiber outgrowth and the maintenance of survival must be mediated by a second messenger mechanism subsequent to the interaction of NGF with membrane receptors.

115.11 A HEPARAN SULFATE PROTEOGLYCAN INDUCES RAPID NEURITE OUTGROWTH IN VITRO. A. D. Lander*, D. K. Fujii*, D. Gospodarowicz*, and L. F. Reichardt. Department of Physiology and Cancer Research Institute, Univ. of California, San Francisco, CA 94143.

The bovine corneal endothelial cell produces, in culture, a basement membrane-like extracellular matrix. When dissociated rat sympathetic ganglion cells were plated on this matrix, rapid and extensive neurite outgrowth was seen in less than 4 hours. Outgrowth occurred in the absence of nerve growth factor (NGF) and was unaffected by antiserum to NGF. Rat sensory and sympathetic neurons also displayed rapid neurite outgrowth when plated onto polylysine-coated dishes that had been preincubated with serum-free medium conditioned by corneal endothelial cells (CM_{SF}). This effect required direct contact of neurons with the treated surface; when only half of a dish was pretreated with CM_{SF}, only neurons on that half responded. A good response did not require the presence of serum in the culture medium.

The activity of CM_{SF} was destroyed by trypsin, by incubation at pH 1.6 or 12.7, and by heating to 80°C, but was stable to heating to 60°C, collagenase, DNase, and neuraminidase. When CM_{SF} was fractionated on Sepharose 6B, a single broad peak of activity was found just behind the void volume. On non-dissociative equilibrium cesium chloride gradients, CM_{SF} activity banded in the density range of 1.3-1.4. The profile of activity coincided with that of a major peak of ^{35}S found when CM_{SF} metabolically labelled with $Na_2[^{35}S]O_4$ was fractionated in this way.

A large molecular size, a density greater than protein, the presence of incorporated sulfate, and tight binding to polycations are characteristics of proteoglycans, macromolecules composed of protein to which sulfated glycosaminoglycan (GAG) chains have been added. It was found that the activity of CsCl-gradient-purified CM_{SF} could be abolished by crude heparinase, an enzyme that degrades heparan sulfate (HeS), the major GAG produced by the bovine corneal endothelial cell in vitro. Chondroitinase ABC, which degrades the other GAGs produced by this cell type, had no effect. However, neither HeS alone, nor any other purified GAG, had neurite outgrowth promoting activity. This, along with the results with trypsin and heparinase, suggests that the activity of the proteoglycan factor requires both its protein and GAG parts.

The observation that a HeS-containing proteoglycan can direct neurite outgrowth in vitro suggests that HeS proteoglycans, which are major constituents of neuronal and target tissues, may serve a related in vivo role.

Supported by USPHS grant GM07618, by NSF and MDA grants (to LFR) and by USPHS grant EY02186 (to DG).

115.12 CONDITIONING FACTOR(S) FOR NEURITE OUTGROWTH: MOLLUSCAN NEURONS IN CULTURE, Richard G. Wong*, Robert D. Hadley, Stanley B. Kater, Garry C. Hauser*, Elaine C. Martel*. Dept. of Zoology, Univ. of Iowa, Iowa City, IA 52242.

Previous work in our laboratory has shown that well characterized identified neurons of the buccal ganglia of the snail Helisoma are capable of neuronal plasticity often involving neurite outgrowth.[1-5] As an approach to the problem of mechanisms of initiation of neurite outgrowth and axonal elongation in this preparation we have developed in vitro culture procedures for studying outgrowth from isolated neurons.

Neurons from central ganglia were isolated by enzymatic and mechanical dissociation and cultured in vitro in modified Liebowitz L-15 medium. Isolated neurons maintained electrical excitability but remained spherical in defined medium throughout culture durations up to 2 weeks. Extensive neurite outgrowth from the isolated neurons occurs with co-cultured intact Helisoma brains (CC) or brain conditioned medium (CM). Growth in vitro (6-40 μm/hr at 23°C) occurs at the tips of neurites by means of growth cones which can exhibit rapid extensions and retractions of membrane. Differential morphologies were observed on collagen as compared to polylysine coated surfaces.

The brain-derived conditioning factor(s) (CF) appears to be conserved in related species (Biomphalaria and Lymnaea) and acts as a noncellular, soluble substance(s) that binds to specific substrates. Its action is not mimicked by NGF or fibronectin. From our studies on CF and its effects on both electrical excitability and neurite extension we conclude that CF acts as a substrate conditioning factor and affects primarily neurite outgrowth with no apparent effect on the maintenance of electrical excitability.

116.1 THE DISTRIBUTION OF NUTRIENTS BETWEEN FETAL BRAIN AND BODY DURING RAT DEVELOPMENT. Stephen Zamenhof and Edith van Marthens*. Mental Retardation Research Center and Brain Research Institute, UCLA School of Medicine, Los Angeles, California 90024.

During prenatal development, the nutrients are distributed between brain and body according to a schedule influenced by many factors; this distribution determines the extent of prenatal brain growth. As indices of the final outcome may serve fetal and neonatal ratios: brain weight/body weight (R_W), brain DNA/body DNA (R_{DNA}) or brain protein/body protein (R_{prot}).

We find that R_W changes from $(7.29\pm1.06)\times10^{-2}$ (16 day fetus) to $(2.76\pm0.19)\times10^{-2}$ (newborns); the dependence on age disappears towards birth. Within one age, R_W shows considerable variability (std. dev. up to 14% of the mean), not only among individual litters, but also within litters. These variations are not due to variable water content: in 18 day fetuses, water contents were brain, 87.3±0.5%, and body, 89.5±0.2%. Thus, R_W ratios of wet weights and dry weights are similar, and the variations in water contents are negligible. For 18 day fetuses R_W = (4.43±0.63)$\times10^{-2}$ (wet wts.) or $(5.31\pm0.76)\times10^{-2}$ (dry wts.), R_{DNA} (dry wts.) $=(7.52\pm1.28)\times10^{-2}$ and R_{prot} (dry wts.) $=(4.76\pm1.10)\times10^{-2}$; thus, R_{DNA} and R_{prot} show even greater variability than R_W. As expected, R_{prot} was similar to R_W.

An extensive study of 2089 normal newborns (from 231 mothers) revealed that 157 animals, or 7.5% (from 63 mothers), had R_W values significantly higher than the mean for the population (more than 2 std. dev. above the mean). Of these, 35.0% had normal body weight (101.3% of the mean) but significantly higher brain weight, as well as higher brain DNA (cell number) and brain protein. Thus, they do not represent previously studied cases of general (brain and body) overdevelopment (Zamenhof et al., Life Sci. 18, 1391 [1976]); rather, they represent cases of favorable brain versus body growth, i.e., distribution of nutrients between brain and body that is more favorable for the brain. In 3% of cases, such favorable distribution affected the entire litters; the causes probably involved maternal factors. In 49% of cases, only one or a few individuals within a litter had such favorable distribution; in such cases individual fetal factors were more likely to be the cause. For such animals, this favorable distribution occurred during prenatal neuron proliferation; depending when it occurs, it would favor different individual cortical layers whose "neuron birth" happens to occur at that time, and would result in differences in neuron distribution among individual animals. (Supported by NIH grants HD-05615 and AG-00162).

116.2 EFFECTS OF EARLY TRYPTOPHAN OR HISTIDINE EXPOSURE ON OFFSPRING SENSORIMOTOR BEHAVIOR IN RATS, P.K. Lundberg*, V.F. Nease*, H. Zenick, and D. Price*, (SPON: A. Michaelson), 1st. Author-Dept. of Psychology, Washington Univ., St. Louis, MO 63130, Others - Dept. of Environmental Health, Univ. of Cincinnati, Cincinnati, Ohio 45220.

Although it is recognized that prenatal exposure to certain drugs can result in behavioral teratogenesis (Vorhees, Brunner & Butcher, Science, 1979, 205:1220-1224), the effects of pre - and post-natal exposure to slight excesses of dietary amino acids are not well-documented. Of particular interest are the behavioral effects of tryptophan (TRY) and histidine (HIS). Since the enzymes tryptophan hydroxylase and histidine decarboxylase are not saturated in vivo (Wurtman & Fernstrom, Am. J. of Clin. Nutr., 1975, 28:638; Schwartz, Lampart & Rose, J. Neurochem., 1972, 19:801-810), exposure of dams to dietary excesses of TRY or HIS may also expose the fetuses to increased serotonin (5-HT) or histamine. Thus the aim of this study was to compare the effects of a maternal control (CON) diet and diets supplemented with l-tryptophan (0.5% & 1.0%) or l-histidine (0.6% & 1.3%) on offspring sensorimotor behavior.

Dams were randomly assigned to diets 2 weeks prior to mating. On post-natal day 3 (PN3) 4 pups per litter were randomly chosen for behavioral testing. The test battery included surface righting response (PN3-7), negative geotaxis (NG;PN6-12), pivoting activity (PA;PN7,9,11), swimming development (SD;PN6-20), startle response (PN10-13), day of eye opening, and open field activity (PN30,60). Other measures included body weights (PN 1, 7, 14, 21), brain weights and brain TRY, 5-HT and 5-hydroxyindoleacetic (5-HIAA) levels (PN 1, 21).

Offspring of the TRY dams showed significantly reduced PA and significant impairment on the NG and SD tasks. TYR offspring were less emotional than controls during PN30 open field testing and significantly more active after amphetamine (1.5 mg/kg) administration during PN60 testing. TRY brain weights were smaller than CON on PN1 but not on PN21. TRY offspring weighed less on PN7, 14 and 21 and their 5-HIAA levels were significantly elevated (PN21). HIS offspring showed superior NG performance and delayed SD. They also exhibited less emotionality during PN30 open field testing. HIS brain weights were smaller than CON on PN21 only while body weights were smaller on PN 7, 14, and 21.

116.3 BRAIN NEUROTRANSMITTER ALTERATION AFTER INTRAUTERINE EXPOSURE TO ETHANOL. W.J. Shoemaker, G. Baetge*, R. Azad*, V. Sapin*, and F.E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA

Neuropeptide and catecholamine neurotransmitter levels were determined in newborn rat pups that had been exposed during gestation to ethanol, protein undernutrition or both. Ethanol-containing liquid diets formulated to produce normal growth rates and birth weight of offspring when fed to pregnant rats are compared to liquid diets that are nutritionally inadequate in order to determine the roles of ethanol (ETOH) and undernutrition on brain neurotransmitters and development. By varying the protein concentration of the diets, we have produced newborn rat pups that have been exposed to one of the following conditions: alcohol plus undernutrition; alcohol with adequate nutrition; undernutrition alone; and control diet alone. All rats received such diets on gestational days 7-21. Newborn brains are dissected into hindbrain, midbrain and telencephalon for radioimmunoassay of β-endorphin and enkephalins. Catecholamines are assayed by HPLC using electrochemical detection. β-endorphin levels (pg/mg protein) in hindbrain and midbrain are consistently and significantly increased in the offspring of alcohol exposed mothers receiving an inadequate diet that contains 5% ethanol (approximate dose = 12 g/kg/day) (midbrain: ETOH-poor diet = 693; ETOH-good diet = 400; pair-fed control = 209; adequate-diet control = 315; $p < .001$, ANOVA). Similar results were obtained for hindbrain: the magnitude of the increase in β-endorphin levels over controls in both brain regions is proportional to the peak value in blood ETOH of the mothers. There were no differences in telencephalic β-endorphin in any group tested. Brain enkephalins were not statistically different in any brain region. Brain norepinephrine, on the other hand, was increased in the telencephalon of ETOH exposed newborns. Telencephalic dopamine was unchanged. These results will be discussed with reference to the anatomical alterations caused by in utero ethanol. (NIAAA 03504).

116.4 MICE IN UTERO WHILE MOTHER IS LACTATING SUFFER HIGHER FREQUENCY OF DEFECTIVE CORPUS CALLOSUM. D. Wahlsten. Dept. of Psychology, Univ. of Waterloo, Waterloo, Ontario, Canada N2L 3G1

Many mice of the BALB/c inbred strain suffer defects of the corpus callosum(CC) ranging from reduced size of the structure to total absence of trans-cortical fibres. However, the frequency of CC defect is much less among mice bred at Waterloo than those bred commercially. Commercial breeders usually leave the parents together so that the female gets pregnant during post partum estrus and delivers another litter soon after the first is weaned, but at Waterloo parents are separated shortly before parturition.

A controlled study was done of this phenomenon with BALB/cCF mice from Carworth Farms maintained as eight separate lines at Waterloo. In the ISOLATE condition males were separated from females before parturition, whereas for their littermates in the STAY condition males remained with females and sired litters in rapid succession. After breeding was completed over a period of three generations, each of 49 STAY litters which survived to maturity was matched with an ISOLATE litter of the same line and generation, and, where possible, the same birth order, season of birth and litter size. Cross-sectional area and length of CC at the mid-sagittal section were measured on brains coded to conceal their group and line identities. A defective CC was defined on the basis of a previous study as one with area less than .85mm^2 and length less than 3.0mm.

The table shows numbers of mice(n), numbers with defective CC(#D) and percent defective CC(%D) in the various groups along with one-tailed tests of significance. Frequencies in the total sample were weighted to give equal n's for the two groups in each generation.

Generation:	1		2		3		Total	
	#D/n	%D	#D/n	%D	#D/n	%D	#D/n	%D
STAY	18/76	23.7%	21/59	35.6%	16/99	16.2%	54/230	23.5%
ISOL.	8/72	11.1%	6/59	10.2%	10/142	7.0%	21/230	9.1%
z	1.769		3.068		2.025		4.039	
p	.0384		.0011		.0214		.00003	

Not only was the frequency higher but the degree of defect was also more severe in the STAY condition, where 9 of 54 mice with CC defect had total absence of transcortical fibres compared to 2 of 24 in the ISOLATE condition. Because CC fibres usually traverse from one hemisphere to the other beginning about 17 days after conception in BALB/cCF mice, the elevated frequency of severe defects of CC in the STAY condition must result from processes acting prenatally during lactation.

116.5 ACTIVITY OF THE ENZYMES DOPAMINE-beta-HYDROXYLASE AND PHENETHYLAMINE-N-METHYLTRANSFERASE IN DISCRETE BRAIN REGIONS OF THE RAT FOLLOWING ALUMINUM INGESTION. G.L. Wenk and K.L. Stemmer*. Institute of Environmental Health, University of Cincinnati, Cincinnati, OH 45267.

We have recently reported changes in Aluminum (Al) distribution within the brain following Al ingestion (Wenk and Stemmer, J. Env. Path. Tox., In Press) and alterations in catecholamine (CA) levels in various brain regions of Al-fed rats (Wenk and Stemmer, J. Neurotoxicol., Vol 2(2), 1981). These changes relate very highly to the dietary intake of the essential trace metals zinc (Zn) and copper (Cu). Al has also been shown to inhibit various enzyme systems (Trapp, J. Neurotoxicol., 1:89, 1980). We report an investigation of whether Al may be influencing endogenous CA levels by altering enzyme activities in the brain. The enzymes DBH and PNMT were investigated in the brains of rats fed diets suboptimal in Cu or Zn with and without Al added (0.1% wt/wt. diet). Thirty rats were maintained in metal-free conditions for 120 days. To adequately control for various metals in the diet, the rats were fed a purified synthetic diet (Teklad Test Diets, Madison, WI). The rats were sacrificed and the frontal cortex, hippocampus, and cerebellum were insolated. DBH was assayed according to the method of Davis and Kissinger (J. Chromatogr.,2:663, 1979); PNMT was assayed according to the method of Borchardt et al.(Anal. Biochem. 82:149, 1977).

An HPLC unit with an electrochemical detector was used to quantitate the CA products. The actitivities of both enzymes in the cortex and hippocampus were decreased in rats fed diets suboptimal in Cu with or without Al and suboptimal Zn without Al. The addition of Al to the diet of suboptimal Zn-fed rats elevated the activity of both DBH and PNMT in the cortex and hippocampus.

116.6 PROTEIN MALNUTRITION IN RATS - EFFECTS ON THE NUCLEUS RAPHE DORSALIS: A MORPHOMETRIC GOLGI STUDY. T. Kemper*, L. Cintra, S. Diaz-Cintra* and P. J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, Mass. 01545.

Using morphometric Golgi techniques, we previously characterized three cell types in the nucleus raphe dorsalis, i.e., multipolar, ovoid and fusiform (Brain Res. 207: 1-16, 1981). In the present experiments we quantitatively examined the effects of a low (8%) protein diet, initiated prenatally, on various cell parameters in these three cell types in rats at 30, 90 and 220 days of age. The oval, fusiform and multipolar cells of normal diet (25% protein) animals all showed significant increases in synaptic spines on primary and secondary dendrites between 30 and 90 days of age. Between 90 and 220 days of age there was a significant decrease in dendritic spines on primary dendrites in the fusiform and multipolar cells and a significant decrease of these spines on secondary dendrites of ovoid cells. Thus, all three cell types showed a decrease in total dendritic spines with normal aging to 220 days. By measuring number of dendrites, length of dendrites and spine density we calculated an index of synaptic input for each cell type in order to establish degrees of synaptic contact for each cell and determine how this is altered by low protein diets. In the protein deprived animals there were minimal changes in synaptic spine densities on primary and secondary dendrites between 30 and 90 days and 90 and 220 days in the fusiform and ovoid cells. The one exception was in the primary dendrites on the ovoid cells which showed a significant increase in spine density between 90 and 220 days of age. The multipolar cells, however, showed a significant increase in dendritic spines between 30 and 90 and between 90 and 220 days of age. When the three cell types in each diet group were compared at each age the multipolar cells in the 8% protein diet rats were found to be the only cells showing increased synaptic input on primary dendrites at 30 days of age and on secondary dendrites at all three ages. With the single exception of the secondary dendrites on fusiform cells at 90 days of age all other comparisons showed either no change or a decreased synaptic spine input in the 8% diet rats as compared to controls. These data indicate that the multipolar cells, which are thought to be the serotonin-containing cells of the raphe, show a response to protein deficiencies different from that of non-serotonin cells (ovoid and fusiform cells), i.e., show increased synaptic input with age in the face of malnutrition and do not lose spines as do the ovoid and fusiform cells. This appears to be in conformity with our studies in which we showed highly significant increases in serotonin in the brain of protein malnourished rats dating from birth. (Supported by grant #06364, NICHHD).

117.1 TWO MUTATIONS IN DROSOPHILA DIFFERENTIALLY AFFECT THE SYNTHESIS OF OCTOPAMINE, DOPAMINE AND SEROTONIN BY ALTERING THE ACTIVITIES OF TWO DIFFERENT AMINO ACID DECARBOXYLASES. Margaret S. Livingstone* (Spon: J.A. Paton) Dept. Biology, Princeton Univ., Princeton, NJ08540

The monoamines octopamine, dopamine and serotonin have been detected in nervous tissue from many insects. Intact Drosophila melanogaster brains, with cuticle removed, can be incubated in radioactive neurotransmitter precursors and analyzed by electrophoresis. When incubated in tritiated tyrosine the brains synthesized and accumulated labeled dopamine, octopamine and tyramine. When incubated in tritiated tryptophan they accumulated labeled serotonin.

Mutations in the Ddc locus, identified by Wright et al. (1976) as the structural gene for the enzyme dopa decarboxylase, decreased the synthesis by brains of both dopamine (see also Wright, 1977) and serotonin but did not affect the synthesis of octopamine or tyramine. Brains from per° flies, on the other hand, accumulated 25% as much octopamine and tyramine as wild type flies, but their synthesis of dopamine and serotonin was normal. The per° mutant, isolated by Konopka & Benzer (1971), has abnormal (arrhythmic) circadian eclosion and activity rhythms, abnormal fluctuations in the male's courtship song (Kyriacou & Hall, 1980) and an abnormally irregular heartbeat (Aceves-Piña, unpublished).

The biochemical results suggest that there are two different aromatic amino acid decarboxylases in drosophila brains: one that decarboxylates ℓ-dopa and 5-hydroxytryptophan and another that decarboxylates tyrosine. Measurements of tyrosine, ℓ-dopa and 5-hydroxytryptophan decarboxylating activity in brain homogenates from the different strains confirmed this suggestion and indicated that the decreased octopamine synthesis in per° brains is due to a reduction in tyrosine decarboxylase activity. Tyramine ß-hydroxylase activity was normal in per° brains.

The per locus is probably not the structural gene for the enzyme tyrosine decarboxylase because flies with deletions of the per locus had some enzyme activity and because per°/+ heterozygotes had normal activity. The per° mutation may affect some property of octopaminergic neurosecretory cells. Konopka (1980) found that the mutation affects the morphology of a group of neurosecretory cells in the brain. The pericardial cells along the heart were also morphologically abnormal in per° flies (and may be responsible for the irregularity of the heartbeat). These cells stained with neutral red and fluoresced yellow with glyoxylic acid, suggesting that they may be octopaminergic. Isolated hearts with the pericardial cells attached accumulated tritiated octopamine when incubated with labeled tyrosine, and octopamine synthesis was reduced in per° hearts. Supported by NIH grants GM25578 (to W.G. Quinn) and F32NS06393.

117.2 A MUTATION IN DROSOPHILA THAT REDUCES DOPAMINE AND SEROTONIN SYNTHESIS ABOLISHES ASSOCIATIVE LEARNING. Bruce L. Tempel* and Margaret S. Livingstone* (SPON: R. Cholewiak). Biology Dept., Princeton University, Princeton NJ 08544.

Monoamine neurotransmitters may be involved in various aspects of vertebrate learning, attentiveness, and reinforcement. (For example, see R.A. Wise.) Here we report that a mutation blocking synthesis of dopamine (DA) and serotonin (5-HT) in Drosophila blocks associative learning but does not affect other forms of behavior.

Using a deletion, Df130, and a temperature sensitive allele of the dopa-decarboxylase gene, Ddc^{tsl} (T.R.F. Wright), known to decrease the levels of DA and 5-HT synthesis (M.S.L., previous abstract), we have bred a number of fly stocks with different genotypes at the Ddc locus. Each of these mutant stocks is raised at a permissive temperature, 21°. We obtain the severely affected $Ddc^{tsl}/Df130$ (29°) mutants by raising them at 21° until the adults have completed cuticle hardening, then shifting them to a restrictive temperature, 29°, at which they survive and appear behaviorally normal for several weeks.

To assay dopa-decarboxylase activity, we dissect out brains of 3 day old flies and incubate them for 30 min with ^{3}H-L-dopa, the precursor of DA. The product, ^{3}H-DA, is isolated by high-voltage paper electrophoresis and measured by liquid scintillation counting. DA synthetic activity of the mutants ranges in the following order from 50% to < 1% of the activity in co-shifted, wild-type C-S control flies:

$$\text{wild-type (30 fmoles/min/brain)} > \frac{Df130}{C\text{-}S} > \frac{Ddc^{tsl}}{C\text{-}S} > \frac{Ddc^{tsl}}{Df130}\ (21^\circ) > \frac{Ddc^{tsl}}{Ddc^{tsl}} > \frac{Ddc^{tsl}}{Df130}\ (29^\circ)\ (< 1 \text{ fmole/min/brain}).$$

Three to five day old, 29° Ddc/Df mutants do not demonstrate associative learning in either a negatively reinforced shock avoidance paradigm (learning index, $\bar{\Lambda}$=0.00±0.02) or in a positively reinforced sucrose reward paradigm ($\bar{\Lambda}$= -0.02±0.04). In contrast, co-shifted, wild-type controls learn normally ($\bar{\Lambda}\ominus$ = 0.32±0.05; $\bar{\Lambda}\oplus$ = 0.22±0.06). The learning deficit in the Ddc/Df flies cannot be explained by general behavioral debility because the phototactic, geotactic and odor discrimination abilities of the mutant are similar to controls. In our other Ddc fly stocks, learning ability closely parallels dopa-decarboxylase enzyme activity levels.

Supported by NIH GM25578 to W.G. Quinn; MSL is an NIH Post-doctoral Fellow; BLT is an NSF Pre-doctoral Fellow.

117.3 VISUAL ORIENTATION OF FLIES AFTER LASER-BEAM ELIMINATION OF SPECIFIC INTERNEURONS, G. Geiger* and D.R. Nässel* (SPON: H. Anderson). European Molecular Biology Lab., 6900 Heidelberg, F.R.G.

To study the role of a specific configuration of nerve cells in information processing in the fly, we selectively eliminated neurons in the larva and then studied the adult animal's visual orientation behaviour. In flies the innermost neuropile region of the optic lobe, the lobula complex, is divided into two parts: an anterior lobula and a posterior lobula plate. In the lobula plate 12 different classes of large neurons have been identified anatomically and electrophysiologically that are directionally motion sensitive. Of these, 3 cells (H-cells) respond to horizontal and 8-11 cells (V-cells) to vertical motion (K. Hausen, z. Naturforsch. 31c:629 1976; H. Eckert and L. Bishop, J. Comp. Physiol. 126:57 1978). The H-cells are believed to be involved in the optomotor turning response and visual orientation towards objects, whereas the V-cells are considered to be important in thrust lift and landing responses. We were able to eliminate reproducibly the large H- and V-cells in one brain hemisphere by making micro laser-beam ablations of their precursors in the 2nd instar larva of Musca domestica. To achieve this, the ablation parameters were progressively tuned by correlating them with the resulting anatomical defects in the optic lobe observed in serial sections stained with reduced silver. The visual orientation of the experimental flies were tested in the following way: a. a flying fly was tethered to a torque-thrust transducer and its torque and thrust response to a vertical stripe moving horizontally clockwise and counterclockwise around the fly were measured. b. the fly's ability to visually fixate a vertical stripe was recorded. The torque and thrust responses were not significantly different between the ablated and normal sides nor between experimental and control flies. However, the response in the ablated side was slightly more noisy. The flies' visual fixation was also normal but more noisy. Following the behaviour tests the lack of H- and V-cells was determined histologically. From our results we conclude that the H- and V-cells are not crucial in information processing of visual orientation towards single objects but are mainly concerned with background motion detection whereas single object motion information is processed elsewhere.

117.4 ROLE OF IDENTIFIABLE PROPRIOCEPTORS IN THE FEEDING MOTOR PROGRAM OF APLYSIA. B. Jahan-Parwar, Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545

Each buccal ganglion of Aplysia contains two identifiable coupled neurons, B4 and B5 (Gardner, J. Neurophysiol., 1977). Other workers have suggested that B4 and B5 are motor neurons or interneurons involved in mediating feeding behavior. Several lines of evidence from my laboratory suggest, however, that B4 and B5 are centrally located somata of the proprioceptors for two ipsilateral buccal nuscles: Both B4 and B5 have their axons in the ventral buccal nerve which innervates these muscles. This was demonstrated by both electrophysiological and morphological (dye filling) criteria; moderate stretch (<4g) applied to the target muscles resulted in a burst of action potential in B4 and B5 with their extracellularly recorded axonal spikes preceding their intracellularly recorded somatic spikes. After blocking synaptic transmission in the CNS the responses of B4, B5 to muscle stretch persisted, but the responses of simultaneously monitored motor neurons for the target muscle did not. In the same preparation, driving a motor neuron by intracellular current injection caused contraction of the target muscle, but driving B4 and B5 failed to do so. These data clearly establish the B4 and B5 as the proprioceptors for these buccal muscles. We have begun to investigate the role of B4 and B5 in the feeding motor program. Recordings were made simultaneously from all buccal nerves in both intact and more simplified preparations. In intact preparations, stimulation of the chemoreceptors with food often produced a highly consistent cyclic pattern of burst activity in the buccal nerves. These patterns of bursting unit discharges were highly stereotyped both within a given nerve and across all buccal nerves. For example, 11 discrete bursts could be distinguished across four nerves which innervate the buccal mass proper. The durations and phase relations of these bursts appeared to remain constant from cycle to cycle and from preparation to preparation. This cyclic across-nerve pattern of activity was always correlated with rhythmic muscle contractions in the buccal mass and thus is likely to represent a part of the feeding motor program. Removal of the buccal mass had no significant effect on most parameters of the motor program, suggesting that it was generated centrally. Using the individual components (bursts) in the central motor program (CMP) as a guide, we have identified a number of neurons in the buccal ganglia which contribute to the CMP. Among these were the previously identified B4 and B5. These were always active during the CMP and contributed to a particular burst in the program. Removal of the buccal mass did not have any significant effect on the B4,B5 discharges during the CMP. Both B4 and B5 receive rhythmic synaptic input from the oscillator system (unpublished observation) and are known to have extensive synaptic interactions with putative sensory and motor neurons. These data and the fact that they can contribute to the CMP suggest that they play an important role in the generation and maintenance of the feeding motor program. This would raise a serious question regarding the present "dogma" on the role of the proprioceptors in the CMP generation in general. (Supported by grant NS 14388)

117.5 PRE-SYNAPTIC INHIBITORY PATHWAYS TO PARACEREBRAL FEEDING COMMAND NEURONS IN PLEUROBRANCHAEA CALIFORNICA, J. A. London and R. Gillette. Dept. of Physiol. & Biophys. Univ. of IL, Urbana, IL 61801.

Food avoidance conditioning in Pleurobranchaea is paralleled by synaptic inhibition of feeding command neurons, the paracerebral neurons, PCNs, in response to food stimuli (Davis and Gillette, Science, 199: 801, 1978). Similar inhibition of the PCNs in response to food has also been observed in naive but satiated animals. Preliminary to investigating the role of these neurons in the mechanisms of food avoidance learning, we are characterizing the circuitry and behavioral context of these neurons in the isolated CNS, the semi-intact (Head, buccal mass, esophagus and CNS) and whole-animal preparations of naive specimens. We have identified neurons which polysynaptically drive IPSPs on the PCNs and have found inhibitory neurons directly presynaptic to the PCNs.

PCN inhibitors, PIs, are a group of cells of unknown number, located on the dorsal surface of the brain, which mediate apparent monosynaptic, short duration IPSPs on the PCNs (n=2). The PI excitor cells, PIEs, also located on the dorsal surface of the brain are found in two bilateral groups, each group composed of at least two electrically coupled neurons. Stimulation of a PIE results in the occurrence of long latency, heterogeneous amplitude IPSPs on the PCNs (n=15). In one experiment, stimulation of a PIE resulted in a slow depolarization on the PI; negative feedback from the PI to the PIE was manifested as apparently monosynaptic IPSPs. The PIEs also appear to make a potent excitatory monosynaptic connection with the MCG previously implicated (Gillette and Davis, J. Comp. Physiol., 116: 129, 1977) in the feeding rhythm (n=5). During cyclic motor activity the PIEs are co-active with bursts of retractor motoneuron activity, in antiphase with PCN activity and in phase with MCG activity.

In 3 whole-animal preparations and 10 semi-intact preparations the PIEs were excited by compound EPSPs in response to food stimuli applied to the oral veil. This application also caused an increase in IPSP activity on the PCNs, consistent with excitation of the PIEs. The MCG was excited by the application of food. An aversive stimulus (10% EtOH) caused prolonged hyperpolarization of the PIEs (n=5 animals). These results are consistent with the role of the PIEs as cyclically active elements of the feeding network and suggests their potential role in the tonic inhibition of the PCNs in food avoidance conditioned animals. Supported by NSF-BNS-79-18329 to R.G.

117.6 CYCLIC ADENOSINE 3',5'-MONOPHOSPHATE PHOSPHODIESTERASE (cAMP-PDE) AND ITS ROLE IN LEARNING IN DROSOPHILA. S. L. Shotwell* (SPON: M. Kennedy). Div. of Biology, California Institute of Technology, Pasadena, CA 91125.

Drosophila can learn in several associative conditioning paradigms. Flies carrying the mutation dunce (dnc) perform poorly in one such task (Dudai et al., PNAS 73:1684, 1976). dnc mutants are deficient in activity for one of the two cAMP-PDEs present in normal flies, PDE II, and have normal activity for the other, PDE I. dnc mutants show elevated levels of cAMP (Byers et al., Nature, 289:79, 1981). The experiments described below indicate that the normal dnc gene (dnc^+) codes for PDE II itself, rather than a regulator that affects PDE II and possibly other activities.

In Drosophila, the amount of gene product, as a rule, is proportional to the number of copies of the gene present. Flies with carefully controlled genetic backgrounds were assayed using a micro-assay technique developed to allow separate measurement of PDE I and PDE II when both are present in a mixture. Homogenates of flies with gene arrangements providing the equivalent of 0, 0.5, 1.0 and 1.5 times the normal dose of dnc^+ had, respectively, 0.0, 0.6, 1.0 and 1.6 times the PDE II specific activity of normal flies. In contrast, PDE I activity was constant. This close correlation between PDE II activity and amount of the dnc^+ gene suggests strongly that this gene codes for PDE II.

To test directly for a modulator of PDE II activity, mixtures were made of homogenates of normal flies with those of flies carrying a small deficiency for the dnc region ($Df(1)N^{77\,1}/w^+y$). Mixtures having 25, 50 and 75% normal homogenate contained 26, 52 and 75% of the normal PDE II activity. Thus the normal homogenate does not activate the deficiency homogenate, nor does the latter inhibit normal PDE II activity.

Two other experiments support the suggested role for PDE II in learning. 1) PDE I and PDE II activities were determined in homogenates of various normal fly tissues. All contained both enzymes, but in different ratios. PDE II specific activity was highest in the nervous system. 2) Larvae carrying a mutant allele dnc^1 fail the larval learning paradigm of Aceves-Piña and Quinn (Science, 206:93, 1979). dnc^1 larvae were assayed, and had similarly reduced PDE II activity as dnc^1 adults.

These data do not directly prove that dnc^+ is the structural gene for PDE II. It could encode a stoichiometrically-required activator subunit. Alternatively, dnc^+ may regulate transcription or translation affecting the final level of PDE II. However, such regulation would seem unlikely to yield the linear relationship demonstrated above between PDE II activity and dose of dnc^+. The data strongly suggest that the normal dnc gene encodes PDE II, indicating that this enzyme plays a role in learning, presumably by controlling levels of cAMP. (Supported by NIH grant 07616, and NSF grant PCM-7911771 to S. Benzer.)

117.7 NEUROPHYSIOLOGICAL CORRELATES OF CONDITIONING IN IDENTIFIED PUTATIVE MOTOR NEURONS IN HERMISSENDA. T. Crow, Dept. of Physiology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

The temporal association of light and a gravitational stimulus, rotation, produces a long-term modification of photopositive behavior of the Pacific nudibranch Hermissenda crassicornis (Crow and Alkon, 1978). The behavioral modification consists of a significant increase in the animals latency to locomote in response to light (Crow and Offenbach, 1979). Cellular neurophysiological correlates of this conditioning have been identified in type B photoreceptors following training (Crow and Alkon, 1980). In this report neuronal correlates of the conditioning procedure are examined in identified presumptive pedal motor neurons.

As an initial step in the cellular analysis of conditioning in the motor system of Hermissenda, intracellular recordings were made from newly identified pedal cells P5 and P6 in the isolated circumesophageal nervous system following training. Intracellular iontophoresis of HRP into P5 and P6 indicated that the presumptive motor neurons had peripheral axons in pedal nerves. Impulse frequency and cyclic burst activity of cells P5 and P6 is altered by illumination of the eyes. The two identified cells in the pedal ganglion probably receive indirect synaptic input from the photoreceptors. The change in neuronal activity is mediated by the visual system and not by extraocular sources. Intracellular recordings from P5 and P6 in preparations where the optic nerves were cut before entry into the cerebropleural ganglion did not result in significant changes in pedal cell activity during illumination. Simultaneous intracellular recordings from P5 and P6 showed no synaptic interactions, but they do receive synaptic input from at least one common source (putative interneuron I).

Animals (N=10) receiving paired presentations of light and rotation showed significant increases in the latency to initiate locomotion in response to illumination as compared with controls (N=10) that received independent random presentations of light and rotation ($p<.025$). Paired animals (N=9) showed a significant decrease in spike frequency and bursting activity in cells P5 and P6 in response to light ($p<.01$) as compared with the random controls (N=7), which actually responded to illumination with an increase in spike frequency and cyclic bursting activity. The neural correlates may reflect changes intrinsic to the motoneurons or alternatively, modifications in cells presynaptic to P5 and P6 such as the photoreceptors. The pre- or postsynaptic nature of the light evoked changes in motoneuron activity following behavioral training is currently being investigated.

117.8 ASSOCIATIVE NEURAL AND BEHAVIORAL CHANGE IN HERMISSENDA: CONSEQUENCES OF NERVOUS SYSTEM ORIENTATION FOR LIGHT- AND PAIRING-SPECIFICITY. Joseph Farley*, Dept. Psychology, Princeton Univ., Princeton, NJ 08544 and Daniel L. Alkon, NINCDS, NIH, MBL, Woods Hole, MA 02543.

Locomotor behavior in the nudibranch Hermissenda, following three training sessions of exposure to paired light (30 sec duration, intensity 4.6×10^3 ergs. cm^{-2}. sec^{-1}) and rotation (94 rpm; 2.24 g) presentations, was characterized by light- and pairing-specific changes whose magnitude depended upon the gravitational orientation of the animals during testing. This associative diminished phototaxic behavior reflected both an increase in the latency for initiation of movement, as well as a decrease in the velocity of locomotion.

Tests of animals' locomotion while oriented vertically rather than horizontally, revealed: 1) a general decrease in locomotor latencies both before and after training, 2) greater light-specificity of the associative behavioral change, 3) greater pairing-specificity.

These associative behavioral changes in intact animals and the relation to test orientation were closely paralleled by the results of intracellular recordings from photoreceptors in the eye of Hermissenda. Type B photoreceptors from animals which had been exposed to paired light-rotation presentations exhibited greater impulse frequencies to a broad range of light intensities, 24 and 48 hours after the conclusion of training, than did cells from animals exposed to random light-rotation presentations. These impulse frequency differences were accompanied by facilitation of paired cells' long-lasting depolarization following offsets of light, increased input resistances of B cells during the dark, but no differences in spontaneous activity during the dark nor resting potential.

These associative changes observed for single type B photoreceptors were also manifest in ther interaction of pairs of type B photoreceptors, as well as pairs of type B and A photoreceptors, 24 hours after training.

The greater light-specificity of changes in locomotor behavior for the vertical testing orientation was accompanied by greater light/dark impulse activity ratios for paired B photoreceptors in the vertical orientation. This greater neural light-specificity is consistent with the tonic synaptic inhibition of B photoreceptors by caudal hair cells of the animals statocyst, which occurs in the vertical orientation.

The data provide evidence that type B photoreceptors define primary locii of neural change, which furthermore are causally related to the observed associative behavioral change.

117.9 ASSOCIATIVE LEARNING BY THE ISOLATED CNS OF A TERRESTRIAL MOLLUSK, LIMAX MAXIMUS, OCCURS CENTRALLY. A. Gelperin, N. Culligan* and S. Wieland. Dept. of Biology, Princeton University, Princeton, N.J. 08544.

We are pursuing the analysis of synaptic events underlying associative learning by developing an isolated CNS preparation which can be conditioned in vitro (J.J. Chang and A. Gelperin, Proc. Natl. Acad. Sci. USA 77: 6204, 1980). The sensory input pathway is via chemoreceptors on the two lips. The output is feeding motor program (FMP) recorded extracellularly from nerve roots of the buccal ganglia. By paired application of a normally attractive food-derived chemostimulus (conditioned stimulus, CS) and an aversive chemostimulus (unconditioned stimulus, US) to the lip chemoreceptors, the in vitro lip-brain-buccal ganglia (LBBG) preparation can be trained to stop emitting FMP in response to the CS, while continuing to emit FMP in response to a second food-derived chemostimulus (S_2) not paired with the aversive taste.

We have extended this basic finding by using a new stimulus delivery system which allows us to apply chemostimuli to either the right lip alone or the left lip alone. Using unilateral chemostimulus application, we applied the CS (e.g., standard potato extract) to the right lip and 5 min. later the US (saturated quinidine sulfate) to the left lip. Subsequent tests with the CS and a new chemostimulus S_2 (e.g., standard carrot extract) applied to the left lip showed a significant reduction or elimination of the FMP response elicited by the CS but not S_2 (4 of 6 preparations). The selective suppression to the CS was expressed only on the side which received the US. These data provide further evidence for associative learning by the isolated LBBG preparation of Limax and support the conclusion that the associative event occurs in the CNS, not at the periphery.

A further test of the central nature of the synaptic change was made by applying the CS and the US sequentially to the same lip, and testing for FMP responses to the CS and S_2 using the opposite lip. In 4 of 10 cases, the preparation showed suppression of the FMP response to the CS but no suppression to S_2 when tested at the "naive" lip. In these 4 preparations the lip where the training occurred also expressed selective suppression to the CS. Only 1 of the 6 preparations which did not express learning at the naive lip showed any signs of learning at the trained lip. These data are further indication of the central nature of the associative event.

We are now mapping the cells and cell clusters of the Limax cerebral ganglion and surgically reducing the LBBG preparation to the smallest remanent that will learn reliably in order to further localize the associative event. Supported by NSF Grant BNS 8005822.

117.10 DIETARY CHOLINE INCREASES RETENTION OF AN ASSOCIATIVE LEARNING TASK IN THE TERRESTRIAL MOLLUSC, LIMAX MAXIMUS. C. L. Sahley, S. R. Feinstein* and A. Gelperin. Dept. of Biology, Princeton University, Princeton, New Jersey 08544.

Recent experiments in our laboratory have been directed toward determining the effect of dietary neurotransmitter precursors on learning and memory. Adult slugs were maintained on choline enriched (11.4g/kg) and choline-deficient (.3g/kg) diets (BioServ). After two weeks on the diet, slugs were tested for acquisition and retention of an associative odor-preference modification task which we have used previously (C. Sahley, A. Gelperin & J.W.Rudy, Proc. Natl. Acad. Sci. USA 78: 640, 1981). Separate groups of slugs were tested for acquisition (24 hr following training) and for long-term retention (7 days following training). Results indicated that no differences in learning were apparent between slugs on choline-deficient and choline-enriched diets on the initial test (24 hr), $p > 1$. In contrast, dramatic differences in performance between slugs on the choline-deficient and choline-enriched diets emerged on the long term retention test. That is, 7 days following training, slugs on the choline-deficient diet showed little evidence of retention of the learned task whereas slugs on the choline-enriched diet showed excellent retention of the learned odor-modification $p < .01$. In fact, performance of slugs on the choline enriched diet 7 days following training was no different from performance of slugs on either diet 24 hr following training, $p > 1$. Dietary choline enrichment then significantly facilitated memory of a learned task.

A radioenzymatic assay for free choline revealed that slugs maintained on a choline-enriched diet possessed significantly higher concentrations of choline in their blood than their counterparts maintained on the choline deficient diet ($p < .01$).

Choline's action may be mediated via increasing ACh synthesis and release at cholinergic synapses. The effect of choline on ACh release was studied at a cholinergic neuromuscular junction (NMJ) between an identified motoneuron, the salivary burster (SB), and the muscle cells of the salivary duct. When the isolated nervous system was incubated in saline enriched with choline at concentrations within the normal physiological range, synaptic transmission at this NMJ was enhanced. Further experiments demonstrated that this effect was due to increased choline uptake, ACh synthesis and release by the SB neuron. Thus, increases in exogenous choline for Limax have both dramatic behavioral and physiological consequences. That is, increasing dietary choline results in facilitated memory for an associative learning task and in vitro exogenous choline significantly augments synaptic transmission at a NMJ. We feel that choline's effect on memory may be related to this synaptic phenomenon.

117.11 ASSOCIATIVE LEARNING IN A SIMPLE REFLEX OF APLYSIA. T. J. Carew, E. T. Walters* and E. R. Kandel. Center for Neurobiol. & Behavior, Depts. Physiol. & Psychiat., P & S, Columbia Univ., and N.Y. State Psychiatric Inst., New York, N.Y. 10032.

The ability of Aplysia and other molluscs to exhibit associative learning has encouraged the search for this type of learning in a behavior controlled by a simple and well analyzed neural circuit. Towards that end we have now produced classical conditioning in the defensive siphon and gill withdrawal reflex of Aplysia.

A light tactile conditioned stimulus (CS) to the siphon was paired for 15 trials (i.t.i.=5 min) with an unconditioned stimulus (US), a 1.5 sec electric shock to the tail. Paired animals (N=10) received the CS immediately prior to the US, unpaired animals (N=10) received the CS and US separated by 2.5 min. Animals were tested (blind) with the CS alone shortly after training. Paired animals showed significantly longer siphon withdrawal in response to the CS ($\bar{x}$=64.7 sec) than unpaired animals ($\bar{x}$=16.7 sec., $p < .005$). We next examined acquisition, extinction and retention of the conditioned response in six groups: (1) paired, (2) unpaired, (3) random CS-US, (4) US alone, (5) CS alone, and (6) untrained. During acquisition siphon withdrawal in the paired group progressively increased from $\bar{x}$=8.6 secs after trial 1 to $\bar{x}$=32.5 secs after trial 31 ($F_{6,48}$=2.8, $p < .05$). Moreover the paired group exhibited significant facilitation compared to random and unpaired groups after only one trial ($p < .025$ and $< .005$ respectively). In the 24-hour retention test the paired group again showed significantly longer siphon withdrawals ($\bar{x}$=55 secs) than all other groups ($p < .005$). In addition several differences not apparent during training and extinction now emerged among the control groups: the US-alone group ($\bar{x}$=20.1 secs) was significantly greater than both unpaired ($\bar{x}$=9.1 secs) and random ($\bar{x}$=10.5 secs) groups ($p < .005$ in both cases) while CS-alone ($\bar{x}$=5.4 secs) and untrained groups ($\bar{x}$=6.8 secs) were significantly lower than all other groups.

Preliminary cellular experiments indicate that conditioning can be monitored in the identified interneurons and motor neurons of the siphon and gill withdrawal reflex. It has also recently been shown that (1) the tail is a powerful input pathway for gill and siphon withdrawal (Carew et al., 1980, 1981); (2) sensory neurons that mediate the US are located in the pleural ganglia (Walters et al., 1981); and (3) the US powerfully activates identified facilitatory interneurons in the abdominal ganglion (Hawkins, 1981). Thus neurons have been identified in pathways for the CS, the US, and the conditioned response. Consequently, it may now be possible to identify neurons causally related to the conditioned response in this simple reflex. Since this reflex exhibits nonassociative learning, it may also be possible to compare associative and nonassociative learning on a mechanistic level.

117.12 IDENTIFICATION OF SENSORY NEURONS INVOLVED IN TWO FORMS OF CLASSICAL CONDITIONING IN APLYSIA. E.T. Walters*, T.J. Carew and E.R. Kandel. Center for Neurobiology & Behavior, Depts. Physiol. & Psychiat., P & S, Columbia Univ., N.Y. State Psychiatric Inst., New York, N.Y. 10032.

Aplysia has now exhibited two forms of aversive classical conditioning and in both cases sensory input from the tail plays a prominent role. Walters et al. (1979, 1981) showed that tail-elicited escape locomotion, inking, and siphon withdrawal are facilitated markedly by a chemosensory conditioned stimulus that has been paired with noxious shock to the head during a classical fear conditioning procedure. More recently Carew et al. (1981) have shown that direct classical conditioning of siphon withdrawal can be produced by pairing weak siphon stimulation with strong shock to the tail. Thus the tail can act both as a test pathway for expressing the effects of fear conditioning, and as the reinforcement pathway for direct conditioning of siphon withdrawal.

We here report the identification of a population of sensory neurons that respond to both tactile and electrical stimulation of the tail. These cells (30-70 μ) are clustered within a large group of sensory neurons on the ventral side of each pleural ganglion. They have receptive fields on the ipsilateral half of the tail while nearby cells have receptive fields adjacent to the tail on the posterior parapodia, body wall, and foot. The properties of these neurons resemble closely those of identified mechanoreceptors in the abdominal and cerebral ganglia (Byrne et al., 1974; Rosen et al., 1980): 1) they show slowly adapting trains of action potentials in response to mechanical or electrical stimulation of the tail; 2) the number of spikes is a graded function of the intensity of the stimulus; 3) the spikes lack prepotentials; 4) spikes can be triggered antidromically by stimulation of appropriate peripheral nerves; and 5) impulses evoked by skin stimulation persist in Co^{++} solutions which block synaptic transmission in the skin and the CNS.

Intracellular stimulation of individual sensory neurons can evoke polysynaptic EPSPs in identified siphon and ink motor neurons. Monosynaptic excitatory connections (0.5-15 mV) from the sensory neurons were found to a group of newly described motor neurons which produce withdrawal of the tail. These tail motor neurons are clustered on the ventral side of each pedal ganglion. As with other sensory neurons in Aplysia, monosynaptic EPSPs from the tail sensory neurons decrement with repeated activation. Preliminary evidence indicates that in fear-conditioned animals these monosynaptic EPSPs are not facilitated by the CS even though concurrently recorded complex EPSPs from tail stimulation are facilitated in ink and siphon motor neurons. Thus the modulation of tail input by classical fear conditioning may act at a locus downstream from the primary sensory neurons.

117.13 IDENTIFIED FACILITATING NEURONS ARE EXCITED BY CUTANEOUS STIMULI USED IN SENSITIZATION AND CLASSICAL CONDITIONING OF APLYSIA. R. D. Hawkins. Center for Neurobiol. & Behavior, Columbia University, P & S, New York, N.Y. 10032.

The Aplysia gill and siphon withdrawal reflex can be sensitized by tactile or electrical stimulation of the neck, mantle shelf, or tail. Electrical stimulation of the pleuroabdominal connectives, which carry input from the neck and tail regions, produces presynaptic facilitation at synapses from siphon mechanosensory neurons to gill and siphon motor neurons (Castellucci et al., 1970; Castellucci and Kandel, 1976). This facilitation can also be produced by intracellular stimulation of single identified neurons, the L29 group, which are excited both orthodromically and antidromically by connective stimulation (Hawkins et al., 1981). As a test of the hypothesis that the L29 neurons mediate the effects of natural sensitizing stimuli, I now report the activity of those neurons in a semi-intact preparation.

Single L29 neurons are excited by cutaneous stimulation over a large area of the body surface including the tail, posterior parapodia and body wall, siphon, and mantle shelf. Stimulation of more anterior portions of the body recruits IPSPs in L29 neurons. Within the excitatory region, stationary tactile stimuli produce an adapting "on" response and also an "off" response, while moving tactile stimuli and strong electrical stimulation produce a high frequency "on" response followed by sustained firing throughout the period of stimulation (average rate = 35 spikes/second).

These results show (1) that L29 neurons are excited by cutaneous stimuli to the tail and mantle shelf which have been used to produce sensitization of the gill and siphon withdrawal reflex, and (2) that rates of L29 firing produced by these stimuli are comparable to those which have been used to produce presynaptic facilitation at sensory neuron to motor neuron synapses with intracellular L29 stimulation (Hawkins et al., 1981). Sensitization of the gill and siphon withdrawal reflex can also be produced by stimulation of anterior body regions which do not excite L29 neurons in the semi-intact preparation, suggesting that other, as yet undiscovered neurons may mediate sensitization from those regions.

Carew, Walters and Kandel (1981) have recently demonstrated classical conditioning of the siphon withdrawal reflex, using tactile or electrical stimulation of the siphon as the CS and and electrical stimulation of the tail as the US. Both the CS and the US produce firing of L29 neurons with the parameters of stimulation used in the behavioral experiments. It therefore seems possible that the L29 neurons may be critically involved in this associative form of learning as well as in nonassociative sensitization of the gill and siphon withdrawal reflex. Experiments are in progress to test this possibility.

118.1 LATERAL GENICULATE NUCLEUS ORIGIN OF THE CORTICOTECTAL PATHWAY IN THE CAT. C.L. Colby, Dept. of Psychology, MIT, Cambridge, MA 02139

The lateral geniculate nucleus (LGN) of the cat has three sets of layers: the A laminae, the C laminae and the medial interlaminar nucleus (MIN). Functionally, three cell types have been identified in cat LGN: X, Y and W cells. These three cell types do not show a clear laminar segregation, yet each of the LGN laminae is quite distinct in the manner in which it projects to visual cortex. Since Y cells appear in all of the magnocellular laminae, it is likely that the functional connectivity of these cells is determined by their laminar origin.

This hypothesis was tested by reversibly blocking synaptic transmission in the LGN by microinjection of cobalt chloride while recording single or multi-unit activity in the topographically corresponding region of the superior colliculus (SC). Inactivation of the A laminae had little or no effect on collicular cell responses to light stimulation. In contrast, inactivation of the C laminae abolished visual responsiveness at one quarter of the SC recording sites, reduced responsiveness at another quarter of the locations and left half of the recording sites unaffected.

These results show that input to corticotectal cells does not arise equally from all LGN layers. The Y cells in the C laminae project extensively onto corticotectal cells while the Y cells in the A laminae appear to have other target sites. These results suggest that one function of the lamination of the lateral geniculate nucleus is to segregate cells according to their projection sites in cortex.

118.2 EFFECTS OF BLOCKING A-LAYER GENICULATE INPUT ON CAT AREA 17. J. G. Malpeli. Dept. of Psychology, 603 E. Daniel St., Champaign, IL 61820.

Injections of 115 nanoliters of 4 millimolar cobalt chloride into layer A of the lateral geniculate nucleus selectively and reversibly block synaptic transmission in this layer without blocking axonal conduction in fibers of passage. I have assessed the effects of layer A inactivation on the activity of single cells and multiple-unit recordings in area 17 of the visual cortex. Blocking layer A virtually abolished visual activity in cortical layers 4 and 6. In contrast, such blocks had little effect on the activity, direction selectivity, or orientation selectivity of complex cells in layers 2 and 3. The effects of layer A blocks on layer 5 cells were quite variable, ranging from complete loss of visually driven activity to no effect. The layer 5 cells least affected by the cobalt block were the special complex type, which are thought to project to the superior colliculus (1,2).

From these observations I conclude:

Major receptive field properties of layer 2 and 3 complex cells and many layer 5 complex cells do not depend on the integrity of interlaminar connections within the cortical column.

Interlaminar connections do not account for the presence of a common orientation selectivity within an orientation column.

Layer 4 simple cell activity is not necessary to support the visually driven activity of complex cells in layers 1 and 2 or the activity of special complex cells in layer 5.

As in the monkey (3), the corticotectal downflow does not strongly depend upon X-cell inputs to cortex.

The division of the lateral geniculate nucleus into discrete layers segregates populations of relay cells having unique patterns of access to individual cortical outputs. This segregation may facilitate selective dynamic modulation of cortical outputs by non-retinal inputs to the visual thalamus.

118.3 AN INTRACELLULAR STUDY OF GENICULO-CORTICAL CONNECTIVITY IN AREA 17 OF THE CAT. D. Ferster* and S. Lindström*. (SPON: T. Wiesel). Dept. of Physiology, University of Göteborg, Sweden.

It is widely held that an understanding of the function of the visual cortex requires detailed knowledge of the arrangement of its input from the lateral geniculate nucleus (LGN). We have therefore undertaken yet another study of the synaptic input to the visual cortex from the LGN. Potentials evoked electrically from the optic tract (OT), LGN, the optic radiation (OR) and the superior colliculus (SC) were recorded intracellularly from cells with identified receptive field properties. Potentials mediated by the geniculo-cortical pathway were distinguished from those due to antidromic activation of intracortical collaterals by their ability to be evoked from the OT, LGN and OR at appropriate latencies, intensities, and frequencies. Intracortical latencies, excluding afferent conduction times, were obtained by extrapolation. A histogram of intracortical latencies for all epsps and ipsps formed 3 peaks of 0.6 ms width beginning at 0.6, 1.1 and 1.7 ms. These were assumed to contain mono-, di- and trisynaptic potentials.

The laminar distribution of monosynaptically activated cells could, in part, be predicted by the distribution of geniculate afferent terminals: all cells recorded in layer 4, the bottom of layer 3 and the upper portion of layer 6 received monosynaptic epsps and disynaptic ipsps. There were also cells outside these layers that received monosynaptic epsps: in layer 5, the lower part of layer 6 and higher parts of layer 3. These latter regions, however, contained cells that were disynaptically excited and di- or tri-synaptically inhibited. As a result, every cell below layer 3 received mono- or disynaptic excitation from the LGN. The only cells whose earliest epsps were trisynaptic were found in layer 2 and possibly the upper part of layer 3.

As previously reported, simple cells were confined to layers 4 and 6 and were therefore all monosynaptically excited from the LGN, whereas complex cells could receive mono-, di- or trisynaptic excitation. Of those cells with subcortical projections, the majority of cortico-collicular cells were disynaptically activated. All cortico-geniculate cells, however, were monosynaptically excited from the LGN, forming a disynaptic excitatory feedback pathway to LGN principle cells.

Our results differ from those obtained in previous extracellular studies of spike latency. We propose several reasons for this: 1)differences in the classification of receptive field types; 2)the use of extrapolation to arrive at intracortical latencies; 3)the variable delay between the onset of an epsp and the initiation of a spike; and 4)further delay or even blocking of the spike by ipsps superimposed on an epsp.

118.4 LINEARITY OF RESPONSE DEPENDENCE ON BAR AND EDGE VELOCITY. Robert C. Emerson and Linda S. Ide. Center for Visual Science, University of Rochester, Rochester, NY 14627.

We tested the extent to which lateral geniculate (LGN) and cortical units in the cat realize linear predictions by comparing unit responses with those of a receptive field (RF) analog whose spatial distribution included one excitatory central and two inhibitory flanking regions. We constructed the analog from silicon photocells and other linear components to facilitate interpretation of its responses and the corresponding effects in actual neurons. When the temporal properties of the analog were adjusted to match LGN and cortical responses to flashing bars, the shape and amplitude of analog responses as a function of position of a moving bar or edge showed a strong dependence on stimulus speed, especially in the 2-32°/sec range. Analog responses as a function of the speed of a bar closely approximated those of most X-LGN units, those of many Y-LGN units at low speeds, and (for the preferred direction) those of simple cortical units with balanced flanking regions. Analog responses to moving edges exhibited clearly separated regions of response to bright- and dark-edge stimuli. This finding suggests a linear basis for the disparate edge discharge centers that are considered diagnostic for simple units, as contrasted with the (nonlinear) overlapping discharge regions of cortical units in the complex family. Responses of complex units to flashing bars also could not be mimicked by a linear analog. The linear analog demonstrates that spatiotemporal interactions in all moving stimuli require responses to be highly dependent on stimulus speed. Comparisons between unit and analog responses, however, indicate that this dependence can be explained roughly on a linear basis for most LGN units and many cortical units of the simple family.

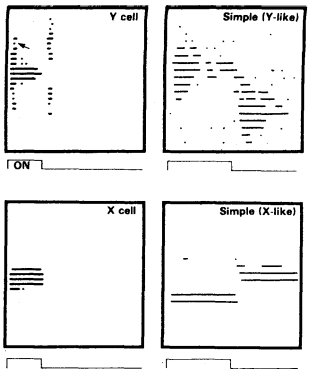
118.5 RECEPTIVE FIELDS AND LAMINAR DISTRIBUTION OF X-LIKE AND Y-LIKE SIMPLE CELLS. W. H. Mullikin*, J. P. Jones*, L. A. Palmer. Dept. Anat., School of Medicine, University of Pennsylvania, Philadelphia, Pa. 19104

There is evidence that simple cells in area 17 of cats may be differentially innervated by Y or X axons. Accordingly, we anticipated that the receptive field organization of simple cells would resemble, in part, properties of geniculate X and Y cells and that X-like and Y-like simple cells would be distributed by lamina according to the distinct patterns of arborization of X and Y axons.

Similarities between the receptive field organization of simple cells and either X or Y LGNd cells were revealed by plotting a cell's firing rate as a function of the position(y-axis) and time course(x-axis) of a small bar of light turned on and off (see figure). The receptive fields of Y-cells were distinguished from those of X-cells by the presence of transient "arms" extending to either side of the central excitatory response (arrow). In a similar manner, the excitatory responses of most simple cells were found either with or without "arms". A few cells had mixed organization (ie. on-excitation without "arms"; off-excitation with "arms"). Simple cells with "arms"(y-like) had a transient response while cells without "arms"(x-like) were sustained.

Y-like simple cells were found in layers III, IVab and VI, corresponding to the terminal distribution of Y axons. X-like simple cells were found at the III-IV border, IVab, IVc and VI, even though X axons have been found to arborise only in layers IVc and VI. X-like cells at the III-IV border and IVab could result from intracortical projections from layer IVc. Presently, no Y-like simple cells have been found in layer IVc.



These results lead us to conclude that many simple cells are dominated by either X or Y inputs from the LGNd. Few cells may receive both X and Y input. Thus, the X and Y pathways may remain largely separate even within striate cortex.

118.6 A COMPARISON OF CYTOCHROME OXIDASE AND DEOXYGLUCOSE PATTERNS IN MACAQUE VISUAL CORTEX, Roger B. H. Tootell* and Martin S Silverman*, Dept. Psychology, Univ. Cal. Berkeley, Cal. 94720 (spon: G. Westheimer).

In order to clarify an initial 2-14C-deoxyglucose (2DG) color study (Tootell, Silverman, and De Valois,1980) which predated the demonstration of endogenous cytochrome oxidase (CO) variations in monkey striate, CO and 2DG patterns were compared in the same section in different monkeys which were shown: 1) a black/white horizontally-oriented pattern of various spatial frequencies; 2) an equiluminant red/grey oriented pattern of various spatial frequencies shown at all orientations; 3) a ganzfeldt; and 4) 5) and 6) large-field, temporally-modulated equiluminant color/grey (n=2), equiluminant multiple-color (n=1), or black/white (n=2) patterns. Sections were cut parallel with the plane of flat-mounted opercular V1 and V2 in order to view lamina-specific patterns over large expanses of cortex.

In striate, 2DG uptake following visual patterns without a constant orientation component appear to superimpose the upper-layer CO dots exactly. Equiluminant colored large-field patterns are quantitatively much more effective in producing 2DG patterns in either V1 and V2 than are black/white patterns with identical spatio-temporal parameters or a ganzfeldt. However, the 2DG patterns produced by large-field color stimuli do not appear to be hue-specific in either V1 or V2. The CO dots near layer 4A are often connected in parallel strips perpendicular to the V1-V2 border, curving to run parallel with the horizontal meridian down the middle of the operculum: a pattern highly reminiscent of the ocular dominance slabs. The major difference between the large-field color/grey 2DG patterns and the striate CO patterns is in layer VI: the 2DG pattern reveals an obvious second tier of dots directly below each upper layer dot; the CO reaction product reveals only a very faint differential stain in layer VI (which nevertheless appears to superimpose the upper layer CO dots). The one single-orientation case we have done gives a different result. When the CO dots in striate layers 3-4A are compared to 2DG (horizontal) orientation columns in the same section, these two patterns apear to be much less clearly related to each other.

In V2, columnar strips of increased CO reactivity can be seen running parallel to each other approximately 3 mm apart and loosely perpendicular to the V1-V2 border. Large-field stimuli produce 2DG patterns which superimpose these CO strips exactly. A columnar horizontal-orientation 2DG pattern appears in V2 (perhaps indicating V2 orientation columns) which is entirely different from the CO slab pattern in the same section.

118.7 ELETROPHYSIOLOGICAL VERIFICATION OF DEOXYGLUCOSE SPATIAL FREQUENCY COLUMNS IN CAT STRIATE CORTEX. Martin S. Silverman* Roger B.H. Tootell* and Russell L. DeValois*,University of California, San Francisco and Berkeley, Calif.

Using the ^{14}C-2-deoxyglucose, (2DG) functional mapping technique a stimulus containing 1 spatial frequency presented at all orientations produces autoradiographic patterns that traverse all cortical laminae. No columnar patterns are seen if multiple spatial frequencies are presented at all orientations. Thus, a columnar organization for spatial frequency is demonstrated (Silverman, et al, ARVO abst., '80, and Tootell, et al, OSA absts., '80). When viewed from the surface these columns are aligned in strips that run in a anteroventral - to - posterodorsal direction along the medial bank of the lateral gyrus (Silverman, et al, ARVO absts., '81).

This columnar organization for spatial frequency as demonstrated by the 2DG technique was verified using single and multiple unit electrophysiological techniques.

The orientation and spatial frequency tuning characteristics of cells and cell groups were determined every 100u or less along electrode penetrations running posterior-to-anterior in the medial bank of the lateral gyrus.

We found that along such penetrations the peak spatial frequency tuning of successively encountered cells changed in a gradual oscillatory manner with a period of about 1mm. This is approximately the repeat distance seen for spatial frequency columns in our 2DG autoradiographs.

Orientation tuning for these same cells also changed in a regular manner as would be expected from the columnar organization for this parameter in cat striate cortex.

In comparing the pattern for spatial frequency and orientation tuning along these electrode penetrations it was found that the oscillations in spatial frequency peak tuning were at least as regular and periodic as those for orientation tuning. This is in agreement with our finding that the spatial frequency columnar organization shown by the 2DG technique was as regular and periodic as the organization for orientation specificity.

118.8 PROJECTION BANDS IN VISUAL CORTEX. C.D. Gilbert and T.N. Wiesel, Dept. of Neurobiology, Harvard Med. Sch., Boston, Mass. 02115.

Cells projecting from one cortical area to a given site in another cortical area are distributed in a number of discrete clusters, as shown by horseradish peroxidase (HRP) tracing experiments. We have now found that even within an individual cortical area, there exist extensive tangential connections that have a similar clustered appearance. This is seen not only with HRP used as an extracellular retrograde tracer, but with 3-dimensional reconstructions of the axons of cells injected intracellularly with HRP. We previously reported that, when reconstructed in three dimensions, the cortico-cortical projection clusters lined up into a system of branching and anastomosing bands which showed no clear relationship to the ocular dominance columns. We have begun to relate the projection bands to the pattern of labeling achieved by 14C 2-deoxyglucose (DOG) uptake after stimulation with lines of a given orientation. In one experiment in which the animal was stimulated with vertical lines we found that the cells in area 17 projecting to area 19 lay between the bands of highest DOG uptake. Whether or not this indicates a relationship between the projection bands and orientation columns requires further experiments.

From HRP experiments we noticed that the clusters projecting from area 17 to area 18 and to area 19 were similar in appearance, though they appeared to have a different sublaminar distribution within the superficial layers. To determine the precise relationship between these two sets of clusters we used two fluorescent retrograde tracer compounds, true blue and bisbenzamide. One dye was injected in area 18 and the other in area 19, with the two injections placed at retinotopically corresponding points. When area 17 was examined for labeled cells, we saw that, as with the HRP experiments, the cells labeled with either dye lay predominantly in the superficial layers, though now we saw many more labeled cells in the deep layers as well. The cells were clustered, and the cells projecting to areas 18 and 19 lay within the same clusters, with intervening unlabeled zones remaining. Numerous cells were labeled with either dye exclusively, and our preliminary impression was that there were no double-labeled cells. Furthermore, though there was overlap, within the superficial layers cells projecting to area 18 were distributed more deeply than cells projecting to area 19. It appears, therefore, that different cell populations project to different areas, though from the same system of bands. The projections of the cells that lie in the unlabeled zones remain to be determined. Our results raise the possibility, however, that cells inside and outside the projection bands may play distinct functional roles. 118.9 THE EFFECT OF COOLING AREA 18 ON CELLULAR RESPONSES IN STRIATE CORTEX OF THE SQUIRREL MONKEY. J.H. SANDELL and P.H. SCHILLER*. Dept. of Psychology, M.I.T., Rm. E10-120, Cambridge, Mass. 02139.

Reciprocal connections between primary visual cortex (Area 17) and extrastriate visual cortex (Area 18) have been anatomically documented in the squirrel monkey (Saimiri sciureus) by Tigges et.al. (JCN, 148:481, 1973). These reciprocal connections exist between retinotopically corresponding regions in the two areas. It is known that cells in Area 18 of the macaque become completely unresponsive when their input from striate cortex is removed (Schiller, P.H. and Malpeli, J.G., Brain Res., 126:366, 1977). However, the functional significance of the input from Area 18 to Area 17 is not known. This question could not be addressed in the rhesus monkey because Area 18 is largely buried under striate cortex. We chose the squirrel monkey for this study since in this species part of Area 18 is present in a strip of cortex 5-6 mm wide adjacent to Area 17 on the dorsolateral surface.

While recording the ongoing activity of cells in Area 17 of paralyzed, anesthetized squirrel monkeys, we reversibly inactivated the corresponding region of Area 18 by cooling the cortex to 10-18°C. The cells' response to optimal visual stimulation was recorded before, during, and after cooling of Area 18. Some cells in Area 17 became completely unresponsive when their input from Area 18 was temporarily removed. Other cells in Area 17 showed a significant increase in firing rate when Area 18 was cooled. Occasionally, this increased response resulted from a discrete change in the stimulus preference of the cell, such as the emergence of a response to an edge moving in the previously non-preferred direction. Not all cells in Area 17 were affected by cooling the corresponding region of Area 18; affected cells were more common in the infragranular layers of the cortex. Often only a few micra separated a cell which was affected by cooling Area 18 from cells which were completely unaffected. Cells in Area 17 which were affected by cooling returned to their pre-cooling firing rates within a few minutes of rewarming Area 18 to body temperature.

Thus the feedback from Area 18 to striate cortex plays a crucial role in defining the response properties of some cells in Area 17 of the squirrel monkey.

118.10 BINOCULAR INTERACTIONS IN CATS WITH UNILATERAL LESIONS OF THE VISUAL CORTEX. J.C. Gardner and M.S. Cynader. Dept. of Psych., Dalhousie Univ., Halifax, N.S., Canada B3H 4J1.

Binocular interactions were examined in over 300 units from the 17/18 border of normal cats and cats with large unilateral lesions of the visual cortex. Stimuli were presented at seven retinal disparities and moved in the same and in opposite directions on the two retinae. Since binocular interactions in normal cats are extremely pronounced in superficial layers and since the corpus callosum is known to project to layer III, we wondered if unilateral visual cortex lesions would differentially effect responses in the superficial and deep cortical layers.

In normal cats, 66% of the units with very large binocular interactions were found in the superficial layers. In this region only 7% of the cells appeared insensitive to stimulus disparity, contrasting to 20% in deep layers. Average dynamic range by depth peaked about 800-900 microns below the cortical surface. To determine if a particular component of the binocular response was responsible for the larger interactions seen in superficial layers, the distributions of maximum inhibitory and excitatory interactions were analyzed seperately. Across the two cortical regions, no differences were seen in excitatory responses but a clear differenced appeared in the strength of the inhibitory component of binocular responses. The larger dynamic range of units in the superficial cortical layers was due to binocular inhibition.

Unilateral lesions of the visual cortex produced a significant reduction in binocular inhibition. No change was seen in excitatory responses. Average dynamic range showed the greatest effect around a depth of 600-1000 microns where a large increase was seen in the number of units which were insensitive to stimulus disparity. A small increase in unselective cells also appeared at the very bottom of the cortex. Differences between the two preparations were significant when the population was considered as a whole, when only superficial units were compared, but not when units in the deep layers were analyzed seperately. Effects were seen across all ocular dominance (OD) groups. Average dynamic range was largest in units of OD groups 1 and 7, followed by units in groups 2 and 6, 3 and 5, and 4. Units in all OD groups showed reduced dynamic range in the superficial layers and no change in deep layers.

In summary, unilateral lesions of the visual cortex had a significant effect on binocular interactions along the opposite 17/18 border. Lesion cats showed reduced binocular inhibition in units of all ocular dominance groups. Effects on binocular interactions appeared quite local in the cortex and corresponded well to the known terminations of callosal fibers.

118.11 POSITRON EMISSION TOMOGRAPHY STUDIES OF HUMAN VISUAL CORTEX. Eric L. Schwartz. Brain Res. Lab.,NYU Med. Ctr. New York,N.Y.

A series of experiments have been performed which make use of hemi-field stimulation,together with specific spatial stimulus structure,in order to provide a recognizable "signature" for cortical area V1 in PETT studies of human cortex. Based on a quantitative model of the topography of V1(Schwartz,Vision Res. 20:645(1980),a computer animation has been constructed on 8mm film,using a 512x521x1 bit digital display. This stimulus consists of picture elements which are scaled according to human cortical magnification, and is designed to be projected in one visual hemi-field.Visual stimulation is obtained by reversing the black and white pixels of the display, in a spatial pattern which consisted of four logarithmically scaled octants of visual field,which were alternately "on" (i.e. reversing) or "off" (i.e. static and blank). The display was restricted to either the right or left hemi-field, relative to a small (1^0 size) fixation letter. If it were possible to view an idealized and "flattened" V1, the representation of this stimulus would resemble a "check--erboard" of four equal sized patches.
This lateralized cortical "checkerboard" was intended to provide a recognizable "signature" for V1 (and possibly V2). The fixation letter was randomly alternated with a test letter(also about 1^0 in size), which was presented for 200 msec with an average interval between tests of 1 sec. The subject was required to verbally report each test letter. A high score was interpreted as evidence of compliance with the fixation task,since it is very difficult to recognize small rapidly changing letters without disciplined fixation.Subjects viewed a film loop(3 min. loop) of this computer graphic for 15 minutes; then, an i.v. injection of F^{18} labeled 2-deoxy-glucose (FDG) was adminstered,followed by fifteen minutes of stimulation. Subjects were then placed in the Brookhaven National Laboratory PET III scanner and serial scans were performed (10-12 minutes/slice). Successful observation of lateralized FDG counts in the presumed area of V1 was obtained, and local variations of FDG counts which were consistent with the topographic structure of the stimulus were observed. Application of this approach to constructing a cortical "signature" may be of increasing importance as higher resolution PETT scanners soon come on-line,since the confident identificat--ion of cortical areas is a necessary pre-condition for using PETT to study the functional architecture of human visual cortex.

118.12 REGIONS OF POOR ORIENTATION TUNING COINCIDE WITH PATCHES OF CYTOCHROME OXIDASE STAINING IN MONKEY STRIATE CORTEX. David H. Hubel and Margaret S. Livingstone*. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

In a field not lacking in controversies it has been generally accepted that cells in layers 2 and 3 of the macaque monkey striate cortex show a high degree of orientation selectivity. Cells with poor orientation tuning when encountered have been difficult to interpret because local injury or deteriorating condition of the animal can lead to a loss of response specificity. In a series of 13 tangential penetrations in striate cortex of macaque monkeys, traversing a total of 54 mm in layers 2 and 3, we were surprised to find irregularly recurring sequences of cells with either poor orientation selectivity or none at all. These sequences occurred roughly every 1 to 2 mm, lasted about 200 μm, and were separated by regions in which all cells had sharp orientation tuning. At the onset and termination of a sequence tuning tended to be broad; in the middle of a sequence cells were often completely unoriented. These completely unoriented cells had center-surround receptive fields and often responded to diffuse light. As the electrode advanced there were the usual regular swings in eye dominance: the groups of cells with poor orientation tuning were centered in regions in which one eye strongly dominated.

The monocularity, size, and spacing of the regions of poor orientation tuning suggested that these regions might coincide with the patches of cytochrome oxidase staining found in layers 2, 3, and 6 of primate striate cortex (Horton & Hubel, Humphrey & Hendrickson: Neurosci. Abs. 1980). These patches or blobs are arranged in rows centered on the eye-dominance columns, are about 150-200 μm in diameter, and are spaced roughly 450 μm apart.

We therefore reconstructed the electrode tracks, using several electrolytic lesions in each track to establish reference points and staining tangential sections for cytochrome oxidase. On 22 occasions the electrode traversed a blob; each time there was an associated sequence of poor orientation tuning. And every sequence of poorly oriented cells was associated with a cytochrome oxidase blob. We conclude that the cytochrome oxidase patches are regions in which cells lack orientation tuning. This result would explain why the regions in layers 2 and 3 that stain most densely for cytochrome oxidase are also labeled by 2-deoxyglucose after stimulation with either diffuse light (Humphrey & Hendrickson) or stripes in any orientation (Horton & Hubel). The denser cytochrome oxidase staining of the blobs could reflect a higher overall rate of activity related to lack of stimulus specificity. It could also reflect differences in the organization of these regions. Supported by NIH grant EY00605.

119.1 BRAIN STEM ELECTROPHYSIOLOGICAL CORRELATES OF THE CLASSICALLY CONDITIONED NICTITATING MEMBRANE RESPONSE IN RABBIT. J. W. Moore, N. E. Berthier, and J. E. Desmond*. Dept. of Psychology, Univ. Mass., Amherst, Mass. 01003.

Electrophysiological recordings of multiple-unit activity (MUA) were obtained from unanesthetized rabbits during classical conditioning of the nictitating membrane response (NMR) to both an auditory and visual conditioned stimulus (CS). The unconditioned stimulus was electrostimulation of facial tissue marginal to one eye (paraorbital shock).

Single monopolar tungsten microelectrodes (Frederick Haer) were implanted stereotaxically into the dorsolateral pontine brain stem for chronic recording during conditioning. Animals were anesthetized during implantation and allowed at least three days of recovery before testing.

Training consisted of two daily sessions of 100 reinforced trials with a constant intertrial interval of 30 sec. Half of these trials employed a light CS and half employed a tone CS, presented in a random sequence and in a forward-delay arrangement. The CS-US interval was .5 sec. throughout. Acquisition training was followed by extinction training in which each CS was presented without the US for at least two sessions. For some animals, acquisition training was preceded by training of the eye contralateral to the electrode. Other animals received preliminary "pseudo-conditioning" to the ipsilateral eye, i.e., the CSs and US were explicitly unpaired.

Concurrent polygraphic recordings of integrated MUA and NMRs from both eyes indicated high correlation between MUA and conditioned responses of the ipsilateral NMR. The degree of coupling was greatest from electrodes located in the dorsolateral tegmentum at the level of the 5th nerve and from electrodes at the level of the 6th nerve near the motor pathway of the NMR.

Stimulation via electrodes located in these regions evoked full extension of the ipsilateral nictitating membrane, suggesting afferent synaptic linkages to relevant motoneurons. In addition, single-pulse stimulation via US electrodes (paraorbital shock) to either eye elicited short-latency (1.5-2 ms) evoked potentials from electrodes in the dorsolateral pons.

119.2 SENSORY-BEHAVIORAL CORRELATES IN INDIVIDUAL HIPPOCAMPAL NEURONS OF THE RAT ACROSS FOUR SITUATIONS. John L. Kubie and James B. Ranck, Jr., Dept. of Physiol., Downstate Med. Ctr., Brooklyn, New York 11203.

A number of studies demonstrate consistent correlations between hippocampal unit firing and behavior for a variety of behavioral situations ranging from classical conditioning to maze running. The most common descriptors used are the animal's position in space and various aspects of conditional stimuli or responses. In most cases the description implies the animal must learn something about his environment for the sensory-behavioral correlate to apply.

The aim of our study was to record from the same neurons during several behaviors performed in distinctly different environments. We hoped to see both consistencies and transformations from one environment to the next. We made chronic recordings of single hippocampal neurons in lactating female rats using either fine wires or moveable microelectrodes. Four environments were used: a large home box containing the rat's pups; a Skinner box in which the rat had learned a DRL-16; a familiar Olton 8-arm radial maze in a familiar room; and an unfamiliar Olton maze in an unfamiliar room. Recordings were made from twenty-four isolated complex-spike cells in at least two of these contexts. Rotating the apparatus within the room and manually carrying the rat through each environment were routinely performed.

We have found: 1) The most common sensory-behavioral correlate was to the rat's position in its environment. This is consistent with the findings of O'Keefe and others. 2) Spatial correlates were always defined by distal cues in the Olton maze and proximal cues in the other environments. 3) A spatial correlate in one environment could not predict a spatial correlate in a second environment, although similarities were often noticed. 4) Many cells turned off almost entirely (less than four action potentials/min) in one of the environments while firing rapidly in the others. 5) Tonic firing rate varied dramatically from one environment to the next. 6) Although most cells were spatial, conditional factors were also important. For instance, carrying a rat through its spatial field could either enhance or diminish the effectiveness of the field. 7) Cells which were recorded in the novel Olton maze (N=5) slowly established spatial correlates over a span of about five minutes.

One model consistent with these findings is that tonic unit firing in the hippocampus relates to context (situation) and phasic firing relates to space, specific to each environment. (Supported by NIH grant NS 14497 and NSF grant BNS 77-09375 to James B. Ranck, Jr. and NIH fellowship 1F32NS06152 to John L. Kubie).

119.3 SENSORY EVOKED POTENTIALS IN THE DENTATE GYRUS OF THE CHRONIC RAT DURING DIFFERENTIAL DISCRIMINATION LEARNING. M.O. West, E.P. Christian*, J.H. Robinson* and S.A. Deadwyler*. Dept. Physiol. and Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103.

Rats prepared for chronic recording by means of a detachable microelectrode drive system were trained on a simple tone discrimination task and then switched to a differential discrimination paradigm in which responses to the previously conditioned tone (3.5 kHz) continued to be reinforced (positive tone), while responses to a second tone (2.4 kHz) were never reinforced (negative tone). Animals received 100 randomly sequenced trials per session and reached criterion behavior (100% responding to the positive tone and less than 10% to the negative tone) within 5-10 sessions. Averaged tone evoked potentials (AEP) recorded from the outer molecular layer (OM) of the dentate gyrus consisted of two monophasic negative components, termed N1 and N2, which were differentially controlled by inputs from entorhinal cortex and medial septum, respectively (Deadwyler et al., Science 211:1181-1183, 1981). OM AEPs recorded during criterion behavior showed that the amplitude of the N1 component, while not differing between the two tones, was significantly larger than during single tone conditioning. N2 amplitude to the positive tone was significantly larger than that to the negative tone and did not differ from that recorded during single tone conditioning. Following reversal of the reward contingency, animals responded maximally (90-100%) to both tones for 3-5 sessions and then reached criterion within 10-15 sessions. OM AEPs showed that N1 increased to both tones during the sessions following reversal and then declined to pre-reversal amplitudes when criterion performance was achieved on the reversed contingency. Conversely, N2 decreased significantly to both tones following reversal and then increased to pre-reversal amplitudes during criterion performance. OM AEPs were also analyzed according to trial sequence. Individual trials obtained during criterion behavior were sorted by a computer according to position in a sequence of like trials, e.g., first positive, second positive and so on, and then separately averaged. No differences were observed between OM AEPs corresponding to first positive vs. first negative tones; prominent N1 and N2 components were present in both. However, as trial sequence progressed, N1 amplitude decreased during positive sequences but increased during negative sequences; conversely, N2 amplitude increased during positive and decreased during negative sequences. These results provide further insight into the apparent reciprocity between the types of information conveyed to the hippocampus by entorhinal and septal inputs regarding the behavioral significance of sensory events.

119.4 HIPPOCAMPAL, MEDIAL SEPTAL AND ENTORHINAL RESPONSES DURING AUDITORY SIGNAL DETECTION BEHAVIOR IN THE RABBIT. Ronald E. Kettner*[1], Gregory A. Clark*[1], Stephen D. Berry[2], and Richard F. Thompson[1]. Dept. of Psych.[1], Stanford Univ., Stanford, CA 94305 and Dept. of Psych.[2], Miami Univ., Oxford, OH 45056.

A model system for studing the neural basis of auditory signal detection behavior was developed using classical conditioning of the rabbit nictitating membrane (NM) response. Animals were conditioned to a white noise conditioned stimulus (CS) using a corneal airpuff unconditioned stimulus. The CS intensity was then reduced to behavioral threshold and multiple or single unit responses were compared on behavioral detect versus nondetect trials at a constant threshold level intensity. In past work, recordings from the anteroventral cochlear nucleus, the central nucleus of the inferior colliculus and the ventral division of the medial geniculate body have indicated that the behavioral variability observed at threshold cannot be accounted for by neural variability within the mainline auditory pathway. These auditory nuclei show well defined and essentially identical responses on detect and nondetect trials to a constant threshold level auditory CS.

In contrast to these auditory nuclei, these data suggest that the CA1 region of the hippocampus and its two major inputs, the medial septum and entorhinal cortex, show responses which relate significantly to signal detection performance. Hippocampal neurons showed a strong increase in firing which formed a temporal "model" of the behavioral NM response on behavioral detect trials. This increase was not present during nondetect trials. The medial septum showed a significant increase in firing to the onset of the auditory CS on detect trials which was reduced or nonexistent on nondetect trials. Entorhinal cortex displayed increases in firing on detect but not nondetect trials which tended to parallel the behavioral NM response. In addition, some entorhinal records also showed an initial inhibition to the CS, but this inhibition was present whether or not behavioral responding occurred. These data suggest that limbic areas are actively involved in determining auditory signal detection behavior.

119.5 REMEMBERING REWARDS IN THE ENVIRONMENT: ENDOGENOUS HIPPOCAMPAL OPIATES MODULATE REINFORCEMENT-MEMORY ASSOCIATIONS. T. J. Collier*, J. S. Miller*, G. Quirk*, J. Travis* and A. Routtenberg. Cresap Neuroscience Laboratory, Northwestern University, Evanston, Ill. 60201.

The granule cells of the hippocampal dentate gyrus support brain stimulation reward (BSR; Collier, T. J., et al., Neurosci.Abs. #41.5, 1980), and appear important for normal performance in spatially-cued working memory tasks (Olton, et al., Behav. Br. Sci., 2 313-365, 1979). Recent histochemical evidence (Gall, et al., in press, 1981) indicates that dentate gyrus granule cells and their mossy fiber axons exhibit enkephalinergic immunoreactivity. To investigate the functional role of these endogenous opiates, we studied the effects of systemic administration of the opiate antagonist naloxone, on dentate gyrus granule cell stimulation in two behavioral paradigms. A) BSR tests. Rats implanted with a single electrophysiologically guided monopolar stimulating electrode in the dentate granule cells were trained to lever press for brain stimulation in daily 15 min BSR tests. Electrodes directly in either limb of the granule cell layer supported low, but reliable rates of responding (mean lever presses/15 min=59.5). Following response stabilization animals received injection of a saline vehicle or naloxone (0.01-5.00 mg/kg) 20 min prior to BSR tests. Granule cell self-stimulation was suppressed in a dose-dependent manner following naloxone, while hypothalamic self-stimulation and operant behavior of controls were not affected by equivalent naloxone doses. B) Radial maze tests. Animals with similar granule cell implants were trained on a 2-trial memory task in a radial 8-arm maze. Animals were required to locate food, present in only one arm, on trial-1, and return to the single baited site, after a delay, on trial-2. Ten seconds of granule cell stimulation administered during the delay disrupted memory for the baited site. Pretreatment with naloxone (1 mg/kg) prevented the stimulation-induced performance deficit. These results suggest a role for opiates in both reward and memory functions. Release of endogenous opiates from the dentate mossy fiber system may participate in an endogenous reinforcement system involved in working memory. Supported by N.I.M.H. 25281 to A. R.

119.6 PREFRONTAL NEURON ACTIVITY RELATED TO TASK REVERSAL. K. KUBOTA AND H. KOMATSU* Dept. Neurophysiol., Primate Res. Inst., Kyoto Univ., Inuyama, Aichi, 484 JAPAN

Single neuron activities were recorded from the dorsolateral and ventral prefrontal cortex of two monkeys, in order to analyze neuronal mechanisms of a task reversal. To release the depressed lever (Go) or to continue lever depression (No-Go) for reward was combined with red or green discriminative stimulus. After fixed intertrial intervals (3 s), a yellow lamp was lighted. If the monkey depressed the lever, the lamp was turned off, 0.9 s later a green or red lamp was lit for 0.8-2.2 s and turned yellow, indicating the response period. Then the monkey performed Go or No-Go response. A correct response was rewarded with juice. The following two tasks were interchangeable. In one task, the monkey released lever to red and continued lever press to green. In the other task, the monkey released the lever to green and continued lever press to red. When the tasks were reversed, the monkey had to recognize the change of stimulus response relations through its own erroneous unrewarded responses.

Out of more than 200 neurons related to task events, 41 neurons showed a clear activity change, when the task was reversed. After the absence of reward, 7 neurons showed a transient increase of activity, 25 showed steady increase, continuing throughout intertrial intervals and 4 showed a mixed pattern. Two neurons showed a transient suppression and 4, a steady suppression. An increased activity continued often until the lamp stimulus onset or rarely until the response period. If, within tasks, the monkey responded erroneously or reward was not delivered to correct responses, these neurons showed changes similar as those in a task reversal. Increased activity was not abolished even if juice was delivered. In 3 neurons increased activity was present during 3-4 initial trials after the reversal. And correct responses were correlated to higher activity during preceeding intertrial interval periods.

It appears that switching of the response to be performed from No-Go to Go or from Go to No-Go is accomplished in the prefrontal cortex as follows: transiently increased neuron activity detects an absence of expected reward presentation and induces a tonic activity which leads to a correct response.

119.7 DRUG EFFECTS ON CLASSICAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE RESPONSE. J. A. Harvey and I. Gormezano*. Departments of Psychology and Pharmacology, The University of Iowa, Iowa City Iowa 52242.

These studies examined the effects of several drug classes on the rate of acquisition of conditioned responses (CRs) during classical conditioning of the nictitating membrane response. Conditioning was accomplished by the presentation of tone and light conditioned stimuli (CSs) for 800 msec prior to delivery of the unconditioned stimulus (UCS) consisting of a 100 msec electric shock to the skin over the paraorbital region of the head. Drug effects were determined by the frequency of CRs over the 10 daily conditioning sessions and by the number of trials required to reach a criterion of 5 consecutive CRs to the tone and light CSs. Haloperidol, a neuroleptic drug, and scopolamine hydrobromide, a muscarinic blocking agent, retarded the rate of CR acquisition to both tone and light CSs. In contrast, the two hallucinogenic agents, d-lysergic acid diethylamide (LSD) and d,l-2,5-dimethoxy-4-methylamphetamine (DOM),enhanced the rate of CR acquisition to both tone and light CSs. d-Amphetamine (AMP), a sympathomimetic, enhanced the rate of CR acquisition to the light CS but had no effect on acquisition to the tone CS. The non-hallucinogenic congener of LSD, d-2-bromolysergic acid diethylamide (BOL) had no effect on CR acquisition to either the tone or light CS. The ED 50s for these drug effects on the rate of CR acquisition were (μg/kg, as the base): haloperidol, 160; scopolamine, 38; LSD, 0.8; DOM, 52; and AMP, 280. To test for possible nonassociative effects of these drugs on CR acquisition, seperate groups of rabbits received explicitly unpaired presentations of stimuli (tone alone, light alone and shock alone). Results from the shock alone trials indicated that none of the drugs affected the amplitude of the unconditioned response elicited by the 3 ma UCS, thus changes in CR acquisition could not be attributed to an effect on the unconditioned nictitating membrane reflex. In addition, responding during the unpaired presentation of CSs was quite low for vehicle controls (1-2%) and not affected by any dose of haloperidol, scopolamine, LSD and AMP. Thus the altered rate of CR acquisition produced by these drugs appeared to be solely due to an effect on associative factors. However, DOM produced small but significant changes in nonassociative responding of approximately 10% above vehicle controls and thus its effects on CR acquisition could not be simply attributed to an effect on associative factors. Additional experiments indicated that the enhanced acquisition of CRs produced by LSD and the retarded acquisition of CRs produced by haloperidol could be attributed to an alteration in the sensory processing of the CSs. This research was supported by DA 01759 and MH 16841.

119.8 CHOLINERGIC DRUG INTERACTIONS: ENHANCEMENT AND IMPAIRMENT OF MEMORY RETENTION. James F. Flood* and Arthur Cherkin. GRECC, VA Medical Center, Sepulveda, CA 91343.

Animals injected with cholinergic agonists after training show striking improvement of memory retention (Flood, Landry and Jarvik, Brain Res., in press). Cholinergic agonists used clinically to alleviate dementia in the elderly produce only modest improvements in memory. Recent efforts to improve clinical results involve combinations of two drugs, e.g., a precursor of acetylcholine (choline or lecithin) with an anticholinesterase (physostigmine) or other agent (e.g., piracetam or L-dopa). The behavioral pharmacology of drug combinations which affect memory processing has received little attention. We have therefore undertaken studies to determine if low doses of combinations of cholinergic drugs can improve retention without undesirable potentiation of toxicity.

Mice received one of four cholinergic agonists, or saline, within 3-min after T-maze footshock avoidance training. The injections were intraventricular, to establish a central mechanism of action. Memory retention was tested 1 wk later. Exp. 1 was a dose response study of the effect of arecoline, deanol, edrophonium chloride or oxotremorine on retention. The results for each drug indicated that relative to controls, very low doses did not affect retention, low doses improved retention ($p<0.001$, t-test) and higher doses impaired retention ($p<0.005$). In Exp. 2, drug interaction effects on retention were studied by administering the 6 possible pairs of the 4 drugs. Each drug was administered at the dose per mouse which was found optimal for improving retention (arecoline, 0.1 μg; deanol, 1 μg; edrophonium chloride, 0.1 μg; oxotremorine, 0.01 μg). If the interaction were only additive (equivalent to giving twice the dose of a single drug) no amnesia would occur, based on the results of the dose-response study (Exp. 1). However, potentiation of either drug in a pair, by a factor of 5 or more, would result in a significant amnestic effect. The results showed significant amnestic effects by all 6 drug combinations; 4 pairs showed potentiation by a factor of at least 10 and 2 pairs by factors of 5-7. Studies in progress indicate that drug pairs also enhance retention, when the dose of each drug is reduced to one-fifth or less of its enhancing dose. Toxicity studies in chicks, using paired combinations of arecoline, deanol and physostigmine, have revealed no potentiation of toxic effects. Appropriate drug combinations may offer a clinically useful means of treating memory disorders associated with senile dementia.

119.9 6-HYDROXYDOPA PRESERVES ILLNESS-INDUCED AVERSIONS TO ODORS IN RAT PUPS. Catherine A. Cornwell-Jones and Leila M. Azar*, Dept. of Psychology, Princeton University, Princeton, NJ 08544.

A treatment which depletes central norepinephrine selectively, prolonged retention of a conditioned odor aversion in rat pups. On the day of birth (Day 0), male Sprague-Dawley rats were injected systemically with either 6-hydroxydopamine HBro (6-OHDA) 100 µg/g, or with 6-OHDOPA, 60 µg/g. On the morning of postnatal Day 2, animals in the 6-OHDOPA groups received a second 60 µg/g injection. Control littermates received saline-ascorbic vehicle. On the evening of Day 2, pups were placed on a screen over lemon-scented pine shavings. They were injected, 5 min later, with either distilled water or with .02 cc/g of 0.15M lithium cloride (LiCl) and placed over the lemon-scented shavings for an additional 30 min.

Fifteen days later, on Day 17, males were given two odor preference tests on an apparatus having a screen floor placed on a two-compartment odor tray. One compartment always contained cedar shavings. The other compartment held either unscented pine shavings, or lemon-scented pine shavings. Pups were tested individually for 2 min and the time spent over the lemon-scented or unscented pine shavings was monitored.

On the cedar vs. pine test, all groups averaged significantly more than half of test time over unscented pine in preference to cedar, indicating an ability to orient to odors in the testing situation. On the lemon vs. pine test, scores of water-treated animals were similar regardless of neurotoxin treatment, while scores of LiCl-treated animals differed significantly, with 6-OHDOPA-treated animals averaging significantly less time over lemon odor than either the NaCl or 6-OHDA lithium-treated groups.

Catecholamine levels in the olfactory cortex and left ventricle of the heart were assayed flourometrically following sacrifice on Day 40-45. Compared to controls, olfactory cortex NE but not DA was reduced by 40-60% in neurotoxin-treated animals, and concentrations in the two groups were statistically similar. In contrast, 6-OHDA decreased ventrical NE levels by 67%, while 6-OHDOPA had no significant effect.

Our data suggest that aversions to odors paired with illness during the first postnatal week persist for two weeks in pups treated neonatally with 6-OHDOPA, but not 6-OHDA or vehicle. The absence of an aversion in 6-OHDA treated animals may indicate that this neurotoxin, by partially denervating the peripheral sympathetic system, reduces the ability of LiCl to induce gastrointestinal illness. These findings imply that brain NE may degrade substrates underlying responses acquired during the early postnatal period.

119.10 RETROGRADE AMNESIA PRODUCED BY ELECTRICAL STIMULATION OF THE AMYGDALA: RELATIONSHIP TO EFFECTS ON CORTICAL NOREPINEPHRINE CONCENTRATION. P. Gold and K. Welsh*. Dept. of Psychology, Univ. of Virginia, Charlottesville, VA 22901.

Under a variety of training-treatment conditions, our laboratory has observed a consistent relationship between transient posttraining changes in brain norepinephrine (NE) concentrations and later retention performance. The extent of these changes is maximal when measured 10 min after training+posttraining treatments that enhance or impair memory storage. Generally, a 15-25% decrease in forebrain NE concentration predicts good retention performance; larger or smaller changes predict poor retention performance. The present experiment used posttraining subseizure electrical stimulation of the amygdala (5 sec delay; 30 µA/side, 100 Hz, 0.1msec pulses for 30 sec) as an amnestic agent and examined changes in cortical NE concentrations 10 min after training and stimulation.

Following bilateral electrode implantation, the animals were trained in a one-trial inhibitory (passive) avoidance task with a 2 mA, 2 sec footshock. Animals were divided into groups for catecholamine assay (decapitated 10 min after training) and groups for behavioral testing 24 hr later.

On the retention tests, animals which received the posttrial amygdala stimulation exhibited retrograde amnesia, confirming the results of several laboratories. NE was measured with a COMT-linked radiometric assay. As observed previously, the training footshock resulted in a significant decrease in cortical NE in unimplanted animals. The major results seen in the implanted animals were: a) Amygdala implantation resulted in decreased cortical NE concentrations. b) Implanted animals exhibited an increase in cortical NE concentrations following the training footshock, as opposed to the decrease observed in unimplanted animals. c) Posttraining amygdala stimulation attenuated the effect of footshock on cortical NE concentrations. Analyses of other brain areas indicate that amygdala stimulation has widespread effects on forebrain NE levels. Thus, well-localized electrical stimulation of the amygdala, and perhaps of other areas as well, may act on memory storage via alterations in transmitter function of disparate brain regions.

119.11 PROPRANOLOL-INDUCED ATTENUATION OF BOTH MEMORY FACILITATION AND AMNESIA PRODUCED BY FRONTAL CORTEX STIMULATION. Debra B. Sternberg, James L. McGaugh, and Paul E. Gold. Department of Psychobiology, University of California, Irvine, CA 92717; and Department of Psychology, University of Virginia, Charlottesville, VA 22901.

When administered shortly after training, many acute treatments, such as electrical stimulation of the brain and inhibition of protein synthesis, impair later retention performance. However, under certain training conditions, many of these amnestic treatments also can enhance retention performance. Previous studies showed that many adrenergic receptor antagonists attenuate the severity of the retrograde amnesia produced by these same agents (cf. Sternberg and Gold, Behavioral and Neural Biology, 29, 289-302, 1980). If common underlying systems are involved in both enhancement and impairment of memory, then adrenergic antagonists should also attenuate the production of memory facilitation. Thus, the purpose of the present study was to obtain facilitation with the classic amnestic treatment of supraseizure frontal cortex stimulation, and then to assess the effects of an adrenergic blocking agent on both the facilitation and the amnesia produced by this treatment.

Male ARS Sprague-Dawley rats (90 days old) were trained in a one-way active avoidance task. Thirty minutes prior to training, animals received an i.p. injection of either the β-adrenergic receptor antagonist propranolol (0.5 mg/kg) or saline. Animals were then given eight training trials using either high or low footshock. Shortly after training, the rats received sham or frontal cortex stimulation (5.0 mA/1.0 sec) through previously implanted cortical screw electrodes. Twenty-four hours later the animals received eight retraining trials. Retention was measured as the number of avoidances on Day 2 minus the number of avoidances on Day 1. The results indicate that frontal cortex stimulation enhances later retention of training with a low footshock, but impairs the retention of high footshock training. Importantly, pretreatment with propranolol resulted in attenuation of both amnesia and facilitation produced by frontal cortex stimulation.

These findings add further support to the view that there may be common mechanisms, including adrenergic involvement, underlying the memory modulation produced by many treatments.

119.12 BEYOND THE 3/2-RULE: UNEQUAL LENGTHS AND DIAMETERS AND THEIR EFFECTS ON TRANSIENT VOLTAGES IN NEURONS WITH BRANCHING DENDRITIC TREES. Barry Horwitz, Physics Department, Texas Woman's University, Denton, Texas 76204.

Much evidence has accumulated which implicates changes in dendritic morphology with learning, aging, and such mental pathologies as senile dementia. The extensive branching of most dendritic arborizations, however, imposes formidible obstacles on studies which seek to elucidate the relation between changes in morphology and associated modifications in neuronal electrical activity. The theoretical models which have been the most utilized in studying electrotonic voltages, especially analytical approaches, have generally avoided the complexities of branching. Rall's model, for example, provides a way to reduce an entire dendritic tree to a single equivalent cylinder. Although this model has been of great use, it requires that the 3/2-rule for dendritic branch diameters be obeyed, which seems not to be the case for many neuronal types (e.g., Hillman, 1979).

I previously reported on a theoretical method I developed which enables one to calculate analytical expressions for voltage transients at specific locations in branching dendritic systems in response to synaptic current inputs at other sites in the trees (Neurosci. Abstr. 1979,1980). Exact results were obtained for a number of systems which possessed certain symmetries: all branch lengths had to be integral multiples of one another, and all branch diameters had to be equal. Because the second of these conditions is unduly restrictive, the method has been generalized to treat dendritic trees whose branch diameters differ from one another. The method entails adding onto the results obtained for the symmetric cases a sum of correction terms. Each term is proportional to a factor which depends on the deviation of the diameters from equality, raised to a power n, and a factor which is evaluated by going to the symmetric limit (when all diameters are equal), and is thus the same for all deviations. The correction terms, as well as the symmetric results, are all written as combinations of two closely related families of functions. These functions provide a precise formalism for analyzing systematically the way in which the voltage transients at a given point depend on the geometrical structure of the dendritic tree. Several examples will be presented which will show how the first order (n=1) and the second order (n=2) corrections alter the transient voltage responses.

120.1 THE ORIGIN OF MONOAMINERGIC PROJECTIONS TO THE SPINAL CORD. STUDIES USING FLUORESCENT TRACERS IN CONJUNCTION WITH THE FALCK-HILLARP METHOD IN THE NORTH AMERICAN OPOSSUM. G.F. Martin, T. Cabana and A.O. Humbertson. Dept. Anat., Sch. Med., The Ohio State Univ., Columbus, Ohio, 43210.

Monoaminergic axons are present in the opossum's spinal cord and after spinal injections of HRP neurons are labelled within brainstem nuclei known to contain monoamines. However, most of the nuclei in question also contain non-monoaminergic neurons making it difficult to know which neuronal type was labelled by the retrograde marker. The purpose of this report is to describe the results of studies which utilized the retrograde transport of fluorescent tracers in conjunction with the Falck-Hillarp method. Injections of either True-Blue or bisbenzimide were made into different levels of the spinal cord in 10 anesthetized opossums. The operated animals were allowed to survive for 1-7 days and prior to sacrifice they were treated with L-tryptophan and Pargyline (Sigma) to enhance indolamine fluorescence. The brain and injected segment of the spinal cord were removed from the deeply anesthetized animal and subjected to a modification of the Falck-Hillarp method. In all cases neurons were labelled by the fluorescent marker in those areas expected from the HRP studies. Such neurons were visualized best at 360nm using a Leitz fluorescence microscope. The fluorescence characteristic of monoamines was seen most easily at 490nm, but it could also be observed at 360nm. Neurons showing the fluorescence of the transported marker as well as catecholamines were found dorsal and medial to the lateral reticular nucleus, adjacent to the superior olivary nucleus, within the dorsolateral and rostrolateral pons as well as within the periventricular nuclei of the hypothalamus. They were most numerous within the dorsolateral pons where they were located within the fascicles of the facial nerve, dorsal and lateral to the motor trigeminal nucleus, within the nucleus coeruleus pars alpha and the adjacent reticular formation as well as within the nucleus locus coeruleus proper. Many of those within the rostrolateral pons were located medial to the ventral nucleus of the lateral lemniscus. Neurons containing the injected marker but not catecholamines were also found in most of the above regions. Neurons containing the transported marker plus indolamines were present in the nuclei raphae pallidus, obscurus and magnus as well as within adjacent areas of the reticular formation. In most areas of the raphe non-indolamine neurons were also found to contain the transported marker.

120.2 ORIGIN OF DENDRITES EXTENDING INTO CORTICOSPINAL TERMINAL FIELDS. Patricia L. Mensah. Dept. of Anatomy, USC School of Medicine, Los Angeles, CA. 90033.

The completely crossed corticospinal tract (CST) of rat travels in the ventralmost portion of the dorsal funiculus (DF) and terminates in the dorsal horn (DH) by forming axodendritic synapses throughout Rexed laminae I-III, and in medial regions of laminae IV and V (Brown, Jr., L.T., Exp. Brain Res., 13: 432-50, 1971). This study was undertaken to test the hypothesis that CST fibers contact dendrites of neurons located throughout the central gray. Twelve adult rats were sacrificed by anesthetic overdose and perfused with a glutaraldehyde-paraformaldehyde solution. Spinal segments C_6-T_1 were removed and treated according to the Golgi-EM procedure of Fairen et al. (J. Neurocytol., 6:311-37, 1977). Laminae I-III neurons extend from one to several dendrites into CST territory. Medial, lamina IV neurons extend a dendrite into both the CST portion of the DF and into the CST terminal field. Lamina V neurons extend medially-coursing dendrites into CST territory in laminae IV-V; while laterally-coursing dendrites lie outside this area. Laminae VII and VIII neurons extend either obliquely- or vertically-ascending dendrites into the medial portion of lamina V, some of which reach the CST terminal field. The main conclusions to be drawn from this data are that: 1) the dendrites of spinal cord neurons extend into several different terminal fields; 2) dendrites from neurons outside the DH project into the CST terminal field; and 3) as in other mammals, the CST of rat may influence both sensory and motor systems. Subsequent work will focus on the hypothesis that all dendrites projecting into CST territory are synaptically contacted by CST axon terminals.

120.3 PONTOMESENCEPHALIC INDUCED HYPERPOLARIZING POTENTIALS IN LUMBAR MOTONEURONS DURING ACTIVE SLEEP. S.J. Fung, P.A. Boxer*, F.R. Morales* and M.H. Chase. Brain Research Institute and Depts. of Physiology and Anatomy, School of Medicine, Univ. of California, Los Angeles, CA 90024.

The pontomesencephalic reticular formation has been shown to exert state-selective postsynaptic inhibition of brainstem motoneurons that arises only during active sleep[1]. The present study was undertaken to determine whether similar inhibitory effects were also present in spinal cord α-motoneurons. Accordingly, 3 cats were prepared for recording intracellularly from antidromically identified motoneurons under chronic conditions during sleep and wakefulness. Electrodes were implanted to record EEG, EOG and EMG activity and to stimulate the pontomesencephalic reticular formation (A1 to P1, H-2 to -4, L2 to 3). Twenty-one motoneurons (action potentials ranging from 55 to 94 mV) were examined during wakefulness (W), quiet sleep (QS) and active sleep (AS). The response of these cells to stimulation of the reticular formation (2 to 4 pulses, 0.5 msec, 1 to 5 volts) was studied with intracellular glass micropipettes filled with 2M K-citrate. In 18 motoneurons reticular formation stimulation promoted, specifically during AS, a hyperpolarizing potential with an average amplitude of 3 mV (maximum 6.4 mV), a latency to peak of 45 msec, and a duration of 20-65 msec. This response was seen neither in QS nor in W. However, in several cases it appeared in the transition period between QS and AS. Spontaneous discharges of the motoneurons were inhibited during these hyperpolarizing potentials. This postsynaptic potential was observed even though motoneurons were hyperpolarized when the cat entered AS. Reticular stimulation also promoted early synaptic potentials that were not state-dependent.

These results indicate that the pontomesencephalic reticular formation stimulation produces, specifically during AS, inhibition of spinal cord motoneurons. Latency measurements further suggest that the pathway mediating this inhibitory action either is polysynaptic and/or contains fibers with a slow conduction velocity. We have proposed that this pattern of motor inhibition is due to the activation of inhibitory interneurons located in the medulla, which may be selectively driven during AS by pontine cells[1]. Supported by NSF Grants INT-7722299 and BNS-79012897.

[1]Chase, M.H. The motor functions of the reticular formation are multifaceted and state-determined. In: The Reticular Formation Revisited, J.A. Hobson, M.A.B. Brazier, eds. Raven Press: New York, 1980, 449-472.

120.4 IS CONTROLLED LOCOMOTION IN CATS PRODUCED BY ACTIVATION OF CEREBELLO-RETICULAR CONNECTIONS? E. Eidelberg, J. Yu and L.H. Nguyen* Res. Program, V.A. Hospital, and U. Texas Health Sci. Cent., San Antonio, TX 78284

It is known that decorticate or thalamic cats are capable of spontaneous locomotor activity. Such activity can also be driven by localized electrical stimulation of the subthalamic region (SLR), of an area ventral to the inferior colliculi (MLR) or of sites in the lateral pontine tegmentum (PLR). This phenomenon is usually referred to as "controlled locomotion". The SLR and MLR lie close to axons of the superior cerebellar peduncle, a major cerebellofugal pathway. We hypothesized that controlled locomotion might be mediated by indirect activation of the reticulospinal system, via cerebello-reticular fibers or through descending collaterals (Cajal) of the superior cerebellar peduncle. However, controlled locomotion could be elicited from SLR and MLR sites in thalamic cats who had been subjected to destruction of the fastigial nuclei, or total cerebellectomy 1-3 weeks previously. This interval was judged to be sufficient for axon degeneration. These results seem to falsify the hypothesis.

120.5 PROJECTIONS OF INDIVIDUAL MUSCLE SENSORY FIBERS TO HOMONYMOUS AND HETERONYMOUS MOTONEURONS IN THE BULLFROG. Jeff W. Lichtman and Eric Frank. Department of Neurobiology, Harvard Medical School, Boston, Mass. 02115.

The size of synaptic potentials in adult spinal cord motoneurons was measured for various individual stretch-sensitive axons using the method of spike-triggered averaging. Discharges from single sensory axons were elicited by tapping sensitive areas on each of the three heads (internal, external, and medial) of the triceps brachii muscle and observed by recording en passant in the mixed nerve to the muscle. The observed action potential was used as a trigger for averaging while we recorded intracellularly at high gain from motoneurons innervating the same muscle head as the sensory axon (homonymous) or motoneurons innervating the other triceps heads (heteronymous).

The homonymous connections were, on average, larger than the heteronymous ones irrespective of which class of sensory axons was tested. Thus sensory axons innervating the medial head of triceps evoked an average depolarization of 221±15μV (±s.e.m.) in motoneurons that innervated the medial head compared to 89±8μV in motoneurons innervating the internal and external heads. Similarly sensory axons from the internal or external heads gave rise to a 171±12 μV depolarization in homonymous motoneurons and a 63±7 μV depolarization in motoneurons innervating the medial head.

The difference between homonymous and heteronymous synaptic connections was due in part to the fact that individual sensory axons innervated nearly all of the homonymous motoneurons tested whereas they produced measurable responses in only about one half of the heteronymous motoneurons. However, a difference in projection frequency was only part of the explanation since homonymous inputs were, on average, about 80-90 μV larger than heteronymous inputs even when comparing only the measurable responses.

These results show that despite the absence of obvious stretch reflexes in the frog, the monosynaptic projections of individual muscle sensory axons onto motoneurons are strong and specific as in the cat. This specificity requires not only that axons find appropriate postsynaptic partners, but also establish synaptic connections of the appropriate strength with those partners.

120.6 LATERAL COLUMN PROJECTION TO LUMBAR MOTONEURONS IN THE FROG: FUNCTION AND SYNAPTIC PHYSIOLOGY RE-EXAMINED. A.R.Blight. Depts. Neurosurg. and Physiol. and Biophys., New York Univ. Med. Ctr., New York, N.Y. 10016.

The lateral column (LC) of the frog spinal cord has been held to terminate in excitatory synapses on somata or proximal dendrites of most ipsilateral lumbar motoneurons (LMs). On the basis of this widespread and powerful excitatory connection, it has been suggested that the LC mediates supraspinal control or initiation of hindlimb extension in the jump. This interpretation was reinvestigated in frogs (Rana temporaria): a) using selective lesions of the upper thoracic cord (segment 4/5) and b) recording intracellular potentials in LMs in response to thoracic LC stimulation. Recordings were made in situ, the frogs decerebrated and paralysed with tubocurarine or succinylcholine.

Unilateral LC destruction had little effect on locomotion as analysed by videotape, except for the presence of a noticeable delay (100 msec to several sec acutely) in bringing the ipsilateral hindlimb into the normal flexed posture after a jump. Bilateral lesions resulted in a general flexion weakness in the hindlimbs, but extension in the jump was little impaired. This suggests that the essential role of the LC in locomotion is the transmission of information related to flexing the hindlimb into the sitting posture as the frog lands. This may be specific visual, vestibular, tactile or proprioceptive forelimb information or a more general, facilitative excitation of flexors.

Electrophysiological analysis showed the upper thoracic LC projection to LMs to be complex and heterogeneous. Monosynaptic potentials (i.e. with latencies less than 2 msec) were found in both flexor and extensor motoneurons, though they were widely variable in amplitude and rise time and several were hyperpolarizing. Few LMs fired an action potential from these monosynaptic components. Polysynaptic potentials (latencies greater than 3 msec) were found in all cells and generally gave rise to action potentials. In contrast, lower thoracic or upper lumbar stimulation (segment 6/7) resulted in monosynaptic activation of most LMs, probably through stimulation of intrinsic lumbar neurons. It is concluded that the LC pathway does not provide a homogeneous direct descending input to ipsilateral LMs but rather has a selective and heterogeneous termination which remains to be defined more closely.

(Work carried out at the Max-Planck Institute for Brain Research in Frankfurt/M, F.R.G., with the aid of a Max-Planck Society fellowship).

120.7 WHAT IS THE ROLE OF THE GOLDFISH MAUTHNER CELL IMPULSE IN THE "TAIL FLIP" REFLEX? John T. Hackett and Donald S. Faber, Div. Neurobiology; Dept. Physiology; SUNYAB, Buffalo, NY 14214.

The teleost Mauthner cell is well suited for initiation of a startle reflex, characterized by a rapid and unilateral tail flip, because of its multimodal inputs and extensive projection to motoneurons in the medulla and spinal cord. In the present study intracellular microelectrodes were employed to analyze the organization of the neural networks underlying the reflex evoked by auditory or optic inputs.

Experiments were performed on goldfish that were maintained by perfusion of water through the mouth. Movements were restricted by supports and flaxedil injection. Fine bipolar electrodes electrically stimulated either the posterior branch of the 8th nerve, the optic tectum, the pretectum, or the spinal cord. The output of the reflex was monitored by recording electromyograms in the mandibular or trunk muscles. Following penetration of a cell, two tests were performed to characterize its function: (1) Does an impulse directly evoked by an intracellular current pulse trigger the entire reflex in an all-or-none fashion? (2) Does orthodromic activation of the cell trigger the reflex, and in turn, can the reflex be blocked when this activation is prevented by hyperpolarizing the axon? Finally, recorded neurons were injected with dyes to provide histological identification.

Whenever the Mauthner axon was activated, its impulse was followed by a fixed latency reflex EMG (about 3 ms), regardless of the mode of stimulation. Mauthner axon hyperpolarization blocked this reflex even when suprathreshold orthodromic stimuli were used which activated other bulbar neurons. Similarly, following injections of strychnine (5 μg/g, i.m.) to increase neuronal excitability, the reflex could still be blocked by hyperpolarizing inactivation of the Mauthner axon spike. In contrast, direct activation of other medullary neurons responsive to the same orthodromic inputs produced a partial reflex. Hyperpolarizing block of their action potentials removed a fraction of the Mauthner mediated reflex.

In conclusion, we provide definitive evidence that a single Mauthner cell impulse can trigger a reflex which is the same as that evoked orthodromically. One excitatory drive to this reflex is from the 8th nerve, though higher threshold afferents were found in the optic pathway. Other neurons, presumably postsynaptic to the Mauthner cell, can relay impulses to motoneurons of the reflex and can be driven independently of the Mauthner cell. These data indicate that the Mauthner cell impulse functions to coordinate cranial and spinal motoneurons for rapid reflex initiation. (Supported by NIH Grant NS15335)

120.8 SPINAL NEURONAL ACTIVITY DURING FICTIVE LOCOMOTION IN THE LAMPREY. K. A. Sigvardt and S. Grillner. Dept. of Physiology III, Karolinska institutet, Lidingövägen 1, S-114 33 Stockholm, Sweden.

Basic vertebrate locomotory patterns are known to be generated by networks of neurons in the spinal cord. An understanding of how these central pattern generators operate requires that we know what neurons in the spinal cord are essential components of the generator as well as the properties of these neurons. The in vitro lamprey spinal cord preparation has been developed to study the neuronal organization of the pattern generator for swimming, one basic type of vertebrate locomotion (Cohen and Wallén, Exp. Brain Res. 41:11, 1980; Poon, J. Comp. Physiol., 136:337, 1980). In the lamprey, fictive locomotion (rhythmic activity recorded in the ventral roots with the same intra- and intersegmental coordination as in swimming) can be initiated by adding excitatory amino acids activating NMDA receptors to the bathing solution (Grillner et al. to be publ.). We have recorded from interneurons and motor neurons in the lamprey spinal cord during fictive swimming using microelectrodes filled with the fluorescent dye Lucifer yellow (Stewart, Cell 14:741, 1978). This procedure reveals both the physiological properties and the anatomy of each neuron. Motor neurons have been recorded from, particularly to elucidate the organization of their presynaptic neurons and to determine the extent of their dendritic arborizations. Interneurons that are active during fictive locomotion have been described that have their activity or membrane oscillations either in phase, in antiphase or in an intermediate phase relationship with the burst of activity recorded in the ventral root of the neuron's hemisegment. The structure of the cells as revealed by Lucifer yellow allowed us to identify these interneurons as local interneurons, intersegmental neurons with ascending and/or descending processes, and whether or not the neuron was limited to one half of the spinal cord or had crossed projections. Tetrodotoxin (TTX, 10^{-6} M) has been added to the bathing solution while recording from the neurons. The membrane potential of most neurons recorded from returns to a flat baseline at the moment the spike activity recorded in the ventral roots is blocked. However, after TTX treatment two neurons whose activity was correlated with the ventral root burst in normal Ringer showed large amplitude (20 mV) oscillations in membrane potential 20 min after ventral root activity has disappeared. The oscillation began with an initial slow depolarization followed by a faster rise to peak. The membrane remained depolarized at about 10-15 mV above rest for approximately 2 s and then returned to baseline to begin the cycle again. Whether or not this membrane oscillation is related to pattern generation is not known.

120.9 SENSORY ACTIVATION OF THE RHYTHMIC SWIMMING MOTOR ACTIVITY IN IN VITRO PREPARATIONS OF THE LAMPREY. A. D. McClellan and S. Grillner, Dept of Physiology III, Karolinska institutet, S-114 33 Stockholm, Sweden.

Electrical stimulation of single "command neurons" in invertebrates and specific brainstem regions in vertebrates can activate the rhythmic motor activity patterns which underlie a variety of behaviors. In some cases, the significance of these findings may be unclear. For example, it is also critical to record from these presumed "command structures" when the same motor activity is elicited by natural means. In this regard, two lamprey preparations (Ichthyomyzon unicuspis) have been developed to examine the organisation of higher order pathways which activate the swimming motor activity.

Brainstem preparation. This in vitro preparation consists of the anterior region of the head with the exposed brainstem and attached spinal cord/notocord. Mechanical pressure or pinching the skin of the head elicits rhythmic, coordinated activity in spinal ventral roots which is characteristic of a turning response followed by forward swimming. This response has been verified by EMG recordings in intact preparations. The response requires an intact trigeminal nerve and electrical stimulation of this nerve can elicit similar swimming activity as the mechanical stimulus. Electrical micro-stimulation of specific regions in the rhombencephalon, similar to the "pontine locomotor region" in the cat have been found to activate strong, well coordinated swimming motor activity in spinal ventral roots. These regions appear to traverse in pathways approximately 200-300 um lateral to the midline. The relationship between the trigeminal sensory inputs and these "rhombencephalon locomotor regions" can now be investigated.

Tail preparation. This second in vitro preparation consists of the caudal 2-3 cm of the tail with the attached spinal cord/notocord. Mechanical pressure or pinching the skin of the tail activates rhythmic activity in spinal ventral roots which can presumably be regarded as part of a forward swimming escape response. This response has been verified by EMG recordings from intact and spinalized (intact) animals. Dorsal spinal tracts localized at the borders between the medial and lateral thirds of the cord appear to be the main pathways for activating this response. It is possible to bathe the middle region of the cord for about 10-12 segments in low Ca^{++} solutions to locally block synaptic transmission. Under these conditions, pinching the tail still activates albeit weaker swimming motor activity in the ventral roots rostral to the block. Thus, at least part of the activation pathway for this response is direct.

(Supported by the Swedish Medical Research Council, proj. nr. 3026, NSF grant SPI79-14858, and NIH grant 1 F32 NS 06321-01).

120.10 NORMAL AND ABNORMAL COUPLING OF CENTRAL PATTERN GENERATORS DURING FICTIVE LOCOMOTION IN THE ATLANTIC STINGRAY (DASYATIS SABINA). M.H. Droge and R.B. Leonard, Mar. Biomed. Inst. and the Dept. of Physiology and Biophysics, The Univ. of TX Med. Br., Galveston, TX 77550

Locomotor rhythms were examined in 10 decerebrated stingrays before and after immobilization with curare (i.v.). Electromyograms (EMG's) were recorded at several segmental levels before paralysis. Neurograms (NG's) were recorded with hook electrodes on elevator and depressor nerves at the same segmental levels following paralysis. Cycle times, intersegmental lag times, EMG and NG burst durations and interrelations among these were used to characterize the rhythms.

Before paralysis, all the animals swam spontaneously with timing relations previously shown to occur in both intact and decerebrated animals. After paralysis, fictive locomotion was observed in 9 of the 10 animals, either spontaneously or in response to mechanical stimulation of the tail. NG's showing rhythmic activity with normal cycle times (0.4-1.2 sec) and normal burst durations (<50% of cycle) were obtained. The relations of cycle time to intersegmental lag and burst duration were also normal in these sequences.

However, sequences with longer cycle times (up to 2 sec) were often recorded. In most of these sequences, and in some with normal times, long burst durations (>50% of cycle) were observed. In this situation, the slopes for cycle time vs. burst durations were higher while those for cycle time vs. intersegmental lag were lower than obtained before paralysis.

More aberrant patterns were also observed. In several animals phasic activity was recorded from different segments without any apparent interrelation between the segments. In all animals short and long bursts were recorded from different segments simultaneously in all possible combinations. In 2 animals the discharge pattern at one segment had higher-order periodicities superimposed on a more normal appearing rhythm. In 3 animals tonic activity was recorded from one segment simultaneously with phasic activity from a more caudal segment which showed nearly normal cycle times and burst durations. In 2 additional animals where only fictive locomotion was examined, NG's from elevator and depressor nerves exhibited rhythmic bursts that were in phase or out of phase at different times.

We conclude that the CNS is capable of generating normal locomotor rhythms in the absence of phasic afferent feedback. The data suggest that multiple spinal oscillators exist for both elevator and depressor muscles. However, the coupling among oscillators becomes labile after paralysis. Supported by grant NS 11255.

120.11 LOCOMOTOR ACTIVITY ELICITED BY SPINAL CORD STIMULATION IN THE STINGRAY, DASYATIS SABINA. C.A. Livingston, B.J. Williams, and R.B. Leonard. Marine Biomedical Institute & Dept. of Physiology & Biophysics, University of Texas Med. Branch, Galveston TX 77550

Earlier reports have indicated that locomotion can be elicited in spinalized animals by stimulation of specific areas of the spinal cord. Effective sites have typically been in the dorsolateral funiculus. However, lesion studies have suggested that portions of the ventral quadrants must be intact in order to elicit locomotion by stimulation of the mesencephalic locomotor region.

Decerebrate stingrays swim spontaneously while stingrays with high spinal transections do not. The effects of spinal cord stimulation were investigated in spinalized stingrays and the activity obtained compared to locomotor rhythms obtained in the same animal prior to spinalization. Each animal was anesthetized, decerebrated at the meso-diencephalic junction, and a series of EMG electrodes inserted in the elevator and depressor muscles of one pectoral fin. The animal was allowed to recover from anesthesia and the EMG activity was recorded during spontaneous restrained swimming. The animal was then reanesthetized and the spinal cord crushed 10-15 segments below the spino-medullary junction. After recovery from anesthesia each animal was examined to be certain it did not locomote spontaneously. The spinal cord was systematically tracked with a stainless steel stimulating microelectrode using 100 µsec. pulses, 60-90 µA in intensity, delivered in long trains between 25 and 70 Hz. Sites from which rhythmic activity was elicited were marked with the Prussian blue technique.

Rhythmic activity in fin muscle can be elicited by stimulation of the contralateral spinal cord in either the dorsolateral or ventrolateral funiculus. The most effective stimulus frequency is about 40 Hz, but the period of the rhythm is affected by the stimulus frequency. The cycle periods during the rhythmic activity evoked by stimulating either location are similar to, but typically of a more restricted range than, those observed in the same animal during decerebrate swimming. Analyses of the relation between the intersegmental lag and the cycle period show that many points during stimulation lie among the points obtained during spontaneous locomotion.

Thus, our evidence indicates that stimulation of the spinal cord at either site can produce rhythmic activity which is similar to that seen in intact or decerebrate stingrays.

Supported by grant NS 11255.

120.12 PROPERTIES OF INTRACELLULARLY RECORDED PECTORAL FIN MOTONEURONS OF THE ATLANTIC STINGRAY, DASYATIS SABINA. Benjamin J. Williams, Michael H. Droge & Robert B. Leonard. Marine Biomedical Inst. & Dept. of Physiol. & Biophys., Univ. of Texas Medical Branch, Galveston, TX 77550

Using intracellular recording techniques, we have obtained data on the cellular properties of motoneurons which innervate the pectoral fin of the stingray. Such information is a prelude to future studies of this motor system and the spinal mechanisms which underlie stingray locomotor behavior.

Decerebration, laminectomy, and exposure of peripheral nerves were performed on anesthetized stingrays. After curarization, animals were artificially respired and allowed to recover from anesthesia. Motoneurons were identified by antidromically stimulating the peripheral nerve component containing only ventral root axons (Coggeshall et al., J. Neurophysiol., 41: 97, 1978).

Stable intracellular recordings from the somata of 30 antidromically activated pectoral fin motoneurons have been made. In 22 impalements, the resting membrane potentials were greater than -60mv. Conduction velocities ranged from 15 to 60 m/s, and these values correspond well with the range of ventral root axonal diameters (Coggeshall et al., ibid). The antidromically activated, overshooting action potentials (APs) typically had an inflection on the rising phase which is comparable to the IS-SD configuration seen in other vertebrate motoneuron recordings. SD spikes can be blocked by hyperpolarization of the soma membrane. In all but 4 cells, delayed depolarizations (D-D) of up to 7 mv in amplitude occur on the repolarizing phase of the AP. Tests have shown that the D-D occurs all-or-none with the full IS-SD spike. Following D-D, a wave of after-hyperpolarization occurs, the duration of which is inversely related to the conduction velocity. By passing up to 8 nA of current through the cell membrane with the intracellular electrode, the input resistance of the soma has been determined. These values range from 0.8 to 4.0 MΩ, and are also inversely proportional to conduction velocity. These properties of stingray motoneurons are quite comparable to those of other vertebrate motoneurons.

Occassionally spontaneous bouts of oscillating membrane potential have been recorded. These oscillations have an amplitude of up to 10 mv and a cycle period of 0.6 to 1.0 s, which is similar to the cycle period of the locomotor rhythm of the intact and decerebrate animal. APs occur on the rising phase and peaks of the oscillations, and vary in number from bursts of 1-2 spikes to 3-5 spikes per cycle. In future experiments, we intend to measure the changes in membrane conductance during such bouts of rhythmic activity. Supported by grants NS 06268 and NS 11255.

121.1 ELECTROPHYSIOLOGICAL RECORDINGS FROM THE NUCLEUS AMBIGUUS OF THE RAT. S. L. Stuesse, S. E. Fish, and K. Stockton*. Neurobiology Program, N.E. Ohio College of Med., Rootstown, OH 44272.

Cardiac efferent innervation regulates myocardial contractile force, automaticity, and conduction times through the heart. Two major areas in the brainstem, the nucleus ambiguus (NA) and dorsal motor nucleus of X, are known to send projections through the vagus to the heart. Recent morphological studies from our laboratory have indicated that the majority of preganglionic parasympathetic fibers which terminate in the myocardium originate from the NA and scattered neurons ventral to it. Very little is known about the possible role these cells play in CNS regulation of cardiac function. Consequently we have made electrophysiological recordings from the medulla of anesthesized rats in an attempt to locate neurons whose activity is correlated with cardiac function.

Extracellular single unit recordings were made in the region of the NA while stimulating the ipsilateral cervical vagus. The locations of recording sites were confirmed by histological reconstruction of electrode tracts. The conduction velocity of the axons of antidromically driven NA cells was in the B fiber range. As yet, we have recorded no spontaneous activity in this portion of the NA. Electrical stimulation of these cells through the recording electrode had no noticable effect on heart rate, so the function of these cells is still to be elucidated. However, the largest concentration of cells projecting to the heart are found in the same area of the NA as the single unit antidromically activated cells. This region of the NA is surrounded by cells whose activity is correlated with respiration. There was a tendency for cells above the NA to fire with bursts of spikes during inspiration while expiratory cells were found below the NA. It has been suggested that respiratory cells are located with the NA. We have found no antidromically driven respiratory cells, however, vagal stimulation occasionally suppressed the activity of respiratory units.

121.2 A CORRELATION BETWEEN MULTIPLE UNIT ACTIVITY IN THE HYPOTHALAMUS AND ELECTROCARDIOGRAPHIC CHANGES OBSERVED AFTER A SUBARACHNOID HEMORRHAGE. Priti S. Lacy* and A.M. Earle. Dept. of Anatomy, University of Nebraska Medical Center, Omaha, NE 68105.

A decrease in the electrical activity of the cortex (EEG) has been observed associated with an increase in intracranial pressure (Moody et al., J. Neurosurg., 30:482, 1969; Meiner et al., Brain Research, 86:439, 1975; Hubschmann and Kornhauser, J. Neurosurg., 52:456, 1980). Transient bradycardia followed by tachycardia has also been observed following a depression in cortical EEG (Meiner et al., Brain Research, 86:439, 1975) after subarachnoid hemorrhage in female albino rats. It was not known, however, if this suppression in cortical EEG extended to subcortical structures including the hypothalamus.

An experimental subarachnoid hemorrhage was simulated in urethane anesthetized male Sprague-Dawley rats under the cirle of Willis. EKG was monitored and multiple unit activity (MUA) recordings were made from a stereotaxically placed tungsten microelectrode (exposed tip = 20 μ, impedance = 4 megaohms) in the posterior lateral hypothalamus before and after subarachnoid hemorrhage. Suppression in MUA, measured as root mean square (RMS activity was observed to precede bradycardia by 5 to 10 seconds. This suppression in MUA was observed throughout the period that bradycardia persisted. Animals showing a transient suppression (5 seconds or less) in MUA and then returning to normal MUA levels did not exhibit bradycardia. Animals which showed recovery to normal heart rate after developing bradycardia also showed a recovery in amplitude of MUA. Sudden bursts in MUA appeared in some animals during the period when MUA was suppressed and bradycardia was present. These bursts in MUA were followed immediatel by premature atrial contractions. In all animals that developed arrhythmias, a decrease in heart rate preceded the appearance of arrhythmias. These results suggest that: (1) a decrease in heart rate observed in experimental subarachnoid hemorrhage may partially result from a suppression of MUA and (2) sudden bursts in MUA when heart rate is decreased may be related to the appearance of premature atrial contractions.

121.3 HYPOTHALAMIC NEURONS WITH ACTIVITY RELATED TO SYMPATHETIC NERVE DISCHARGE (SND). Susan M. Barman and Gerard L. Gebber. Dept. of Pharmacol./Toxicol., Michigan State Univ., East Lansing, MI 48824.

Spike-triggered averaging was used to examine the relationships between the spontaneously occurring discharges of single hypothalamic neurons, inferior cardiac SND and cortical activity (EEG). In addition, post-R wave interval analysis was used to determine whether hypothalamic unit discharges were influenced by the baroreceptor reflexes. These analyses allowed us to identify 3 hypothalamic unit types with activity related to SND in 12 baroreceptor-innervated cats. The discharges of SR neurons (n= 11) were temporally related to SND and the R wave of the ECG. The discharges of SER neurons (n=10) were in addition related to EEG activity. The discharges of SE neurons (n=12) were related to SND and EEG activity but not to the R wave. SR and SE neurons could be subdivided into 2 groups depending upon whether their activity was followed by an increase or a decrease in SND. The discharges of SER neurons were always followed by a decrease in SND.

Bilateral section of the carotid sinus, aortic depressor, and vagus nerves (12 cats) was performed to eliminate the relationships in spike-triggered averages arising as a consequence of baroreceptor input shared by "non-sympathetic" hypothalamic units and central networks governing SND. Under these conditions, 10 hypothalamic units with activity related only to SND (S neurons) were found. These neurons are tentatively classified as elements of hypothalamic sympathetic networks and may be counterparts of SR neurons in the baroreceptor-innervated cat. In this regard, S and SR neurons were similarly distributed in anterior, dorsal, lateral and posterior hypothalamic regions.

SE neurons (n=31) were also located in baroreceptor-denervated cats. As was the case for SE units in baroreceptor-innervated cats, the results with spike-triggered averaging suggested that most of these cells received cortical inputs and directed their outputs to sympathetic nerves. However, other SE units (and all SER units in baroreceptor-innervated cats) appeared to affect both SND and cortical activity. Such a unit discharge pattern presumably is indicative of coupling between functionally distinct hypothalamic networks via local mechanisms.

These data support the view that the hypothalamus is involved in setting the level of SND in the anesthetized cat and that at least one (SR unit) of the neuronal types in the hypothalamic sympathetic network is under baroreceptor reflex control. (Supported by PHS Grant HL-13187 and a Michigan Heart Association Grant-in-Aid.)

121.4 CAUDAL RAPHE NEURONS INVOLVED IN GENERATING THE CARDIAC-RELATED RHYTHM IN SYMPATHETIC NERVE DISCHARGE (SND). S.F. Morrison and G.L. Gebber. Dept. of Pharmacol./Toxicol., Michigan State Univ., East Lansing, MI 48824.

The cardiac-related rhythm in SND results from the entrainment of a brain stem oscillator by the baroreceptor reflexes (Gebber, Am. J. Physiol. 239: H143-H155, 1980). Thus, it is possible to alter the phase relations between the pulse-synchronous components of baroreceptor and sympathetic nerve discharges by changing heart rate. This observation presented us with the opportunity of distinguishing neurons which comprise or receive inputs from the brain stem sympathetic oscillator from other unit types which exhibit pulse-synchronous discharges. Spike-triggered averaging and post-R wave interval analysis were used to locate 34 neurons in the caudal raphe nuclei of the cat medulla with discharges synchronized to the cardiac-related slow wave in the inferior cardiac sympathetic nerve. The temporal relations among the point of peak probability of unit discharge (as determined from spike-triggered averages), the onsets of the rising and falling phases of the cardiac-related slow wave of SND and the arterial pulse wave were compared at different heart rates (set between 1.5 and 4 beats/s with ventricular pacing) in the same experiment. The interval between the point of peak probability of discharge of 20 raphe units and the onset of the rising phase of the cardiac-related SND was not changed during increases or decreases in heart rate which led to marked alterations in the phase relations between SND and the arterial pulse wave. The interval between the discharges of 10 additional units and the onset of the falling phase of cardiac-related SND remained constant when heart rate was increased or decreased. These unit types presumbly were contained within or received inputs from those components of the brain stem oscillator responsible for the rising and falling phases of cardiac-related SND.

The point of peak probability of discharge for the remaining 4 raphe units changed with regard to the onsets of both the rising and falling phases of cardiac-related SND when heart rate was increased or decreased. In contrast, the phase relations between the discharges of these units and the arterial pulse wave remained constant during ventricular pacing. Peak probability of discharge of 2 of these neurons occurred 70 ms after the R wave of the ECG. This observation suggests that these units were interneurons in the afferent limb of the baroreceptor reflex arc. The other 2 neurons exhibited a period of reduced activity time-locked to the pulse-synchronous component of baroreceptor nerve discharge. (Supported by PHS Grants HL-13187 and NS-06693.)

121.5 SYMPATHETIC NERVE DISCHARGE (SND) IN CHRONIC SPINAL CATS. J.L. Ardell*, S.M. Barman and G.L. Gebber. Dept. of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824.

Recordings were made from the central ends of the sectioned external carotid (ECN) and renal (RN) postganglionic sympathetic nerves one month after transection of the spinal cord at the sixth cervical segment (4 chloralose-anesthetized cats). In contrast to the asynchronous character of SND in acute spinal cats under normocapnic conditions (McCall and Gebber, Brain Res. 89: 139-143, 1975), SND in chronic spinal preparations exhibited synchronous slow wave activity in the 2-6 c/s range. This rhythmic activity pattern could be synchronized to single shocks applied at a rate of 1/s to the afferent sciatic nerve. No evidence was obtained for a baroreceptor-like reflex mechanism acting to control SND in chronic spinal cats. In this regard, there was no locking of 2-6 c/s SND to the cardiac cycle either at control or elevated levels of blood pressure (as determined with post-R wave interval analysis). Furthermore, there was no consistent change in the amplitude of 2-6 c/s SND during the pressor response produced by intravenous norepinephrine.

Crosscorrelation analysis demonstrated locking between 2-6 c/s activity recorded from different postganglionic nerves (left ECN → right ECN) whose preganglionic inputs arise from the same spinal segments. This observation reveals the existence of intraspinal pathways which function to synchronize the discharges of separate groups of preganglionic sympathetic neurons. However, crosscorrelation analysis failed to reveal a relationship between 2-6 c/s activity recorded from postganglionic nerves (ECN → RN) whose preganglionic inputs arise from different spinal segments.

The phase relations between the R wave-related component of SND and the arterial pulse wave in animals with an intact neuraxis can be shifted by changing heart rate (Gebber, Am. J. Physiol. 230: 263-270, 1976). Such shifts reflect the ability of the baroreceptor reflexes to entrain those central oscillators responsible for 2-6 c/s SND. In 3 acute spinal cats (C_1 transected), we found 8 brain stem raphe neurons whose R wave-related discharges shifted in time with respect to the arterial pulse wave when heart rate was slowed with ventricular pacing. On the basis of criteria developed by Morrison and Gebber (this volume), it can be assumed that these neurons were contained in sympathetic networks. Thus, we conclude that 2-6 c/s SND can be generated either in brain stem or spinal circuits which can act independently of each other. (Supported by PHS Grant HL-13187.)

121.6 CORRELATIONS OF SINGLE-NEURON ACTIVITIES IN THE GIGANTOCELLULAR RETICULAR NUCLEUS WITH CARDIOVASCULAR EVENTS IN THE CAT. Julie Y. Hwa and Samuel H.H. Chan. Dept. of Life Sciences, Indiana State University, Terre Haute, IN 47809.

Previous studies from our laboratory suggested that the gigantocellular reticular nucleus (GRN) in the medulla oblongata of the cat is intimately involved in the regulation of arterial blood pressure (ABP) and heart rate (HR). Electrical activation of the GRN elicits significant vasodepression and bradycardia. Furthermore, the antihypertensive agent clonidine may utilize the GRN to promote hypotension and cardioinhibition. The present study was carried out to further delineate the role of the GRN in cardiovascular controls, using electrophysiologic techniques.

Experiments were performed on adult cats that were anesthetized with α-chloralose and urethane (40 and 350 mg/kg, i.p.). Extracellular single-neuron activities were recorded from bilateral GRN (6-9 mm anterior to the obex, 1.5-2.5 mm lateral to the midline, 2-4 mm from the ventral surface) using tungsten microelectrodes and conventional electronic devices. They were monitored simultaneously with ABP and HR.

Evaluation of 611 spontaneously discharging GRN neurons revealed that they exhibited a wide spectrum of spike frequencies (0.5-100 Hz), although 60% of them had a discharge rate of 0.5-20 Hz. Furthermore, most GRN neurons recorded displayed an irregular discharge pattern, and almost all of them did not manifest a time-locked correlation with baseline ABP and HR.

Administration of phenylephrine (5 μg/kg, i.v.) elicited a transient hypertension, followed by a reflex bradycardia. Of the 60 GRN neurons studied, 40 responded to this cardiovascular perturbation with a drastic decrease in the spike frequency, while 14 displayed an increase in the discharge rate, and 6 did not show any change in their activities.

Intravenous injection of clonidine (10 μg/kg) resulted in an immediate bradycardia, and a transient hypertension followed by a prolonged hypotension. Interestingly, the GRN neurons also exhibited an initial brief decline in discharge rate and a subsequent long-lasting heightened activity that paralleled the time courses of the cardiovascular changes. However, these events were only manifested by those reticular neurons that responded to phenylephrine-induced hypertension and reflex bradycardia with a reduction in spike discharges.

These results substantiated our previous postulation that the GRN may be a modulator of the baroreceptor reflexes. Furthermore, the GRN may be an active site for clonidine to exert its antihypertensive effects.

121.7 SINGLE UNITS IN THE AMYGDALA OF THE CAT RESPONDING TO STIMULATION OF BUFFER NERVES. D. Cechetto* and F.R. Calaresu. Dept. of Physiology, Univ. of Western Ontario, London, Canada. N6A 5C1.

Stimulation of the amygdala is known to elicit cardiovascular changes and to influence the baroreceptor reflex. Anatomical evidence showing a projection from the nucleus tractus solitarius (a known site of termination of cardiovascular afferents) to the amygdala suggests that buffer nerves may alter the activity in neurons in the amygdala. This possibility was tested in 11 cats anesthetized with chloralose. Electrical activity of spontaneously active units in histologically verified sites in the amygdala was monitored for changes in firing frequency during electrical stimulation of the carotid sinus (CSN) and aortic depressor (ADN) nerves. Stimulation of the ipsilateral CSN altered the firing frequency of 35% (49/139) of the units in the amygdala. Of these units 59% (29/49) were inhibited with a mean latency of 65±4.3 ms and the remaining units were excited with a delay of 38±5.2. Units excited were found mainly in the lateral amygdala and the medial area of the basal amygdala. Units inhibited were found mainly in the lateral amygdala with a few scattered throughout the basal and central amygdala. Stimulation of the ipsilateral ADN elicited a change in firing frequency of 18% (29/157) of the units. Of these 72% (21/29) were excited with a mean latency of 19±2.2 ms while 8 units were inhibited with a delay of 49±2.2 ms. Responsive units which showed an excitatory response were located in the lateral and central amygdala and the lateral portions of the basal amygdala. The few units which were inhibited were not localized to specific regions within the amygdala. To study the possibility of convergence of inputs from the CSN and the ADN on the same unit 104 units were tested for a response to both CSN and ADN stimulation. Of the 44 responsive units 32 responded only to stimulation of the CSN, 5 responded only to stimulation of the ADN and the remaining 7 responded to stimulation of both nerves. These results show that the CSN inhibits a slightly larger proportion of units than it excites whereas stimulation of the ADN predominantly excites units in the amygdala. In addition, it has been shown that a small proportion (7%) of units tested for responsiveness to ADN and CSN stimulation responded to both buffer nerves. These demonstrated differences in responses of single units in the amygdala to stimulation of the two buffer nerves may have functional implications in accounting for the role of this limbic structure in the control of the cardiovascular system.

121.8 CENTRAL SEROTONERGIC NEURONS FACILITATE SYMPATHETIC NERVOUS DISCHARGE (SND). Robert B. McCall and Stephen J. Humphrey.* The Upjohn Company, Kalamazoo, Michigan 49001.

The presence of serotonergic neurons in vasoactive areas of the brain stem and spinal cord suggests that serotonin (5-HT) has a role in the central regulation of blood pressure. The nature of the interaction between serotonergic neurons and central sympathetic pathways has not been determined. For example, centrally administered 5-HT has been shown to increase or decrease mean arterial blood pressure (MAP) and SND. The present investigation was designed to determine the effects of 5-HT on central sympathetic outflow by studying the actions of 5-HT agonists and antagonists on MAP, heart rate (HR) and SND recorded from the external carotid and splanchnic nerves of anesthetized, baroreceptor denervated cats. Intravenous administration of the 5-HT antagonists methysergide (UML, .05-1.6 mg/kg), metergoline (Met, .01-.32 mg/kg), cyproheptadine (Cyp, .05-2.4 mg/kg), and cinanserin (Cin, .20-6.4 mg/kg) was associated with a prolonged, dose-related inhibition of SND. SND was significantly reduced within 5 minutes of the administration of these agents and was maximally inhibited by the largest doses of UML (-83%), Met (-82%), Cyp (-77%), and Cin (-65%). MAP and HR were also decreased in a dose-related manner by UML (-41 mmHg/-74 bpm), Cyp (-33 mmHg/-38 bpm) and Cin (-37 mmHg/-40 bpm). Met failed to alter MAP and HR. Administration of vehicle failed to alter MAP, HR or SND. The effects of UML, Met, and Cyp were also tested in cats depleted of 5-HT by prior administration of the 5-HT synthesis inhibitor p-chlorophenylalanine (PCPA). The 5-HT antagonists failed to reduce SND in PCPA pretreated cats. Clonidine significantly inhibited SND (-73%) in these cats. These data suggest that 5-HT antagonists reduce SND via their ability to block 5-HT receptors. Finally, the effects of the selective presynaptic 5-HT agonists lisuride (Lis) and 5-methoxydimethyltryptamine (5-MeODMT) on MAP, SND, and HR were tested. At low doses, these compounds have been shown to inhibit 5-HT cell firing while having little effect on postsynaptic 5-HT receptors. 5-MeODMT (10-50 μg/kg, i.v.) and Lis (5-10 μg/kg, i.v.) markedly reduced MAP, HR, and SND. The onset of the depressor effects were rapid, while the duration of the effect was transient (3-5 minutes) with 5-MeODMT and prolonged (>1 hour) with Lis. Thus, the time course of the depressor effects of 5-MeODMT and Lis correlate well with their ability to inhibit 5-HT cell firing. This study indicates that agents which act presynaptically to inhibit 5-HT cell firing and agents which act postsynaptically to antagonize the effect of synaptically released 5-HT both mediate a central reduction in SND. Thus, these data suggest that central 5-HT neurons normally facilitate transmission in central sympathetic pathways.

121.9 RENAL AND ADRENAL NERVE ACTIVITY IN SPONTANEOUSLY HYPERTENSIVE RATS AFTER SPINAL TRANSECTION. L.P. Schramm, E.S. Chornoboy*, O.R. Simon* and K.E. McKenna* The Johns Hopkins University School of Medicine, Dept. Biomed. Engr., Baltimore, MD 21205

Spontaneously hypertensive rats (SHR's) exhibit both elevated spontaneous sympathetic activity and sympathetic hyperexcitability. The role of spinal and/or ganglionic systems in generating this hyperactivity has not been determined directly. SHR's and normotensive Wistar-Kyoto rats (WKY's), 12 to 14 weeks old, were anesthetized with alpha-chloralose, paralyzed and artificially respired. Rectified and integrated multiunit activity was measured on renal and adrenal nerves. Adrenal nerve activity was monitored after ganglionic blockade with hexamethonium and atropine. We transected spinal cords at C1 and electrically activated descending sympathoexcitatory and sympathoinhibitory pathways lying in the dorsolateral and lateral funiculi. Stimulus-response curves for both sympathoexcitation and sympathoinhibition were generated using stimulus frequencies of 5,10, 20,50, and 100 Hz. Spontaneous renal nerve activity was elevated in SHR's, and this difference persisted during both sympathoexcitatory and sympathoinhibitory stimulation. Spontaneous adrenal nerve activity was not significantly elevated in SHR's. However, sympathoexcitatory stimulation elicited larger responses in adrenal nerves of SHR's. Sympathoinhibitory stimulation was only minimally effective in reducing adrenal nerve activity in both SHR's and WKY's. To test the hypothesis that inhibition of adrenal activity was marginal because spontaneous levels of adrenal activity were low, we increased baseline adrenal nerve activity by spinal sympathoexcitatory stimulation. Superimposed sympathoinhibitory stimulation still elicited only small decreases in adrenal nerve activity.

We conclude that a component of the elevated renal nerve activity exhibited by SHR's may be generated by spinal and/or ganglionic systems. The hyperreactivity of preganglionic adrenal nerve responses in SHR's was of spinal origin. The mechanism responsible for the differential sensitivity to sympathoinhibitory stimulation of renal and adrenal activity remains to be determined. However, the relative weakness of sympathoinhibition in adrenal nerves was not simply a function of lower baseline activity.

121.10 Differential patterns of sympathetic outflow initiated by stimulation of visceral afferent neurones. R. Meckler#, H. Fry# and L. Weaver. Dept. of Physiol., Mich. State Univ., E. Lansing, MI

Various inputs to the central nervous system cause fractionated, differential response patterns in different components of sympathetic outflow. The patterns of sympathetic responses to stimulation of cardiac vagal and thoracic and abdominal visceral spinal afferent neurones are not well known. Therefore, this study was undertaken to compare sympathetic reflex patterns caused by stimulation of receptors within the heart, upper abdominal viscera and arterial components of the vasculature. Experiments were performed in chloralose-anesthetized cats in which arterial baroreceptors had been denervated and upper thoracic (T1-T6) sympathetic chains had been removed. Activity of splenic, renal and cardiac sympathetic efferent nerves and systemic arterial pressure were recorded. Discharge of at least two nerves was recorded simultaneously. Occlusion of the celiac or superior mesenteric artery stimulated lower thoracic spinal afferent neurones to elicit greater excitation of splenic than renal or cardiac nerves. These reflexes were easily demonstrated after C1 spinal transection. Stimulation of cardiac vagal afferent neurones by intra-atrial administration of veratridine caused greater inhibition of renal than splenic sympathetic outflow. Occlusion of the descending thoracic aorta causes mechanical activation of cardiac receptors and ischemia-induced excitation of receptors in the abdominal viscera. Such occlusion caused biphasic (inhibition-excitation) responses in renal nerves and excitatory responses in splenic nerves. After cervical vagotomy, aortic occlusion caused only greater excitation in both nerves. Stimulation of cardiac vagal and peri-arterial receptors by intra-atrial injections of bradykinin also caused biphasic (inhibition-excitation) renal nerve responses and only excitatory splenic nerve responses. Again, inhibition was eliminated and excitation was enhanced by vagotomy. Stimulating peri-arterial receptors with intra-arterial injections of bradykinin caused greater excitation of splenic than renal nerves. These findings illustrate that: 1) abdominal visceral ischemia or chemical stimulation of peri-arterial receptors causes excitation of sympathetic outflow which is more pronounced in splenic than renal or cardiac nerves, 2) inhibitory influences of the cardiac vagal afferent neurons are more pronounced in renal than splenic nerves, 3) summation of these excitatory and inhibitory inputs generally leads to greater excitation of splenic nerve activity or greater inhibition of renal nerve activity. It is concluded that renal and splenic components of splanchnic sympathetic outflow receive different patterns of synaptic inputs from visceral afferent neurones. Support: National HLBI grant HL21436.

121.11 Contribution of spinal pathways to reflex influences of cardiac sympathetic afferent neurones on sympathetic outflow. H. Fry#, R. Meckler#, and L. Weaver (SPON: J. Krier). Dept. of Physiol., Mich. State Univ., E. Lansing, MI. 48824.

The extent to which neural circuits confined to the spinal cord are adequate to mediate excitatory sympatho-sympathetic reflexes of cardiac origin is not well understood. Although cardio-cardiac sympathetic reflexes are well documented in spinalized cats, the autonomy of spinal networks in the excitation of lower thoracic sympathetic outflow or in the presence of an intact neuraxis remains ambiguous. Further resolution of this question may contribute to the understanding of the organization of other spinal visceral afferent influences on the sympathetic nervous system. Experiments were conducted in anesthetized, vagotomized, sino-aortic denervated cats. Cardiac sympathetic afferent neurones were excited by epicardial superfusions of bradykinin and responses of cardiac, renal, and splenic sympathetic nerves were recorded simultaneously. Response patterns of these sympathetic nerves were compared prior to and 1, 3, and 6 hours following C1 spinal cord transection. Prior to transection, cardiac sympathetic afferent stimulation caused greater excitation of cardiac than renal activity and greater excitation of splenic than cardiac or renal activity. The same patterns were observed at all times tested after transection. The magnitude of cardiac and splenic excitatory responses often was not diminished immediately following transection and generally all responses increased with time. A second group of experiments were performed to determine if medullary neurones which could be excited by electrical stimulation of cardiac sympathetic afferent nerves similarly were excited by chemical stimulation of these nerves. These experiments were considered preliminary investigations of potential brainstem components of the sympatho-sympathetic reflex. Activity of medullary neurones was recorded with multibarreled micropipettes and enhanced, when necessary, using microiontophoretic techniques. Stimulation of cardiac receptors by bradykinin excited few of the neurones which had responded to electrical afferent stimulation. Only spontaneously active neurones responded to both electrical and chemical stimulation and these were located throughout the reticular formation near the level of the obex. Neurones which could be correlated with sympathetic activity were not excited by chemical afferent stimulation. The observation that sympathetic reflexes of cardiac origin were similar in magnitude and pattern before and after spinal transection suggests that these reflexes are largely complete within the spinal cord. The failure of medullary neurones to respond to the chemical afferent stimulation which excites sympathetic outflow also is consistent with this contention. Support: HL21436, Mich Heart Assoc

122.1 STUDIES ON THE INTERACTIONS BETWEEN SEROTONIN AND SEROTONIN BINDING PROTEIN. H. Tamir and Kuo-peing Liu,* New York State Psychiatric Institute, Division of Neuroscience and Columbia University, Department of Psychiatry, New York, New York 10032.

Serotonergic neurons of both brain and gut contain a specific serotonin binding protein that is probably a component of the amine storage mechanism. We wish to report now on the nature of the interaction between the protein and serotonin. Rat brain serotonin binding protein (SBP) was found to have essential -S-S and -SH groups. Both reduction of the disulfide bond by dithiothreitol or mercaptoethanol and modification of -SH group(s) by Ellman reagent or alkylating agents, caused loss of binding capacity. In contrast, formation of mixed disulfide bond with sodium metabisulfite did not affect the binding capacity. Serotonin, in the presence of Fe^{+2} and phosphate was found to bind to either an -SH group or to a site in very close proximity. Since addition of serotonin protected -SH groups from modification by Ellman reagent and from denaturation of protein upon storage. Lipids that enhance binding of serotonin to SBP also protected -SH groups from modification. Nucleotides were found to be strong inhibitors of the binding of serotonin to SBP. The inhibitory effect of nucleotides was due to their chelating properties and not to phosphorylation of or binding to the protein. Inhibition by nucleotides and other chelators was reversible. Binding capacity being fully restored after removal of the chelator by molecular sieve chromatography and addition of Fe^{+2}. A partial reversal of the inhibition by nucleotides was also achieved when the concentration of phosphate ions, required for binding, was elevated. The ionic environment had a marked effect on the binding: intracellular ions such as K^+ were found to enhance the binding, and extracellular ions such as Na^+ and Ca^+ inhibited the binding. Consistent with our data is formation of a complex of SBP-S-Fe-S that in hydrophobic surrounding could bind up to four molecules of serotonin in coordination bond with Fe^{+2}. Extracellular ionic conditions which favor the dissociation of the complex would free the amine to interact with its receptor or the presynaptic reuptake carrier. These results and previous studies strongly indicate that SBP is an intracellular protein that acts as a storage protein. The binding of the amine to the protein may serve to reduce the osmotic pressure within the vesicles.

122.2 SYNAPTOSOMES CONTAIN TWO NONMITOCHONDRIAL ATP-DEPENDENT CALCIUM TRANSPORT ACTIVITIES DIFFERING IN THEIR REGULATION BY CALMODULIN. Diane M. Papazian,* Hannah Rahamimoff,* and Stanley M. Goldin (SPON: Shew Y. Chan) Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

Synaptosomes contain two nonmitochondrial ATP-dependent Ca^{++} transport activities. These activities can be separated by fractionation of lysed synaptosomes. The synaptic plasma membrane fraction contains an ATPase activity stimulated by Ca^{++} in the presence of millimolar levels of free Mg^{++}. The Ca^{++}-stimulated ATPase is activated several-fold by calmodulin after removal of endogenous calmodulin; this observation confirms earlier reports (Sobue, K., et al., FEBS Let. 99:199-202, 1979; Sorensen, R., and Mahler, H.R., Soc. Neurosci. Abstr. 5:309,1979). The Ca^{++}-stimulated ATPase catalyzes ATP-dependent Ca^{++} transport after reconstitution into artificial phospholipid vesicles.

The synaptosomal vesicle fraction, obtained by high speed centrifugation of synaptosomal lysates, catalyzes ATP-dependent Ca^{++} uptake into native and reconstituted vesicles. The synaptosomal vesicle Ca^{++} transport activity is not stimulated by calmodulin even after removal of greater than 95% of the calmodulin endogenous to the preparation. Furthermore, the ATPase activity associated with synaptosomal vesicles, measured in the presence of millimolar levels of free Mg^{++}, is not Ca^{++} or calmodulin stimulated. Therefore, the synaptosomal vesicle Ca^{++} transport activity is distinct from the Ca^{++} stimulated, calmodulin sensitive ATPase found in synaptic plasma membranes. Since these two Ca^{++}-transport activities differ in their sensitivity to calmodulin, and in their distribution in fractions of synaptosomal lysates, they may represent two Ca^{++} pumps distinct in their regulation, location, and physiological roles within nerve terminals.

122.3 NOREPINEPHRINE NEURONAL UPTAKE SITES LABELED WITH [^{3}H] DESIPRAMINE. C.M. Lee and S.H. Snyder. Johns Hopkins University, Sch. of Med., Dept. of Neuroscience, Pharmacology and Psychiatry, Baltimore, MD 21205.

Biochemical characterization of the neuronal norepinephrine (NE) uptake processes has long been based on the measurement of the accumulation of the amine into nerve terminals. However, these analyses do not permit the distinction between interactions with the ligand recognition site from that with the translocation mechanism. It is generally known that tricyclic antidepressants of the tertiary amine type like chlorimipramine and imipramine are potent inhibitors of neuronal 5-hydroxytryptamine (5HT) uptake while those of the secondary amine type like desipramine (DMI) preferentially inhibited NE uptake. Recent evidence suggested that [^{3}H] imipramine labeled neuronal 5HT uptake recognition site (Langer, S.Z. and Briley, M., Trends in Neurosciences, 4: 28-31, 1981). We now report that the high affinity [^{3}H]DMI binding in rat brain membranes may be associated with the NE neuronal uptake site. The evidence to support this notion include drug specificity, sodium dependency and selective decrease in [^{3}H]DMI binding by 6-hydroxydopamine (6OHDA) lesion.

The absolute molar potencies of a series of antidepressant drugs in inhibiting the [^{3}H]DMI binding to cerebral cortex membranes correlated quite well with their potencies in inhibiting the cortical uptake of [^{3}H]NE, with DMI more potent than imipramine and chlorimipramine which in turn are much more potent than iprindole. Similar to the situation in neuronal NE uptake, [^{3}H]DMI binding is dependent on the presence of sodium ions. A 5-fold stimulation of [^{3}H]DMI binding was observed at 150 mM and a maximal 7-fold stimulation was observed at 300 mM sodium chloride. This effect was specific for sodium as similar concentrations of potassium, lithium and choline chloride gave little or no stimulation on [^{3}H]DMI binding. Finally, in 6 OHDA lesioned animals the loss of NE nerve terminals was accompanied by a parallel decrease in the high affinity [^{3}H]DMI binding but not that of [^{3}H]imipramine binding.

122.4 DISTRIBUTION OF γ-AMINOBUTYRIC ACID (GABA) TRANSPORT SITES IN EMBRYONIC CHICK SPINAL CORD NEURONS IN CELL CULTURE. L. A. Borden*, C. M. Czajkowski* and D. H. Farb* (SPON: J. S. Jakway). Dept. of Anatomy & Cell Biology, SUNY Downstate Med. Ctr., Brooklyn, NY 11203.

GABA is thought to be an inhibitory neurotransmitter in the CNS. Evidence suggests a similar role for GABA in 7 day embryonic chick spinal cord neurons maintained in cell culture (Choi, Farb and Fischbach, Nature 269:342, 1977). ^{3}H-GABA is accumulated by $\simeq$ 20% of the neurons in culture by a specific, high-affinity (Km = 4μM) energy dependent process (Farb, Berg, and Fischbach, J. Cell Biol. 80:651, 1979). A possible function of this system is the rapid removal of endogenously released GABA from the synaptic cleft. After 10 days in culture, accumulation of ^{3}H-GABA and the number of spontaneously occurring GABA-like IPSP's both decrease similarly with age in culture (Farb, Choi, Fischbach, unpublished). This suggests that neurons that accumulate ^{3}H-GABA are those that release GABA from synaptic terminals. Labeled neurons were identified by autoradiography and were found to be completely labeled (cell body and processes). Either ^{3}H-GABA is retrogradely transported to the cell body, or transport sites are located on all parts of the cell. To block axonal transport, cells were preincubated for 45 min. with either colchicine (10μM), vinblastine (0.5μM) or cytochalasin B (5μg/ml), and ^{3}H-GABA (final conc. 30nM) was then added. After 30 min., cells were washed, fixed, and processed for autoradiography. Label was observed over both cell bodies and processes. Assuming the maximal known rate of axonal transport (400 mm/day) substances can move $\simeq$ 25μm in 5 seconds. Cultures were incubated for 5 seconds with 250nM ^{3}H-GABA, followed by a brief wash (<5sec), and rapid fixation. Neurons with processes greater than 100μ were identified and were found to be uniformly labeled. In order to directly determine of transport sites are present on cell bodies, 4.5μM ^{3}H-GABA was applied locally to individual perikarya. Focal application was accomplished by applying brief ($\simeq$1 sec) pulses of ^{3}H-GABA by pressure ejection from micropipettes (tip diameter $\simeq$ 10μ). 15 neuronal cell bodies but not their processes were found to be labeled. Thus, GABA uptake sites are located on both processes and cell bodies of spinal cord neurons in cell culture.

(Supported by NSF grant BNS-80-0487 to D. H. Farb)

122.5 EFFECT OF PROTONS AND BICARBONATE ON STIMULATED ACETYLCHOLINE UPTAKE BY TORPEDO SYNAPTIC VESICLES. D. C. Anderson‡ Steven C. King‡ and Stanley M. Parsons. Department of Chemistry, University of California, Santa Barbara, CA 93106

In order to better define the energetics of acetylcholine (ACh) uptake into synaptic vesicles isolated from Torpedo californica we have investigated the effects of a number of mitochondrial uncouplers on both MgATP stimulated [^{3}H] ACh uptake and on the activity of the vesicle-associated ATPase. Low concentrations of nigericin, FCCP, S-13 and A23187 completely inhibit stimulated [^{3}H] ACh uptake. FCCP and S-13 also stimulate the ATPase activity by approximately 50%. These effects of uncouplers suggest that a proton gradient generated by the ATPase is coupled to concentrative uptake. Valinomycin inhibits [^{3}H] ACh uptake and also stimulates the ATPase. At low concentrations, however, valinomycin slightly stimulates [^{3}H] ACh uptake, suggesting that it may have a complex mode of action.

We also have extended earlier investigations (Parsons and Koenigsberger, Proc. Natl. Acad. Sci. USA 77, 6234, 1980) of the effect of bicarbonate on ACh uptake by looking at the pH-dependence of both the bicarbonate stimulation of [^{3}H] ACh uptake in the presence of MgATP and the specificity of active uptake with respect to [^{14}C] choline. MgATP-stimulated uptake in the absence of bicarbonate increases greatly with increasing pH from 6.6 to 7.8, where it reaches a plateau. This behavior is most consistent with inward directed proton pumping by the ATPase. Bicarbonate (40 mM) increases MgATP-stimulated uptake at pH values at or below 7.6 but has no effect at pH values greater than 7.8. Similarly, bicarbonate enhances the uptake of [^{3}H] ACh relative to [^{14}C] choline at pH values at or below 7.6, but it has no effect above pH 7.8. Corresponding direct bicarbonate stimulation of vesicle-associated ATPase activity occurs (Rothlein and Parsons, Biochem. Biophys. Res. Comm. 95, 1869, 1980). Thus, bicarbonate is not obligatory to active ACh uptake but it stimulates ACh uptake at lower pH values by stimulating the ATPase activity.

122.6 EFFECTS OF XYLAMINE ON THE RELEASE OF NOREPINEPHRINE FROM ORGAN-CULTURED RAT SUPERIOR CERVICAL GANGLIA. J.B. Fischer and A.K. Cho*. Brain Research Institute and Department of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024.

Xylamine (XYL; N-2'-chloroethyl-N-ethyl-2-methylbenzylamine) is a selective irreversible inhibitor of norepinephrine (NE) uptake which has an IC_{50} of about 0.1 μM in all in vitro preparations tested. After a single IP injection, XYL causes an inhibition of NE uptake in cerebrocortical synaptosomes that shows no recovery between 4 hr and 10 days, while striatal dopamine (DA) uptake is not affected. The same in vivo treatment causes a long lasting depletion of NE levels in the cortex and hypothalamus but no depletion of DA levels in the striatum. We have used organ-cultured rat superior cervical ganglia to examine XYL's depleting actions, a preparation that has been shown to synthesize, take up, and store NE, and to release this transmitter via a Ca++-dependent mechanism to appropriate stimuli (Vogel et al., European J. Pharmacol. 20 (1972) 308).

SCG cultured for two days (Fischer & Cho, Neuroscience Abstr. 6 #22.5, 1980) were incubated with 0.2 μM (^{3}H)NE (1 Ci/mmol) for 30 min in Krebs-Ringer bicarbonate (KRBS), then incubated with or without 10 uM XYL for 30 min, followed by two 15 min wash incubations to remove unbound XYL. The SCG were then incubated for 30 min in either normal KRBS, KRBS with 10 μM tyramine (TY), KRBS with 20 μM amphetamine (AM), or modified KRBS with 50 mM K+ and reduced Na+. Radioactivity was measured in samples from each of the incubation and wash baths. During exposure to XYL, no additional (^{3}H)NE was lost compared to control SCG. XYL caused a small increase in the efflux of (^{3}H)NE from the SCG after the wash incubations, up to 27% greater than control values. TY increase the efflux of (^{3}H)NE to 222% of control values; this increase was reduced to 49% by prior XYL exposure. AM caused a 114% increase in efflux which was reduced to 61% by XYL. 50 mM K+ increased (^{3}H)NE efflux by 120%, and prior XYL exposure increased this efflux slightly to 174%.

The actions of XYL on NE efflux are consistent with its action as an irreversible NE uptake inhibitor. TY- and AM-caused efflux probably occur via the uptake carrier, and are therefore inhibited by XYL. K+-induced release is thought to occur via exocytosis, and XYL should prevent the reuptake of the released NE, thereby increasing the (^{3}H)NE in the medium. The slight increase in efflux caused by XYL after the wash incubations but not during XYL exposure suggests a slowly developing action of XYL to cause an efflux of NE. Such an action could be involved in the in vivo depletion by XYL of NE in the brain.

123.1 AGE-EFFECTS ON FACILITATORY PROCESSES AT A SYNAPSE BETWEEN CENTRAL MOTOR NEURON L_7 AND GILL MUSCULATURE IN APLYSIA. B. Peretz and G. L. Ringham. Dept. of Physiology and Biophysics and College of Pharmacy, U. of Kentucky Med. Ctr., Lexington, KY 40536.

We have described previously an age-related change in the motor neuronal function of L_7 in the parietovisceral ganglion (PVG) of Aplysia (Peretz et al, 1980). Specifically, contraction of the antiflaring gill musculature elicited by stimulation of L_7 developed less tension in old animals (minimally 200 days old) than in mature animals (ca 120 days old). We report here that the decreased tension is associated with altered synaptic efficacy between the terminals of L_7 and the antiflaring muscles of the gill pinnules. With the innervation between the PVG and the gill intact, an intracellular electrode in L_7 permitted simultaneous recording and stimulation. A suction electrode on the pinnule overlying the antiflaring musculature provided an extracellular record of the synaptic potentials (compound junctional potentials, CJP's) produced in the muscle cells by L_7 stimulation. This technique permitted recording of evoked CJP's while measuring the tension of pinnule contraction with a force transducer.

Trains of spikes in L_7 are required to elicit antiflaring. We examined age-effects on facilitatory processes at L_7's terminals using both double pulses and 3 sec spike trains in L_7. The resulting CJP's were analyzed by calculating the ratio, $f = [CJP_i/CJP_1] - 1$, where CJP_1 is the first evoked response and CJP_i is any subsequent response. No difference was found between the two age groups for double pulse facilitation with interspike intervals of 40-500 msec. The maximum f values for mature and old animals, 1.9 ± 0.5 (n=5) and 1.7 ± 0.4 (n=5) respectively, were obtained with interspike intervals of 70-100 msec. Within each group the facilitation decayed to one-half its peak value in approximately 80 msec. A similar analysis was made of augmentation, defined here as facilitation during a 3 sec spike train. For low frequency trains (those near threshold for producing muscle contraction, 8-18 spikes/3 sec) there was no difference in augmentation of CJP's from old and mature animals. At intermediate frequencies (those which always elicited contraction, 21-28 spikes/3 sec) CJP's from mature pinnules showed more augmentation than did those from old animals, although the differences were not significant ($p > 0.05$). At high frequencies (those producing maximal contraction, 39-48 spikes/3 sec) the augmentation of CJP's was significantly greater in mature than in old animals ($p < 0.05$, n=5). Also, in old animals augmentation levels were not sustained as they were in mature animals.

These results suggest that diminished motor neuronal function of L_7 results from decreased synaptic facilitation during trains between L_7 and the pinnule musculature in old Aplysia. (MH18611)

123.2 CEREBRAL BLOOD FLOW AND CEREBRAL METABOLIC RATES FOR OXYGEN, GLUCOSE AND CARBON DIOXIDE IN FISCHER-344 RATS OF DIFFERENT AGES. H. Takei*, W.R. Fredericks*, E.D. London and S.I. Rapoport. Laboratory of Neurosciences, National Institute on Aging, Gerontology Research Center, Baltimore, Maryland 21224.

Global cerebral blood flow (CBF) and the cerebral metabolic rates for O_2 ($CMRO_2$), glucose (CMRglc) and CO_2 ($CMRCO_2$) were measured in male, conscious, partially-immobilized Fischer-344 rats at the ages of 3, 12 and 24 months. CBF was determined with ^{14}C-iodoantipyrine which was infused intravenously for 45 sec. Radioactivity in timed arterial blood samples and in the brain at 45 sec was determined by scintillation counting (Sakurada et al., Am. J. Physiol. 234, H59, 1978; Ohno et al., Stroke, 10, 62, 1979). The metabolic rates for O_2, glucose and CO_2 were calculated from the concentrations of these substances in femoral artery and sagittal sinus blood, from which arteriovenous differences were obtained and multiplied by CBF. Differences and correlations noted below were significant at $P < 0.05$.

In fourteen 3-month old rats, CBF = 1.20 ± 0.08 ml/g/min (mean ± S.E.M.), $CMRO_2$ = 4.71 ± 0.32 μmol/g/min, CMRglc = 0.72 ± 0.09 μmol/g/min and $CMRCO_2$ = -4.86 ± 1.17 μmol/g/min. Whereas CBF, $CMRO_2$ and $CMRCO_2$ did not change significantly with age ($p > 0.05$) CMRglc was greater at 12 months than at 3 months. The ratio of $CMRO_2$/CMRglc was 6.97 ± 0.51 at 3 months, and did not change significantly with age. In individual rats, CBF was positively correlated with $CMRO_2$ and CMRglc, due to coupling between blood flow and oxidative metabolism, and negatively correlated with arterial hematocrit (which was reduced by blood loss). As the superior sagittal sinus drains venous blood mainly from supratentorial cortical regions, the results indicate that global CBF and indices of cerebral cortical oxidative metabolism do not decline with age in the conscious partially-immobilized rat.

The results are not in conflict with previous observations in aging rats, that decreases in CMRglc of most cortical areas are usually less than 20% (Smith et al., Brain, 103, 351, 1980; London et al., J. Neurochem., 1981, in press). Such small decrements may be obscured by experimental errors in determinations of global CBF, CMRglc and regional CMRglc.

123.3 AGING OF DIENCEPHALIC CATECHOLAMINE NEURONS (A-11, A-12, A-13, A-14) IN THE FISCHER 344 MALE RAT. L.D. Selemon* and J.R. Sladek, Jr. (SPON: W.E. O'Neill). Center for Brain Research and Dept. of Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

A-12 dopamine neurons have been implicated in a LHRH modulatory activity and inhibitory control of prolactin release from the anterior pituitary. In turn, the level of activity of A-12 neurons is regulated by peripheral steroid and prolactin levels. The function of and relevant inputs to incertohypothalamic catecholamine neurons (A-11, A-13, A-14) has yet to be established. Age-matched sets, which included one Fischer 344 male rat at 3, 20, and 30 months of age, were processed simultaneously for formaldehyde-induced fluorescence. Nucleated cell profiles and total cell profiles were counted in every tenth section of serial paraffin sections. These raw counts were corrected for split-cell errors and errors due to unseen small profiles using a modified Abercombie (1946) formula. A-12 soma exhibited a visible increase in fluorescence intensity as a function of age which was confirmed by microspectrofluorometric analysis. In contrast, the visible fluorescence intensity of incertohypothalamic neurons either declined (A-13) or was unchanged (A-11, A-14) in the aged versus the young rat. Similarly, cell counts of A-12 neurons revealed a 73-100% increase in visible cell population while the visible cell population of A-11 neurons decreased 10-81%; A-13 neurons decreased 24-42%. Only a small number of A-14 neurons were counted in any of the animals studied, and age-related changes in the A-14 cell population were extremely variable between sets. Since the age-related changes seen in A-12 dopamine neurons were not mirrored by A-11, A-13, or A-14 neurons, a generalized aging mechanism for diencephalic catecholamine groups is not supported by these data. However, the reduction in fluorescence intensity noted in A-13 soma parallels that seen in brain stem catecholamine groups (Sladek and Blanchard, Anat. Rec. 199:239A, 1981). The increases in transmitter content of A-12 soma are unique to tuberoinfundibular neurons and may be linked to the endocrine function of this dopaminergic system. Alternately, failure of the axon transport mechanism may occur selectively in A-12 neurons resulting in accumulation of transmitter in A-12 soma. Supported by USPHS Grants NS 15816 and AG 00847 (JRS).

123.4 SECRETION OF HYPOTHALAMIC DOPAMINE INTO HYPOPHYSIAL PORTAL BLOOD OF AGED FEMALE RATS. M. J. Reymond* and J. C. Porter. Cecil H. and Ida Green Center for Reproductive Biology Sciences, Depts. Ob-Gyn and Physiology, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

There is considerable indirect evidence for the view that neuronal function is impaired in the aged brain, including the hypothalamus. In order to study the effect of aging on neuronal function, we have investigated the neurosecretory activity of dopaminergic tuberoinfundibular neurons of aged female rats by determining the concentration of dopamine in hypophysial portal blood and calculating the rate of secretion of dopamine into portal blood. Although blood flow in the pituitary stalk vasculature of both old and young rats was the same, the concentration of dopamine in plasma of hypophysial portal blood of old constant estrous rats (20-24 months of age) was much less than that of young estrous rats (3-4 months of age) (1.25 ± 0.42 vs. 5.56 ± 0.78 ng/ml plasma, mean ± SE). The secretion rates of dopamine by hypothalamic neurons were 0.36 ± 0.14 ng/hr in old female rats and 1.65 ± 0.33 ng/hr in young female rats. The low concentrations of dopamine in hypophysial portal blood of aged rats were associated with high concentrations of prolactin in arterial blood. In aged female rats compared to young female rats, the concentrations of dopamine were reduced in the median eminence, a region that contains terminals of dopaminergic tuberoinfundibular neurons. The impaired hypothalamic secretion of dopamine observed in old rats was not affected by increased availability of L-tyrosine (200 mg/kg BW, IP) administered 60 min before beginning the collection of pituitary stalk blood. However, when old rats were treated with L-DOPA (200 mg/kg BW, IP), very high concentrations of dopamine were found in hypophysial stalk plasma compared to those of vehicle-treated old rats (64.1 ± 9.7 ng/ml vs. 1.25 ± 0.42 ng/ml). The high concentration of dopamine in hypophysial portal plasma of L-DOPA-treated old rats is believed to be a consequence of the conversion of L-DOPA to dopamine by hypothalamic neurons since the concentration of dopamine in the serum of arterial blood of the same animals was much less (1.56 ± 0.27 ng/ml) than that in portal plasma. On the basis of these data, it is concluded that the neurosecretory activity of the dopaminergic neurons of the hypothalamus is impaired in old constant estrous rats. This impaired neurosecretory activity can be overcome by increasing the availability of L-DOPA, the precursor of dopamine, but not of L-tyrosine.

123.5 AGE DIFFERENCES IN RECOVERY FROM INJURY TO THE NIGROSTRIATAL DOPAMINERGIC PROJECTION. J. F. Marshall, M. Drew*. Dept. of Psychobiology, University of California, Irvine, CA 92717

After unilateral injury to the mesotelencephalic dopaminergic projection rats show marked contralateral sensorimotor impairments, including an inability to orient to touch of the body surface. Rats with this injury frequently recover from this somatosensory localization deficit, and the extent of recovery is directly correlated with the dopamine (DA) content of the affected neostriatum at sacrifice.

Because aged rodents have marked changes in the neurochemistry of the nigrostriatal projection and its target site, and because they show no proliferation of striatal DA receptor sites after chronic neuroleptics, it was important to compare the extent of recovery of somatosensory localization in aged (26+ mos.) and young adult (4-6 mos.) Fischer 344 rats given 6-hydroxydopamine (6-OH-DA) injections (2, 4, or 6 µg) into the left ventral tegmentum after desmethylimipramine pretreatment (15 mg/kg, i.p., 30 min.). Somatosensory localization was studied for one month postoperatively, after which the animals were sacrificed for striatal catecholamine analysis.

Old rats given small (2 µg) 6-OH-DA injections showed substantially less recovery of somatosensory localization than did young rats given the same amount of this neurotoxin. The depletions of striatal norepinephine (20-30%) achieved by this 6-OHDA dose were similar in young and old rats. However, the neostriatal DA depletions of young rats (20%) were significantly less than were those of old rats (90%).

When the extent of recovery of each animal was plotted as a function of that animal's striatal DA depletion, significant correlations (-.71 and -.62) were obtained for the young and old groups. (Correlations between recovery and striatal NE depletions (-.64 and -.44) were somewhat smaller). However, the regression lines relating recovery to striatal DA depletions did not differ for the young and old groups.

The results suggest that young and old rats recover similarly after an equivalent degree of dopamine cell loss. Thus, the neural changes underlying this recovery are similar in both age groups. Our findings also suggest an enhanced susceptibility of the dopaminergic projection to the neurotoxic actions of 6-OHDA in aged rats.

Supported by NIH grant AG-00538 to J.F.M.

123.6 DIETARY CHOLINE INCREASES DENDRITIC SPINE POPULATION IN AGING MOUSE NEOCORTEX. Ronald Mervis and Raymond T. Bartus. Dept of Pathology (Neuropathology), The Ohio State University College of Medicine, Columbus, OH 43210, and Dept. of CNS Research, Medical Research Div., American Cyanamid Co., Pearl River, NY 10965.

Dietary choline enrichment (ChE) or deficiency (ChD) has been shown to alter the behavior of mice in ways that are quantitatively and qualitatively similar in comparison to those occurring naturally along the lifespan of mice on baseline control (BC) diets (Bartus et al, Science 209:301, 1980). Thus, when 8.5 month-old mice were placed on a ChE diet for 4.5 months and later behaviorally tested when 13-months-old, they performed as well as 3-month-old control mice. Similarly, ChD mice performed as poorly as senescent (23-month-old) mice. The mice were subsequently maintained on their respective dietary regimens for an additional six months and sacrificed (when 19-months-old). Hemispheres were coronally sectioned, impregnated using the Rapid Golgi method, and, in a blind study, randomly chosen layer V neocortical pyramidal cells were selected from coded slides for analysis of dendritic spine populations along selected lengths from both apical and basilar portions of their dendritic trees. This study evaluated over 120 neurons from 26 brains divided among the 3 dietary groups. In general, ChE mice had greater, and ChD mice, fewer, numbers of dendritic spines along the sampled areas in comparison to the age-matched control mice. In particular, ChE mice showed a highly statistically significant increase in spine population along the terminal tips of both apical ($p<.01$) and basilar ($p<.05$) branches in comparison to controls. This provides the first correlative evidence for structural-functional alterations which may be attributed directly to dietary choline. It further implies that dietary choline may not only manipulate cholinergic neurotransmitter mechanisms, but, by influencing phospholipid synthesis, such long-term dietary treatment may enhance the production of dendritic membrane.

(Supported by the OSU Development Fund #6822)

124.1 AGE-RELATED IMPAIRMENT OF HIPPOCAMPAL FREQUENCY POTENTIATION: EVIDENCE OF AN UNDERLYING DEFICIT IN TRANSMITTER RELEASE FROM STUDIES OF MAGNESIUM-BATHED HIPPOCAMPAL SLICES. P.W. Landfield, Dept. Physiol. & Pharmacol., Bowman Gray School of Medicine, Winston-Salem, NC 27103.

We have previously found that one of the most characteristic neurophysiological alterations in hippocampus of healthy, aging rats is an impairment of monosynaptic frequency potentiation of the extracellular population spike (in field CA1) during repetitive stimulation, which impairment is restricted to orthodromic stimulation. The pattern of potentiation impairment suggests that a deficit in transmitter functions may be involved (Landfield et al., 78, Brain Res.; Landfield, 80, in: Psychobiol. of Aging, Elsevier), although the data are not conclusive.

Recently, it was reported that bathing hippocampal slices from young animals in high Mg^{++}-low Ca^{++} media substantially enhanced monosynaptic frequency potentiation in comparison to potentiation in standard media, presumably by preventing transmitter depletion (Landfield, 80, Soc. Neurosci. Abstr.)

In the present studies, hippocampal slices from both aged and young Fischer rats were studied in high magnesium (2.7 mM)-low calcium (1.0 mM) media, and compared on measures of frequency potentiation of both the population spike and the "field EPSP" in the Schaffer collaterals of the CA1 apical dendrites. Both the spike and the EPSP exhibited less potentiation in slices from aged rats and, moreover, the EPSP and spike followed very similar temporal patterns of potentiation and depression during repetitive stimulation. When spike potentiation failed, so did EPSP potentiation. Changes in the dendritic fiber potential did not account for these changes. These data strongly indicate that the age-related deficit in spike potentiation is synaptic (as opposed to, for example, being due to dendritic electrotonus or to somal spike thresholds).

Additionally, it was found that high Mg^{++} media increased potentiation of the EPSP and the spike in slices from aged as well as from young rats, although the increase was larger in slices from young rats.

The primary effect of magnesium on synaptic potentials is known to be presynaptic in many systems. The ability of Mg^{++} to counteract the age deficit in hippocampal EPSP potentiation, therefore, suggests that the mechanism underlying the age deficit may be related to impaired transmitter release from presynaptic terminals.

124.2 BRAIN NORADRENERGIC RESPONSES TO A SINGLE TRAINING FOOTSHOCK IN THE AGING RAT. K. Welsh* and P. Gold (SPON: P. J. Best). Dept. of Psychol., Univ. of Virginia, Charlottesville, VA 22901.

Recent evidence in the Fischer F-344 rat demonstrates age-related declines in retention performance at long intervals after avoidance training. These memory impairments may be explained in part by altered neurobiological systems which modulate the extent to which recent information is stored. For example, central noradrenergic systems are particularly sensitive to avoidance training and to memory modulating treatments. In the present experiment, we were interested in measuring the central noradrenergic responsiveness to the acute stress elicited by footshock in an inhibitory avoidance task.

F-344 rats (Charles River) were obtained at 60 days, 1 year, and 2 years of age and were housed individually. Three weeks following arrival each rat was placed in a rectangular shock compartment where it received a single, moderately intense footshock (2.0 mA, 2 sec duration). Ten mintues following this experience, the animals were decapitated, the brains were removed and subsequently divided into a brainstem sample (including the medulla, pons, and midbrain) and a forebrain (telencephalon-diencephalon) sample. Norepinephrine (NE), dopamine (DA), and epinephrine content were assessed with a sensitive COMT assay.

In general forebrain and brainstem catecholamine levels did not differ among the three age groups. Forebrain DA proved to be the exception, demonstrating a progressive decrease in concentration with age but reaching significance only in the oldest age group ($P < 0.05$). This result complements the deficits in DA metabolism already well characterized in the aging rodent (Finch, Brain Research, 52, 1973). Only the noradrenergic system exhibited concentration changes following the acute footshock experience. Moreover, this system appeared to be differentially sensitive to stress depending on the age group analyzed. Following footshock, both the 70 day and 1 year old rats demonstrated 20-30% decreases (Ps < 0.05) in both forebrain and brainstem NE. In the oldest animals, NE concentration was not significantly altered by the footshock experience. These findings are consistent with earlier findings from our laboratory which indicate that post-training NE responses are correlated with later retention performance under a variety of training and post-training treatment conditions. The present results, therefore, suggest that age-related declines in central noradrenergic responsiveness to training-related stress may contribute to age-related memory deficits.

Supported by USPHS grants AG 01642 and MH 31141 and by NSF grant SER 76-18457.

124.3 MEMORY CONSOLIDATION IN SENESCENCE: EFFECTS OF CO_2, AMPHETAMINE AND MORPHINE. R.B. Messing, H. Rigter, and V. Nickolson*. Scientific Devel. Grp., Organon International, Oss, The Netherlands.

Alterations in memory storage processes that occur in senescence were investigated by challenging young (4 month old) and old (30 month old) female "small Wistar" rats with posttraining administration of CO_2, amphetamine or morphine and measuring retention performance. Rats were trained in a one-trial inhibitory avoidance step through task, in which they were given a 0.5 mA, 3 sec footshock upon entering a dark compartment. They were then placed in a box saturated with CO_2 and returned to their home cages. The next day, the latencies of rats to enter the dark (shock) compartment were measured. Animals treated with CO_2 for 10-30 sec were amnestic, as indicated by shorter latencies than untreated controls to enter the compartment in which footshock had been administered. Neither duration of CO_2 immersion, nor the time of CO_2 treatment after training had a differential effect with age on retention performance. Challenge with drugs, however, did reveal age-related alterations in memory storage processes. Amphetamine (0.3 or 1.0 mg/kg, i.p.) administered immediately after training, and just prior to placement of rats in CO_2, attenuated the CO_2-induced amnesia in young rats, but had no effect in old rats. This could not be attributed to a general decline in response to amphetamine in old rats, because amphetamine increased open field activity of both young and old rats. In another experiment, the amnestic effects of morphine were investigated, using a hot plate escape task. Rats were placed on a hot plate (54.5 or 56.5°C) inside a glass cylinder 18-19 cm high, and the latency to escape by jumping to the top of the cylinder was recorded. Immediately after a single training trial, rats were injected with saline or morphine (3 or 10 mg/kg, i.p.) and returned to their home cages. Escape latencies were again measured two days later. Old rats treated with 3 mg/kg of morphine failed to learn, as indicated by the lack of a significant decrease in jump latencies in the retention as compared to the training trial. Old rats treated with saline did exhibit signficant learning, and also had longer retention latencies than morphine-treated rats. In contrast, young rats treated with morphine or saline exhibited a significant decrease in retention as compared to training latencies, and no effect of morphine on retention performance was observed. Thus, morphine induced an amnesia only in old rats.

These results indicate that the memory modulatory role of catecholamine and opioid systems may be altered in senescence.

124.4 REGIONAL BRAIN METABOLISM AND COGNITIVE DEFICITS IN AGING AND SENILE DEMENTIA. S.H. Ferris, M.J. de Leon*, D. Christman*, B. Reisberg*, J. Fowler*, A. George*, M. Emmerich*, C. Gentes*, T. Farkas* and A.P. Wolf*. Dept. of Psychiatry, N.Y.U. Med. Ctr., N.Y., N.Y. 10016 and Brookhaven National Labs., Upton, N.Y. 11973

Positron Emission Tomography (PET) is a new technique for studying regional brain function. ^{18}F-2-deoxy-2-fluro-D-glucose (FDG) is a positron emitting tracer for rate of glucose utilization in brain tissue. When a PET scanner is used following intravenous injection of FDG, in vivo quantitative measurements in man of regional glucose utilization can be obtained. Periodic "arteriolized" venous blood samples are obtained for determining the time course of the tracer, glucose and blood gases. The FDG is "trapped" in the brain cells as a 6-phosphorylated derivative. The trapping rate is proportional to the metabolic rate and provides a usable functional index after about 30 min. From emission data provided by the PET scanner, a computer reconstructs tomographic images representing the regional distribution of tracer uptake in the brain. Using a mathematical model for FDG and glucose metabolism, the rate of glucose utilization (mg/100g of tissue/min) may be quantified for various regions of interest in the brain.

We applied the PET-FDG technique to study regional brain metabolism in normal elderly subjects (N=6) and in senile dementia patients (N=12) with mild to moderately severe cognitive impairment. Patients with Primary Degenerative Dementia (Alzheimer's disease) were selected based upon extensive diagnostic evaluation Regional metabolic data were obtained using the PETT III scanner (spatial resolution = 1.7 cm^3).

At the level of the basal ganglia (CM plane x 40mm), the dementia patients showed marked diminution in metabolism (35-45%) as compared to age-matched controls (p's<.001). The regions sampled included frontal and temporal cortex, thalamus and caudate. The degree of diminution was highly correlated (p's<.05) with measures of cognitive impairment, particularly with deficits in memory. Less diminution (15-20%) was found at the level of the centrum semiovale (CM + 70mm). We also examined the relation between metabolic and structural changes by sampling computed tomography (CT) densities for various brain regions. The results did not indicate a simple pattern of PET-CT correlation. Interestingly, thalamic CT changes correlated with metabolism in most other brain regions.

The PET-FDG technique shows great promise for studying in vivo the brain changes related to aging and senile dementia. It also may prove helpful for studying brain pathways related to cognitive processes, and for evaluation of drug effects.

124.5 NEUROMETRIC CORRELATES OF COGNITIVE DYSFUNCTION IN THE ELDERLY. L. Prichep*, F. Gomez-Mont*[1], H. Kaye, E.R. John, S. Ferris & J. Fridman*[2]. (SPON: H. Ahn). Brain Research Lab., Dept. of Psychiatry, N.Y.U. Medical Center, N.Y., 10016. [1]Informatics Unit, Mexican Institute of Psychiatry. [2]Neurometrics Inc., N.Y.

The electroencephalogram (EEG) and averaged evoked potentials (EPs) can be used to assess the anatomical integrity, functional status and maturational development of the brain, as well as to evaluate information processing related to sensory, perceptual and cognitive functions. Using neurometrics, features of clinical diagnostic utility are extracted from a battery of EEG and EP conditions by objective quantitative procedures. These features are evaluated statistically relative to a normative data base, yielding the objective probability of abnormality for each measure. Studying the normative distributions, we found that the frequency composition of the EEG in the normative population could be described by a set of linear equations as a function of age. Deviations from the values predicted by the neurometric equations were few in large groups of culturally different normal children (6-16 yrs.), while a high incidence of significant deviations were found in children with learning disabilities and those at risk for neurological disorders.

The extension of these findings to include adults through senescence and the ability of such EEG and EP data to discriminate between normal (N=55) and cognitively impaired (N=75) elderly is the primary focus of this paper. Preliminary results indicate that based on the predicted EEG values for adults we can obtain very high discriminant accuracy in this population. Using only 10 EEG variables selected on the basis of a portion of univariate results, we were able to correctly identify 88% of the normal and 84% of the dysfunctional patients. (Split-half replication was approximately 80% for both groups). The results based on the addition of evoked potential measures and a more optimal set of EEG features to the dicriminant analysis will be presented.

In a previous study of a population of elderly patients we were able to identify homogeneous subgroups within the population using cluster analysis. The extension of such analyses to the present population and the usefulness of such differential identification of subgroups for the purpose of understanding and treating the elderly will be discussed.

124.6 "I DON'T KNOW" RESPONSES IN DEMENTIA AND DEPRESSION. R. C. Young and M. Manley*. Dept. of Psychiatry, Cornell Univ. Med. Coll. and New York Hosp.-Cornell Med. Ctr., Westchester Div., White Plains, New York 10605.

Dementia and depressive illness are sometimes difficult to distinguish in the elderly. Clinicians have suggested that depressives with "pseudodementia" give "I don't know" responses on mental status examination while demented patients do not. Documentation of the frequency of such responses was sought.

Nineteen patients aged 58 to 90 were interviewed. Nine had primary degenerative dementia (PDD), eight had primary recurrent major depression (PRMD), and two presented with both major depression and dementia. Severity of depressive symptomatology was rated with the Hamilton Scale (HRS) and cognitive performance was tested with the Minimental State scale (MMS). Responses on the MMS were categorized as correct, incorrect or irrelevant, or "I don't know"/"I can't".

As expected, subjects with PRMD had higher HRS scores (median 25; range 18-30) than those with PDD (median 8; range 4-17; $p < .002$; Mann Whitney U test, 2tailed). The two subjects with both depressive and dementia syndromes had HRS scores of 29 and 31. Again, as expected, subjects with PDD had lower MMS scores (median 12; range 3-22/30) than those with PRMD (median 28; range 20-30; $p < .002$). The MMS scores of the two subjects with depression and dementia were both 17.

The subjects with PDD gave more "I don't know" responses (median 6; range 0-10) than those with PRMD (median 0; range 0-8; $p < .02$). While 8 of 9 subjects with PDD gave "I don't know" responses, only 3 of 8 with PRMD did so ($p = .04$; Fisher's exact test). The two subjects with depression and dementia gave 2 and 3 "I don't know" responses.

These preliminary findings call into question the usefulness of "I don't know" responses in differential diagnosis since they may be elicited often in patients with PDD.

124.7 TURNOVER OF NEUROTRANSMITTERS AND METALS IN RABBIT BRAIN AFTER TREATMENT WITH ALUMINUM AND CHELATING AGENTS. K. S. Rajan, S. Mainer, Nina L. Rajan, IIT Research Institute, Chicago, IL, and B. I. Diamond, R. L. Borison and J. M. Davis, Illinois State Psych. Institute, Chicago, IL.

A possible role for Al(III) in the neuropathology of Alzheimer's disease has been considered by a number of reports. In this context, it is important to know, (1) the nature of incorporation of excess Al(III) and the associated changes in neurotransmitter levels in the brain and (2) the effect of therapeutic removal of Al(III) on the turnover of the neurotransmitters and the cerebral metals. Studies were undertaken to determine the brain levels of Al and dopamine metabolites as a result of treatment with chelating agents. On the basis of physicochemical studies directed toward exploring suitable chelating agents for *in vivo* interaction with cerebral aluminum, two compounds have been found to be suitable, i.e., ethylenediamine di-(o-hydroxyphenylacetic acid) [EDDHA], and N,N-'di-(2-hydroxybenzyl) ethylenediamine-N,N'-diacetic acid [HBED]. The stabilities of their Al(III)-chelates (log K_{ML}) were 24.48 ± 0.06 and 24.78 ± 0.23. I.V. treatments of New Zealand rabbits (2.5 Kg, male) with the two chelating agents (7.7 mg/Kg) resulted in a 14 to 24% decrease in brain levels of Al(III). The levels of dopamine (1.1 µg/g) homovanillic acid (1.7 µg/g) and dihydroxyphenyl acetic acid (0.6 µg/g) in the caudate increased to 3.8, 4.4, and 0.9 µg/g, respectively after chelate treatment. The results are discussed in terms of a possible chelation approach to dopamine turnover and the alteration of the levels of Al and other metals in the brain. (Supported by NIH Grant No. NS11556.)

124.8 EFFECT OF REPETITIVE HYPOXIA ON LOCOMOTOR ACTIVITY AND LEVELS OF CATECHOLAMINES IN BRAIN REGIONS OF AGED RATS. Isaac F. Roubein, Larry J. Embree, David W. Jackson*, and Danny Kay*. VA Med. Cen., and Dept of Neurology, LSU Med. Cen., Shreveport, LA 71130.

Previous work in our laboratory has shown that when aged rats were exposed to 10% oxygen for 2, 13, and 36h, the levels of dopamine (DA) and norepinephrine (NE) in the brain regions examined remained unchanged after 2h, but after 13h of hypoxia, NE concentration in hypothalamus and midbrain decreased significantly; and after 36h, levels of this monoamine returned to normal (In Press, Neurobiology of Aging). The current study was undertaken to investigate the effects of repetitive hypoxia on locomotor activity and the levels of catecholamines in seven regions of aged rat brain. Groups of aged male rats (25-26 months old) and young adults (10-12 weeks old) were exposed to 10% oxygen for 6h daily for five consecutive days. Thereafter the animals were left in their shelter for 48h; at the end of this period the animals were again exposed to the hypoxic atmosphere for another 5 days and then returned to their shelter for two days; (total days of exposure to 10% oxygen were 20). Young adult animals were exposed similarly to the hypoxia. Control animals of identical ages received air under similar conditions. Behavioral studies: On 5, 10, 15, and 20 day of exposure to 10% O_2 or air, the locomotor activity was measured, using OPTO-VARIMEX. The activity of the animals was recorded every 15 minutes for 6h. At the end of the experiment, the rats were decapitated, the brain excised and dissected into the following regions: cerebral cortex, hippocampus, striatum, hypothalamus, midbrain, cerebellum, pons and medulla. Levels of DA were determined using HPLC. Protein was determined by the Lowry Procedure. DA levels were determined in hippocampus, hypothalamus, midbrain and striatum. Statistical analysis indicated that the levels of DA decreased significantly in the aged hypoxic striatum and midbrain as compared with the same brain regions of the young adult hypoxic animals. There were no significant differences in the levels of DA in the same regions from both air receiving controls (25-26 months and 10-12 weeks). An analysis of variance showed there was no group, weeks, or time of day effect in locomotor activity. The results of this investigation indicate that repetitive hypoxia had differential effects on the levels of DA in striatum and midbrain of aged and young rats. These differences seem to depend on age-related changes in DA metabolism in two specific regions of the aged rat brain exposed repeatedly to hypoxic environment. NE levels in brain regions are currently under investigation and will be reported. Supported by Veterans Administration and the LSUMC, Shreveport, LA.

124.9 RELATIONSHIP OF PLASMA NOREPINEPHRINE, BLOOD PRESSURE, RESPIRATION AND HYPOXIA IN TWO OLDER INDIVIDUALS WITH RESPIRATORY DYSFUNCTION. M.V. Vitiello*, P.N. Prinz, E.C. Giblin*, R.B. Schoene* and J.B. Halter* (SPON: R. Martin). Depts. of Psychiatry, Physiological Nursing and Medicine, Univ. of Washington, and American Lake and Seattle Veterans Admin. Hospitals, Seattle, WA 98195.

Recent studies suggest that the aging process may increase respiratory dysfunctions during sleep. These respiratory dysfunctions may be either apneas, cessation of airflow for 10 or more seconds, or hypopneas, a decrease in the amount of airflow. Either of these conditions can result in a decrease in oxygen saturation (SaO_2) and usually results in an arousal from sleep. The present study evaluated breathing and SaO_2 during sleep and its relationship to sleep patterns, plasma norepinephrine (NE) and blood pressure (BP) in 2 individuals with extensive respiratory dysfunction during sleep.

LG is a 55 year old female and OM a 59 year old male, both complained of excessive daytime sleepiness and had been previously diagnosed as narcoleptic. Subjects were off major medications 2 or more weeks prior to study. Both slept in the laboratory 3 consecutive nights. On night 3 LG received 1-2 litres/hour O_2. Nothing was administered on any of the other nights. Sleep was recorded using nasal and oral thermistors and thoracic and abdominal strain gauges. SaO_2 was recorded using ear oximetry. In addition, blood samples were obtained using an indwelling venous catheter and BP using an Arteriosonde on nights 2 and 3 for LG and night 3 for OM.

Both individuals displayed marked respiratory impairment across the night. While LG's SaO_2 was improved on the O_2 night, her sleep pattern remained severely disturbed. For both subjects there were 2 or more marked periods of oxygen desaturation per night. These desaturations always preceeded REM onset and continued throughout REM. This relationship continued during LG's O_2 night. This relationship has been observed in the general population with apneic episodes associated with REM. Hypoxemia was usually associated with a surge in NE and a labile BP. High pulse pressure occurred frequently throughout the study.

OM, who showed primarily mixed apnea, displayed smaller NE and BP responses than did LG, who had both apneic and hypopneic episodes. This association between hypopnea and apnea and NE and BP changes may be a contributing factor to the increased incidence of hypertension seen with aging.

124.10 SLEEP/WAKING PATTERNS AND PLASMA NOREPINEPHRINE IN YOUNG AND AGED NORMAL MEN. P.N. Prinz, M.V. Vitiello* and J.B. Halter*. American Lake and Seattle Veterans Admin. Hospitals, and Depts. of Psychiatry and Medicine, Univ. of Washington, Seattle, WA 98195.

It is well documented that sleep patterns change with age. Older individuals awaken more during the night and spend less time in rapid eye movement (REM) sleep and slow wave sleep (SWS) than do younger individuals. Recent studies have shown that an increase in daytime plasma norepinephrine (NE) also accompanies the aging process. This study examines plasma NE in young and aged normals during the day and at night in relation to sleep/waking patterns. All subjects were paid volunteers; normotensive nonsmokers in good physical health (based on physical examination)(16 young normals, aged 21-28 years, and 10 aged normals, aged 55-82 years). All subjects had one or more adaptation nights at the Clinical Research Center, University Hospital. Following adaptation hourly blood samples were obtained via indwelling venous catheters, and sleep stages were recorded using conventional techniques. A significantly greater plasma NE level was observed in the older subjects both at night and during the day. Additionally, a diurnal variation of plasma NE was observed in both groups with NE values lowest during sleep and highest during the late morning (approx. 11:00). It was observed that sleep quality was correlated with mean plasma NE levels during sleep ($R=.624$, $p<.01$).

These finding raise the possibility that the well known age effect on sleep may be related to increased sympathetic nervous system activity at night.

	Daytime NE c. 11:00	Nighttime NE c.23:00-6:00	% SWS of Time in Bed	% REM of Time in Bed	% Waking of Time in Bed
AN	327.00± 34.76*	225.30± 19.94	8.34± 2.21	13.79± 2.04	26.09± 5.18
YN	212.50± 26.87*	151.61± 9.35	20.91± 2.01	21.37± 1.54	9.78± 1.62

124.11 EFFECT OF AGING ON FLUID HOMEOSTASIS: RESPONSE TO ACUTE OSMOTIC CHALLENGE. C.D. Sladek, T.H. McNeill, C.M. Gregg‡ M.L. Blair‡ Depts. of Neurology, Anatomy, Physiology, University of Rochester, Rochester, N.Y., 14642; and Dept. of Biology, Pennsylvania State University, University Park, Pennsylvania.

Abnormalities in vasopressin (VP) secretion may contribute to the alteration in body fluid homeostasis associated with aging. In aged rats, the serum VP response to chronic dehydration is attenuated (Sladek et al, Anat. Record 199:239A, 1980). The current study evaluates the ability of aged rats to respond to acute osmotic stimulation. Three mos. (246±5 gms) and 30 mos. (364±9 gms) male Fischer 344 rats received intraperitoneal injections of hypertonic (1,000 mosm/kg) or isotonic (285 mosm/kg) saline and were decapitated 15, 30, or 60 min. later. Control animals received no injections. Serum VP and renin concentrations (SRC) and VP content of the supraoptic nuclei (SON), paraventricular nuclei (PVN), and posterior pituitary (PP) were determined by radioimmunoassay. Injection of isotonic saline did not alter any of these parameters. Kidney function was adequate in the old rats as indicated by normal BUN, plasma albumin concentration, and protein excretion rate. Serum VP and VP content of the SON, PVN, and PP were not significantly different between the 3 and 30 mos. rats. However, relative to body and PP weight, PP concentration of VP was reduced in the old rats ($p < .025$). The hypertonic saline injection resulted in an increase in plasma osmolality (pOsm) by 15 min in both young ($p < .05$) and old ($p < .005$) animals. The increase in pOsm was greater in the old animals than in the young ($p < .005$). Serum VP was elevated ($p < .025$) and SRC was suppressed in both groups. PP and PVN content of VP were not significantly altered, but VP content of the SON was decreased 15 min post injection in the old rats ($p < .025$). Thus, the VP and renin response to hypertonic saline are maintained in aged rats. Evidence was not obtained for increased sensitivity to osmotic stimulation as observed in humans (Robertson and Rowe, Peptides 1:Suppl. 1: 159, 1980). In fact, the converse is suggested by the comparable serum VP concentrations in aged rats in spite of greater osmotic stimulation.

124.12 INCREASE IN IMMUNOREACTIVE β-ENDORPHIN IN THE PLASMA OF OLD MALE RATS: PRESENCE OF A HIGH MOLECULAR WEIGHT FORM, L.J. Forman*, W.E. Sonntag*, N. Miki*, D.A. Van Vugt* and J. Meites* (SPON: R. Bernard). Dept. of Physiol., Neuroendocrine Res. Lab., Mich. State Univ., East Lansing, MI 48824.

In young rats, β-endorphin decreases hypothalamic dopamine and increases serotonin metabolism; decreases release of gonadotropins and increases pituitary release of PRL. A similar condition is found in old male rats since the metabolism of hypothalamic dopamine is reduced, whereas the metabolism of serotonin is increased; and pituitary PRL release is increased, whereas gonadotropin release is reduced. In the present study, plasma levels of immunoreactive β-endorphin (IR-β-ENDO) were measured in young (3-4 mo) and old (19-21 mo) male rats using a highly specific radioimmunoassay. A four-fold increase in plasma IR-β-ENDO was observed in old as compared to young male rats, and pituitary content and concentration of IR-β-ENDO was increased approximately 60% in the old rats. Chromatographic analysis of the plasma of the old and the young rats revealed that the elevated plasma level of IR-β-ENDO in the old male rats was due solely to the present of a high molecular weight form of IR-β-ENDO which was not detected in the plasma of the young male rats. The biological significance of this high molecular weight form of IR-β-ENDO in the old male rats remains to be determined. The greater release of IR-β-ENDO in the old male rats may be related to the changes mentioned above in hypothalamic and pituitary function. (Aided in part by NIH research grant AG00416 to J. Meites, and NIH post-doctoral fellowships to L. Forman, AG05208, and to W. Sonntag, AG05147 from the National Inst. on Aging).

124.13 ALTERATIONS IN ADRENERGIC CONTROL OF VASCULAR SMOOTH MUSCLE DURING AGING. S.P. Duckles. Dept. of Pharmacology, College of Medicine, University of Arizona, Tucson, AZ 85724.

A number of significant alterations in circulatory hemodynamics are known to occur in both animals and man with advancing age. However, little is known about possible changes in adrenergic control of blood vessels that may contribute to hemodynamic alterations. Therefore, the adrenergic neuroeffector mechanism of vascular smooth muscle was characterized using in vitro techniques. Blood vessels from two groups of New Zealand white rabbits were compared: young rabbits (90 days old, 2-3 kg body weight) and aged rabbits (at least 4 years old, 4-5 kg). The life span of domestic rabbits is 7 to 8 years. The content of norepinephrine (NE) measured with a phenylethanolamine-N-methyl transferase radioenzymatic assay was determined in a series of vessels. The ear artery, basilar artery, middle, anterior and posterior cerebral arteries, circle of Willis, thoracic aorta, and mesenteric artery and vein were studied. No significant differences were found in NE content in any of these vessels. Release of endogenous NE evoked by transmural electrical stimulation of superfused vessels in vitro was measured using a radioenzymatic assay. Cocaine (10^{-5} M) and desoxycorticosterone (4×10^{-5} M) were present throughout to prevent neuronal and extraneuronal metabolism. At a frequency of 8 Hz, the fractional release of NE from the ear artery was decreased in vessels from the aged rabbits. Fractional release of NE/pulse ($\times 10^{-5}$) averaged 0.73 ± 0.23 in the aged ear artery compared to 2.0 ± 0.3 in the young ear artery ($p < 0.05$). Responses of vascular smooth muscle to adrenergic nerve stimulation were compared in the two groups of animals by measuring contraction to transmural electrical stimulation in vitro. The optimum resting tension was selected in preliminary experiments. This was not different for 5 mm ring segments from young and old rabbits, being 1 gram in both cases. No significant differences in contractile responses to transmural nerve stimulation were seen. Contractile responses of the ear artery to 200 pulses at 2 Hz averaged 30% of the maximum response in young animals compared to 29% in the aged animals. Maximum contractile responses to adrenergic nerve stimulation averaged 2.27 ± 0.09 grams in the young rabbit ear artery compared to 2.15 ± 0.35 grams in the aged. Further investigation will be necessary to determine the mechanism by which contractile responses of blood vessels to adrenergic nerve stimulation are unaltered even though it appears that a smaller amount of norepinephrine is released.

124.14 AGING-LIKE BRAIN MORPHOLOGICAL CHANGE IS INCREASED IN TWO RODENT MODELS OF PROLONGED HYPERTENSION. T.A. Pitler*, R.I. Baskin*, J.A. Wren* and P.W. Landfield (SPON: J.G. McCormick). Dept. of Physiol. & Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103.

The nature of the interaction of hypertension and brain aging, if any, has not yet been clarified. Although humans with senile dementia exhibit lower than average blood pressures (Busse and Wang, 74, In: Normal Aging, Duke Univ. Press.), elevated blood pressure is also correlated with cognitive impairment in aging humans (Wilkie and Eisdorfer, 71, Science).

In order to determine whether hypertension can retard or accelerate aging-like brain morphological changes, two models of prolonged hypertension were examined for brain morphological patterns, with particular emphasis on glial changes that are known to occur in brains of aging rats.

In the first experiments, 3 mo.-old male Sprague-Dawley rats were unilaterally nephrectomized, and were given a saline solution to drink. Injections of deoxycorticosterone acetate (DOCA) were given for a period of 2.5 mo. (3-6 mg/rat, 2 x week). Blood pressures (BP) were monitored with a tail cuff method. By 2 mo. BP in the DOCA treated rats ranged from 180 to greater than 220 mm Hg, and some hypertensive animals began to exhibit pathological signs of malignant hypertension. All hypertensive and control rats were sacrificed at about 2.5 mo. and their brains were stained with Cajal's gold chloride stain for astrocytes. Hypertensive rats showed increased astrocyte reactivity, and a few of the animals exhibited massive astroglial reactivity, and signs of brain edema or stroke. However, some animals with BPs below 200 mm Hg showed milder glial reactions, which appeared to be very similar in topography to the patterns of astroglial reactivity seen in the hippocampus of normally aging rats (Landfield et al., 77, J. Gerontol.; Lindsey et al., 78, ibid).

In the second experiments, male SHR and WKY controls were maintained from age 4-5 mo. until age 21-24 mo., and semithin sections were then prepared from the hippocampus of each animal. Data analyses indicate that age-related glial reactivity is more pronounced in hippocampus of aged SHRs (BP ~175 mm Hg) than of aged WKYs (BP ~115 mm Hg). Female SHRs are currently under study.

Since the patterns of glial changes that are increased in hypertensive rats are very similar to those seen in normally aging rats, these data suggest that non-lethal levels of hypertension may accelerate some aspects of aging-like changes in the brains of rats. Studies are continuing to determine whether these effects are due to direct or indirect actions on the brain.

125.1 CORTICAL CONTROL OF SELECTIVE ATTENTION IN MAN. A REGIONAL CEREBRAL BLOOD FLOW STUDY. P.E.Roland. Dept. Clin.Physiol. Bispebjerg Hospital DK 2400 NV, Denmark.

How does the cerebral cortex select the sensory cha -nnel from which it wants to extract information, and what happens to irrelevant information from other cha -nnels? Ten subjects were simultaneously stimulated with pairs of objects pressed against their palm, pairs of ellipses projected on a screen and pairs of tones. They were asked to discriminate the input from one channel and ignore inputs from the two other channels. During the two-alternative forced-choice discrimination (2AFCD) the regional cerebral blood flow (rCBF) was measured in 254 cortical regions with the 133-Xe-intracarotid injection technique. Under normal physiological conditions the rCBF is an indicator of the regional cerebral metabolism. Previous measurements of rCBF during 2AFCD with the described stimuli and selective stimulation of either the somatosensory channel (som-ch), the visual channel (vis-ch) or the auditory channel (aud-ch) provoked rCBF increases in these areas: the visual association cortex (vis-ch), posterior superior parietal cortex (vis-ch), parieto-temporo-occipital cortex (vis-ch,aud-ch), right inferior parietal cortex (aud-ch, vis-ch), intraparietal cortex (aud-ch,vis-ch), somatosensory cortex (som-ch), auditory association (aud-ch), inferior posterior fron -tal cortex (aud-ch), frontal eye fields (aud-ch,vis-ch), superior dysgranular cortex (aud-ch,som-ch,vis-ch), anterior part of lateral prefrontal cortex (aud-ch,vis-ch), posterior part of lateral prefrontal cortex (som-ch,aud-ch,vis-ch), and the superior part of the prefrontal cortex (som-ch,aud-ch,vis-ch). Present results: An identical pattern of rCBF increases appeared, no matter what channel the subjects focussed their attention upon. This pattern was composed of increases of rCBF in all the above areas plus an increase in the left inferior parietal cortex. The rCBF increase in the superior dysgranular cortex was particularly high suggesting that this area controls the direction of attention. These results indicate that sensory information, even if it is irrelevant, is processed by the cortex as long as it does not interfere with the processing of the information actually being discriminated. Turning the attention towards either the visual or the auditory channel enhanced the rCBF further in the respective association cortex.

125.2 THE REGIONAL DISTRIBUTION OF MANGANESE IN THE NORMAL HUMAN BRAIN. E. Bonilla, E. Salazar,* J.J. Villasmil* and R. Villalobos*. Instituto de Investigaciones Clínicas. Fac. de Medicina, Universidad del Zulia, Apartado 1151, Maracaibo, Venezuela.

The cause of the higher vulnerability of the nervous tissue and the reasons for the unequal regional distribution of the brain lesions in chronic manganese intoxication are unknown. It is therefore important for the understanding of the pathogenesis of manganese poisoning to gain insight into the topographical distribution of this metal in the brain. The present study includes results from 39 areas of 8 normal human brains. The persons studied comprised 8 men with ages ranging from 11 to 75 years. The manganese content was determined by flameless atomic absorption spectrophotometry. All samples were analyzed by the method of standard additions. The general lineal model from Statistical Analysis Systems was used for the analysis of variance and the comparison between the means.

The highest content of manganese was found in the pineal gland (4.2±2.5 ug/g dry weight). It was observed that the gray matter yielded higher concentrations of manganese than the white matter (1.54 ug/g for gray matter, 0.93 ug/g for white matter). The difference was statistically significant ($p < 0.01$).

No difference was demonstrated for the concentrations of manganese in the frontal (1.60 ug/g), occipital (1.57 ug/g), and parietal (1.54 ug/g) lobes, but when comparing any of these with the content of manganese in the temporal lobe (1.22 ug/g) and with the mean obtained in the white matter of the lobes (0.78 ug/g) the differences were significant at the 5% level.

No difference was detected between the content of manganese in the head (1.29 ug/g) and the body (1.41 ug/g) of caudate nucleus. However, when comparing each of these means with the manganese concentration of the tail of caudate (1.89 ug/g) the differences were significant at the 5% level.

A regression analysis of the amount of manganese in brain and age showed no significant correlation between them. However, the significance started to be detected when alpha = 0.10. Therefore, it is convenient to repeat this analysis with a larger number of brains of different ages. (Supported by CONDES-LUZ).

125.3 AMINO ACID CHANGES FOLLOWING CONDITIONED EMOTIONAL RESPONSE. J.D. Altazan*, M.P. Sands*, D.R. Cherek, J.E. Smith and J.D. Lane (SPON: J.W. Dailey). Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130

Conditioned emotional response (CER) is thought to be an animal model for anxiety. CER has frequently been used to evaluate behavioral-drug effects, with anxiolytics clearly attenuating the emotional response. To evaluate the neurochemical changes associated with this paradigm, groups of three littermate Fisher F-344 rats were food deprived and shaped to lever press in a standard operant chamber. Lever pressing was maintained by a variable interval (VI) 1 min schedule of food presentation. Following stabilization of responding, one hour classical conditioning sessions were initiated. Classical conditioning consisted of presenting conditioned stimulus (tone) of varying lengths (2 min-10 min) and unconditioned stimulus (foot shock, 1mA, 500 msec) approximately 8 times during each session. UCS was presented at the end of CS. One rat of each group received this classical conditioning for 5 sessions. To isolate the conditioning component from the shock history and animal activity, the other two littermates received yoked CS (tone) or USC (shock) only. On test day, the CS was presented to the triads of 15 minutes while lever pressing was maintained by the food presentation schedule, after which the animals were totally frozen and stored at -70°C until analysis. The pre-tone and post-tone responding on the VII schedule were compared. The CER animal responded very little (<<1 res/min) after tone presentation, while both controls continued at pre-stimulus rates (circa 15 res/min). Brains were dissected into discrete cortical and sub-cortical areas and the content and utilization of biogenic amines and amino acid neurotransmitters determined. There were very few changes in content of neurotransmitters or their metabolites, suggesting that small functional pools were being utilized. Comparison of shock history (shock only versus tone only) revealed a general decrease in the turnover of Asp, Glu and GABA in multiple areas. Comparison of the conditioning/emotional component (CER versus shock only) revealed a general increase in turnover of Asp and Glu in multiple areas and mixed changes in turnover of GABA in limbic versus motor areas. These data are consistent with CER being a model for studying emotional behavior in the presence of an aversive stimulus. Since amino acids are the neurotransmitters at a majority of CNS synapses, both general and specific roles for them in conditioning and emotion are predictable. (supported by USPHS Grant MH-31835).

125.4 RECEPTOR CHANGES FOLLOWING THE REVERSAL OF CONDITIONED EMOTIONAL RESPONSE. G.F. Guerin*, C.M. Crenshaw*, J.E. Smith, D.R. Cherek and J.D. Lane (SPON: C.D. Wood). Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Conditioned emotional response (CER) is thought to be an animal model for anxiety. CER has frequently been used to evaluate behavioral-drug effects with anxiolytics clearly attenuating the emotional response. To evaluate the neurochemical changes associated with this paradigm, groups of three littermate Fisher F-344 rats were food deprived and shaped to lever press in a standard operant chamber. Lever pressing was maintained by a variable interval (VI) 1 min schedule of food presentation. Following stabilization of responding, one hour classical conditioning sessions were initiated. Classical conditioning consisted of presenting conditioned stimulus (tone) of varying lengths (2 min-10 min) and unconditioned stimulus (foot shock, 1 mA, 500 msec) approximately 8 times during each session. UCS was presented at the end of CS. One rat of each group received this classical conditioning for 5 sessions. To isolate the conditioning component from the shock history and animal activity, the other two littermates received yoked CS (tone) or USC (shock) only. On test day, the CS was presented to the triads for 15 minutes while lever pressing was maintained by the food presentation schedule, after which the animals were decapitated and stored at -70°C until analysis. The pre-tone and post-tone responding on the VII schedule were compared. The CER animal responded very little (<<1 res/min) after tone presentation, while both controls continued at pre-stimulus rates (circa 15 res/min). If the CER conditioned animals were given an acute i.p. dose of diazepam, the suppression and emotional behavior were attenuated, and pre-CS VII responding returned. Brains were dissected into discrete cortical and sub-cortical areas and total particulate membrane fractions were prepared. Membrane suspensions were evaluated for binding of tritiated QNB, spiperone, muscimol, WB4101, DHA, 5-HT, imipramine and diazepam in the presence or absence of displacing agent. When comparing the CER animals with their shock-only controls, frontal and associatiative cortical areas had decreased benzodiazepine and increased muscarinic acetylcholine receptors. Diazepam administration effected QNB, spiperone, DHA, but not diazepam binding. This data is consistent with CER being a model for studying emotional behavior in the presence of an aversive stimulus and indicates that CER and its reversal by benzodiazepines is mediated by classic neurotransmitters. (Supported by USPHS Grant MH-31835).

125.5 ALTERED METABOLIC ACTIVITY IN RAT BRAIN PRODUCED BY PHENCYCLIDINE ANALOGUES: A 2-DEOXY-D-GLUCOSE STUDY. R. P. Hammer, Jr. and M. Herkenham., Lab. of Neurophysiology, NIMH, Bethesda, MD 20205

Phencyclidine-induced changes in brain metabolism have been reported to predominate in limbic structures (Meibach et al., Nature, 1979, 282:625). We have examined patterns of metabolic activity in brains of rats exposed to phencyclidine and phencyclidine analogues using ^{14}C- and ^{3}H-2-deoxy-D-glucose. Brain sections were exposed either to X-ray film, ^{3}H-sensitive LKB Ultrofilm, or Kodak NTB-2 emulsion for autoradiography. Our preliminary autoradiograms show striking patterns of columns and laminae selectively marked in various cortical regions. Comparatively greater glucose utilization occurs in the molecular layers of hippocampus, dentate gyrus, subiculum and parahippocampal cortex. The densest labeling in the entire brain is found in layer I of posterior entorhinal cortex. A striking variation of neocortical glucose utilization is noted in the form of columns which appear in register with granule cell-poor zones in layer IV of somatic sensory-motor cortex. The patterned labeling of large portions of neocortex, including at least all of SI cortex, suggests that metabolic columns are not caused by phencyclidine-induced "whisking" which would limit their appearance to vibrissal barrel fields. Rather, columns occur in cortical regions spared by inputs from thalamic relay for somatic sensation. Increased metabolic activity in the molecular layer of the hippocampus and dentate gyrus may be correlated with terminations of pathways from regions rich in phencyclidine receptors, including dentate gyrus and entorhinal and cingulate cortices (Quirion et al., PNAS, 1981, in press). Descriptions of phencyclidine "anesthesia" as a functional dissociation of cortical areas could be explained by the differential activation of limbic and neocortical zones by phencyclidine-stimulated systems. These results further elucidate the influence of phencyclidine (PCP) on brain metabolism by affecting the activity of neo- and archicortical systems.

125.6 HISTOPATHOLOGICAL CORRELATES OF REGIONAL UPTAKE OF ^{14}C-DEOXYGLUCOSE (DG) IN CAT BRAIN AFTER CONCUSSIVE INJURY. C. M. Pechura,* J. Povlishock, D. P. Becker and R. L. Hayes* (SPON: K. Corley). Div. of Neurosurgery, Med. Coll. VA, Richmond, VA 23298.

The ^{14}C-deoxyglucose (DG) technique (Sokoloff et al., J. Neurochem. 28:897, 1977) has been used to define patterns of local glucose utilization (LGU) in the CNS associated with various pathophysiological conditions. The present study examined whether or not specific patterns of DG uptake could be associated with the various histopathologies seen following mechanical brain injury in cats. The DG technique was combined with horseradish peroxidase (HRP) and hematoxylin and eosin (H&E) histological methods.

Surgical preparations were performed under Brevital. Subsequently, cats (2.5-3.0 kg) were paralyzed and ventilated under nitrous oxide (70% N_2O, 30% O_2) anesthesia. Graded head injury (n=4) was produced via a fluid pressure pulse measured in atmospheres of pressure (Sullivan et al., J. Neurosurg. 45:520, 1976). Four cats were surgically prepared but not injured. Nitrous oxide anesthesia was withdrawn following injury in the experimental group. Five minutes prior to injury HRP was injected (i.v., 50-75 mg/kg) to assess blood-brain barrier (BBB) status and the presence of contusions or hemorrhage (Povlishock et al., Brain Res. 153:223, 1978). DG (i.v., 75-100 µCi/kg) was injected one hour following insult or completion of sham surgery. Forty-five minutes following the DG injection, animals were killed by an overdose of barbiturate, perfused, the brains frozen and prepared for DG autoradiography in the standard manner. Alternate serial sections were collected for HRP visualization and H&E staining.

DG uptake decreased in contused brain areas and showed a spatial relationship to areas of tissue destruction indicated by exudation of HRP. Subarachnoid hemorrhages, seen as extracerebral fringes of HRP reaction product or H&E staining were also visible in the autoradiographs. Small intraparenchymal hemorrhages, as identified by HRP reaction and H&E staining, appeared as corresponding spots of dense DG labelling in the autoradiographs. DG uptake did not exhibit a spatial relationship to HRP extravasation associated with BBB opening produced by injury. Regions normally excluded from the BBB showed corresponding patterns of HRP reaction product and uptake of DG. These data suggest that patterns of DG uptake can be reliably associated with certain pathophysiologic events following concussive injury. These methodologies allow evaluation of the possible contributions of histopathology to changes in functional activity, inferred by the DG method, following head injury. Supported by NIH Grant # NS 12587.

125.7 MEASUREMENT OF LOCAL BLOOD FLOW AND GLUCOSE METABOLISM WITHIN THE SAME TISSUE SAMPLES IN THE FELINE CNS. D. S. DeWitt,* M. J. Rosner,* D. P. Becker and R. L. Hayes* (SPON: W. I. Rosenblum). Div. of Neurosurgery, Med. Coll. VA, Richmond, VA 23298.

Previous data have shown that, under normal circumstances, cerebral blood flow (CBF) and metabolism are believed to be positively correlated. This hypothesis was further tested in nitrous anesthetized cats using the radioactive microspheres (RMS) to calculate CBF (Rudolph & Heymann, Circ. Res. 21:163, 1967) and the [^{14}C] 2-deoxyglucose (DG) techniques (Sokoloff et al., J. Neurochem. 28:897, 1977) or to calculate local rates of glucose utilization (LGU).

Male cats (2.5-3.0 kg) were initially anesthetized with sodium methohexital. Following tracheostomy, they were paralyzed and ventilated with 70% N_2O and 30% O_2. Further surgical procedures were carried out using local anesthesia. Four CBF measurements were done over a period of two hours using 15 µm RMS labelled with ^{125}I, ^{141}Ce, ^{85}Sr, or ^{46}Sc (3M). Approximately one million RMS were injected into the left atrium for each determination and simultaneous reference samples were withdrawn from the brachial and femoral arteries for 90 seconds after the start of the injection. Flows were done prior to and during the period following the injection of DG. The animals were sacrificed 45 minutes after the DG injection by an overdose of sodium pentobarbital. The brains were removed immediately and dissected into 14 regions bilaterally. Following gamma counting, tissue samples were dissolved in a tissue solubilizer. Once the tissue was dissolved, the samples were diluted with scintillation cocktail and filtered through 10 µm teflon Millipore filters. Filtering removed over 95% of the RMS but less than 3% of the DG. This procedure prevented the overlap of the energy spectra of the gamma-labelled RMS with that of the ^{14}C-labelled DG. Samples could then be counted on a liquid scintillation counter and the amounts of LGU thus determined.

Measurements of CBF showed that the flows did not differ significantly over the two hour period of the study. Resting blood flows for the whole brain were 65.7 ± 22.7 (n=7). Preliminary studies of glucose metabolism and CBF indicate that flow and metabolism are related with the following linear regression equation: CBF = .218 + .719 (LGU) $p<.01$. This study further demonstrates the normal coupling between CBF and metabolism, a phenomenon previously undescribed in nitrous oxide anesthetized cats. Supported by NIH Grant # NS 12587.

125.8 LOCAL RATES OF GLUCOSE UTILIZATION (LGU) IN THE BRAIN STEM OF THE CAT AFTER CONCUSSIVE HEAD INJURY. R. L. Hayes,* C. M. Pechura* and D. P. Becker (SPON: A. Snow). Div. of Neurosurg., Med. Coll. of VA, Richmond, VA 23298.

Concussive injury to the brain is associated with certain disturbances in systemic and cerebral functions which may be related to disruption of brain stem activity. The present study used the method of Sokoloff et al. (J. Neurochem. 28:897, 1977) to examine changes in the uptake of [^{14}C] deoxyglucose (DG) and LGU in brain stem loci after concussive injury. Ten cats (2.5-3.0 kg) were anesthetized with sodium methohexital, paralyzed, artificially ventilated with 70% N_2O and 30% O_2 and prepared for induction of mechanical brain injury (Sullivan et al., J. Neurosurg. 45:520, 1976). The technique produces levels of injury correlated with the magnitudes of pressure transients (in atmospheres, atms) which produce deformation of neural tissue. Five cats were surgically prepared, maintained on N_2O anesthesia and not injured. Five cats were injured and anesthesia discontinued 10 minutes later. One hour after injury or completion of surgery, DG was injected (75 µCi/kg, i.v.). In 6 cats (3 uninjured, 3 injured), timed plasma samples of DG and glucose were taken to calculate LGU. The injury level was 1.9 atms, a magnitude for which morbidity and mortality (30%) were defined in a separate group of animals (n=13). Forty-five minutes after injection of DG, animals were killed by a barbiturate overdose, the brain perfused, frozen and sectioned for autoradiographic analyses by standard DG techniques.

Preliminary analyses of LGU in 15 brain stem regions indicate that, with 2 exceptions, the functional activity of brain stem structures of injured cats is depressed. For the regions showing decreased activity, mean LGU in uninjured cats was 37.3 (± 2.5 µmoles/100g/min) and 28.7 (± 3.2) in injured cats. Injury resulted in the greatest relative decreases in LGU in the vicinity of the locus coeruleus (>40%) and regions surrounding the ventral tegmental nucleus (VTN) (>50%). Smaller depressions in LGU were seen in the inferior colliculi (<10%). Increases in LGU were seen in some regions of the pyramidal tract and the VTN. Qualitative analyses of the relative amounts of glucose sequestered in neural tissue (µCi/g) yielded results consistent with the data on LGU. These data suggest that: (1) concussive brain injury results in heterogeneous regional changes in glucose utilization in brain stem structures of the cat; (2) increases in the functional activity of certain brain stem structures may mediate some of the acute responses to concussive injury. Supported by NIH Grant # NS 12587.

125.9 ELECTRODE PLACEMENT AND METABOLIC EFFECTS OF ELECTROSHOCK. A. L. Miller, D. J. Jones, W. B. Stavinoha and A. T. Modak. Departments of Psychiatry, Anesthesiology and Pharmacology, The University of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

Clinical research on electroconvulsive therapy over the past 15 years has shown that electrode placement is an important parameter influencing the behavioral effects of treatment. Bilateral stimulation, with the electrodes placed over the temporal regions, produces more confusion and memory impairment than does unilateral stimulation, with both electrodes over the non-dominant hemisphere. Unilateral treatment may have slightly less anti-depressant efficacy than bilateral, but this difference is much less pronounced than are the different cognitive effects of the two placements.

To investigate possible biochemical correlates of these behavioral effects, male guinea pigs were given right-sided unilateral or bilateral electroconvulsive shock and sacrificed 7-10 s later in a 915 MHz microwave enzyme inactivator with 1.0 s of irradiation to the head. Hemispheres were processed separately and analyzed for their levels of acetylcholine, cyclic AMP, and a number of intermediates of glucose metabolism. Preliminary results indicate several trends, which require confirmation by further experiments. (1) Levels of cyclic AMP were higher in all shocked animals, as compared to controls, and were highest in the right hemispheres of right unilaterally stimulated animals. (2) Acetylcholine levels were higher in the right hemisphere of right unilaterally stimulated animals. (3) Levels of intermediary metabolites indicated a stimulation of glycolysis in all shocked animals, with no differences between hemispheres.

As stated, these results are preliminary and further studies are in progress. To this point, however, it appears that electrode placement does influence some of the biochemical consequences of electroshock.

125.10 CHANGES IN GLUCOSE AND GLYCOGEN CONCENTRATIONS IN BRAINS OF C57BL/6J MICE AFTER AUDIOGENIC PRIMING: POSSIBLE EVIDENCE FOR ENERGY RESERVES DEFICITS UNDERLYING SUSCEPTIBILITY TO AUDIOGENIC SEIZURES. Robert A. Schreiber, Dept. of Biochemistry, Univ. of TN. Center for the Health Sciences, Memphis, TN. 38163, USA.

The onset of susceptibility to audiogenic seizures (AGS) in genetic-developmentally AGS-prone DBA/2J mice coincides with the transition from suckling to dietary self-sufficiency. During suckling the brain is primarily dependent on ketone bodies derived from β-oxidation of fatty acids from the dam's high-fat milk as a source of acetyl-CoA for brain growth and for energy. By the end of the suckling period at 14 to 15 days of age, the brain has reached near-adult size, and begins to shift to carbohydrate-derived sources of glucose as a source of acetyl-CoA for brain.

DBA/2J mice appear to have difficulty in this transition, and as a result, the brain immediate energy reserve, glycogen, is temporarily reduced, with a time course similar to the time course (days) of susceptibility to AGS (Schreiber: J. Neurochem., 1981, in press). An external-stimulus induced large energy expenditure, such as that induced by an appropriate acoustic stimulus to newly opened acoustic pathways, may result in a functional depletion of the already reduced energy reserve during the few seconds until energy repletion processes begin; as a result, CNS activity may then briefly become disorganized, resulting in the onset of an AGS (Med. Hypot., 5, 487, 1979).

Should this heuristic model hold, then audiogenic priming should lead to similar changes in brain glycogen levels during the transient (days) period of susceptibility to AGS. C57BL/6J mice were subjected to 60 sec. of 127 ± 2 dB at 16 days of age. Mice were sacrificed in liquid N_2; 10 mg samples of brain tissue were taken, extracted, and assayed for glucose, glycogen, ATP, and phosphocreatine as previously described (Soc. Neurosci. Abstr., 6, 720, 1980). The developmental course of AGS is shown (diamonds). Pooled preliminary data ± SEM for glucose (circles) and glycogen (squares) are shown for primed (solid) and nonprimed (open) C57BL/6J mice. (N = 8 to 20 parts of brain per point; no significant differences among areas). At 20 and 21 days of age, $p < .05$ for glycogen. No differences have been found between littermate primed vs nonprimed mice in ATP and phosphocreatine.

125.11 NOREPINEPHRINE DEPLETION ALTERS THE RESPONSE OF CEREBRAL CORTEX TO ISCHEMIA. S.I. Harik, R. Busto* and E. Martinez*. Department of Neurology, University of Miami School of Medicine, Miami, FL 33101.

Locus ceruleus (LC) lesion and the resultant depletion of norepinephrine (NE) in the ipsilateral cerebral cortex results in definite abnormalities of cerebral mitochondrial oxidative metabolism that become manifest under conditions of increased metabolic activity (Harik, et al., Science 206:69, 1979; La Manna, et al., Brain Res. 204:87, 1981). We have recently collected evidence suggesting that this imbalance in oxidative metabolic homeostasis is probably due to impaired substrate availability most likely due to the inability of the NE-depleted cortex to use glycogen during conditions of heightened energy demand, such as status epilepticus. In this study we sought to confirm this possibility under conditions of total cerebral ischemia induced by decapitation.

Unilateral LC lesions were performed in adult male Wistar rats by the stereotaxic infusion of 6-hydroxydopamine into the LC. Two weeks after LC lesion, rats were decapitated and the heads maintained at 37°C for 1 and 2.5 min before immersion in liquid N_2. Bilaterally symmetrical regions of the frozen cerebral cortex were punched out in a cold box at -20°C and tissue samples were assayed for NE, creatine phosphate, ATP, ADP, AMP, cAMP, glycogen, glucose, pyruvate and lactate. Results from the NE-depleted cerebral cortex ipsilateral to LC lesion were compared to these from the contralateral cortex by the paired t test (2-tailed). Average NE levels in the ipsilateral cortex were decreased to about 10% of the contralateral side. In both time periods studied, glycogen was significantly elevated by about 20% ($p < 0.005$) and cAMP decreased by about 25% ($p < 0.001$) in the NE-depleted cortex. These results indicate that cerebral glycogen breakdown during total cerebral ischemia is modulated by central NE. The exact mechanism through which such modulation is effected and whether it is mediated by cAMP remains unknown. (Supported by PHS Grants NS 16617 and NS 05820).

125.12 FOCAL CEREBRAL ISCHEMIA: A NOVEL AND REPRODUCIBLE EXPERIMENTAL MODEL IN THE RAT. R. Busto*, M. Ginsberg*, I. Cendan*, E. Martinez*, and P. Scheinberg (SPON: E. Ramsay). Cerebral Vascular Disease Research Center, University of Miami School of Medicine, Miami, FL 33101

Previous studies of stroke in experimental animals have been hindered by lack of an easily reversible means for producing high-grade focal ischemia resulting in consistent hemodynamic and metabolic alterations. In the present study, we report a novel and reproducible focal cerebral ischemia in the anesthetized rat. Furthermore, the severity of ischemia could be graded. Wistar rats anesthetized with N_2O received unilateral (right) common carotid artery ligation followed by elevation of intracranial pressure to 30-45 mm Hg by the intracisternal infusion of mock CSF. Mean arterial blood pressure was reduced to 110-120 mm Hg by hemorrhage. Cerebral perfusion pressure to the left hemisphere remained at 50-70 mm Hg, whereas right hemispheral perfusion was reduced to the ischemic range. After 15 or 30 min. of ischemia, animals were infused with ^{14}C-iodoantipyrine to measure relative cerebral perfusion, and the brains were frozen transcalvarially for metabolite levels. NADH fluorescence examination of coronal brain sections revealed a consistent right-sided metabolic lesion involving the hippocampus, a wedge of lateral thalamus, and the portion of the neocortex nourished by the middle cerebral artery (MCA). The territory of the anterior cerebral artery was spared. Sharp transition of phosphocreatine and ATP were observed, from values of 4.04 and 2.77 mmol/Kg in the medial neocortex to 0.74 and 0.65 mmol/Kg in the involved lateral cortex, and 0.89 and 0.47 mmol/Kg in the hippocampus. A sharp PhCr and ATP transition was also observed in the thalamic region from values of 2.56 and 1.51 mmol/Kg in the medial thalamus to 0.76 and 0.39 mmol/Kg in the lateral thalamus. ^{14}C-activity in the right MCA territory (neocortex, hippocampus, and thalamus) were 19.8, 18.2, and 30.7% of their respective left hemisphere values. Addition of prior bilateral vertebral artery occlusions to this model accentuated the metabolic gradient observed in the ischemic hemisphere and produced a milder metabolic lesion of the contralateral hemisphere. (Supported by PHS Grant NS 05820).

125.13 MULTIPARAMETER MONITORING OF THE AWAKE CEREBRAL CORTEX EXPOSED TO DECAPITATION.
A. Mayevsky, C.M. Freidli* and D.L. Sclarsky*.
Johnson Res. Fdn. and Cerebrovascular Res. Ctr., Dept. of Neurology, Univ. of Pennsylvania, Scho. of Med., Phila., PA 19104

In order to study the metabolic, ionic and electrical responses of the awake cerebral cortex to complete ischemia the decapitation model was used. By decapitation the brain is transferred into a closed system in which oxygen input is zero but energy consuming processes are going on until the complete depletion of available energy. The aim of our study was to identify the exact pattern and timing of the various changes taken place in the awake brain under complete ischemia insult. We monitored pO_2, NADH oxidation reduction state, K_e^+, DC potential, Electro corticogram, Temperature and pH from the surface of awake rats (200 gr) and gerbils (60-70 gr). The technical details of the multiprobe assembly are described elsewhere (Friedli, Sclarsky and Mayevsky, in preparation, 1981). Due to the limitation of the cannula size, pO_2 electrode was used alternatively with the pH electrode but the other parameters were monitored in all experiments.

The animal was anesthetized and operated on as described previously (Mayevsky et al. Neurological Res. 1, 213, 1980). After decapitation (done in the awake animal) the first event to appear was an increase in NADH simultaneously with the decrease in pO_2 values. Electro corticogram was decreased gradually and reached its minimal level within 10-20 sec from decapitation, and it was correlated to the increase of NADH as well as a decrease in pO_2. Brain temperature decreased only slightly after decapitation (0.4-0.8°C within the first 2 min). The extracellular K^+ level showed two phases in its increase after decapitiation. The first step was a slow leakage of K^+ (0.5-1 min) followed by a fast efflux of K^+ which occurred at the time when DC potential showed a large negative shift (indicating a complete depolarization). At the same time, when the large negative shift occurred, the 366 nm reflectance trace showed a large increase although the NADH level was at its maximum and pO_2 was zero. The pH response to decapitation was a gradual acidification of the tissue starting a few sec after the decapitation. The DC response to decapitation appeared in the entire area monitored and it was identified by 3 different DC electrodes located near the NADH, pH, and K^+ probes. The same sequence of events in response to decaptitation was recorded also when complete cerebral ischemia was induced by bilateral carotid arteries ligation in the gerbil.

126.1 INCREASED PAIN SENSITIVITY IN DEPRESSED PATIENTS WITH HYPERSECRETION OF CORTISOL. M. S. Joseph* and V. I. Reus* (SPON: E. Callaway). Langley Porter Neuropsychiatric Institute, San Francisco, CA 94143.

50% of endogenously depressed patients exhibit a failure to suppress plasma cortisol levels after the administration of dexamethasone. Corticotropin (ACTH) has been associated with alterations in experimental pain sensitivity. Depressed patients often demonstrate an increase in somatic pains. To explore the possibility of neuroendocrine basis for this observation we examined experimental pain sensitivity in depressed patients undergoing a dexamethasone suppression test.

Patients admitted over a two month period with the diagnosis of primary depression were tested during their first week of hospitalization in a medication free period. After obtaining informed consent patients received dexamethasone (dex) 1 mg orally at 11:30 p.m. The following day (post-dex) plasma was collected at 8:00 a.m., 4:00 p.m. and 11:00 p.m. and assayed for cortisol, ACTH, beta-endorphin and arginine vasopressin (AVP). At 9:00 a.m. on the post-dex day the patients underwent measurement of experimental pain sensitivity using the submaximal effort tourniquet technique. Each patient also underwent a second baseline pain test either two days before or two days after the post-dex session in a randomized counterbalanced design.

A total of 15 patients were tested. There was no difference between the baseline and post-dex tourniquet times; however, the mean time (in minutes) of the second session, 7.9 ± 6.6, was significantly shorter than the first, 11.0 ± 8.1 ($p < .025$). Because of this order effect only first session times were considered. Examination of cortisol levels showed 9 patients suppressed and 6 were nonsuppressors (cortisol > 5 ng/ml at either 4:00 p.m. or 11:00 p.m.). Each group's respective mean tourniquet time was 14.4 ± 8.2 and 5.9 ± 4.6. This demonstrates a significantly shorter time in the nonsuppressors compared to the suppressors ($p < .001$). The 11:00 p.m. cortisol values were negatively correlated with tourniquet times in nonsuppressors ($r = .819$, $p < .05$).

These data suggest an association between a neuroendocrine marker for depression and pain sensitivity. It is likely that the neuropeptides which are responsible for the cortisol hypersecretion are also involved in pain sensitivity. The above results will be related to concurrent plasma levels of ACTH, beta-endorphin and AVP. (Supported in part by NIMH grant 5 T32 MH14609-05.)

126.2 ELECTROSHOCK (ECS) INDUCED ALTERATIONS OF THYROTROPIN-RELEASING HORMONE (TRH) IN THE RAT. M.J. Kubek, D. Etchison*, and A. Sattin. Dept. Anatomy and Inst. Psychiat. Res., Indiana Univ. Sch. of Med. and V.A. Hosp., Indianapolis, IN. 46223

TRH, the hypothalamic tripeptide responsible for thyroid regulation, has been localized throughout the CNS of man and several animal species. This peptide may play a role as a Neurotransmitter or neuromodulator by interacting with brain monoamine systems. Clinical studies have shown that changes in the TSH response to TRH during ECT can predict the post-treatment course of depression. In view of these findings we examined the effect of ECS and a dopamine agonist, apomorphine (APO) on TRH content in several CNS loci in the rat.

Male S-D rats (150-180g) were given ECS or sham ECS (without current) via ear clip electrodes for 1s. The induction of a grand mal seizure required 22mA (constant current). After 5 treatments given on alternate days at 4PM, all rats were decapitated 45-51h after the last ECS and brains were immediately dissected and frozen on solid CO_2. ECS and sham controls were compared in 3 experiments of 8-14 rats each. One experiment included injection of APO(2mg/kgi.p.) 24h after the last ECS or sham treatment. TRH was assayed by a specific RIA following HAc extraction and results were expressed as pg/mg tissue (mean $\pm$ SEM). Tissue weights were not significantly different between treatment groups. Student's t-tests were performed on log-transformed data for simple and interactional effects in 2X2 tables of the dependent variable.

ECS alone increased TRH content in Ant. pituitary (AP)(5.25 ± 0.56vs9.99 ± 1.08, $P<.001$), post. pituitary (41.27 ± 8.03vs192.65 ± 38.88, $P<.001$), Brain stem (BS)(27.82 ± 2.7vs40.51 ± 5.49, $P<.02$), temporal lobe (TL)(7.06 ± 1.25vs29.02 ± 4.02, $P<.001$), and striatum (8.35 ± 1.36vs15.74 ± 3.12, $P<.001$) but had no effect on hypothalamic (H) or cortical TRH. Similar results were seen in the APO treated group ($R<.001$ in all cases) except that in H TRH decreased two-fold following ECS. APO alone produced a two-fold decrease in TL TRH and was found to potentiate the ECS effects on TRH in AP($P<.01$), BS($P<.001$), and TL($P<.001$).

These results indicate: (1)that ECS, given in a temporal paradigm used clinically, can induce significant elevations in TRH content in the pituitary and several brain loci for up to 50h, (2)APO may have a direct effect on TRH in TL, and (3)APO, given as a single dose 24h after the last ECS, can enhance the ECS effects on TRH in specific loci. Thus, elevations in brain TRH may be a favorable consequence of ECT treatment for depression since it has been shown that TRH has an overall excitatory effect on CNS activities. 126.3 VASOPRESSINERGIC MODULATION OF SHORT-TERM BEHAVIOURAL HABITUATION: DOSE, AGE, STRAIN AND SEX DEPENDENT ACTIVATING AND DE-ACTIVATING EFFECTS. A.G.Sadile, A.Cerbone* and L.A.Cioffi*. Inst. Human Physiology, 1st Med. Sch., Univ. Naples, 80138-Italy.

A diffuse network of vasopressinergic terminals has been shown to synapse in the hippocampal formation, among other extra-hypothalamic target areas (Buijis, R.M.,Cell Tissue Res., 192:423, 1978). In the present research, the physiological significance of these peptidergic pathways in the control of behavioural output has been investigated throughout postnatal development and adulthood in two strains of genetically selected rats, the Naples Sprague-Dawley High and Low Excitable (NSD-HE and -LE) of both sexes.

Dose-response curves for acute effects of a single lysin-8-vasopressin dose (LVP, 4.4, 44 and 440ng.100g b.w.$^{-1}$, s.c.) or saline, given immediately before a 10min-exposure to a novel environment, upon short-term habituation (ST-HAB) of behavioural arousal, were obtained by trend analysis of horizontal and vertical activity by a PDP11/34 computer (Sadile, A.G. et al., Abh. Akad. Wiss. DDR, 5:205, 1979). In NSD-HE strain LVP is de-activating and as early as the 16PND with 440ng only in females and this effect persists at 18PND, when it matures also in males and when 44ng become de-activating in females. In adult age (60PND) the de-activating effect of the highest dose is still present in both sexes and is accompanied by hypotonia, ataxya and sedation. In NSD-LE rats, pre-trial LVP has biphasic effects: it is activating at 16PND and only in females with 4.4 and 44ng, whereas at 18PND remains activating only in females and 44 and 440ng become de-activating, the latter only in females and the former in both sexes. At 60PND the 440ng dose has a significant de-activating effect only in females, with no behavioural abnormalities, as in the NSD-HEs.

The differential, multifactorially dependent, activating and/or de-activating acute effects of pre-trial lysin-vasopressin are suggested to be due to activation of different VPergic receptor and circuitries, which seem to mature at different developmental periods, at various organizational levels, in a genotype- and sex-dependent way.

126.4 THE EFFECT OF REM SLEEP DEPRIVATION ON SUBSTANCE P-LEVELS AND SOMATOSTATIN IN DISCRETE AREAS OF THE RAT BRAIN. L.A.Mattiace,J.Farber,A.Negro-Vilar,Departments of Psychiatry and Physiology, University of Texas Health Science Center at Dallas, Dallas, Texas 75235. (SPON: H.P. ROFFWARG).

Although peptide substance P has been extensively mapped in the periphery, it has recently been demonstrated to be located in discrete cell bodies and terminals of the CNS.Similarly, somatostatin is widely distributed in the brain and has been localized in primary sensory neurons.(Hokfelt,1976).However, the functional role of these peptides in the CNS is as yet unknown.It has been suggested that, as in the periphery, substance P may be involved in the sensory processing of pain:(Henry,1977).One method of altering sensory processing is through REM deprivation, which appears to increase neural excitation (Cohen &Dement,1965) and also waking motivational behaviors (Dement,1965;Morden et al;1968; Steiner & Ellman,1972).Using the pedestal-water technique of REM sleep deprivation (Jouvet,1964),Sprague-Dawley male rats were kept for 3 days either on a small platform (n=5)or on a large stree-control platform (n=5).The rats were sacrificed by decapitation and the brains quickly removed and frozen.Several brain areas were punched according to the Palkovits(1973)procedure. Substance P and somatostatin were extracted in 1N acetic acid and measured by radioimmunioassay.Levels of peptides were determined in a number of areas throughout the brain including the forebrain areas of the caudate,preoptic and medial hypothalamus;the midbrain areas of the medial habenula(MH), substantia nigra pars compacta (NRC) and reticulata (SNR),ventral tegmental area (A10); and the hindbrain areas of the dorsal (DR) and medial raphe (MR), central grey (CG) and the locus coeruleus (LC).Decreases in substance P levels were seen in most neuroanatomical areas examined in REM deprived animals, with greater differences observed in the SNR,RD,LC and MH.Measurements of another neural peptide,somatostin, in the same areas revealed an increased in peptide levels with REM deprivation in the more rostral regions examined (preoptic,medialhypothalamus and MH).However, in the more caudal regions, a clear decrease in somatostatin levels was observed, particularly in the CG,LC,MR and DR.The decreases in levels of substance P following REM deprivation may indicate a change in centrally-mediated pain sensitivity.Support for this notion is suggested by changes in pain sensitivity thresholds following both REM deprivation(Hicks,et al,1973;Hicks et al,1978;Hicks et al, 1979)and hindbrain lesions(Bodnar et al,1978).REM deprivation, in addition to changing catecholamine levels also appears to affect peptide levels such as substance P and somatostatin.Accordingly, the biochemical and neurochemical changes that accompany REMD do not appear to be confined to the monoaminergic neurotransmitters in the CNS.

126.5 BOMBESIN WORKS AT BOTH ENDS. J. Gibbs and D.J. Fauser*. Dept. of Psychiatry, Cornell University Medical College and E.W. Bourne Laboratory, The New York Hospital, White Plains, NY 10605.

Bombesin (BBS)-like immunoreactivity has been identified in neural and/or endocrine tissue throughout the gastrointestinal tract of several species, including rat and human. The concentration of BBS-like immunoreactivity is high in colon. While carrying out experiments to determine the satiating effect of BBS and cholecystokinin on feeding behavior, we noted a markedly increased rate of defecation following administration of exogenous BBS.

Eleven male Sprague Dawley rats were injected intraperitoneally with synthetic BBS (courtesy of R. de Castiglione, Farmitalia Carlo Erba, Milan), the synthetic C-terminal octapeptide of cholecystokinin (CCK-8, courtesy of M. Ondetti, Squibb Institute, Princeton) or equivolumetric 0.15 M NaCl control 5 min before presentation of a balanced liquid food (25% EC 116, GIBCO) during the light phase following a 3-hour food deprivation; drinking water was always available. In additional tests, the same rats were similarly injected 5 min before presentation of drinking water following a 12.5-hour water deprivation; food was removed 30 min before water presentation. During all tests, defecation was measured by counting boluses at 5, 15, 30, and 45 min following food or water presentation.

When food was present and being consumed, BBS produced a marked, dose-related increase in number of formed boluses excreted. The threshold dose of 2 $\mu g\text{-}kg^{-1}$ produced a five-fold increase during the entire 45 min period ($P < .001$). The maximally effective dose of 8 $\mu g\text{-}kg^{-1}$ produced a ten-fold increase ($P < .001$). The latency for a significant increase was 15 min. When water was consumed instead of food, the shape of the dose-response curve was identical, but the potency of BBS was reduced at each point by approximately 50%. At no time did BBS produce diarrhea. CCK-8 (1.5 $\mu g\text{-}kg^{-1}$ and 3.0 $\mu g\text{-}kg^{-1}$) also significantly increased bolus excretion, but CCK-8 was less potent than BBS and failed to produce a dose-response relationship.

The strikingly increased rate of defecation produced by exogenous BBS, particularly when food is being consumed, together with radioimmunoassay data demonstrating high concentrations of BBS-like immunoreactivity in colon (Walsh & Dockray, Gastroenterol. 74:1108, 1978), raises the possibility that one function of endogenous BBS-like peptides may be to play a role in the colonic response to eating ("gastrocolic reflex").

126.6 NEUROPEPTIDES IN ANIMAL MODELS OF AGING. R.L. Dean, C. Loullis, D.L. Watkins*, and R.T. Bartus. Department of CNS Research, Medical Research Division of American Cyanamid, Pearl River, NY.

In recent years, evidence has accumulated that neuropeptides of hypothalamic and pituitary origins may influence behavior, independent of their neuroendocrine effects. It has been reported that, in several mammalian species, several of these neuropeptides affect many of the same behaviors which are significantly altered in the elderly. During the last few years, we have developed a number of animal models of aging based on a multidisciplinary set of criteria involving behavioral, biochemical and pharmacological factors. Several different neuropeptides (such as $ACTH_{4\text{-}10}$, vasopressin, oxytocin, etc.) were tested in these procedures over a wide range of doses to help characterize their behavioral and biochemical effects.

The results of these studies demonstrated that these neuropeptides indeed possess many interesting and differential qualities which may be relevant to correcting or compensating for certain age-related, neurobehavioral dysfunctions. These include: (1) protection of neural function under various conditions of energy deficiency, (2) alterations in certain neurotransmitter functions in rats, and (3) reduction in age-related deficits on a memory task in monkeys. These findings will be discussed as they relate to possible direct and indirect influences on neurotransmitter function in the young and aged brain.

126.7 TRIGGERING AND MODULATION OF THE CENTRAL PROGRAM FOR LOCOMOTION BY SEROTONIN AND BAG CELL EXTRACT (EGG LAYING HORMONE). S. Mackey*, T.J. Carew, and E.R. Kandel. (SPON: I. Kupfermann). Center for Neurobiol. & Behav., Dept. Physiol. & Psychiat., P & S, Columbia Univ., and N.Y. State Psychiatric Inst., New York, N.Y. 10032

Locomotion is a centrally programmed behavior in Aplysia which is triggered by appetitive and aversive stimuli and is modulated by hormonal states (Strumwasser et al., 1969) and learning (Walters et al., 1979). Thus locomotion is a useful system to explore the cellular mechanisms involved in the triggering and modulation of a complex behavior. As a first step in this direction we have examined the triggering effects of several biogenic amines and the modulating effects of bag cell extract (BCE) which contains the neuropeptide egg laying hormone.

We recorded locomotion in a modified split foot preparation (Henning et al., 1979) with strain gauges attached to the body wall and foot. After a 5 minute baseline period, we injected 1 ml. of a solution containing 5HT into the anterior aorta. A 1 ml. injection of sea water was used as a control. Threshold for locomotion was 10^{-7} 5HT which produced $\bar{x}$=1.5 steps (N=4) within 90 seconds of application compared to 0 steps (N=5) after a 1 ml. injection of sea water ($p < .05$). Increasing the concentration of 5HT produced (1) a monotonic increase in the number of steps, reaching $\bar{x}$=25.0 at 10^{-3} 5HT (N=5), and (2) a progressive decrease in the latency for locomotion. 5HT injected into the anterior aorta of freely moving, intact animals also elicited walking. Three other biogenic amines found in Aplysia (dopamine, octopamine, histamine) failed to elicit locomotion in concentrations up to 10^{-3} in preparations in which 10^{-3} 5HT produced vigorous locomotion.

We next explored the actions of BCE and found that it suppressed 5HT-elicited locomotion. We first triggered locomotion with an injection of 1 ml. 10^{-3} 5HT. Twenty minutes later a second injection of 5HT was delivered. In the experimental group (N=5) the second injection was preceded (by 2 min) by a 1 ml. injection of BCE. In the control group (N=7) a 1 ml. sea water injection replaced BCE. Experimental animals showed a 52% decrease in the number of steps following BCE compared to a 6% reduction in controls ($p < .002$). The suppressive effects were reversible. The number of steps produced by 5HT in experimental animals usually approached initial (pre-BCE) levels within 40 minutes.

Our results suggest that 5HT might be an endogenous trigger for locomotion in Aplysia. Since 5HT elicited locomotion is significantly inhibited by prior application of BCE, this should enable the study of the triggering and modulation of locomotion on a cellular level. It will also be of interest to examine the effects of BCE on withdrawal reflexes and inking in Aplysia in an attempt to characterize the modulatory effects of a known neuropeptide on a variety of defensive behaviors.

126.8 THE DISCOVERY OF A NEW ENDOGENOUS LIGAND FOR BENZODIAZEPINE RECEPTORS. D. Jackson*, B. Beer, L.R. Meyerson and A. Lippa. Dept. CNS Research, Medical Research Div. Lederle Labs, Pearl River, NY 10965.

The discovery of a pharmacologically relevant, high affinity binding site for benzodiazepines (BDZ) has raised the possibility that these sites may act as receptors for some as yet unidentified neurotransmitter systems. Several endogenous substances (i.e., purines, nicotinamide and an unidentified peptide) have been isolated from mammalian brains and are able to competitively inhibit ^{3}H-BDZ binding. Since various hormonal systems are able to modulate the anxiolytic effects of BDZ, we have searched for possible endogenous ligands in the blood of rats and humans. While crude serum is able to displace ^{3}H-BDZ binding, the presence of albumin may contribute to this effect. Albumin was removed from serum by either boiling (100°C for 30 minutes), acid precipitation (5% TCA) or ultrafiltration (with molecular weight exclusion of 20,000 daltons). In each case, approximately 30-40% inhibition of ^{3}H-flunitrazepam binding (^{3}H-FLU) was observed. Scatchard analysis demonstrated that extracts competitively inhibited ^{3}H-FLU binding. Molecular weight determinations using HPLC revealed the presence of two active fractions which co-eluted with globular proteins of 3,000 and 18,000 daltons. The hydrophilic nature of these fractions was revealed by exposure to a hydrophobic medium. Furthermore, inhibitory activity was reduced by >50% after exposure to 100°C for 10 minutes. These results demonstrate the presence in mammalian blood of hydrophilic, thermo-labile proteins which competitively inhibit ^{3}H-BDZ binding. The larger component may act as a precursor for the smaller.

127.1 THE DORSAL SUPRAOPTIC DECUSSATION AND INTEROCULAR TRANSFER IN THE PIGEON. M. A. Goodale and D. Stewart*. Psychology Department, University of Western Ontario, London, Ontario, N6A 5C2.

Pigeons trained to discriminate between visual stimuli in a key-pecking task normally show excellent interocular transfer (IOT) when trained with only one eye and then tested with the "naive" eye. However, when the dorsal supraoptic decussation (DSO) was sectioned and pigeons were then trained to peck at illuminated keys in an interocular transfer experiment, they failed to show normal IOT of a simultaneous horizontal-vertical discrimination. In contrast, another group of pigeons, in which the DSO was sectioned after they had already learned the discrimination with one eye covered, showed excellent IOT post-operatively when the blindfold was moved to the other eye. Both groups later failed to show IOT on a new visual discrimination. The results of this experiment confirm and extend earlier observations in the domestic chick (O'Connell, N. unpublished Ph.D. thesis, University of Rochester, 1979).

In a second experiment high-speed films were made of pigeons pecking at illuminated keys in a discrimination task. A subsequent frame-by-frame analysis of these films revealed that the discriminative stimulus fell within the binocular portion of the retina during the final two head fixations immediately prior to pecking. Even when the pigeons were pecking at the keys while wearing a monocular blindfold, they regarded the stimulus key with the portion of their uncovered eye that was normally binocular.

Since the DSO carries input from the binocular portion of the retina, the results of the two experiments taken together strongly suggest that IOT in the pigeon is the simple consequence of information reaching both hemispheres from a single eye via converging binocular pathways. Thus, cutting the DSO before training with the first eye eliminates IOT whereas cutting it after training with the first eye does not -- since information has already reached both hemispheres from the (normally) binocular portion of that eye. These findings complement the work of Goodale and Graves (Physiol. Behav., 25:39-43, 1980) showing that IOT is absent in normal pigeons in those situations in which they scan the discriminative stimuli with the monocular portion of their visual fields.

This investigation was supported by Natural Sciences and Engineering Research Council (Canada) A6313.

127.2 A TACHYSTOSCOPIC STUDY OF INTRA- AND INTERHEMISPHERIC PROCESSING OF VISUAL INFORMATION IN CALLOSAL AGENESIS. Hannelore Sauerwein*, Maryse Lassonde and Guy Geoffroy.* Laboratoire de Neuropsychologie expérimentale, Université du Québec à Trois-Rivières, C.P. 500, Trois-Rivières, Qué., Canada and Ste-Justine Hospital, Montréal.

Numerous studies using tachystoscopically presented stimulus material in normal individuals have established the presence of a right hemifield/left hemisphere superiority for verbal and a left hemifield/right hemisphere advantage for non-verbal stimulus processing. They have further shown that information simultaneously presented to the two visual half fields is accessible to both hemispheres due to the integrative function of the cerebral commissures, especially the corpus callosum. In contrast, tachystoscopic studies of patients suffering from agenesis of the corpus callosum have generated conflicting results concerning cerebral dominance and interhemispheric integration of visual information.

The purpose of the present study was to further elucidate the problem of cerebral asymmetry and interhemispheric communication in callosal agenesis patients. The agenic group was composed of 5 subjects, aged 12 to 22, with total agenesis of the corpus callosum as revealed by CT scan. The agenic patients were compared with two matched control groups: one group of individuals with comparable IQs and a second group of subjects with normal intelligence. The experimental task consisted of verbal identification or intra- and interocular comparisons (same-different judgements) of letters, numbers, shapes and colors presented tachystoscopically to either or both peripheral visual hemifields. Error scores and reaction times were monitored.

In the intra-hemispheric conditions both control groups displayed typically a right hemifield advantage for the verbal and a left hemifield effect for the non-verbal material. This differential response was not found in the agenic sample. The agenic patients made also significantly more errors and were markedly slower in their responses. On the interocular comparison task all groups performed above chance level. However the performance of the agenic patients was once again significantly poorer than that of the controls with respect to correctness and response latencies.

The absence of unilateral effects in the agenic sample seems to suggest a bilateral representation of function in these patients. Furthermore, the fact that the agenic subjects were able of correct interocular comparisons would point to the existence of an alternative pathway of interhemispheric transmission. This pathway, however, may be less efficient and less expedient that the callosal route.

127.3 DICHOTIC LISTENING IN CALLOSAL AGENESIS. Jean Lortie,* Maryse Lassonde and Maurice Ptito. Laboratoire de Neuropsychologie expérimentale, Université du Québec à Trois-Rivières, C.P. 500, Trois-Rivières, Qué. Canada, G9A 5H7

A previous study (Lassonde et al, 1981) has shown that two patients suffering from a congenital absence of the corpus callosum demonstrated a left ear advantage in a dichotic paradigm regardless of the nature of the stimuli. However, other experiments conducted in our laboratories (Sauerwein et al, 1981) revealed a bilateral organization of speech in the visual and somesthetic modes when callosal agenesis patients were tested. Therefore, in order to assess if the right hemisphere superiority effect could be generalised to all acallosal subjects, another auditory study was conducted using a larger sample of subjects and stimuli.

Five subjects, 3 boys and 2 girls were included in the study. All were right-handed except M.G. who showed a left-hand preference. The subjects' age varied between 11 and 23 years. All patients tested had a complete callosal agenesis as revealed by P.E.G. or CT scan. The subjects' IQ varied between 45 and 97.

Four types of stimuli were presented dichotically. They consisted of verbal material (familiar words and nonsense syllabes), and non-verbal stimuli (pure tones varying between 400 Hz - 17KHz and melodies). Each type of stimulus was presented 125 times, the first five trials being used as examples. After hearing the sample stimuli, S was presented with a binaural test stimulus. The subject's task was to decide whether or not the test stimulus was previously heard. The first administration required a verbal response. In a subsequent session the subject answered using the preferred hand. The technical set-up used in the experiment was automatized in such a way that the subjects could initiate their own trials.

An analysis of variance performed on the reaction times revealed that they varied according to the stimulus type (words, syllables, tones and melodies). The subjects were slower to respond to the melodies than to any other stimulus. Interestingly, the mode of response (manual or oral) had no significant effect nor did the stimulation site (left or right ear). Indeed no differences were found between the left or the right ear.

In opposition to previous findings (Ettlinger et al, 1972; Bryden and Zuriff, 1970; and even Lassonde et al, 1981), it therefore seems that auditory hemispheric organization in callosal agenesis patients is bilateral. The hemispheric "symmetry" could explain the characteristic slowness of response usually observed in callosal agenesis (e.g. Lassonde et al, 1981); Indeed, data processing might be delayed in these patients because of a crowding of verbal and non-verbal functions in both hemispheres.

127.4 DEPTH PERCEPTION DEFICITS IN CALLOSAL AGENESIS. Maryse Lassonde, Sylvain Bernier*, Jean Ouellet* and Michel Volle*. Laboratoire de Neuropsychologie expérimentale, Université du Québec à Trois-Rivières, Trois-Rivières, Qué., Canada, G9A 5H7.

Midline stereopsis has sometimes been reported to be deficient in patients suffering from a congenital absence of the corpus callosum (Jeeves, 1980). Similarly, a loss of binocular depth perception in the vertical meridian has been observed in a commissurotomized patient. Recently, however, the possibility was raised that at least in animals, the influence of the corpus callosum in binocular integration extends well over the vertical meridian (Payne, 1980). In order to test this assumption, we studied intra- and interhemispheric analysis of depth perception in 6 patients suffering from a total callosal agenesis. They were matched on age, sex and IQ with 6 control SS. Two solid objects differing only by their color and occasionnally their size were presented a) at 3.5° of visual angle, one to the right and the other to the left of a central fixation point (diode, 3.5 volts); b) one at 3.0 and the other at 4°, to the left or the right of the fixation point; c) one at 0.5° and the other at 3.5° to the left or the right of the fixation point; d) one to the left, the other to the right of the fixation point, the distance between both objects being less than 1°. The objects were placed on a table whose heigth corresponded to the S's eye level when seated. In the vertical plane, the objects were kept 10 cm apart. The room was completely dark and a photostimulator (Grass model PS2) located 3m above the table allowed the illumination of the objects during 150 msec. Sixty four trials were used for each condition and S's task consisted in indicating which stimulus was closer. The results showed that when the objects were presented in the peripheral field, (conditions a) and b)) the mean number of correct responses was significantly lower in the experimental group than that of the control group. Furthermore, a chi-square analysis performed on the data obtained by the agenic patients revealed that the acallosal subjects performed at chance level in both conditions. On the other hand, when at least one object was presented centrally (conditions c) and d)) the performance of the agenic subjects was above the chance level. However, their number of correct responses was once again significantly poorer than that of the control group. Noteworthy, the agenic patients were markedly better (70% of success) when both objects were presented centrally. These results confirm the findings that the involvement of corpus callosum in depth perception extends over the whole retina and further indicates that its role in binocular integration is more important in the periphery of the visual field. Finally, our results suggest that callosal disruption prevents the development of normal depth perception.

127.5 ANATOMICAL AND QUANTITATIVE ASPECTS OF THE HUMAN CORPUS CALLOSUM
C.deLacoste-Utamsing,R.L.Holloway*,J.B.Kirkpatrick & E.D.Ross
Dept.Anthro. Columbia Univ. N.Y.,N.Y. 10027. Dept.Neurol. U.T.Heath Science Center, Dallas, TX 75235

While there is an ever-increasing interest in the neuropsychology of interhemispheric relations, there are few anatomical data on the major cerebral commissure -- the corpus callosum. Our study was undertaken to investigate the topographical organization and laminar termination of the fibers of this commissure. In addition, we obtained quantitative measurements of male and female corpora callosa. Methods included computer-assisted planimetric measurements of total and partial callosal surface areas as well as a modified trichrome stain, general histological stains, and the Albrecht Fernstrom silver stain to respectively delineate extent of lesions, isolate callosal degeneration and identify terminating degenerated fibers.

The study of degeneration in the corpus callosum subsequent to focal cerebral insult, occuring generally 1-2 years antemortem, evidenced that while orbital, inferior frontal and pre- and post-central fibers course rostral to the superior and middle frontal fibers,the inferior, middle and superior temporal fibers course caudal to the frontal fibers but rostral to the occipital and parietal fibers. Selective silver impregnation of degenerated fibers in contralateral homotopic cortex demonstrated that callosal fibers terminate mainly in layers IV and V.

Planimetric measurements of corpora callosa (N=28;M=15,F=13) yielded an average callosal surface area of 662.2 sq.mm (min. 444; max. 962; std. dev. 120.9; 10-15% shrinkage was observed). A quantitative analysis of the relationship between callosal surface area and brain weight evidenced a sexual dimorphism in that the female but not the male callosal area correlated significantly with brain size (Pearson R=.47(F),.05(M)). Furthermore, a computation of maximum dorsoventral splenial width demonstrated a nearly bimodal distribution for males and females (range .9-1.41cm(M);1.4-1.8cm(F); p=.000). Planimetric measurements of the partial surface area of the posterior fifth of the corpus callosum (determined to be representative of splenial area) substantiated our observation that females have a larger splenium than males(p=.05). This sex difference is actually visually obvious: the female splenium is more bulbous than the male counterpart. We believe that our callosal topography may be clinically significant both in the evaluation of neurological syndromes and in recovery of function. Our finding of sexual dimorphism in the callosum may have neuropsychological implications for postulated gender differences in degree of cerebral lateralization.

127.6 HEMISPHERIC ASYMMETRY IN VISUO-SPATIAL PROCESSING: DIFFERENTIAL EFFECT ON REACTION TIME, ACCURACY, AND CRITERION. B. Koss. Department of Psychology, Queens College, City University of New York, New York, N.Y. 11367.

An investigation was carried out on six normal subjects to study the relative influence of perceptual difficulty and decisional strategies on cerebral asymmetry in recognition of line orientation. The dependent variables included reaction time (RT) for correct response, percentage of accurate response and two signal detection measures based on rating scales. Stimuli were black rectangles flashed tachistoscopically in the left or right visual fields (LVF, RVF) under two stimulus conditions. In condition vertical-oblique (V-O), the rectangles were oriented 90 or 95 degrees from the horizontal, whereas in condition oblique-oblique (O-O), rectangles were oriented 95 or 100 degrees from horizontal. In both conditions, subjects responded to the 95 degree stimulus by depressing a telegraph key.

With accuracy, the results support the often hypothesized right hemisphere superiority for visuo-spatial processing. The positive results obtained with accuracy, reputedly rather insensitive to laterality differences, were attributed to a combination of enhancing factors: use of male subjects, control of eye dominance, perceptual difficulty of the task and memory factors. In contrast, no difference was observed between the performance of the two hemispheres with RT. However, a highly significant interaction between VF and stimulus condition indicated that the easier condition V-O was processed faster when presented in the LVF whereas the more difficult condition O-O was processed faster when presented to the RVF. Results can be best explained by an interaction between task difficulty (leading to a right hemisphere superiority for the V-O condition) and the use of verbal coding allowing fast processing by the left hemisphere when task complexity increases. This interpretation is confirmed by signal detection analysis, which showed that different decisional strategies were used by the two cerebral hemispheres. The apparent superiority displayed by the left hemisphere for the more difficult task was the expression of more liberal judgmental standards, and not the greater competence of that hemisphere. The absence of overlap between results obtained with accuracy and RT suggests that these measures provide qualitatively different expressions of laterality differences. This experiment suggests that laterality studies should include testing with several simultaneous measures in order to distinguish between differences due to cognitive or to decisional strategies.

127.7 DIFFERENTIAL HEMISPHERIC PARTICIPATION: A CASE DEMONSTRATING VOLUNTARY SELECTION. E.C. Hughes, P.S. Gott,* and K. Whipple. Departments of Otolaryngology, Neurology, and Psychiatry, LAC-USC Medical Center, Los Angeles, CA 90033.

An extraordinary woman reported she could instantaneously, "at will" switch between two disparate mental and emotional states differentiated by features suggesting left hemisphere predominance in one, right in the other. She was extensively studied to elucidate characteristics and document the psychophysiological correlates of her separate states. The subject was an apparently normal female with no detectable neurological or psychiatric disorder.

Her self description of the two states provided a clear dichotomy of interests and capabilities. Formal psychological testing revealed no split personality traits. While her I.Q. and other broad mental capacities were superior and generally equal in both states, marked differences in performance between states were evident on specific tasks. In "State I" she was superior in sequential or verbal tasks, whereas in "State II" spatial tests were more accurate.

Electrophysiological tests documented differences in brain activity between states. Amplitude of the EEG alpha activity showed a large difference between states. Moreover, comparison of hemisphere alpha ratio (R/L) showed significant hemisphere differences correlated with the state held during spatial and verbal tasks. A Vibrotactile Somatosensory Evoked Response and the concomitant measurement of interhemisphere transmission time provided further data indicating differences between states.

Results support the probability that the subject can voluntarily place herself in one of the two states, I or II, associated with left or right hemisphere predominance, respectively. Her capacity for differential hemisphere participation may account for her somewhat exceptional talents in both spatial and verbal skills.

127.8 ELECTROPHYSIOLOGICAL AND NEUROPSYCHOLOGICAL CORRELATES IN PATIENTS WITH SECTION OF THE CORPUS CALLOSUM. Guy Geoffroy*, Maryse C. Lassonde, Hannelore Sauerweir* and Janine Flessas.* Ste-Justine Hospital, Montreal and Laboratoire de Neuropsychologie expérimentale de l'Université du Québec à Trois-Rivières.

It has often been suggested that sectioning of the corpus callosum prevents the spread of epileptic activity from one hemisphere to the other. In line with this assumption, lesion of the corpus callosum (callosotomy) and of many cerebral commissures (commissurotomy) have been performed therapeutically in patients suffering from intractable epilepsy. However, its effectiveness in reducing both the frequency and severity of the seizures has often been contested and neuropsychological sequelae have sometimes been reported. The present analysis focuses on nine patients, aged 5-16 years whose epilepsy resisted all conventional means of treatment. The purpose of the study was to examine, by employing extensive pre- and post-surgical evaluations whether or not this technique can really be considered as effective. Electroencephalography revealed multifocal activity in five and right-sided epileptic foci in four of the patients. The patients underwent a callosotomy according to the technique of Wilson. The method of investigation varied according to the physical and mental stage of the patient from observation and simple operations to complete neuropsychological examination, using the Michigan and the Reitan batteries as well as other tests designed to determine cognitive and perceptual skills, sensori-motor functions, cerebral dominance and interhemispheric communication. Postoperative EEGs revealed a significant reduction of epileptogenic activity in all but one of the patients. These findings were accompanied by an important reduction in both frequency and severity of epileptic seizures and a marked improvement in the general behavior of the patients. Furthermore, the reduction of anticonvulsive medication probably contributed to the observed improvement of memory, perceptual and motor functions in the majority of the cases. All patients achieved pre-operative levels of performance with regard to bimanual coordination and interhemispheric transfer of tactile and somesthetic information. However, post-operative tests of laterality showed temporary or persistent reversal of manual dominance in three and reversal of manual and ear preference in one of the patients. These results suggest that hemispheric disconnection with anterior commissure sparing can be successful in the control of epileptic seizures. Furthermore, the intervention seems to improve the patient's cognitive and motor behavior. Finally, the reversal of lateral dominance observed in some of the patients indicates that the corpus callosum may exert an inhibitory effect on the activity of the non-dominant pathway which may be neutralized by the callosal section.

127.9 INFORMATION PROCESSING FOLLOWING BRAIN BISECTION. J. D. Holtzman* and M. S. Gazzaniga. Division of Cognitive Neuroscience, Department of Neurology, Cornell University Medical College, New York, New York 10021

In a previous study, we reported that the commissurotomy patient has access to spatial information from both visual half-fields for the control of selective visual attention. We also found that, in contrast, when spatial information was required for explicit stimulus localization, the visual half-fields were disconnected: Significant impairments in performance were noted for tasks which required a comparison of the locations of stimuli appearing on both sides of the visual midline.

The present studies were designed to examine further the independence of perceptual processing in the disconnected hemispheres. The performance of commissurotomy patients at bilateral concurrent tasks has typically focused on tasks which include a bilateral motor component. Our studies assessed the information-processing capabilites of the two hemispheres independent of possible interactions at the output stage. On each trial two series of three items were presented sequentially, one series to each hemisphere via lateralized visual presentation, with an inter-item interval of 500 msec. On half of the trials, the two series contained the same elements in the same order; on half of the trials, a different series appeared in each field. Following a 1 sec delay, a probe item appeared in one visual field and the observer was required to indicate with a forced-choice key press whether the probe was an element of that field's list.

The performance of two commissurotomy patients did not differ significantly for our two conditions: There were no reductions in response latencies or errors when both hemispheres were concurrently engaged at processing identical lists. This finding contrasts with the performance of normal observers, who show facilitation in performance when the two visual half-fields contain identical information.

It was also determined that, although the hemispheres appeared to acquire the two lists independently, the performance of one hemisphere was found to vary when the cognitive load was manipulated in the other hemisphere. Our findings are consistent with the view that, while activation of the disconnected hemispheres is derived from a common resource pool, the cerebral hemispheres maintain functional independence at the level of stimulus processing. 128.1 CHARACTERISTICS OF THE VENTROMEDIAL HYPOTHALAMIC OPIATE RECEPTOR ASSOCIATED WITH FEEDING AND TEMPERATURE RESPONSES IN THE RAT. F.S. Tepperman, M. Hirst and C.W. Gowdey*. University of Western Ontario, London, Ontario, Canada.

In rats, ventromedial hypothalamic (VMH) injections of small quantities of morphine initiate a protracted feeding response and hyperthermia. The present studies were undertaken to determine whether these responses require stereoselective, specific interactions with narcotic agonists.

Male Sprague-Dawley rats were housed individually and maintained on a 12 hr light-dark cycle. All were implanted stereotaxically with a cannula which extended to the right VMH. The animals became accustomed to being handled and sham-injected before experiments were initiated. On experimental days the free-feeding rats were injected between 12:15 and 12:45 p.m. with the appropriate drugs, always in a volume of 0.5 µl sterile, pyrogen-free saline. Food eaten and core temperature were recorded hourly for 3 hours.

In the first series, a Latin square design was used to arrange treatment of animals with levorphanol, its stereoisomer dextrorphan, and codeine. Levorphanol stimulated feeding significantly more than dextrorphan or codeine, but core temperature remained unaffected.

In a second series, another group of animals were treated in a Latin square design with saline, or equimolar doses of morphine, ketocyclazocine or phencyclidine. Only morphine significantly increased both feeding and temperature.

In a third series, animals were treated with saline, morphine, or various doses of D-ala^2-D-leu^5-enkephalin (a Type II opiate receptor agonist). Our data suggest that this peptide can increase food intake and core temperature over saline controls.

The results demonstrate that the opiate receptors in the VMH involved in feeding appear to exhibit stereospecificity and to be sensitive to µ (and perhaps δ) opiate agonists rather than to κ or σ agonists . Furthermore, Type II receptors may have a role in this response. Our findings also indicate that enhanced feeding need not be integrally related to increased temperature, for levorphanol can increase feeding without altering body temperature. 128.2 LACK OF OPIATE-SENSITIVE FEEDING SYSTEM IN HAMSTERS. M. T. Lowy* and G. K. W. Yim (SPON: L. Pellegrino), Department of Pharmacology and Toxicology, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, Indiana 47907.

Endogenous opioids (EO) appear to be involved in consummatory behavior as opiate antagonists, such as naloxone, attenuate various types of feeding and drinking behavior, while opiate agonists stimulate food and water intake. Since most of these studies have used rats or mice, it was of interest to examine the effect of various opiate agents on the consummatory behavior of male golden hamsters. Four daily injections of the long-lasting opiate antagonist, nalrexone (NTX; 1 and 10 mg/kg) significantly decreased rat, but not hamster daily food and water intake. Hamsters increased food intake following insulin (50 U/kg) administration, but not after 24 hr food deprivation or 2-deoxy-D-glucose (800 mg/kg) injection. NTX, 1 and 10 mg/kg, had no effect on the feeding of these hamsters. However, NTX, 1 and 10 mg/kg, markedly attenuated hamster drinking induced by 48 hr water deprivation or hypertonic saline injection. Dexamethasone (DEX), a glucocorticoid which depletes pituitary β-endorphin and produces anorexia in rats had no effect on hamster daily food intake. Since the normal feeding profile of the hamster is similar to that of naloxone and DEX treated rats (Life Sci. 26: 2113; 27: 2553, 1980), hamsters appear to lack an opiate sensitive feeding system. In support of this, hamsters did not increase food or water intake following administration of morphine (6.25 - 800 mg/kg) or ketocyclazocine (0.26 - 16 mg/kg), opiate agonists which increase food and water intake in rats (Neurosci. Abs. 6: 528, 1980). In contrast, some aspects of hamster drinking behavior are opiate-sensitive. Thus, there are marked species differences concerning the involvement of EO in consummatory behavior. 128.3 NALOXONE INDUCED SUPPRESSION OF FOOD INTAKE IS POTENTIATED BY NEONATAL ADMINISTRATION OF MONOSODIUM GLUTAMATE TO MICE. R. Dawson, Jr., and Z. Annau. Dept. of Environ. Hlth. Sci., Division of Toxicology, The Johns Hopkins University, Baltimore, MD. 21205.

Neonatal administration of monosodium glutamate (MSG) to rodents results in a massive loss of neurons within the arcuate nucleus of the hypothalamus and significant reductions in hypothalamic, immunoreactive β-endorphin, ACTH, α MSH and dopamine. These anatomical and neurochemical alterations result in a syndrome characterized by obesity, endocrine dysfunction and behavioral deficits. The present study was conducted to evaluate the anorectic potency of naloxone and fenfluramine in MSG-treated (4mg/g MSG on post-natal day 4) male mice.

The effect of naloxone and fenfluramine on food and water intake at doses of 1,5,10 and 20 mg/kg was compared to food and water intake following saline injections. Naloxone at 5,10 and 20 mg/kg was more effective ($p<.05$) in suppressing food intake in MSG-treated mice (n=14) than in controls (n=14). In contrast, naloxone suppressed water intake in controls at 5 and 10 mg/kg ($p<.05$) and produced only a slight drop in water intake in the MSG-treated mice. Both treated and control mice exhibited a significant suppression of water intake at 20 mg/kg. Fenfluramine produced a dose dependent decrease in food intake in both the MSG-treated and control mice. Water intake was suppressed at 5,10 and 20 mg/kg ($p<.05$) in controls, however only 20 mg/kg produced a significant decrease in water intake in MSG-treated mice.

In a separate study, plasma estrogen levels were measured in female MSG-treated (n=16) and control mice (n=16). Trunk blood from 4 mice was pooled to give enough plasma for one sample to be assayed in duplicate. MSG-treated mice (8.4±8.4 pg/ml) had significantly lower plasma estrogen than controls (36.3±4.2 pg/ml).

In summary, naloxone produced a specific and more pronounced suppression of food intake in MGS-treated mice, whereas fenfluramine was equipotent in suppressing food intake for both MSG-treated and control mice. MSG treatment did not alter the anoretic action of fenfluramine demonstrating the specificity of MSG treatment in its enhancement of naloxone-induced food intake suppression. The increased sensitivity to naloxone exhibited by the MSG-treated mice may reflect an alteration in endogenous levels of hypothalamic β-endorphin. MSG-treated mice also exhibited decreased plasma estrogen which parallels the marked ovarian atrophy found in MSG-treated mice.

128.4 EFFECTS OF NALOXONE ON FOOD AND FLUID CONSUMPTION IN VAGOTOMIZED RATS. D. B. Clarkson*, R. D. Olson, B. M. King, R. C. Hemmer*, G. A. Olson, and A. J. Kastin. Department of Psychology, University of New Orleans, New Orleans, LA 70122

Several studies have shown that opiate antagonists like naloxone reliably suppress food and fluid intake under a variety of conditions. The site of action for this effect, however, is still not clear, although the vagal nerve has been implicated by other investigators as a possible mediator.

To more fully evaluate the role of the vagal nerve, testing was completed under the main conditions known to influence consumption in vagotomized rats. Accordingly, 40 male rats underwent either a subdiaphragmatic vagotomy (VAG) or a sham vagotomy (SHAM) and then were assigned to appetitive or deprivation-induced motivational conditions. All four independent groups of rats were then tested in a repeated measures design using a solid sucrose pellet or liquid 20% sucrose solution after being injected intraperitoneally with 0.0, 1.0, 2.0, 4.0, or 8.0 mg/kg of naloxone. The number of grams consumed in two consecutive 30-minute intervals was the primary dependent variable.

The results of the mixed analysis of variance indicate that the main effect for surgery was not significant, with VAG and SHAM rats consuming nearly idnetical amounts of liquids and solids. This finding shows that the vagal nerve is not a significant mediator of naloxone's effect on consumption. Further, the reliable interaction of VAG with liquids and solids showed that VAG rats drank more liquids and ate less solid food than SHAM rats, suggesting that surgery had an effect on ingestion independent of any action by naloxone. No other interactions involving naloxone were significant. The results also indicate a main effect for motivational condition, with rats tested under appetitive conditions ingesting less food and fluid. This is consistent with our previous results that appetitively-induced drinking is not as vigorous as deprivation-induced drinking. A main effect showing more liquids than solids consumed was also obtained. Test period was reliable, with more consumption in the first 30 minutes than in the second period. The main effect for naloxone was also significant, with consumption decreasing in a dose-dependent fashion as expected. Several interactions involving naloxone administration were obtained. Liquid consumption was noticeably suppressed in a dose-dependent fashion while solid consumption only decreased slightly, which is consistent with our previous data. Further, the test period by naloxone interaction showed that the 8.0 mg/kg dose led to maximum suppression in the first 30 minutes followed by a "rebound effect" on increased consumption in the second test period. In summary, the results show that the vagal nerve is not required for the mediation of naloxone effects.

128.5 EFFECTS OF NALOXONE, MIF-I, AND MIF-I ANALOGS ON FLUID CONSUMPTION IN RATS. R. D. Olson, R. C. Fernandez*, A. J. Kastin, G. A. Olson T. K. vonAlmen*, D. G. Erickson*, D. B. Clarkson*, and D. H. Coy*. Department of Psychology, University of New Orleans, New Orleans, LA 70122

We have shown previously that MIF-I suppresses fluid intake in rats in a manner comparable to that demonstrated by naloxone. Further, following high doses of naloxone, a "rebound effect" characterized by greatly increased consumption occurs after the initial suppression of drinking. The main purpose of this study was to determine the lowest dose of an opiate antagonist that would suppress consumption. A second purpose was to look at possible interactions with sex, which previous work in this laboratory has shown to be very significant.

Albino rats (48 male, 48 female) were randomly assigned to the appropriate experimental group, naloxone, Pro-Leu-Gly-NH_2 (MIF-I), Tyr-Pro-Leu-Gly-NH_2 (Tyr-MIF-I), or pGlu-Leu-Gly-NH_2 (pGlu), and received an intraperitoneal injection of either 0.01, 0.1, or 1.0 mg/kg of each test substance. A control group of 4 males and 4 females was also tested using the diluent vehicle. Consumption of a 20% sucrose solution was measured in grams every 30 minutes for 10 hours.

A mixed analysis of variance indicated the main effect for test substance to be significant. Scheffe's test for individual comparisons showed that rats injected with MIF-I and the pGlu analog drank the most followed by rats injected with naloxone, Tyr-MIF-I, and the controls. The main effect for dose was also significant, with consumption decreasing in a dose-dependent fashion. Dunnett's test showed all experimental groups to be reliably above the control except the groups receiving the 1.0 mg/kg dose of Tyr-MIF-I and the 1.0 mg/kg dose of naloxone, which were not reliably different from each other or the control. The main effect for sex was not significant, but the interactions of sex by peptides and also sex by dose were highly significant. Males drank more than females after injections of MIF-I or naloxone, about the same after injections of the pGlu analog, and less after injections of Tyr-MIF-I. In all tests, females drank the least at the 0.1 mg/kg dose while males drank the most at the same dose.

The data vary significantly from previous studies using larger doses of opiate antagonists in that the lowest doses in the current study all produced reliable increases in consumption rather than the typical decreases associated with such antagonists. The results show that MIF-I and its analogs have actions comparable to naloxone in modulating fluid consumption in rats.

128.6 **EFFECT OF ANORECTIC DOSES OF ETHANOLAMINE-O-SULFATE (EOS) ON REGIONAL BRAIN UPTAKE OF ^{14}C-2-DEOXY-D-GLUCOSE (^{14}C-2DG).** **J.N. Nobrega, D.V. Coscina, J. Chambers* and J.S. Yeomans (Biopsychol. Sect., Clarke Inst. Psychiat. and Psychol. Dept., Univ. of Toronto, Toronto, Ont., Canada).**

Central injections of EOS, an irreversible inhibitor of GABA transaminase, increases brain GABA levels while depressing food intake in a dose-dependent manner (Cooper et al, Life Sci, 1980, 26, 1997). EOS has also been shown to reverse the overeating induced by medial hypothalamic lesions, systemic 2-DG injection, or highly palatable diets (Coscina & Muir, East. Psychol. Assoc. Abs. 1981, 52, 108). In an effort to gain information on possible brain sites mediating these effects we investigated the regional brain uptake of ^{14}C-2DG by autoradiography and scintillation counting after intracerebral EOS. Under ether anesthesia, male rats (300-400 g) received one intracisternal injection of 400 ug EOS. This dose has been previously shown to induce a pronounced elevation of brain GABA and reliable anorexia for several days. Twenty-four hours later, rats received 20 uCi of ^{14}C-2DG i.p., and were sacrificed 45 min later. Brains were removed and frozen for subsequent sectioning or were dissected in situ into nine regions (cerebellum, hypothalamus, septum, hippocampus, striatum, thalamus, cortex, midbrain and hindbrain) for liquid scintillation counting. A marked reduction in ^{14}C-2DG uptake was found in EOS-treated brains (mean reduction in CPM /mg tissue: 78% ± 3%). This reduction was fairly uniform across the nine regions studied (range: 74% in hypothalamus to 84% in striatum). The generalized nature of this effect was confirmed in the autoradiographs. In all cases, sections from EOS-treated brains appeared homogeneously pale compared to corresponding sections from control brains exposed on the same X-ray film. These results suggest that anorexia-inducing elevation of GABA levels by EOS is associated with a profound and generalized decrease in brain glucose uptake. The uniformly massive decrease in ^{14}C-2DG uptake across brain regions might suggest that the behavioural deficits observed are associated with a general metabolic effect of GABA elevation as opposed to inhibition of specific neuronal circuits. Consistent with this possibility, Olgiati et al. (Psychopharm., 1980, 68, 163) have shown that the anorectic effects of EOS are not blocked by the GABA receptor blocker bicuculline.

J.N.N. is a Fellow of MRC of Canada and CNPq of Brazil.

128.7 REDUCTION OF LONG-TERM FOOD INTAKE FOLLOWING VENTRICULAR INFUSION OF ETHANOLAMINE-O-SULPHATE. P.Bishop* and J. Panksepp, Dept. of Psych., Bowling Green State University, Bowling Green, Ohio 43403.

Long-term body energy regulation may be mediated by the encoding of metabolic information via GABA shunt intermediates in neural circuits which inhibit feeding related behaviors. The GABA shunt provides an ideal mechanism by which inhibitory neuroactive information concerning the overall energy status of an organism could be generated from intermediary metabolism. To further evaluate this possibility, we have chronically infused the GABA-transaminase inhibitor, ethanolamine-O-sulphate (EOS), into the 3rd ventricle of freely fed Long-Evans female rats. Week long infusions of EOS with Alzet minipumps produced dose dependent reductions in feeding and body weight. 200 ug EOS/day inhibited all feeding behavior and animals died within 5 days. 100 ug/day led to a 67% reduction in daily food intake and a 27% reduction in body weight. Animals exhibited symptoms similar to those with lateral hypothalamic lesions. 50 ug/day led to a 45% reduction in food intake and a 16% decrease in body weight. The animal appeared normal. The GABA-antagonist, picrotoxin, was infused in a similar manner (24 ug/day) over the course of one week resulting in no reliable effects on either food intake or body weight. However, when this dose of picrotoxin was paired with EOS (50 ug/day), the reduction in food intake and body weight previously observed with the EOS alone was partially attenuated.

These data implicate the involvement of a GABA receptor system in the effects of EOS on food intake and body weight and provide further convergent evidence for the hypothesis that GABA exerts inhibitory control over long term body energy regulation via control of feeding behavior.

128.8 PROSTAGLANDIN E_2 SUPPRESSES SALINE INTAKE OF RATS WITH RESTRICTED ACCESS TO SALT. Karen E. Moe* and Nancy J. Kenney, Dept. of Psychology, University of Washington, Seattle, WA 98195.

Prostaglandin E (PGE) has been repeatedly implicated in the regulation of body fluid homeostasis. Administration of PGE either centrally (Kenney & Epstein, 1978) or peripherally (Kenney et al., in press) attenuates the water consumption that occurs in response to a variety of dipsogens, including angiotensin II, hypertonic saline, polyethylene glycol and water deprivation. Prostaglandin E may also be involved in the control of sodium excretion, though whether it is natriuretic (Bartha, 1977) or anti-natriuretic (Kirschenbaum & Stein, 1976) is still a controversy. The experiments reported here examined the role of prostaglandin E_2 (PGE_2) in the sodium appetite of rats with restricted access to salt.

Male rats were trained to consume a saline solution (1.5%) for two hours each day. Throughout the experiment, including the training period, the rats had continuous access to a sodium-deficient diet and de-ionized water. Thus, consumption of saline during the 2-hour period was their only means of obtaining salt. After saline consumption had stabilized, all animals received a daily intraperitoneal (IP) injection of either PGE_2 (10, 50 or 100 µg/ml/kg) or the PGE_2 vehicle (1 ml/kg) immediately prior to the NaCl access. Each prostaglandin treatment day was preceded and followed by a vehicle treatment day. Saline and water consumption were monitored during the entire 2 hours.

Saline consumption was significantly ($p < .05$) suppressed by IP injection of PGE_2 at all three doses used, though the degree and duration of the suppression varied with dose employed. In general, actual consumption was reduced for only the first 30 minutes. However, as consumption during the remaining 90 min was no different from that of vehicle days, cumulative saline intake remained depressed for a much longer time. Only the 100 µg/kg dose affected water intake, reducing it for the first 30 minutes relative to control values.

To determine if the PGE treatment inhibits saline intake by making animals sick, a second experiment utilized the conditioned taste aversion paradigm (Garcia & Koelling, 1966) to test for the presence of malaise. IP injection of PGE_2 (50 or 100 µg/kg) was paired with consumption of a novel-tasting substance to determine whether such PGE treatment will lead to the formation of a conditioned taste aversion. The resulting failure to elicit a taste aversion suggests that IP PGE_2 does not induce sickness. Therefore, the attenuation of NaCl consumption by IP PGE_2 is more likely the result of a specific inhibitory mechanism rather than general malaise or inability to respond.

Supported by NIH grant AM22024 to Nancy J. Kenney.

128.9 NOREPINEPHRINE METABOLISM IN MEDIAL HYPOTHALAMUS IS INCREASED BY ACUTE AND CHRONIC DEHYDRATION. Harry Klemfuss* and Lewis Seiden (SPON: M. Hollyday). Dept. of Pharmacol. & Physiol. Sciences, University of Chicago, Chicago, IL 60637.

Concentrations and turnover rates of hypothalamic catecholamines (CA) were altered after manipulations which interfere with water homeostasis in the rat. Chronic dehydration was produced by limiting access to water to a 10-min period starting at 1000 hrs. After 7 days of this treatment, rats were injected with either saline or 200 mg/kg α-methyl-p-tyrosine methylester HCl (AMT) at approximately 0800 hrs and were killed 2 hrs later. Brain regions were assayed for CA using high performance liquid chromatography with electrochemical detection. Turnover rate was determined by comparing CA levels after AMT pretreatment to matched controls treated with saline. Chronic dehydration reliably increased both levels and turnover of norepinephrine (NE) in the hypothalamus, but not in amygdala, mesolimbic area, septum, telencephalon, or brainstem. Within the hypothalamus, chronic dehydration did not affect NE metabolism in paraventricular nucleus, preoptic area, or lateral hypothalamus, but in medial hypothalamus NE concentrations increased to 144% of control ($p < 0.005$ level). NE turnover was also significantly increased ($p < 0.05$). Dopamine metabolism was unchanged by chronic dehydration in caudate, substantia nigra, limbic areas or any hypothalamic region studied. There are several stimuli which activate compensatory mechanisms for maintaining water homeostasis. Hypernatremia stimulates hypothalamic osmoreceptors. Hypovolemia is signalled by both peripheral nerves and by circulating angiotensin II. Hypernatremia and hypovolemia can be experimentally induced by injecting hypertonic saline or hyperoncotic colloid, respectively. Angiotensin II levels can be raised without altering plasma volume by ligating the inferior vena cava above the renal veins. In the rat, none of these manipulations altered NE concentrations in the medial hypothalamus. On the other hand, both hypernatremia and caval ligation increased the turnover of NE in the hypothalamus ($p < .05$). We are currently examining dehydration effects on dopamine and epinephrine metabolism in the rest of the hypothalamus. (Supported by PHS MH-11191; RSA MH-10562; MH-14274).

128.10 PHARMACOLOGICAL DEPLETION OF NOREPINEPHRINE AND FEEDING BEHAVIOR IN THE RAT. John Rossi III*, R. F. Davies*, A. J. Zolovick* and Jaak Panksepp. (SPON: F. G. DeEskinazi) Dept. of Psychology Bowling Green State University, Bowling Green, OH 43403

Both norepinephrine (NE) and serotonin (5-HT) have been implicated in the neurochemical control of feeding. Although previous findings suggest that manipulations which facilitate activity in brain NE systems can increase feeding and those which increase activity in the 5-HT system can decrease feeding, disagreement exists concerning feeding effects following reduction of activity in these systems. In the present study, feeding behavior was examined after acute pharmacological depletion of NE alone or in combination with specific 5-HT reuptake inhibition.

Dopamine-B-hydroxylase (DBH) inhibition with FLA-63 (10 mg/kg) disrupted free feeding behavior in satiated rats. While the average number of meals taken was not different than vehicle injected controls, meal size was reduced 58% in the first 9 hrs after treatment with FLA-63. In starved animals, FLA-63, produced little effect on feeding behavior, even though NE depletion was in excess of 40%. When FLA-63 was given in combination with the vesicular depleting drug RO4-1284 (5 mg/kg), feeding was reduced to 16% of control intake and NE was specifically depleted in excess of 98%. Starvation feeding was reliably reinstated in animals which received FLA-63 plus RO4-1284 with either dl-threo-DOPS, a metabolic precursor to NE, or direct intrahypothalamic injections of NE. These findings suggest that the feeding suppression observed after these manipulations was due to disruption of transmission in brain NE systems.

When starved rats are co-treated with FLA-63 (10 mg/kg) and the specific 5-HT reuptake blocker Ll10-140 (3.75 or 7.5 mg/kg) the suppression of feeding observed is much greater than when either drug is given seperately and is as great as that observed after nearly total NE depletion with FLA plus RO4-1284. Furthermore, neither FLA-63 nor Ll10-140 when given seperately or in combination reduced deprivation induced drinking behavior indicating that their interaction in the suppression of feeding may be specific.

Taken collectively, these findings suggest that the primary role of NE in feeding is maintenence of the consumatory response and that these effects are expressed in relation to activity in other neurochemical systems such as 5-HT.

128.11 BEHAVIORAL EFFECTS OF NOREPINEPHRINE AND/OR DOPAMINE DEPLETIONS. J. H. McLean, S. B. Hutson*, B. M. King, and R. M. Kostrzewa. Dept. Psychology, University of New Orleans and Dept. of Pharmacology, East Tennessee State University College of Medicine.

Various dosages of 6-hydroxydopamine were administered intraventricularly to rats on days 5 and 7 after birth to deplete selectively central norepinephrine (low NE), dopamine (low DA), or both (low NEDA); saline was administered similarly to control animals. Animals were studied at 3 months of age on a variety of behavioral tasks before being sacrificed at approximately 5 months of age. Significant differences between groups were found in activity, emotionality, daily food and water intake, nonprandial drinking, sucrose solution intake, and feeding in response to insulin. Significant differences were found more frequently between the treatment groups than between the control group and treatment groups. No significant differences were found between groups in active and passive avoidance, intake of quinine solution, response to hypertonic saline injection, and feeding in response to two 2-deoxy-d-glucose dosages. In comparison to saline animals, significant depletions of endogenous NE were found in the hippocampus, hypothalamus, and cortex for animals receiving one large dose of 6-hydroxydopamine (low NEDA) and animals receiving two small doses of 6-hydroxydopamine (low NE). Striatal dopamine was significantly depleted in all treatment groups. Norepinephrine content of the cardiac ventricle was not significantly affected in any group.

128.12 RESTORATION OF REGULATORY DRINKING IN RESPONSE TO HYPERTONIC SALINE IN 6-HYDROXYDOPAMINE-TREATED RATS: A TEST OF DOPAMINE RECEPTOR STIMULATION. C.T. Dourish*, R.S.G. Jones (SPON: J.D. McQueen) Psychiatric Research Div., University Hosp., Sask., Canada S7N OXO

Brain dopamine (DA) neurons have been implicated in the control of regulatory drinking responses since bilateral 6-hydroxydopamine (6-OHDA) lesions of the nigrostriatal bundle cause a syndrome of aphagia and adipsia which is similar to the deficits induced by bilateral electrolytic lesions of the lateral hypothalamus (LH). Following LH or 6-OHDA lesions rats do not drink in response to physiological stimuli such as hypertonic saline (HS) which elicits thirst in intact animals. It has been demonstrated (Marshall and Ungerstedt, Physiol. Behav., 17:817, 1976) that the systemic administration of a low dose of the DA agonist apomorphine can restore drinking in response to HS or isoproterenol in 6-OHDA lesioned rats, but not in rats with LH lesions. We have extended this observation and used a similar procedure to examine the postulated DA agonist properties of a number of drugs. We studied 3 groups of male Sprague-Dawley rats: unoperated controls (n=16), rats given bilateral 6-OHDA lesions of the ventral tegmentum (n=8) and rats given bilateral radio-frequency lesions of the LH. Following surgery lesioned animals were aphagic and adipsic and had to be fed intragastrically to maintain body weight. The rats were tested over a period of 7 days (beginning 2 days after surgery) for drinking responses to HS, apomorphine, piribedil, lergotrile, β-phenylethylamine and tyramine. Each drug was administered i.p. alone and in combination with HS. In control rats HS elicited a strong drinking response (x=7.5 ml) but had no effect in lesioned animals. When HS was followed by apomorphine, piribedil or lergotrile, rats with 6-OHDA lesions became activated and drank a similar volume of water (x=6.0 ml) to that consumed by controls. β-Phenylethylamine and tyramine did not induce drinking when administered with HS in 6-OHDA lesioned animals. Rats with LH lesions did not drink in response to HS regardless of whether it was administered in combination with apomorphine, piribedil or lergotrile.

These observations confirm the findings of Marshall and Ungerstedt and support the hypothesis that DA pathways are involved in the control of regulatory drinking. Since this study can be interpreted as a test of DA receptor stimulation, however, the results cast doubt on the proposed status of β-phenylethylamine (Antelman et al., Brain Res. 127:317, 1977) as a direct DA receptor agonist. Supported by Sask. Health and the M.R.C. of Canada.

128.13 NEUROCHEMICAL AND BEHAVIORAL EFFECTS OF MONOSODIUM GLUTAMATE ADMINISTRATION TO NEONATAL MICE. M.F. Callahan, R. Dawson, Jr. and Z. Annau. Dept. of Pharmacology, Chicago Medical School, North Chicago, IL. 60064 & Dept. Environ. Hlth. Sci., Division of Toxicology, The Johns Hopkins University, Baltimore, MD 21205

Monosodium glutamate (MSG) administation of neonatal mice results in destruction of the arcuate nucleus of the hypothalamus and reductions in hypothalamic and pituitary dopamine (DA). The neurochemical changes following MSG treatment contribute to a syndrome characterized by obesity, endocrine dysfunction and behavioral deficits. In the present study, hypothalamic DA and norepinephrine (NE) turnover was estimated in 20 adult, male mice treated with a single subcutaneous dose of MSG (4mg/g) on postnatal day 4 and an equal number of control mice utilizing α-methyl-p-tyrosone (α MPT) (400 mg/kg) and a sensitive radioenzymatic assay procedure. Groups of 5 animals were decapitated at 1,2 and 3 hours following the injection of α MPT.

Steady state levels of hypothalamic NE and DA were not significantly altered by MSG treatment. The turnover rate of NE in MSG-treated mice did not differ significantly from that of the controls. DA turnover rate in the hypothalamus of MSG-treated mice did not differ from the controls over the 3 hour time course of DA synthesis inhibition, however, DA levels in the MSG-treated mice were significantly lower than controls 1 hour after α MPT injection. This suggest a more rapid utilization of DA in MSG-treated mice. Further studies at different time points are being conducted to clarify this finding.

Taste reactivity testing, and activity levels were also evaluated. One hour consumption of a number of flavored solutions was evaluated in 14 male MSG-treated and 14 control mice. Both groups significantly ($p<.05$) increased their intake of 0.9% saline, however neither group increased their intake of a 0.1% sacchrin solution. Control mice drank significantly less ($p<.05$) of a 0.1% quinine solution, whereas MSG-treated mice exhibited a nonsignificant decrease. Activity levels were monitered in 7 male MSG-treated and an equal number of control mice at 65,90 and 200 days of age. The MSG-treated mice exhibited increased activity levels at all time points, reaching significance at day 65 ($p<.02$) and 200 ($p<.02$).

The neurochemical findings suggest that dopaminergic function may be altered in those DA neurons that survive MSG treatment. It is concluded from the behavioral studies that the hypoactivity reported in MSG-treated mice is a function weight gain and not of MSG-treatment per se. It also appears that MSG-treated mice do not exhibit the finickiness characteristic of damage to the ventromedial nucleus.

128.14 NOCTURNAL FOOD-CONTINGENT HYPERDIPSIA IN THE SPONTANEOUSLY HYPERTENSIVE RAT. F.S. Kraly, A.F. Moore*, L.A. Miller*, L.J. Morrison* and A. Drexler*. Psych. Dept., Colgate Univ., Hamilton, NY 13346 and Norwich-Eaton Pharm., Norwich, NY 13815.

Male spontaneously hypertensive rats (SHR; 5 mo. of age, $n = 10$; Taconic Farms) ate the same in 24 hr. as normotensive Wistar-Kyoto (WKY; $n = 6$) rats with continuous access to standard laboratory pellets and tap water (Table 1). SHR rats drank more water, however, and this hyperdipsia was reflected in a higher water to food ratio (W:F) for SHR rats.

Table 1 (24-hr. day & night)

	WKY	p	SHR
Food (g/100g)	6.5 ± .2	>.20	6.6 ± .1
Water (ml/100g)	10.9 ± .4	<.02	12.9 ± .5
W:F (ml/g)	1.7 ± .05	<.05	2.0 ± .1

When rats ate in the day phase of a 12:12 light/dark cycle after 24-hr. food deprivation, SHR rats ate and drank the same as did WKY rats and SHR rats had a similar W:F in a 60-min. test (Table 2). When the same rats ate in the night phase after 24-hr. food deprivation, however, SHR rats were hyperdipsic: They ate the same as WKY rats, but SHR rats drank significantly more and had a higher W:F (Table 2). SHR rats were also observed to groom less ($p<.01$), to explore the home cage less ($p<.01$), to recline in the cage more often ($p<.001$) and to interrupt eating by drinking more often ($p<.05$) than WKY rats when tested eating and drinking at night.

Table 2

	WKY	p	SHR
Day Phase			
Food (g/100g)	1.6 ± .1	>.20	1.5 ± .2
Water (ml/100g)	2.1 ± .2	>.20	2.2 ± .2
W:F (ml/g)	1.4 ± .1	>.10	1.5 ± .1
Night Phase			
Food (g/100g)	1.8 ± .1	>.20	1.7 ± .1
Water (ml/100g)	2.5 ± .1	<.001	3.2 ± .1
W:F (ml/g)	1.4 ± .1	<.01	1.9 ± .1

This relative hyperdipsia reflects the increased ability of ingestion of food to stimulate drinking in SHR rats, because when food was absent for a 60-min. test at night SHR rats drank the same as did WKY rats (SHR: .8 ± .2 ml/100g; WKY: 1.0 ± .2 ml/100g; $p>.20$).

This nocturnal food-related hyperdipsia in SHR rats appears not to be mediated by peripheral angiotensin II (AII), because the AII converting enzyme inhibitor SQ 14,225 (50 mg/kg p.o. 60 min. prior to eating) failed to inhibit drinking ($p>.20$) or to reduce W:F ($p>.20$) in SHR rats.

128.15 LOW DIETARY PROTEIN AND THE FACILITATION OF AGGRESSIVE BEHAVIOR IN RATS. K.M. Kantak and B. Eichelman. Laboratory of Behavioral Neurochemistry, University of Wisconsin and William S. Middleton Veterans Hospital, Madison, Wisconsin 53705.

Dietary intake of protein is important for growth and physical and mental development. The effects of low protein intake on feeding behavior and body weight maintenance are well described. Since the ingestion of protein affects many neurochemical parameters, it is reasonable to expect that the intake of low levels of protein affects many other behavioral measures as well. In the present study, rats were maintained on either an 8% low protein diet or a 25% isocaloric normal protein control diet and tested for changes in aggressive behavior. For shock-induced fighting, which tests for defensive aggression, the low protein diet significantly elevated the level of fighting two weeks following its initiation with no effects 24 hr and 1 week following its initiation. After three weeks return to normal protein chow the levels of fighting returned to baseline levels. For mouse-killing behavior, which tests for predatory aggression, the low protein diet significantly reduced the latencies to sniff, attack and kill mice and significantly increased the number of mice killed one week and two weeks following its initiation in rats which were experienced spontaneous killers. In experienced non-killer rats, the low protein diet failed to affect the incidence of mouse-killing, indicating that 8% low dietary protein does not influence the initiation of mouse-killing but facilitates its maintenance. After three weeks return to normal protein chow mouse-killing was no longer facilitated in spontaneous killer rats. The facilitation of shock-induced fighting and mouse-killing in killer rats following ingestion of a low protein diet was independent of potential physical debilitating effects of the diet since body weight levels were maintained at pre-low protein diet levels. These data indicate that the intake of low levels of dietary protein can modulate behavior in rats which in the present study is a facilitation of both defensive and predatory aggression.

128.16 EFFECTS OF ESTRADIOL ON SHORT-TERM AND LONG TERM FEEDING SYSTEMS C.W. Simpson,* C.Dudley,* and C. Deluca,* K. Moore.*
(Spon: J. Schaeffer) Dept. of Biology and Sch. of Medicine Univ. of Missouri-K.C., Kansas City, MO. 64110

Estrogen reduces body weight and ad. lib. feeding in normally cycling rats. We have shown in previous work that estrogen level alters catecholamine elicited eating at anterior hypothalamic sites. Norepinephrine (NE) elicited feeding is not disrupted and may be potentiated at these anterior sites in the presence of estrogen. Dopamine (DA) elicited feeding, at these same sites is inhibited in the presence of estrogen. Neither NE or DA significantly altered 24 hour food intakes or body weight following central injections. Rats at different levels of body weight were microinjected at catecholamine sensitive sites in the anterior hypothalamus under different estrogen conditions. Ovariectomized groups of rats at 3 significantly different levels of body weight were injected with NE and DA in the anterior hypothalamic sites. Ne and DA significantly increased 1-2 hours feeding in all weight groups. All groups were then reduced to lower absolute levels of body weight by daily estrogen injection 2µg/day in oil. All weight groups were again microinjected with NE and DA in anterior hypothalamic sites in the presence of estrogen. Under these conditions estrogen continued to reduce body weights and 24 hour food intake for all groups but did not alter the increases in 1-2 hour food intake following injections of NE or in this experiment DA. The mechanism of action for the estrogen effects on catecholamine eating was investigated by direct implantation of estrogen in estrogen sensitive sites as described by (Stumpf W. Am. J. ANAT. 129, 1970.) and concurrent catecholamine injections in the anterior hypothalamic sites. Animals were fitted with 2 sets of cannulas, one in the catecholamine feeding site and the other set in different groups of animals in LPO, VmH or anterior hypothalamic estrogen sensitive sites. Estrogen crystals in doses > 5µg/day but not cholesterol crystals, significantly reduced 24 hour food intakes and daily body weights when placed in LPO, VmH and anterior hypothalamic estrogen sensitive sites. While the boby weight loss and decrease in 24 hour intakes was consistent for all groups, estrogen effects on 1-2 hour feeding following NE or DA injections were differentially affected. NE elicited increases in short-term food intake irrespective of hormone condition at any site. Conversely DA elicited increases in 1-2 hour intakes only when estrogen was at the LPO site. When estrogen preceded DA in the anterior hypothalamic or VmH sites short-term food intake increases were inhibited.

128.17 FOOD PREFERENCES, EATING PATTERNS, AND CALORIC INTAKE IN NORMAL AND COMPULSIVE EATERS. B. J. Sahakian, S. Bingham*, P. Murgatroyd*, M. Lean*, and W.P.T. James*. Dunn Clinical Nutrition Centre, University of Cambridge and M.R.C. Dunn Nutrition Unit, Cambridge, CB2 1QE, England.

The food preferences, eating patterns, and caloric intake of human subjects with and without eating disorders were studied by means of a food machine (Silverstone, T. In: Recent Advances in Obesity Research : II, ed. by G. Bray, London: Newman, 421-432, 1978) and an ACORN microprocessor. Considerable differences in caloric intake (MJ/24h) in subjects with similar weight/height^2 indexes were found. Correlations of subjects' eating patterns, food choices, caloric intake, weight/height^2 indexes, and responses on scales of restrained vs. unrestrained eating (Polivy, J., Herman, C.P. and Warsh, S., J.Abnormal Psychol., 87, 497, 1978) were performed.

This method appears to be an excellent means of quantifying food preferences, patterns of eating, and caloric intake in human subjects in long-term studies, and therefore can be used to assess drug treatments in patients with eating disorders. After determination of baseline measures of preferences, patterns, and caloric intake in a patient with bulimia nervosa (Russell, G., Psychologic.Med., 9, 429, 1979), double-blind trials of naloxone, chlorpromazine, or placebo were undertaken to see whether these agents would suppress the patient's compulsive eating. The findings of these drug trials were negative. Trials with other subjects are currently underway to determine whether these or other drugs would prove effective in the treatment of patients with a different type of compulsive eating disorder, such as compulsive overeating in obesity.

129.1 SINGLE UNIT RESPONSES IN MLD OF THE REDWING BLACKBIRD. N. A. O'Connell and M. B. Sachs*. Dept. of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, Md. 21205

Responses of single cells in nucleus mescencephalicus lateralis pars dorsalis (MLD) to sound stimuli were recorded in redwing blackbirds. Mapping studies of MLD in anesthetized birds revealed a tonotopic organization with characteristic frequency increasing in the dorsal to ventral and anterior to posterior directions. Response properties of cells in anesthetized and awake birds will be presented. Stimuli included digitized recordings of blackbird and cowbird vocalizations as well as tones and broadband noise. Response maps showing regions of excitation and inhibition in the sound level-frequency plane were constructed. In anesthetized birds most response maps showed excitatory centers; maps for units with significant spontaneous activity often had inhibitory sidebands. A strong onset response to tones was the most common response type. Many units in unanesthetized birds had an excitatory onset response followed by inhibition for most tones. Response maps for onset and sustained responses of these units were mapped separately. The onset response was typically excitatory over a broad range of levels and frequencies. The sustained response was inhibitory over a wide range with no excitatory regions. This work was supported by a grant from the National Institute of Neurological and Communicative Diseases and Stroke. N. A. O'Connell is a National Institutes of Health Postdoctoral Fellow.

129.2 SPATIAL SELECTIVITY OF AUDITORY NEURONS IN THE CEREBELLUM. Jane C. Norris. Neurobiology Dept., Stanford University School of Medicine, Stanford, CA 94305.

The cerebellum receives a variety of sensory afferents including an auditory projection. Although the functional significance of this input remains unresolved, results of binaural interaction studies have suggested that these neurons may be involved in sound localization or in coordinating movements related to orienting to an auditory stimulus in space. Previous studies of the auditory centers of the barn owl have revealed a class of neurons distinguished by its selective responses to sounds originating only from a restricted area of space (Knudsen and Konishi, Sicence, 200, 1978). Such limited-field neurons could play an important role in sound localization.

The present investigation was designed to locate the auditory projection area in the owl cerebellum and to determine if cerebellar auditory neurons were selectively responsive to the spatial location of an acoustic stimulus. Extracellular recordings of auditory cerebellar unit activity in ketamine anesthetized owls were made. Stimuli consisted of noise or tone bursts delivered in a free-field from a speaker which was movable in both azimuth and elevation. The auditory receptive fields of neurons were obtained from spike counts collected as the auditory stimulus location was changed. Lesions made at locations where spatially sensitive auditory neurons were found allowed subsequent histological verification of the auditory projection area.

The results indicated that the majority of auditory units were located in folia VII and VIII. Most units were sensitive to sound location; that is, they had definite auditory receptive fields within which the spike rate markedly changed. Most of the limited field units demonstrated excitatory responses to sound but some had inhibitory fields. The size of the field (ranging from 18° to 43° in azimuth) was usually, but not always, independent of stimulus intensity. A smaller group of units preferred a certain spatial location but responded at a lower rate to all locations. Some of these units showed complex response patterns with both excitatory and inhibitory areas. Another small group responded in a spatially independent manner. These results suggest that precise auditory spatial information is available for processing in the cerebellum.

129.3 IONTOPHORETIC APPLICATION OF PUTATIVE INHIBITORY NEUROTRANSMITTERS ONTO BINAURAL UNITS IN THE SUPERIOR OLIVE. Maurus Moore*, D.M. Caspary and D. Colleen Havey. Department of Pharmacology, Southern Illinois Univ. Sch. Med., Springfield, IL 62702.

The first conjunction of bilateral afferent pathways in the auditory system occurs in the superior olivary complex (SOC). Binaural neurons in these structures possess a two-dimensional dendritic input from opposite ears (Scheibel and Scheibel, Exp. Neurol., 43:339, 1974), and may be involved in dichotic sound localization (Erulkar, Physiol. Rev., 53:237, 1972). Many of these neurons may be excited by stimulating one ear, but this activity may be inhibited by simultaneous stimulation of the other ear (IE units, Goldberg and Brown, J. Neurophysiol., 31:639, 1968). This provides an opportunity to examine the interaction of synaptically mediated excitation and inhibition at the same neuron by manipulation of the acoustical input to each ear.

The present study examined the effects of iontophoretic application of putative inhibitory amino acid neurotransmitters and their antagonists onto IE neurons of the SOC. The experimental paradigm attempted 1) mimicry of the inhibitory input using GABA or glycine; 2) antagonism of the acoustically-evoked inhibitory synaptic input using bicuculline or strychnine; and 3) antagonism of the effects of the iontophoretically applied agonist. Sixty-nine IE neurons from the SOC were examined, 47 of which were extensively studied using iontophoretic application of candidate transmitters and their antagonists. Acoustically-evoked monaural excitation could be effectively inhibited by glycine in most cases. This inhibition could be antagonized by the glycine antagonist strychnine, but not by bicuculline. IE neurons generally display a binaural response that is markedly reduced from the monaural condition. In 28 neurons, strychnine application during binaural stimulation resulted in a response comparable to the monaural excitatory condition. Thus, it appears strychnine can effectively antagonize the acoustically-evoked inhibitory synaptic input to these neurons. At the peak of the strychnine antagonism of the synaptically-mediated inhibition, iontophoretic application of glycine had no effect. A number of neurons were inhibited by GABA, but antagonism of this effect and of inhibitory synaptic effects by bicuculline were rarely seen. Results of these studies suggest a glycinergic input to certain neurons of the superior olivary complex. (Supported by NIH grant #NS15640-02)

129.4 AUDITORY BRAINSTEM ANOMALIES IN ALBINO CATS. D. Creel, J.W. Conlee*, and T.N. Parks. VAMC, Salt Lake City, UT 84148; and Dept. of Anatomy, Univ. of Utah Coll. Med., Salt Lake City, UT 84132.

Abnormal routing of retinal fibers in albinos of 10 species of mammals has been described. The disorganization of visual pathways is correlated with reduced retinal pigmentation in mammals having mutations that cause ocular or oculocutaneous forms of albinism. The amount of melanin in the inner ear of pigmented mammals is positively correlated with the general pigmentation of the body and specifically with the amount of pigmentation in the eye. Pigment is absent in the inner ear of albino humans and animals. Electrophysiological evidence of significant differences in brainstem auditory pathways between albinos and pigmented humans has been reported.

Brainstem auditory evoked potentials (BAEP's) were recorded from 5 pigmented cats and 5 albino cats. The albinos were complete tyrosinase-negative (c), not the dominant white (W) variety. The cats were anesthetized and stimulated monaurally by 100 μsec clicks at a rate of 11.3 per second. Click intensities of 70,75,80, and 85 dB peak SPL (40-55 dB HL) were used. Potentials evoked by 1,000 clicks were averaged; the period of analysis was 10 msec from the onset of each click. Electrodes were placed 5 mm lateral to the midline at the vertex and were referred to the ipsilateral mastoid process.

In pigmented cats, asymmetry of BAEP's was limited to amplitude variations of 20-40% for components appearing between 2 and 3.5 msec, plus the expected faster ipsilateral latencies for components in the first 5 msec. Albinos, however, demonstrated a dramatic diminution of contralateral components appearing between 2 and 3.5 msec. At the lower click intensities (70,75 dB SPL), there were no contralateral components in this region.

These data indicate probable significant differences between the decussated and nondecussated auditory pathways at the level of the superior olivary nuclei and subsequent ascending pathways in the albino cat. This is further evidence of the anomalous decussation of brainstem auditory pathways in albinos.

129.5 MORPHOLOGY AND ORIGIN OF AXONAL ENDINGS IN NUCLEUS LAMINARIS OF THE CHICKEN. T.N. Parks, A.J. Robinson*, and J.W. Conlee*. Department of Anatomy, University of Utah College of Medicine, Salt Lake City, UT 84132.

The morphology of axon terminals in nucleus laminaris (NL), a 3rd-order auditory center, was studied in aldehyde-osmium fixed double-stained material from adult White Leghorn chickens. Structural correlates of physiological response properties and baseline data for evaluating normal development of NL and the effects of various experimental manipulations were sought. From montages of electron micrographs, 528 terminals on 16 cells at 6 posterior-to-anterior levels within NL were analyzed; in 20 of these endings, the packing density of synaptic vesicles and the width of the intercellular cleft separating ending and cell were also measured. 98% of all endings could be unequivocally assigned to one of two categories. Type M endings typically arise from large unmyelinated preterminal fibers; the mean (±S.E.M.) apposition length for these terminals is 2.39±0.21 μm, cross-sectional area is 6.17±1.83 μm^2, the area:length ratio is 5.94±1.75, the packing density of synaptic vesicles (mean±S.D.) is 41.7±13.9 per μm^2, and the mean width of the intercellular cleft is 35.7±14.7 nm. Large, clear, round synaptic vesicles cluster near small punctate synaptic junctions; both pre- and postsynaptic membranes bear pronounced densities. 54% of the type M terminals end on proximal dendrites--the rest end directly on cell bodies. Type M endings predominate on distal NL dendrites. In preliminary studies involving injection of horseradish peroxidase (HRP) into the crossed dorsal cochlear tract carrying axons from nucleus magnocellularis (NM) to NL, type M terminals are preferentially labeled; this suggests an origin in NM. The smaller, more elongated type D terminals have a mean (±S.E.M.) apposition length of 3.08±0.19 μm, a cross-sectional area of 2.42±0.21 μm^2, an area:length ratio of 1.38±0.04, a synaptic vesicle packing density (mean±S.D.) of 85.0±29.0 per μm^2, and an intercellular cleft width of 21.2±3.3 nm. In these endings, smaller round clear vesicles are arrayed behind a large symmetric synaptic contact, with very slight densities on both pre- and postsynaptic membranes. 81% of the type D terminals end on the cell body; 19% are found on proximal dendrites or capping short somatic processes or spines. Type D endings were not commonly found on distal dendrites; it seems likely that they supply descending inhibitory input. There were no significant regional variations in ending morphology or distribution along the posterior-to anterior axis of NL.

Supported by grants to T.N.P. from the Public Health Service (#NS 15132) and the March of Dimes Birth Defects Foundation.

129.6 ANURAN MIDBRAIN RESPONSES TO MULTIPLE TONE STIMULATION: INHIBITORY AND FACILITATORY INTERACTIONS. Z.M. Fuzessery* and A.S. Feng. Dept. Phyiology & Biophysics, Univ. of Illinois, Urbana, IL 61801.

Single unit recordings in the principle and magnocellular nuclei of the torus semicircularis of Rana p. pipiens show these neuronal populations exhibit a wide range of selectivity in both the spectral and intensity domains. At the extremes, some neurons are responsive to the entire audible range at intensities up to 120 dB SPL, while others have closed excitatory tuning curves limited to 200 Hz bands and 25 dB intensity ranges. Two-tone stimulation revealed that over 75% of neurons studied could be totally inhibited by frequencies lower and/or higher than the best excitatory frequency. Of this population, over 90% could be totally inhibited by lower frequencies, excluding neurons with excitatory ranges extending to the lower limit of the audible range. In nearly all cases in which neurons were inhibited by both higher and lower frequencies, the lower inhibitory threshold was at least 10 dB lower than that of the higher inhibitory frequency. Thresholds for total inhibition were sometimes lower than the excitatory threshold; such neurons were unresponsive to noise. In many cases, the inhibitory threshold was fixed, ie., once this threshold was reached, the neuron remained totally inihibited regardless of the intensity of the excitatory frequency. Such central inhibition is in marked contrast to peripheral two-tone inhibition, where only higher frequencies are inhibitory, and only at 10-20 dB above the excitatory frequency intensity. Furthermore, best higher inhibitory frequencies were often immediately adjacent to best excitatory frequencies in the torus, while in the periphery there is a 200-300 Hz separation between the two frequencies.

Many torus neurons responded to noise, but not to single tones. Such neurons were found to be highly selective for specific combinations of two or three tones, and were completely unresponsive if one of the tones was subtracted. A majority of such neurons were responsive to combinations of tones within the spectral peak of the species mating call, suggesting such neuronal specificity may play a role in the selective detection of this call.

129.7 AUDITORY INFORMATION PROCESSING IN THE TELEOST DIENCEPHALON. Stephen M. Echteler. Neurobiol. Unit, Scripps Instit. of Oceanog. and Dept. of Neurosci., U.C.S.D., La Jolla, CA 92093.

Behavioral experiments have established conclusively that, despite the absence of a structurally well differentiated auditory labyrinth, fish not only respond to sound but are capable of pitch discrimination and sound source localization. The Ostariophysi, a group of fishes with direct connections between the swimbladder and the inner ear, via a chain of specialized vertebrae, have especially well developed auditory capacities.

Electrophysiological studies of the teleost auditory system have concentrated on the inner ear microphonic potentials, primary VIII nerve afferents, medulla, and the torus semicircularis (TS) (a midbrain structure suspected to be homologous to the mammalian inferior colliculus). The precise locations of auditory centers in the teleost forebrain are not known.

In the present study averaged evoked potentials (AEPs) and multiunit activity (MUA) were recorded from the midbrain and diencephalon of an ostariophysian fish, Carassius auratus, in response to airborne clicks of 1 millisecond (ms) duration and 12-20 dB (re 1 μbar) intensity. In addition to simple repetitive stimuli, click pairs and click trains were presented to the animal to compare the adaptation characteristics of the acoustic centers in the midbrain and diencephalon. The Prussian Blue marking technique was used to verify the recording sites.

The TS field potential was biphasic with a characteristic negative wave (N-8) occurring 8 ms following stimulus onset. The N-8 wave reached maximum amplitude in the central and medial TS at depths of 1500-2500 μm below the surface of the caudal tectum. Frequently, the N-8 wave reversed polarity at depths of 2500-3000 μm. MUA phase locked to the click stimulus was usually recorded at the reversal depth of the N-8 wave.

In the diencephalon neuronal activity in response to clicks was especially strong at a depth of 1500-2000 μm below the tectal surface in an area of the caudal thalamus possibly equivalent to the central posterior thalamic nucleus (Northcutt & Butler, Brain Res., 190:33, 1980). After electrode penetration of this area the AEP underwent a sudden transformation with the N-8 wave, characteristic of the TS, being replaced by a new negative wave with a latency of approximately 18 ms (N-18). Just dorsal (within 100-200 μm) to the appearance of this N-18 wave MUA phase locked to the click stimulus was encountered.

In response to click pair and click train tests the auditory AEPs in the diencephalon showed a much more rapid onset and longer duration of adaptation than auditory AEPs recorded in the TS.

129.8 ORGANIZATION OF NEWBORN RABBIT AUDITORY CORTEX. N. T. McMullen and E. M. Glaser. Dept. of Physiology, Univ. of Maryland School of Medicine, Baltimore, MD. 21201

Newborn (P-0) to three day old (P-3) New Zealand rabbits were used. The brains were removed following exsanguination and processed with the Van der Loos Golgi-Cox Nissl method. Frontal sections, 200 μm thick, through the presumptive auditory cortex were processed and counterstained with methylene blue. Well impregnated neurons were traced with either a camera lucida or a computer microscope. Cortex at Birth: The auditory cortex at birth is 63% of its adult thickness. The cortical plate is present and is characterized by densely packed radially aligned neurons. The Golgi method reveals that mostly pyramidal-type neurons are present within the cortical plate although a few nonpyramidal neurons are present at the top of the subplate zone. Upper cortical plate neurons exhibit multiple branched apical dendrite arbors extending into the marginal zone and almost no basal dendrites. Pyramidal neurons deep in the cortical plate have poorly developed apical dendrites with several collateral branches which invariably terminate with growth cones. Their basal dendrites are thin, relatively unbranched and exhibit terminal and preterminal growth cones. Numerous incipient branches sprout from the somatic surface. Spines are rarely seen. In the subplate zone, both pyramidal and nonpyramidal neurons are present. The somata and apical dendrites of larger pyramids exhibit profusely branched dendrites. Nonpyramidal neurons in the subplate, although not as developed as the large pyramids, have dendrites which are more developed than cortical plate nonpyramidal neurons. Cortex at P-3: The cortical plate has acquired a trilaminar organization. Neurons in the marginal zone and deep cortical plate are particularly more developed in comparison to their appearance at P-0. The bottom cell-dense layer of the cortical plate is populated with developing stellate neurons with local axons. In addition to growth cones, spine-type structures are present on the dendritic shafts. Subplate pyramidal neurons have well developed dendrites which also exhibit primitive spicules. We conclude that neuronal growth and differentiation in the rabbit auditory cortex begins well before the onset of hearing at approximately P-7. Data comparing the length, branching pattern and spatial orientation of dendrites for neonatal and adults will be presented.

129.9 EFFECTS OF SONG LEARNING ON AUDITORY NEURONS IN THE FOREBRAIN OF AN AWAKE BIRD. H.-J. Leppelsack, Lehrstuhl für Allgemeine Zoologie, Ruhr-Universität Bochum, 4630 Bochum, West Germany.

White-crowned sparrows (Zonotrichia leucophrys) as with many other songbirds have to learn their conspecific song from a tutor (Konishi, M., Z. Tierpsychol., 22:770-783, 1965). The way this usually happens is that the young bird at the age of a few weeks hears the song of the father and keeps it in a memory. At age several months, it starts developing the individual song by comparing its own sound production with the memorized pattern. Deafening a bird at this stage will inhibit the development of a species-specific song. It is possible to influence the development of the individual song by experimental modifications of the tutor song. White-crowned sparrows do not change their song for their life time.

These behavioral findings indicate processes of neural plasticity in the auditory pathway during ontogeny. The aim of this study was to find functional indications of this plasticity on the single unit basis. 1200 auditory units were studied by glass micropipette recording in 18 awake birds. The animals had learned models of conspecific songs in which the direction of frequency modulation in the trill segment was going either upward or downward. Adequate song versions were used as stimulus during the recording experiments. 11.3% of all auditory neurons respond to only one of the two alternative trill versions. Of these units usually more can be found that only respond to the song which was learned than to the alternative one. There is a preference of 2:1 and 3:1 for the song that was learned. Statistical tests show a high significance of differences between the alternative groups of birds. This indicates some causal relationships between the number of specialized neurons and the song learning. Most of the neurons are highly specialized and respond to only a narrow range of steepness in the modulation.

The neurons described here are located in the Neostriatum caudale pars mediale, the central part of which is tonotopically organized. A relatively high number of specialized neurons is found between the isofrequency lines of 2 and 5 kHz.

129.10 PATTERNS OF CAT AUDITORY CORTICAL FIELD PROJECTIONS TO THE BASAL GANGLIA. Richard A. Reale* and Thomas J. Imig (SPON: R. Bleier). Dept. of Neurophys. and Waisman Ctr. on Ment. Retard. and Hum. Dev., Univ. of Wisconsin Med. Sch., Madison, WI 53706.

We have studied anatomical projections from auditory cortical fields by combining microelectrode and autoradiographic techniques. In these experiments best frequency (BF) maps are obtained to delimit four auditory cortical fields each of which contain a complete and orderly tonotopic representation. These fields have been designated as anterior (A), primary (AI), posterior (P) and ventroposterior (VP) (Reale and Imig, JCN, 192:256-92, 1981). By varying the amount and injection site of the radioactive amino acid, we found each field to be a source of projections to the homolateral basal ganglia. Cortical terminations were always restriced to the caudal one-half of the putamen following each injection. Additionally, fields A, AI and the low-to-mid BF(s) of field P each project to the body of the caudate nucleus. By comparison, field VP and the mid-to-high BF(s) of field P were the only sources found to produce labeling in the lateral amygdaloid nucleus. The organization of these projections is compatible with previous descriptions of a widespread corticostriatal projection system. The dorsal portion of the cortical-projection zone in the basal ganglia is strongly connected with the most anterior and dorsally situated cortical fields (A & AI), while the ventral portion of the cortical-projection zone is strongly related to the posterior and ventrally situated fields (P & VP).

When the source of the projection is confined to a portion of a cortical field labeling often appears as dense patches of silver grains separated from each other by areas of less dense labeling. In frontal sections, the dense patches of silver grains are distributed within a single elongated band curving from dorso medial to ventrolateral. This curving band can include adjacent regions of the caudate and putamen (separated by the internal capsule) or adjacent regions in the putamen and lateral amygdaloid nucleus (separated by the external capsule). In horizontal sections, the patchy distribution of cortical inputs is elongated from anteromedial to posterolateral. Two dense bands of label are seen when the lowest BF and highest BF representations were each used as injection sites in either fields AI or P. Thus in three dimensions the cortical-projection zone can be viewed as a laminated region with each lamina compressed mediolaterally.

When the sources of cortical projections includes most or all of an auditory field more complex patterns of labeling occur. The distributions of silver grains labeling the axon terminals are irregular, circular, ellipsoidal or annular and can vary in form along the extent of the projection.

129.11 AUDITORY CORTICAL CONNECTIONS IN THE KITTEN. J. Z. Feng* and J. F. Brugge* (SPON: C. N. Woolsey). Dept. of Neurophysiology and Waisman Ctr., Univ. Wisconsin, Madison, WI 53706.

Tritiated proline or HRP was injected into the middle ectosylvian cortex of one hemisphere in kittens during the first few weeks postpartum. Survival time was 24-96 hrs. The TMB (Mesulam) method was used to process HRP material. By the first postnatal day (PND 1) most neurons retrogradely filled in the contralateral auditory cortex form a densely packed, continuous band that presumably represents mainly layer III. This continuous pattern is in contrast to that seen in the adult cat where callosal neurons tend to segregate into clusters. Other retrogradely-labelled cells are more sparsely distributed in deeper layers with the greatest accumulation being in layer VI. At this time callosal neurons are elongated, with their long axes parallel to radial cell columns. In autoradiographs on PND 2, silver grains are seen throughout the thickness of the cortex indicating that callosal axons have reached the upper layers of the gray matter. Neither the alternating vertical columns nor the laminar bands of callosal afferents that characterize this projection in the adult is clearly seen in kittens of this age. By PND 1 the pattern of projections to the medial geniculate body and inferior colliculi are very similar to those in the adult. In several experiments small injections of HRP (conjugated to WGA) were made into middle ectosylvian cortex in kittens on PND 2-6. The distributions of retrogradely-filled neurons within small, restricted regions of the MGB were essentially coextensive with the distributions of anterogradely-labeled axonal terminals, suggesting the presence of topographically organized, reciprocal patterns of connections between cortex and MGB, as is seen in the adult. Projections are also seen to the putamen, caudate nucleus and pons. By PND 8-12 the segregation of callosal afferents into vertical columns and horizontal laminae is evident in the gray matter; by PND 16 these patterns are well developed. On the other hand, the somata of callosal neurons of layer III retain their juvenile continuous distribution beyond PND 18, even though they have by this time developed their adult shapes. Preliminary results suggest that the projections to subcortical structures from auditory cortex develop considerably earlier than auditory callosal projections and that the adult distribution patterns of auditory callosal sources and terminals first appear at different times postpartum. 129.12 CONNECTIONAL DIFFERENCES BETWEEN AUDITORY FIELDS IN A CF-FM BAT J.B.Fritz*, J.Olsen, N.Suga and E.G.Jones (SPON: J. Wallach) Depts. of Biology, and Anatomy & Neurobiology, Washington Univ., St. Louis, MO 63110

We have been studying the auditory system of the Panamanian mustasched bat, *Pteronotus parnellii rubiginosus*, which uses echo location to orient, and capture prey. Its auditory cortex is composed of several functional areas which have been defined neurophysiologically. They include the DSCF, FM-FM and CF/CF areas, each of which is specialized for the systematic representation and processing of different features of the bat's biosonar signal and echo; such as target size, location, distance and velocity (Suga, O'Neill and Manabe Science 203:270, 1979). In order to investigate the anatomical basis of these functional areas, we carried out experiments with anatomical tracing techniques. In 15 bats, tracer was injected in separate cortical loci under electro physiological guidance. In the autoradiographic studies, we made small localized injections of ^{3}H-proline/leucine (5-25μCi). The horseradish peroxidase (HRP) injections were also small (.05-.1μL of 20% HRP solution). Retrograde and anterograde transport of HRP was visualized using tetramethylbenzidine.

Our results show that the FM-FM and CF/CF areas are reciprocally connected with their contralateral homologues and ipsi- and controlaterally connected with three other cortical areas. The DSCF area has reciprocal connections with its contralateral homologue and ipsi- and contralateral connections with only one other cortical area. We have yet to characterize the heterotopic cortico-cortical projection areas physiologically. Injections into the FM-FM area resulted in anterograde labelling of a large number of cells within a dorsal division of the medial geniculate body (MGB). A few scattered cells were also found within a medial division. Anterograde label within the MGB was coextensive with the retrograde label. The pattern of thalamic labelling after CF/CF injections was similar to that seen in the FM-FM case. However a different pattern of labelling in the MGB was observed following injections into the DSCF area; this is connected to a ventral division of the MGB. All areas projected to the pontine nuclei, the inferior and superior colliculi, the striatum and had reciprocal connections with the claustrum. In addition, the DSCF area was found to project bilaterally to the basolateral amygdala. It is known that the DSCF area responds optimally to single tones and that the FM-FM and CF/CF areas show facilitation for paired auditory stimuli. Our results indicate some neuroanatomical correlates of this neurophysiological distinction.

129.13 ACTIVITY IN AUDITORY CORTEX AND ITS THALAMIC AFFERENTS ELICITED BY HUMAN SPEECH SOUNDS IN THE MONKEY. Mitchell Steinschneider*, Joseph C. Arezzo and Herbert G. Vaughan, Jr. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

To determine whether phonetic features are reflected in the patterns of neural activity in the auditory cortex and its thalamic afferents, responses to 3 synthetic syllables: /da/, /ba/, and /ta/, which vary in their place of articulation or voice onset time (VOT), were recorded in awake monkeys. The stimuli were presented at 80 dB SPL to the ear contralateral to the recording sites. /Da/ and /ba/ were identical except during the 40 msec of formant transitions. /Ta/ differed from /da/ by an increase in the VOT from 0 to 80 msec. Averaged multiple unit activity was obtained from electrodes which passed vertically through the superior temporal plane and into the underlying white matter. When single units could be isolated, PST histograms were constructed. Cortical activity was differentiated from activity in afferent fibers on the basis of response latencies to click stimulation and histological verification of recording sites.

VOT was related to the discharge patterns of thalamocortical axons and cortical units. 'On' responses to /ta/ differed from 'on' responses to /da/ and /ba/ in that a second activity burst 80 msec after the first was associated with the onset of the voiced portion of the stimulus. Phase-locked responses to the vowel fundamental frequency were recorded to all 3 stimuli. Whereas the phase-locked responses to /da/ and /ba/ began near stimulus onset and continued throughout the duration of the syllables, the periodic response to /ta/ was delayed by an interval that reflected the VOT.

Differential responses related to the consonants' place of articulation were also seen. Short-latency 'on' responses were sometimes noted to /da/ and /ta/ but not to /ba/; while occasionally the opposite pattern was seen. During the acoustically identical steady-state portions of /da/ and /ba/, phase-locked activity was very similar for the 2 syllables. However, during the early formant transition period, where the frequency compositions of the 2 stimuli were different, phase-locked activity could occur to one but not the other.

Activity patterns in thalamocortical axons and cortical cells also differed. While cortical neurons, especially in layer 4, demonstrated phase-locking to the fundamental frequency of vowels, this type of activity was more pronounced and consistent in thalamocortical axons. Cortical cells, on the other hand, more often responded with sustained activity and/or to the transients of the speech stimuli.

129.14 SINGLE UNIT ACTIVITY RELATED TO SENSORY-MOTOR ASSOCIATION IN THE AUDITORY CORTEX OF A MONKEY. E. Vaadia*, Y. Gottlieb* and M. Abeles* (SPON: M. H. Goldstein, Jr.). Dept. of Physiology, Hadassah Medical School, Jerusalem, Israel.

Stimulus induced behavior has been classically interpreted as an interaction between "sensory systems" and a "motor system" through the involvement of an "association system." In this research we studied some aspects of the role of the auditory cortex in the process of sensory motor association.

The activity of 146 units in the auditory cortex of a rhesus monkey was recorded during performance of auditory discrimination reversal task in which each of two stimuli was associated with each of two learned motor responses. Seventy-two units were in the primary cortex (areas Kam and Kalt), seventy-four units were in the lateral portion of the belt area (Pa Alt). The units were recorded from 40 recording sites, 2-6 single units were recorded simultaneously in each site. We found that:

(A) The spike activity of a fraction (9-17%) of the units in the auditory cortex reflects the process of sensory motor association.

(B) These neurons have a component of their evoked response which is sensory and a component which reflects sensory motor association.

(C) Units exhibiting association activity did not show any clustering.

(D) On the average, units of the koniocortex tend to respond strongly and with shorter latency to sound stimuli compared to the units of the lateral belt area. However, units exhibiting sensory motor association activity are equally distributed in both areas.

On the basis of these findings it is suggested that the association system need not be separated anatomically from the cortical sensory system. We suggest that the mechanism by which sensory-motor association occur may be better studied in further research, on the basis of the premise that a single neuron can participate in the performance of different functions.

129.15 NEUROPHYSIOLOGICAL MECHANISMS OF ANTICIPATION IN THE AUDITORY CORTEX OF THE MONKEY. S. Hocherman*, A. Itzhaki*, (SPON: R. Ashkenazi). Dept. of Physiology & Biophysics, Faculty of Medicine, Technion, Israel Inst. of Technol., P.O.B. 9649, Haifa, Israel.

Evoked unit activity was recorded in the auditory cortices of rhesus monkeys. Two types of auditory stimuli were used. One consisted of 100 msec burst of white noise, and the other was a 100 msec burst of a pure tone, of any frequency. The monkeys were trained to discriminate between these two types of auditory stimuli by making a corresponding lever push. In most trials, a light flash that preceded the auditory stimulus by 700 msec indicated to the monkey the type of the following auditory stimulus. Occasionally, however, the wrong auditory stimulus was made to follow the light signal. Analysis of the monkeys' behaviour ascertained that they indeed anticipated the nature of the auditory stimuli on the basis of the visual signals.

Quantitative analysis revealed that the evoked activity of about half of the 92 units that were studied was affected by the monkeys' anticipation of the auditory stimulus. The affected units could be grouped in two categories. 1. Units that showed response facilitation to correctly anticipated auditory stimuli, and response inhibition to wrongly anticipated auditory stimuli. 2. Units that responded at a base line intensity level to correctly anticipated stimuli, but that showed strong response facilitation to wrongly anticipated auditory stimuli. These findings are indicative of the neurophysiological processes that may underly the mechanism of anticipation.

129.16 LESIONS OF RESTRICTED FREQUENCY REPRESENTATIONAL SECTORS WITHIN PRIMARY AUDITORY CORTEX PRODUCE FREQUENCY DEPENDENT SOUND LOCALIZATION DEFICITS. W.M. Jenkins and M.M. Merzenich*. Coleman Memorial Lab., University of California, S.F., San Francisco, CA 94143.

It has long been known that auditory cortex contributes to the ability to localize a sound source. Recent evidence has indicated that even unilateral lesions of auditory cortex produce severe permanent contralateral hemifield sound localization deficits.

We have attempted to answer the questions: 1) Is sound localization dependent upon the integrity of primary auditory cortex (AI)? 2) How is sound localization behavior affected by partial lesions of this auditory field, e.g., lesions of restricted frequency representational sectors, or of given binaural bands? To answer these questions, microelectrode best frequency and binaural response maps of AI cortex were obtained under sterile conditions. After definition of boundaries, frequency organization and internal binaural structure, restricted lesions were effected by coagulation of cortical surface microvasculature. These adult cats' sound localization ability was evaluated in a seven-choice free sound field apparatus, using tonal and broad-spectrum stimuli before and after such lesions.

Preliminary results indicate that restricted lesions within the frequency domain produce predicted frequency-dependent deficits in sound localization ability. The ability to detect these deficits is dependent upon selection of an appropriate behavioral test, and on use of stimuli of brief duration. Continuing experiments are directed toward definition of the behavioral band(s) of AI that is (are) requisite for normal localization in the contralateral hemifield. (Supported by NIH grant NS 10414 and the Coleman Fund.

130.1 INHIBITION OF SENSORY TRANSMISSION AND DEPRESSION OF BLOOD PRESSURE BY ELECTRICAL STIMULATION WITHIN THE MEDULLARY RAPHE NUCLEI OF THE CAT. P.S. Blum, Department of Physiology, Thomas Jefferson University, Philadelphia, PA 19107.

Previous studies have shown that electrical stimulation within the medullary raphe nuclei (nucleus raphe magnus, nucleus raphe pallidus, nucleus raphe obscurus; MRN) can both change arterial blood pressure and inhibit sensory transmission in the spinothalamic tract (ST). The present experiment was designed to determine if these two effects are interrelated. The experiments were performed in four adult cats anesthetized with alpha-chloralose and paralyzed with gallamine. Sensory transmission was measured from the amplitude of averaged evoked potentials in the ST following stimulation of the superficial radial (SR) nerve. Mean arterial blood pressure (MABP) was measured via an intra-arterial catheter. In each experiment up to 10 MRN sites (total= 31) were selected for stimulation. These sites were spread evenly in a region from the pyramidal tract to the fourth ventricle and from the pontomedullary border to the obex. At each site, single pulse electrical stimuli were used to determine if stimulation within the MRN reduced the amplitude of SR-evoked ST potentials and 10 sec trains of stimuli were tested for the ability to change MABP. Fourteen sites (46%) were identified where electrical stimuli inhibited SR-evoked activity in the ST. Stimulation at the same 31 sites produced elevation of MABP at 2 sites (6%) and depression of MABP at 10 sites (33%). Seven sites were both inhibition-producing sites and depressor sites. These represent half of the inhibition-producing sites (7 of 14) and 70% of the depressor sites (7 of 10). Five of these dual effect sites were clustered in the rostral portion of the MRN, just dorsal to the trapezoid body. The other two sites were located approximately 2 mm caudally. These data support the concept that single neurons located in the rostral MRN can influence sensory transmission and blood pressure, probably via a descending projection to the sensory neurons of the dorsal horn and preganglionic sympathetic neurons.

130.2 MODULATION OF LATERAL CERVICAL NUCLEUS NEURON RESPONSES BY PERIAQUEDUCTAL GRAY AND RAPHE MAGNUS STIMULATION. J.O. Dostrovsky and P. Chang*. Dept. of Physiology, University of Toronto, Toronto, Ontario M5S 1A8, Canada

Stimulation of the periaqueductal gray (PAG) and nucleus raphe magnus (NRM) is known to inhibit nociceptive responses of spinal and medullary dorsal horn neurons. Recent studies have also shown that stimulation of these regions can inhibit non-nociceptive responses in spinal cord, trigeminal nuclei oralis and candalis, and dorsal column nuclei. The present study examines the effects of PAG and NRM stimulation on the transmission of information in the spinocervicothalamic pathway.

Experiments were performed on 8 chloralose anesthetized cats. Extracellular single unit recordings of lateral cervical nucleus (LCN) neurons were obtained using carbon fiber microelectrodes. Most of these neurons could be antidromically activated from the thalamus and had low threshold cutaneous receptive fields on the fore-or hind-limb. Conditioning stimuli consisted of 100 ms, 500Hz trains and were delivered to bipolar electrodes located in subsequently histologically verified loci in the PAG and NRM. In some experiments a microstimulation electrode was inserted in the dorsolateral funiculus (DLF) at L1. Stimulation of PAG and NRM 130 ms prior to delivering an electrical stimulus to the neuron's receptive field was found to powerfully inhibit the responses of 31 of 34 LCN neurons. This inhibition could be produced using stimulation currents in the range 50 to 250 uA which are comparable to intensities found necessary to inhibit spinal cord nociceptive and non-nociceptive neurons. However, these conditioning stimuli failed to block or increase the latency of the antidromic spikes in all but 3 of 28 units tested. Furthermore, they produced no effect on the responses produced by DLF stimulation in 5 units and only a weak inhibition at high stimulation intensities in the remaining 5 units tested. These latter findings imply that there is only a limited, or no direct inhibitory input from PAG and NRM to LCN. In summary, this study has shown that stimulation of the PAG and NRM markedly inhibits transmission of sensory information in the spinocervicothalamic pathway and that the inhibition is primarily mediated by an action at the spinal level.

Supported by Canadian MRC.

130.3 IS THERE A CROSSED INNERVATION OF THE ANTERIOR TEETH? P.M. Fuller, S. Wilson, J. Winfrey* and P. Johns* Departments of Anatomy and Oral Biology, University of Louisville School of Dentistry, Louisville, Kentucky 40232.

In the past few years there has been a re-newed interest in the question of a possible crossed or "transmedian" innervation of the anterior teeth. The use of various neuroanatomical and neurophysiological methods have led some investigators to conclude there is an extensive crossed innervation of both the maxillary and mandibular teeth, that extends as far laterally as the first premolar teeth. These conclusions are supported by data from the clinician who often is confronted with incomplete anesthesia of the anterior teeth after a unilateral mandibular nerve block. This leads the clinician to support the theory of a crossed innervation. In an effort to determine the precise innervation of the anterior teeth and to attempt to resolve the question of a possible crossed innervation, the present study was undertaken. The first set of experiments consisted of making a cavity preparation in either the maxillary or mandibular canine tooth in 15 adult cats. The second set of experiments concerned the incisor teeth. In this series, a cavity preparation was made in one of the mandibular incisor teeth, for a total of 18 experiments. In each of the experiments, 0.5-3.0 µl of fresh Horseradish Peroxidase (Sigma, type VI; 15% concentration) was placed in the cavity preparation. After 10 minutes the cavity was filled with gelfoam and capped with dental acrylic. Survival times ranged from 12-96 hours. The animals were then perfused with 0.1M cacodylate buffer, followed by an equal amount of fixative. The following tissues were quickly removed and placed in fresh fixative: the ipsilateral and contralateral trigeminal ganglia, the inferior alveolar nerve and the nerve to mylohyoid. Frozen serial sections were cut at 50µ and processed according to the histochemical procedure of Mesulam and then counterstained with Neutral Red. The results from the series of 15 experiments on the canine teeth showed that all of the labeled cells were in the ipsilateral trigeminal ganglia, and the number of labeled cells ranged from 96-248. The experiments with the mandibular incisor teeth also showed that all of the labeled cells were in the ipsilateral ganglia. In addition, a portion of the sensory fibers to the incisor teeth in the cat reach the teeth by way of the nerve to mylohyoid. Our data clearly shows that the mandibular and maxillary canine teeth and the mandibular incisor teeth in the cat are supplied entirely from the ipsilateral side of the mandible, and there is no basis for the claim of a crossed innervation of the anterior teeth in the cat.

130.4 PROPERTIES OF CELLS ACTIVATED BY VIBRISSAL MOVEMENT IN THE SUPERIOR COLLICULUS OF THE RODENT. J. McHaffie* and B.E. Stein (SPON: S.J. Goldberg). Department of Physiology, Medical College of Virginia, Richmond, VA 23298.

The vibrissae are specialized hairs which can play a significant role in the orientation and exploration behaviors of rodents. They are well represented in the intermediate and deep laminae of the superior colliculus, a structure intimately involved in these behaviors. The present study was an attempt to determine the properties of vibrissa-activated cells in the superior colliculus and to compare these properties to similar cells elsewhere in the central nervous system.

Single-unit recordings were made in the superior colliculi of urethane-anesthetized rats and hamsters. Cells activated by the displacement of the vibrissae were studied using an electronically-controlled moving coil vibrator with which stimulus velocity and amplitude could be precisely regulated. Generally, colliculus cells were activated by several adjacent contralateral vibrissae and were very sensitive to small displacements of any one of these. In each instance, a single vibrissa was inserted into a hollow stylus and moved at various velocities and amplitudes. In all cases a transient response was evoked, even to sustained displacements. Unlike elsewhere in the nervous system, no 'slowly adapting' vibrissal units were located. Furthermore, unlike vibrissa-activated cells in the cortex and thalamus, colliculus cells seemed poorly suited for coding stimulus amplitude and velocity. While most of the cells studied were exquisitely sensitive to small displacements and low velocities, they did not show a regular increase in impulse frequency to increasingly large displacements or higher velocities. Vibrissa-activated colliculus cells in these rodents seemed well-adapted to signaling the presence and location of a stimulus but not the specific characteristics of that stimulus.

(Supported by grant BNS 8021559).

130.5 RESPONSES OF CELLS IN CAT CUNEATE NUCLEUS TO ITERATIVE STIMULATION OF FOREARM NERVES. R.J. Weinberg* and A.L. Towe (SPON: T.T. Kennedy). Dept. of Physiology and Biophysics, University of Washington, Seattle, WA 98195.

Standard single unit techniques were used to record from neurons in the cuneate nucleus of chloralose-anesthetized, paralyzed cats. Most microelectrode tracks were made 1-4 mm. caudolateral to the obex. The responses of cells to natural stimulation of the skin and to electrical stimulation of three major forearm nerves by implanted silastic cuffs were observed. Particular attention was directed to the responses to different iterative stimulus rates. An array of bipolar stimulating electrodes was placed in the medial lemniscus just caudal to the thalamus to identify cuneothalamic projection (CTP) cells by antidromic activation; less than a third of the sample tested met the criteria for thalamic projection.

The sample was partitioned into units that responded only to one nerve (Type I; 2/3 of the sample) and cells that responded to two or more nerves (Type II; 1/3 of the sample). Fully 3/4 of the Type I units, but only 1/3 of the Type II cells, were isolated in the dorsal half of the nucleus. Furthermore, 2/5 of the Type I units, but only 1/10 of the Type II cells tested qualified as CTP neurons. Attention was focused on the maximum iterative stimulation rate that each cell would faithfully follow (f_{max}). More than 1/2 of Type I units tested showed f_{max} >50/sec., whereas only 1/5 of the Type II cells exceeded this value. Among the Type II cells, when f_{max} was high (or low) for one nerve it was usually high (or low) for the other nerve(s). There was a clear gradient in mean f_{max} as a function of depth of isolation, grading from high f_{max} dorsally to low f_{max} ventrally in the nucleus.

When a Type II neuron was driven to exhaustion by prolonged iterative stimulation of one nerve near f_{max} for that cell, it remained responsive to stimulation of the other nerve(s) (though usually not as briskly as prior to the conditioning stimulation.) This implies that some portion of the frequency-following failure is due to homosynaptic depression. The mild reduction in responsiveness to the second nerve points to the possibility that an orthodromic inhibitory system with high f_{max} could play a role in frequency-following failure. Prolonged iterative antidromic activation of CTP neurons had little effect on their responsiveness to orthodromic input. This implies that a recurrent inhibitory mechanism involving CTP neurons cannot account for the frequency-following failure.

Portions of this research were supported by NIH grants NS05136 and GM07108.

130.6 WHITE NOISE ANALYSIS OF RECEPTIVE FIELD PROPERTIES OF SINGLE UNITS IN THE CUNEATE NUCLEUS OF CATS. D.J. Surmeier, Jr.*, A.L. Towe, and R.J. Weinberg*. Dept. of Physioloby and Biophysics, University of Washington School of Medicine, Seattle, WA 98195.

White noise analysis was used to describe the temporal patterns of excitability produced in cuneate neurons by cutaneous stimuli that were varied in strength and position, and to characterize the manner in which two spatially separated stimuli interact to produce neuronal activity. Single unit recordings were obtained from chloralose-anesthetized domestic cats using tungsten microelectrodes and standard amplification equipment. Following isolation, each unit's sub-modality sensitivity was determined, and its cutaneous excitatory receptive field (ERF) mapped using fine mechanical probes. In some experiments, units were tested for antidromic activation from the medial lemniscus. Bipolar needle electrodes were placed in the center of the ERF and at loci inside and outside the ERF boundary. Two independent 10/sec. pseudo-Poisson process impulse trains were used to simultaneously drive stimulators connected to the two needle electrodes. The spike train elicited was led into a window discriminator, the digital output of which, along with stimulus event pulses, was fed into an on-line computer that stored the information on magnetic disk. Upon completion of a noise run, spike train stationarity was tested, and first- and second-order Wiener kernels were computed using a crosscorrelation technique. This procedure was repeated at several stimulus intensities.

Analysis of initial results showed that: (1) The majority of neurons, regardless of sub-modality class, responded to a stimulus within their ERF with an initial period of increased excitability, followed by a clear decrease in excitability. The most notable exception was a subset of the hair-sensitive class. (2) Short latency facilitation and/or inhibition following stimulation outside the ERF was common to all sub-modality groups; apparently only the hair-sensitive class displays an exclusively inhibitory surround. (3) Stimulation of the margin of the ERF significantly altered the first- and second-order kernels derived from the center, indicating the existence of circuitry requiring spatial summation for activation. (4) Units driven by muscle, tendon, or joint afferents often received a cutaneous input, usually facilitatory-inhibitory in nature, but rarely frankly excitatory.

Portions of this research were supported by NIH grants NS05136 and GM7108.

130.7 SOMATOTOPIC ORGANIZATION OF SUBCUTANEOUS PROJECTIONS FROM TAIL, HINDLIMB AND ABDOMEN TO NUCLEUS Z IN FOX SQUIRRELS. E.-M. Ostapoff*, J. I. Johnson and B. C. Albright. Neuroscience Program and Psychology, Biophysics and Zoology Depts., Michigan State University, East Lansing, MI 48824; and Dept. of Anatomy, Univ. of North Dakota Medical School, Grand Forks, ND 58202.

Nucleus z wraps around the rostral pole of the gracile nucleus, and can be distinguished from the gracile by cytoarchitecture (e.g., smaller cells), input pathway (via lateral rather than dorsal spinal columns), and dominant physiological projections (from hindlimb muscles rather than skin), in primates and carnivores. In a similar region in fox squirrels (Sciurus niger) arboreal rodents, we mapped responses to mechanical stimulation using tungsten microelectrodes and urethane anesthesia. We found two types of projections (z vs. gracile) corresponding to distinct cytoarchitectural regions. While the ranges of cell (perikaryal) diameters of the z and gracile populations overlapped (n = 10 cells per region in 4 separate samples = 40; range of z = 12-32 μm, range of gracile = 16-34 μm) all but 3 of the 40 z cells were smaller than the mean of the 40 gracile cells (this mean of gracile was 25.9 μm, mean of z was 20.0 μm). For these measures the boundaries between gracile and z were established by the location of contrasting projections along tracks of electrode penetrations (54 responding loci in 17 electrode penetrations from 5 animals). The z type projections were located within a volume whose maximal extent was 0.6 mm in any dimension; these projections were all from subcutaneous receptors and were somatotopically organized. Projections from the tail were located rostromedially, lateral to these were projections from the hind limb and foot, and most lateral were projections from the abdomen. The contrasting projections to the gracile (large-celled) region were primarily from cutaneous surfaces of hind limb, tail, and posterior trunk, but did include some subcutaneous input. There was a break in somatotopic continuity as electrode penetrations passed from gracile to z regions. These results indicate that fox squirrels possess a region physiologically and cytoarchitecturally similar to the nucleus z of other species;that in addition to the hindlimb projections reported in other species it receives projections from tail and abdominal regions; and that these projections are somatotopically organized. (Supported by NSF grant BNS - 7903421).

130.8 INDEPENDENT PROJECTIONS FROM THE DORSAL COLUMN NUCLEI TO THE TECTAL AREA, PRETECTAL AREA AND THALAMUS IN CATS. M.S. Bull*, S.K. Mitchell* and K.J. Berkley (SPON: D.R. Kenshalo). Dept. Psychol., Fl. St. Univ., Tallahassee, FL 32306.

When ablations or injections of ^{3}H-leucine are made in the dorsal column nuclei (DCN), projections can be traced from DCN not only to the thalamus, but also to specific targets in discrete portions of the tectal area (external and pericentral inferior colliculus, intercollicular area, deep layers of superior colliculus) and of the pretectal area (anterior pretectal n., pars compacta and a small region in the middle of the posterior pretectal n.). The purpose of the present experiments was to characterize, anatomically, the neuronal populations within DCN that project to each of these three major terminal areas.

A double retrograde labeling strategy was used in which two different tracers were injected into any two of the three terminal areas in the same cat. The tracers were: horseradish peroxidase (HRP), tritiated inactivated HRP (^{3}H-apo-HRP), HRP conjugated to wheat germ agglutinin (WGA:HRP) and tritiated acetyl-WGA (^{3}H-acetylWGA). The usual combinations were ^{3}H-apoHRP with HRP and ^{3}H-acetylWGA with WGA:HRP. Following 24-72h survival times, a set of sections was processed for autoradiography and HRP histochemistry using diaminobenzidine. One of the adjacent sets of sections was processed only for autoradiography; the other only for HRP histochemistry using tetramethylbenzidine.

Double-labeled neurons were only rarely observed in DCN in experiments involving accurately-placed, non-overlapping injections. Analysis of the adjacent sections suggested that this lack of double-labeling was not due to insensitivity of the methods. In agreement, many double-labeled neurons were clearly observed in other experiments where the injections overlapped or invaded another of the territories.

The neurons projecting to the tectal or pretectal areas were of mixed morphology and tended to occupy similar positions within DCN. The two groups formed a loose network around the edges of and between the gracile n. and cuneate n. in regions generally unoccupied by the relatively homogeneous population of large and round thalamic-projecting neurons. The few double-labeled neurons observed in each experiment were usually located at the border between the cuneate n. and spinal trigeminal n.

These results demonstrate an almost complete independence of the neuronal populations in DCN which project to the three target areas. The results also suggest, however, that the tectal and pretectal-projecting neurons may be functionally related to each other, but different from the thalamic-projecting neurons.

130.9 A SOMATIC SENSORY PROJECTION SYSTEM INVOLVING THE DORSAL COLUMN NUCLEUS, PRETECTAL AREA AND INFERIOR OLIVE AS VISUALIZED WITH THREE DIFFERENT BIDIRECTIONAL TRACERS IN CATS. (SPON: H.H. Molinari). S.K. Mitchell*, M.S. Bull* and K.J. Berkley. Dept. Psychol., Fl. St. Univ., Tallahassee, FL 32306

Following ablations or injections of ^{3}H-leucine into the dorsal column nuclei (DCN) of cats, distinct and densely-focused projections can be traced from DCN to specific portions of the contralateral anterior and posterior pretectal nuclei as well as to the dorsal and medial accessory divisions of the contralateral inferior olive. Relevant to these findings are the results of a number of authors demonstrating that neurons in different portions of the pretectal area appear to project to different portions of the ipsilateral inferior olive. These results suggest that the DCN-recipient zones located in the pretectal area and inferior olive might themselves be specifically connected.

In order to determine if this triadic somatic sensory projection exists, three different tracers were injected into the anterior pretectal area of different cats. The tracers used were: tritiated inactivated horseradish peroxidase (^{3}H-apoHRP), tritiated acetyl-wheat germ agglutinin (^{3}H-acetyl-WGA), and wheat germ agglutinin conjugated to HRP (WGA:HRP). Following a survival period of 72h, the tissue was processed for autoradiography and/or horseradish peroxidase histochemistry using both tetramethylbenzidine and diaminobenzidine as chromagens. As expected, retrogradely-labeled neurons were observed in specific portions of DCN in every case. In addition, dense, orthogradely-labeled terminal zones located in the DCN-recipient portions of the inferior olive could also be observed in every case.

These results demonstrate that ^{3}H-apoHRP, ^{3}H-acetyl-WGA and WGA:HRP can all be used effectively as orthograde as well as retrograde tracers. In addition, the results firmly establish the existence in the cat of a well-organized, somatic sensory-related projection system involving specific neurons in DCN and specific portions of the pretectal area and the inferior olive.

130.10 SOMATOSENSORY INFORMATION PROCESSING WITHIN THE RACCOON THALAMIC VENTROBASAL COMPLEX. Susan Warren*, and Benjamin H. Pubols Jr. Department of Anatomy, College of Medicine, Pennsylvania State University, Hershey, PA 17033.

The differential role of neurons of the thalamic ventrobasal complex in tactile information processing has been examined by comparing the properties of such neurons with those of single neurons of the cuneate neucleus (Rowinski, Haring, and Pubols, Brain Res., 1981; Haring, Pubols, and Rowinski, J. Physiol., 1981) and primary afferent fibers of the cuneate fasciculus (Pubols and Pubols, J. Neurophysiol., 1973), previously studied utilizing similar procedures. Tungsten microelectrodes have been used to detect extracellular unit responses to mechanical stimulation of glabrous surfaces of the forepaw in methoxyflurane or barbiturate anesthetized raccoons, and all recording loci have been histologically verified as falling within the ventrobasal complex.

Twenty-five units have been classified according to their response to controlled mechanical stimuli as rapidly adapting (RA; N = 18), slowly adapting (SA; N = 3), or Pacinian (Pc; N = 4). Percentages derived from these figures are similar to those found at levels of both the cuneate nucleus and the upper cervical cuneate fasciculus.

Peripheral receptive field (RF) areas are smaller on digital surfaces (median = 30 mm^2) than on palmar surfaces (median = 105 mm^2). These values are approximately 4 X the corresponding values for the cuneate nucleus, which, in turn, are 40 X (digital RFs) and 100 X (palmar RFs) values for primary afferents.

The relationship between instantaneous spike frequency during displacement ramp stimulation, and ramp velocity, was examined in 1 SA and 7 RA units. Although a power function provided the best fit in 6 of the 8 cases (least squares method), both the exponents of the power function equation (b), and indices of goodness of fit (r) were considerably lower than values for units of both the cuneate nucleus and cuneate fasciculus. Most values of r were between .67 and .76, while 6 of the values of b were < .35, in contrast to values of b of .40 or higher at the two lower levels.

A comparison of neural properties at the three levels of the dorsal column-medial lemniscal system suggests that there is a greater loss in fidelity of spatial information transmission by single neurons within the cuneate nucleus, but a greater loss of quantitative information transmission capability by single neurons within the ventrobasal complex. (Supported in part by research grant NS-13418, USPHS.)

130.11 A THALAMIC TERMINUS FOR THE LATERAL CERVICAL NUCLEUS. D.C.N. da Costa*, R.S. Metherate*, P. Herron and R.W. Dykes (SPON:L.O'Kelly). Microsurgery Lab. Depts. of Surgery, Neurology and Neurosurgery, and Physiology, McGill University, Montreal, Quebec H3A 1A1

When horseradish peroxidase (HRP) was injected into the feline posterior thalamus at sites centered on the ventroposterior inferior nucleus (VPI), retrogradely labelled cells were located in the posterior part of dorsal column nuclei (DCN) and in the lateral cervical nucleus (LCN). The VPI was known to receive input from predominantly Pacinian corpuscles, hence several questions arose: (i) Does LCN project to VPI or did the VPI-centered HRP injection spread to an adjacent region of the posterior thalamus that serves LCN? (ii) Does the LCN relay Pacinian information, as does posterior DCN, or are its neurons conveying another class of afferent input?

To answer these questions experiments were performed on nembutal-anaesthetized mongrel cats using glass-coated tungsten electrodes and/or NaCl-filled glass micropipettes. Single units were recorded in the LCN and identified on the basis of their large cutaneous rapidly-adapting receptive fields; they were characterized as being post-synaptic cells by their inability to follow high frequency electrical stimulation applied to the center of the receptive field. Electrode trajectories were reconstructed in 80 um thionin-stained frozen sections. Of 53 penetrations, 15 were histologically verified as having passed through LCN. Thirty-four LCN units were found within the cytoarchitectonic limits of the LCN. In each case, their response properties demonstrated a lack of Pacinian afferent input and a convergence of information from numerous hair-associated, rapidly-adapting fibers.

A subsequent HRP injection into the medial part of VPI failed to label the LCN and exploration of the region around the VPI with metal electrodes provided evidence that a discrete volume of the posterior thalamus beneath the lateral geniculate nucleus receives input predominantly from hair-associated rapidly-adapting cutaneous afferent fibers. The cells in this region have very large receptive fields and appear to be submodality-specific; stimuli to deep structures or sustained or noxious cutaneous stimuli did not activate the cells. In these respects the neuronal response properties parallel the response properties of cells in the LCN. Presumably this thalamic site receives a major excitatory input from the LCN. Generally large thalamic receptive fields are associated with posterior group neurons having non-lemniscal and nociceptive inputs. Our experiments suggest that at least a part of the posterior thalamus contains neurons receiving submodality-specific input devoid of convergence from nociceptors. 130.12 DISTRIBUTION OF TRIGEMINOTHALAMIC SYNAPSES ON IDENTIFIED THALAMOCORTICAL RELAY NEURONS IN THE VENTROBASAL COMPLEX OF THE MOUSE. Gary R. Belford and Edward L. White. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118

Early attempts to identify thalamocortical relay (TCR) neurons relied on indirect evidence: the free disappearance within the section of the axons of Golgi-impregnated neurons. Presumably, these axons enter myelin sheaths and are not impregnated. With the advent of retrograde labeling of neurons with horseradish peroxidase (HRP), it became possible to inject HRP into the cortex and thereby label the somata of TCR neurons. However, since only the most proximal portions of dendrites were labeled, the full extent of the dendritic trees could not be visualized (e.g., Ralston and Sharp, BR 62:273, '73; Saporta and Kruger, JCN 174:187, '77). Recently, the retrograde transport of HRP was used to label entire dendritic trees of neurons in cortex (White et al., Neurosci. Let. 19:149, '80). In the present study this technique has been coupled with lesion-induced degeneration to study the distribution of trigeminothalamic synapses on unequivocally-identified TCR neurons in the ventrobasal complex (VB) of the mouse.

The vibrissal area of the principal trigeminal nucleus was lesioned in adult male CD-1 mice. One day later, HRP was injected into the corresponding 'barrel' region of the contralateral SmI cortex. Two days after this the animals were perfused and their brains sectioned and reacted for HRP. After light microscopic evaluation, sections containing labeled TCR cells were embedded and serially thin sectioned.

TCR neurons, as identified by HRP labeling, have 4 to 10 primary dendrites, which may branch into tufts of secondary dendrites, branch only once or not at all. Dendrites may extend hundreds of microns from the soma. Each of 4 TCR cells examined with the electron microscope forms trigeminothalamic synapses on its soma or primary dendrites. Those on somata tend to be near the bases of primary dendrites; those on dendrites, near branch points. Nearly all of 4 dendrites belonging to one labeled TCR cell have been reconstructed from an unbroken series in excess of 1000 sections. One dendrite (101 μms in length) forms no trigeminothalamic synapses. 75% of the trigeminothalamic synapses formed by the other dendrites occur within 15 μms of the soma. Although trigeminothalamic synapses (8/ 303 μms dendritic length) comprise only a small proportion of the synapses formed with the reconstructed dendrites, they are well situated to dominate the electrical activity of the thalamocortical relay neuron.

130.13 CONNECTIONS OF THE VENTROPOSTERIOR INFERIOR NUCLEUS OF THE THALAMUS IN CATS. P. Herron* and R.W. Dykes. Departments of Physiology, Surgery, Neurology & Neurosurgery, McGill University, Montreal, Quebec, Canada H3A 1A1.

Based on neurophysiological evidence, several investigators have hypothesized that the inputs of each mechanoreceptor class are spatially segregated in the dorsal column-medial lemniscal pathway (DC-ML). Recent neurophysiological studies of nuclear areas in the DC-ML have shown that the segregated sites of Pacinian inputs are the caudal poles of the dorsal column nuclei (DCN), ventroposterior inferior nucleus (VPI) of the ventroposterior nuclei of the thalamus, and somatosensory area II (SII).

In this study, we tested the anatomical implications of this hypothesis; we injected horseradish peroxidase (HRP) into VPI in order to determine the organization of its connections with the DCN and somatosensory cortical areas I (SI) and II. The areas of Pacinian inputs in SII and VPI were carefully delineated with tungsten microelectrodes and electrolytic lesions were made on the boundaries of the Pacinian-input zone. Pipette electrodes were filled with a solution of HRP in tris buffer and then used to record the Pacinian responses again. Following identification of the Pacinian-input zone, a single small iontophoretic injection of HRP was injected.

The results indicate that the VPI nucleus and a portion of SII are principal sites that are activated by Pacinian inputs in the thalamus and cortex, respectively. When HRP was placed in VPI labeled cell bodies were observed in SI, SII, and the DCN. There were a greater number of labeled cell bodies in SII than there were in SI. The labeled cell bodies observed in the DCN were localized in the cytoarchitecturally distinct caudal poles of the gracile and cuneate nuclei; the labeled cell bodies were located in the same region previous experiments have shown was activated by Pacinian inputs. In addition, labeled cell bodies were observed in adjacent thalamic nuclei. Injections of HRP on the lateral border of VPI resulted in labeled cell bodies in both the caudal poles of the DCN and the spinal lateral cervical nucleus.

We conclude that discrete regions in the medulla relay afferent information from Pacinian corpuscles to the VPI nucleus and, assuming reciprocity of thalamocortical and corticothalamic connections, the VPI nucleus relays Pacinian information to the SII cortex. This study provides another example of a submodality-specific pathway for cutaneous afferent signals to be delivered to the cerebral cortex.

130.14 FACIAL AND DENTAL PULP-EVOKED POTENTIALS IN THE THALAMUS OF CYNOMOLOGUS MONKEYS PERFORMING A SHOCK-AVOIDANCE THRESHOLD TASK. Ronald F. Young, M.D., Kent M. Perryman, Ph.D.* Division of Neurosurgery, UCLA School of Medicine, Harbor/UCLA Medical Center, Torrance, California 90509

Macaca fascicularis monkeys were behaviorally trained to depress a lever which terminated a brief period of electrical stimulation of facial skin or the dental pulp. The animal's pain (escape) threshold was then determined using a random presentation of ten stimulus current intensities which ranged from innocuous to noxious levels. Slow-wave evoked potential (SEP's) were simultaneously recorded from bipolar concentric macroelectrodes chronically implanted in the contralateral ventralis postero-medialis (VPM) and centrum medianum (CM) thalamic nuclei during the behavioral testing sessions. Computer-averaged evoked potentials were obtained at each of the ten different stimulus intensities. Recording sites were histologically confirmed.

SEP's recorded from CM evoked by dental pulp or cutaneous facial stimulation were characterized by two prominent early components with 20 and 50 msec latencies. Both components increased in amplitude with increasing stimulus intensity. Dental stimulation evoked potentials in CM which were of significantly greater amplitude than those evoked by cutaneous facial stimulation. Additionally a long latency, long duration (max. 125 msec) delayed potential was sometimes recorded in CM at stimulus intensities above escape thresholds.

SEP's recorded from VPM showed early components evoked by both dental and cutaneous stimulation which were similar in latency and configuration to these seen in CM. A delayed potential was also sometimes seen in VPM but its duration was shorter than the similar potential recorded in CM.

These recordings are unique because of the lack of anesthetic agents and the correlation with behavioral parameters. They will serve as a basis for future studies of single unit activity and the effect of ablative lesions in a similar primate model. Supported by National Institute of Dental Research Grant DE05208.

130.15 NEURONAL MECHANISMS OF INFORMATION PROCESSING AND THEIR PHARMACOLOGICAL MODULATION IN THE SOMATOSENSORY THALAMUS (VPm). K.-M. Gottschaldt, C. Vahle-Hinz* and T.P. Hicks*. Max Planck Institut for Biophys. Chem., Dept. Neurobiol., 34 Göttingen, FRG

We have developed a method which yields DC-recordings with steel microelectrodes in an "Imminent Membrane Contact" (IMC) electrode position from functionally identified neurons in the trigeminal component of the ventrobasal thalamus in the cat. With this technique, changes in intracellular potential can be recorded from an extracellular electrode position and the activity of single neurons in response to quantitative stimulation of sinus hairs or skin can be studied for long periods of time.

In most neurons afferent impulses elicit small all-or-nothing prepotentials, reflecting presumably dendritic spike components, which trigger full-blown soma spikes. While the transmission of afferent impulses into prepotentials is very stable, the conversion rate of the prepotentials into soma spikes varies with the peripheral stimulus condition. The receptive field of prepotentials may differ from that of soma spikes, as may the characteristics of the prepotential response from those of the soma spike response. The analysis of over 200 IMC-recordings suggests that the control of input-output relations in single neurons operates mainly through a change in the rate of conversion of prepotentials into soma spikes and that this mechanism differs from the classic presynaptic and postsynaptic control mechanisms in neuronal information processing.

To test this hypothesis we have combined steel microelectrodes with multibarrel glasspipettes for iontophoretic administration of various inhibitory and excitatory agonists and their antagonists. The results, again obtained with IMC-recordings, support our original hypothesis that the elicitation of soma spikes is independent of the amplitude of the prepotentials. With the administration of GABA, the amplitude of prepotentials may increase while soma spikes are blocked. However, when additional glutamate is given, the amplitude of the prepotentials remains enlarged but the discharging of soma spikes is facilitated. Bicuculline decreases the prepotential amplitude and antagonizes the GABA-elicited blockade of soma spikes.

The results, although preliminary, suggest that GABA and glutamate act upon different mechanisms which can independently modulate the elicitation of soma spikes and thus the input-output relationship of thalamic neurons. The combination of IMC-recording with microiontophoresis is a promising technique for studying the bases of the neuronal control mechanisms in operation during information processing under natural stimulus conditions.

Supported by the SFB 33 of the Deutsche Forschungsgemeinschaft.

130.16 SOME CONNECTIONS OF SI AND SII IN THE RAT. C.S. Lin, and J.K. Chapin. Dept. Anatomy, Duke Univ. Durham, N.C. 27710 and Dept. Cell Biology, The Univ. of Texas Health Science Center, Dallas, TX. 75235.

The aim of this study was to identify sources of cortical and subcortical projections to somatosensory areas I and II in the rat. Body parts in SI and SII were mapped electrophysiologically prior to iontophoretic HRP injections (2-3 uAmp for 15-30 minutes) from glass microelectrodes (tip size 20-30 um) containing a mixture of L-lysophosphatidyl choline (1-3%) in a 20-30% HRP (Sigma VI) solution. Brain sections were pretreated with $CoCl_2$ and then reacted with DAB. This technique allowed visualization of the detailed dentritic morphology of the cells projecting to the injection sites.

Following injections of the vibrissa area in either SI or SII, the zones of labelled cells in the ventrobasal nucleus (VB) of the thalamus were organized into rostro-caudal columns. However, the labelled neurons comprised less than 60% of the total population of cells in these columns. The soma size of the labelled neurons varied from medium to large. Following injections in either SI or SII, labelled neurons were also found in the intralaminar nuclei and posterior nuclear complex. A zone (UZ) in which cells are unresponsive to light cutaneous stimuli received afferents from neurons located dorso-medially to VB. Cytoarchitectonically, this labelled region appears to be continuous with the posterior nuclear complex.

The ipsilateral cortical neurons labelled after injections in SII were pyramidal cells located primarily in layers II/III and V in SI. Most of the completely back-filled cells were located near the lower border of layer III. The neurons in SII labelled after injections in SI are also found in layers II/III and V (Neuroscience Abst.,6:62 '80). These results suggest the presence of precise reciprocal connections between cells in layers II/III and V of SI and SII. Finally, the neurons labelled in the contralateral SII after injections in SII were also located in layers II/III and V.

130.17 THALAMIC AFFERENTS TO THE ANTERIOR ECTOSYLVIAN SULCUS IN THE CAT. J.M.Roda* and F.Reinoso-Suárez (SPON: I. de Andrés). Departamento de Morfología. Facultad de Medicina. Universidad Autónoma. Arzobispo Morcillo 2. Madrid 34. Spain.

The cortex of the anterior ectosylvian sulcus (AES), that has been included in the proximal association cortex (Graybiel, 1972), is the main and constant source of cortical afferents to the superior colliculus (Tortelly, Reinoso-Suárez and Llamas, 1980). The AES has been described to receive thalamic projections from the posterior nuclear group (Po) and the lateral posterior-pulvinar complex (LP-Pu; Heath and Jones, 1971, Graybiel, 1972, 1973), but a systematic description of its afferents has not been reported heretofore. The aim of this report is to investigate the thalamic afferents to both banks of the AES. In adult cats multiple or single small injections of a 50% aqueous solution of HRP were placed in AES. After a survival period of two days, the animals were perfused and processed in accordance to Mesulam technique (1978). All the experimental animals showed a large amount of labeled neurons in the nucleus ventralis medialis thalami (VM). In the case with multiple injections of HRP, which affected the entires AES cortex, in addition to VM retrograde labeling, labeled cells were observed in: lateral medial-supragenicuiate complex, magnocellular division of the medial geniculate, intermediate and lateral division of Po and ventral and caudal part of the LP-Pu. Some HRP positive cells were also found in: VL,VA, VPl, MD, intralaminar nuclei, medial division of Po and VPi. The results in cases with small single injections allow to point out several topographical differences in neuronal distribution with respect to which bank of AES was injected. The main differences are: 1) The VM labeled cells after AES dorsal bank injections are located more medially and extend more caudally than those cells labeled after ventral bank injections; 2) The most caudal labeled neurons are situated dorsolaterally after AES ventral bank injections and ventromedially after dorsal bank injections.

130.18 MANUAL DISCOORDINATION AFTER DCN LESION. D.E. Teodoru, T.A. Tran*, A.J. Berman. Bronx V.A. Hospital, Bronx, N.Y. 10468

Monkeys tested with vision after dorsal column nuclei (DCN) lesion exhibit poor coordination of hand and fingers (Teodoru, Tran, & Berman, 1978). A similar deficit ("optic ataxia" and "finger agnosia") is found after parietal lobe lesion (Damasio & Benton, 1979). This symptomatology has been attributed to poor visuo-somatosensory integration, consistent with the view that DCN & posterior parietal cortex are part of the same system controlling guidance of hand movements (Stein, 1978; Iwamura, 1979). This explanation, however, has been challenged by Hartje & Ettlinger (1973) who reported similar incoordination in monkeys after parietal lesion when tested both in light and dark. On the basis of this study, Ettlinger (1978) argued that touch was dominant over vision in the guidance of distal forelimb movements.

Berman, Teodoru, and Tran (1980), reported that monkeys tested with vision after DCN lesion recovered distal coordination only when dorsal rhizotomy (DR) was superimposed, indicating that the original deficit resulted from distortion of somatosensory guidance of the hand due to DCN lesion. To test the hypothesis that vision did not play a role in the recovery process, four monkeys were trained to seize small food pellets from a narrow platform and from a dexterity board while blindfolded. After bilateral DCN lesion, they were retested. Distal discoordination was present, identical to that seen in DCN-lesioned monkeys tested with vision. Extensive practice did not result in any improvement. Testing on the dexterity board revealed the same deficits as after S-I lesion (Cole & Glees, 1954), supporting the conclusion that it is tactile and proprioceptive information that are poorly integrated after lesion at any level of the lemniscal system (Norrsell, 1980). Since the distal discoordination resulting from DCN, parietal cortex or S-I lesion is unaffected by the presence or absence of vision, it is suggested that tactile information is dominant over visual information in guiding distal forelimb movements. Furthermore, even though vision is known to exert an inhibitory effect on DCN (Atweh & Jabbar, 1974), this is not sufficient to overcome the dominance of somatosensory guidance even when this guidance is defective. This is supportive of the view that the lemniscal system may integrate the submodalities of somesthesis but does not integrate somatosensory with visual information.

131.1 DIFFERENCES IN SPECIALIZATION OF FAST AND SLOW-TWITCH CHICK MUSCLES AND WORK-DEPENDENT CYTOSOLIC CREATINE KINASE ONTOGENY. O. Ramírez and Margarita Hernández*
Dept. Biochemistry, Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional. México 14, D.F.

Development of isometric twitch contractions is not the same in all skeletal muscles of higher vertebrates. In the chick, much work has been performed with the slow anterior latissimus dorsi (ALD) and the fast posterior latissimus dorsi (PLD) in regard to electrical and mechanical properties during development, in vivo and in vitro. It is suggested that specific differentiation of the two muscles is determined by their innervation (Purves, R.D. and Vroba, G., J. Cell Physiol. 84; 97, 1974). It seems to be that a good correlation exists between the speed of contraction of skeletal muscles and their content in phosphotransferases in the adult rat (Shainberg et al., Develop. Biol. 25:1 1917). However, 17 day-old Rhode Island chick embryos showed that 120 msec for PLD and 280 msec for ALD were the times for isometric twitch contraction, whereas creatine kinase (CK) specific activities for the same state averaged 91.5 units* for PLD and 148.6 for ALD. Previously at day 14, PLD averaged 32.1 units and ALD 36.7. On the other hand, at hatching, PLD had 1072.9 units and only 329 were in ALD. In ovo, ALD and PLD do not seem to work very much during development, for anatomical reasons. Since it was thought that CK activity could be work-dependent, time-courses of CK in the proper embryonic muscles showed that indeed this was the case. Breast (white-fast) non-working muscle and leg (mixed) working muscles began to differ from day 12 of incubation and at hatching 1220 CPK units were in favour of the working leg muscles. These findings in vivo are in agreement with those in cultures of skeletal muscle cells of the chick embryo, subjected to repetitive electric stimulation. The contraction increased mostly the synthesis of proteins associated with the contractile apparatus, as the myosin-heavy chain.

On the other hand, this work also showed that membrane and cytosolic differentiation in skeletal muscle occur separately during development.

*nmoles of substrate transformed/min/mg protein.

131.2 DEVELOPMENTAL INCREASE IN ACETYLCHOLINE RELEASE FROM CHICK EMBRYO NEURAL RETINA. Jeffrey M. Thompson and Clint Makino*. Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore, MD 21224.

When the neural retina layer is removed from the embryonic chick, it will take up [^{3}H]-choline, synthesize [^{3}H]-acetylcholine ([^{3}H]-Ach) and release [^{3}H]-Ach in response to KCl or glutamate. These properties can be used to determine developmental changes in the functional release of acetylcholine from retina neurons. After incubation in [^{3}H]-choline, the retina layers are washed and placed in a multi-channel perfusion system. The perfusate is collected in timed samples and the amount of [^{3}H]-choline and [^{3}H]-Ach in each sample measured before and during addition of 80 mM KCl or 5 mM glutamate to the perfusing medium. Six-day retina do not release [^{3}H]-Ach in response to either KCl or glutamate, 8-day retina show a moderate response to the drugs and older retina show further increases. Sixteen-day retina, the oldest age tested, released the largest amounts of [^{3}H]-Ach. The developmental increase in Ach release parallels the developmental increase in choline acetyltransferase activity (Puro et al., Proc. Natl. Acad. Sci. USA, 74, 4977-4981, 1977; Bader et al., Proc. Natl. Acad. Sci. USA, 75, 2525-2529, 1978). However, when the release data is normalized to eliminate differences in uptake and synthesis, a developmental increase in release is still observed. Thus, the total release reflects a summation of synthesis and release processes.

The developmental changes reported for synapse formation between chick embryo retina neurons and muscle cells in culture (Ruffolo et al., Proc. Natl. Acad. Sci. USA, 75, 2281-2285, 1978) are not correlated with the observed changes in ACh release. Eight-day retina neurons have the greatest capacity to form cholinergic synapses on muscle, while 16-day retina neurons do not form any synapses. Acetylcholine can be released from 16-day retina in large quantities as shown in this study, yet synapses are not formed. Thus, the mechanisms for synapse formation and neurotransmitter synthesis and release are not coupled in the developing chick retina.

131.3 ACETYLATION OF POLYAMINES IN THE MOUSE BRAIN. Ortiz, J.G., Giacobini, E. and Schmidt-Glenewinkel, T. (Sponsor, M. Wilson)
Dept. of Biobehavioral Sciences, University of Connecticut, Storrs, CT 06268 USA

Putrescine, spermidine and spermine have been shown to be acetylated in several mammalian tissues (Seiler, N. and Al Therib, M.J., Biochem. Biophys. Acta. 354:206, 1974, Blanckenship, J. and Walle, T., Arch. Biochem. Biophys. 177:237, 1977). The acetylation of these compounds and of cadaverine in the mouse brain has been examined in our laboratory.

Polyamine Acetyltransferase (PAT) activity could only be detected in brain nuclear and microsomal fractions. Substrate kinetics with the nuclear preparations, indicate that these compounds are acetylated at physiological concentrations. The Km's for putrescine, cadaverine, spermidine and spermine are 3.0 mM, 5.2 mM, 1.2 mM and 3.5 mM, respectively. The microsomal fraction has comparable levels of activity and appears to have similar substrate preference.

Regional studies with spermidine indicate that the olfactory bulb and cerebellum have the highest activity (per mg protein), followed by cortex, midbrain and brainstem. Preliminary results with putrescine and cadaverine suggests that their acetylation follows a similar regional distribution. Interestingly, ornithine decarboxylase activity has a very similar regional pattern as the acetylation of polyamines (Rochel, S. and Margolis, F.L., J. Neurochem. 35:850, 1980). In some regions, the cell number (DNA levels) may account for the regional distribution observed.

The possible relationship between Polyamine Acetyltransferase and Ornithine Decarboxylase activities in brain is discussed.

(Supported by PHS grants NS 11430 and 14086 to E.G. and Ford Foundation Fellowship to JGO).

131.4 INTRACELLULAR ACCUMULATION OF ACHE INDUCED BY EARLY OLFACTORY BULB LESIONS: INTRALITTER SIMILARITIES. Celeste R. Wirsig, Joan Morasco* & Christiana M. Leonard. Dept Neuroscience, College of Medicine, University of Florida, Gainesville FLA 32610.

Removal of the olfactory bulb (OBx) in the 5 day old hamster causes cellular changes in the ventral forebrain (VF) which are accompanied by abnormalities in neonatal thermoregulatory and social behavior. Work in our laboratory suggests that the behavioral pathology may be due to lesion-induced abnormalities in cholinergic function (Leonard, Williamson & Freund, this volume). Twenty-four hrs after the lesion, a number of cells in the ipsilateral caudal anterior olfactory nucleus (AON) and olfactory tubercle (OT), collectively the VF, show an increased amount of AChE intracellularly. These reactive cells may project centrifugally to the OB and/or anterior AON and thus had their axons severed by the lesion. Muscarinic cholinergic receptor binding density assessed with QNB in the ipsilateral VF is also elevated by the lesion. The number of reactive cells varies greatly between pups from different litters (as does QNB binding), but correlates with the amount of QNB binding in the pooled VFs of littermates. This suggested that the variability we have found in both histochemical and biochemical measures might reflect an underlying genetic variability in cholinergic function. The aim of the present study was to determine whether the number and distribution of reactive cells is comparable in littermates.

The brains of 6 pairs of pups (3 pairs ROBx & 3 pairs LOBx) from 6 litters of the out-bred Charles River strain were examined. Animals were bulbectomized on day 5 and perfused 24 hrs later. The brains were sectioned (80 μ) and stained for AChE using the Tsuji method. Each section was drawn and the reactive cells were counted caudal to the lesion. All animals demonstrated reactive cells throughout the caudal AON and in most cases in the OT. Reactive cell density generally peaked at the beginning of the OT. Although the number and distribution of cells in the OTs among litters differed greatly (cell # range = 1-112), the number and distribution of these cells were highly correlated in littermates ($r=.83$, $p<.02$; $r=.91$, $p<.01$, respectively). To date no left-right differences in cell distribution have been seen.

The differential location of these cells along the rostrocaudal axis of the VF may reflect differences in developmental status among litters or may be due to genetic variation in the cellular distribution. We are presently examining the possibility of the former by comparing the effects of bulbectomies performed at various postnatal ages.

131.5 MESOLIMBIC LESIONS DELAY DEVELOPMENT OF SOCIAL HUDDLING IN GOLDEN HAMSTER PUPS. Dorothy K. Burt*, Cynthia L. Rodriguez*, Neal R. Kramarcy and Christiana M. Leonard. Department of Neuroscience, Univ. Fla. Coll.Med., Gainesville, FL 32610.

During the first week of postnatal life, golden hamster pups use thermal rooting (R), an active behavior characterized by dives and displacements in a tightly knit group, as a form of behavioral thermoregulation. Quiet huddling (S) replaces R during the second week. The pups crouch together in a loose association and activity is limited to head movements and grooming.

Previous work in our laboratory has implicated the olfactory system, particularly the olfactory tubercle (OT), in behavioral changes occurring between the first and second week. Since the olfactory tubercle is a major target of mesolimbic dopaminergic (DA) projections arising in the ventral tegmental area (VTA) we decided to investigate the effect of 6-OHDA placed in this area at 5 days on huddling behavior measured at 10 days of age.

Eighteen litters of 7 or 8 pups were assigned to either 6-OHDA (D), sham (S) or untreated control (U) groups. Pups in the D and S groups were pretreated with desipramine hydrochloride (DMI: 20 mg/kg, ip, 60 min before surgery). Either 6-OHDA (2 µg/µl) or 0.2% ascorbic acid vehicle (1 µl; 0.5 µl/min) was infused into VTA on the left side through a 33 g cannula (placement determined stereotaxically). The behavior of three-pup groups (run blind) was videotaped in 8 min tests on a mild thermal gradient (20 to 30°C). Thermoregulatory and social contact behaviors were categorized every 15 sec and rectal temperature was monitored throughout by means of a thermistor inserted in one of the pups. On day 18 pups were sacrificed and DA levels in OT assayed with HPLC.

The pups that had received 6-OHDA were much more active than shams or controls. They displayed thermal rooting 60% of the time compared to 18% for the controls and 34% for the shams (D vs S, $p < .05$). Conversely, controls displayed quiet huddling 52% of the tme, shams 42% and D 20% (D vs S, $p < .05$). The groups did not differ in weight, body temperature, time spent in the warmth or amount of total social contact.

We conclude that the maturation of VTA projections into OT may play a role in the onset of quiet huddling. The effect of the lesion is not permanent, however, as behavior and dopamine levels were similar in all groups at sacrifice. Whether dopamine is significantly depleted at the age when behavior is abnormal remains to be determined.

131.6 ASYMMETRICAL EFFECTS OF EARLY OLFACTORY BULB LESIONS: IS THE HAMSTER BRAIN LATERALIZED? C.M. Leonard, M. Williamson*, G. Freund. Dept. of Neuroscience and Dept. of Medicine, Univ. Florida Coll. Med. Gainesville, FL 32610.

Language, species specific calls, and songs are social behaviors controlled and decoded by the left hemisphere. Although the right hemisphere in humans is thought to specialize in nonverbal communication, interpreting and organizing emotional responses, the possibility that the right hemisphere in animals might also specialize in directing nonverbal social interactions has not been proposed. Since even solitary species like the golden hamster Mesocricetus auratus have a number of stereotyped social behaviors with a presumed communicative function, we decided to investigate whether control of their behavior was lateralized.

We used neonatal hamsters because the type and duration of their social interactions can be precisely controlled by varying thermal conditions in the environment. When placed on a thermal gradient pups maintain their body temperature by varying the percent time they spend in asocial thermotaxis (strung out singly on the warm side), social huddling (a loose aggregation somewhat resembling a campfire circle) and exploration. Since huddling is under olfactory control we compared the effect of left and right olfactory bulbectomy (OBx) on day 5 after birth on social huddling measured on day 12. Six litters of LOBx and 6 litters of ROBx were compared to a control group of 3 sham operated and 3 intact litters.

The behavioral strategy used to maintain temperature was strongly affected by the side of the lesion. After LOBx, pups increased their time huddling in the warmth while ROBx pups spent more time in asocial thermotaxis. Mean huddling/ thermotaxis ratios were 1.6 for LOBx, 1.3 for controls and 0.9 for ROBx.

Since the ventral forebrain (VF) projections of OB are characterized by large amounts of acetylcholine, we determined the density of cholinergic muscarinic receptor binding with labelled QNB in VF. We found an L/R asymmetry in binding density which was increased after LOBx but reversed after ROBx (L/R ratios for controls = 1.12; LOBx = 1.23, ROBx - .91). The ratios for individual litters correlated positively with their H/T scores ($r = .47$, $p < .05$) and time huddling was negatively correlated with binding density in the right but not the left VF ($r = -.64$, $p < .01$).

These results suggest that the two hemispheres are asymmetrically involved in the control of social behavior in the golden hamster pup. Whether the asymmetry is a characteristic of sensory, motor, or motivational processes remains to be determined.

131.7 DEVELOPMENT OF NEUROTRANSMITTER SYNTHESIS AND ACCUMULATION IN PRIMARY AND SECONDARY NEURAL CREST CULTURES. G. D. Maxwell, P. D. Sietz* and C. E. Rafford*, Dept. of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032.

Primary cultures of quail trunk neural crest cells, without exogenously added non-neural crest cells, develop histochemically demonstrable catecholamine (CA)-containing cells as well as dopamine-ß-hydroxylase and choline acetyltransferase enzyme activities (Cohen 1977 PNAS 74: 2899; Kahn et al., 1980 Dev. Biol. 77: 340).

In order to further characterize the ontogeny and control of neuronal phenotypic expression of neural crest cells in vitro, we have examined the capacity of such cultures to synthesize and store putative neurotransmitters from [^{3}H]tyrosine, [^{3}H]choline and [^{3}H]tryptophan using the screening procedure of Hildebrand et al., (1971 J. Neurobiol. 2: 231).

In primary cultures, the synthesis and storage of [^{3}H]CA per mg protein from [^{3}H]tyrosine is negligible until 3 days in vitro, and rises 4-fold between 3 and 7 days. A similar developmental increase is seen when [^{3}H]CA is normalized to cell associated [^{3}H]tyrosine present at the end of the incubation. This suggests that the increase in [^{3}H]CA synthesis and storage is not due to increased tyrosine uptake. The time course of the increase in [^{3}H]CA synthesis and storage agrees well with published data on dopamine-ß-hydroxylase activity and histochemically detectable CA-containing cells. The CA synthesized in these cultures include [^{3}H]dopamine, [^{3}H]norepinephrine, and sometimes [^{3}H]epinephrine. These compounds were identified using ascending chromatography following electrophoresis and independently by HPLC analysis (performed by Dr. Thomas O. Fox).

Secondary cultures, prepared from 2-day primary cultures, show no [^{3}H]CA accumulation on the first day after subculture. [^{3}H]CA synthesis and storage increases between 3 and 8 days after subculture with the amount of [^{3}H]CA per mg protein reaching levels comparable to those seen in primary cultures.

Acetylcholine (ACh) synthesis and storage from [^{3}H]choline is also observed to develop in primary cultures. Little [^{3}H]ACh is produced for the first 3 days in vitro. [^{3}H]ACh accumulation per mg protein rises 7-fold between 3 and 7 days in vitro.

Primary cultures exhibit little or no ability to synthesize and accumulate [^{3}H]5HT from [^{3}H]tryptophan over the period of 2 to 10 days in vitro.

131.8 EARLY DEVELOPMENT OF CHOLINERGIC FUNCTION IN RAT RETINA. B-A. Battelle, D.G. Puro and K.H. Hansmann.* Laboratory of Vision Research, National Eye Institute, NIH, Bethesda, MD. (Spon: H. H. Hess).

To examine aspects of cholinergic development in rat retina, acetylcholine (ACh) synthesis, choline acetyltransferase (CAT) activity and ACh release were assayed. ACh synthesis from ^{3}H-choline (15µM) was assayed in intact, isolated retinas incubated in vitro. Labeled ACh formed was quantified following high voltage electrophoresis of extracts from retinal homogenates. In these assays, carnitine acetyltransferase was not a source of confusion since NVP, a specific inhibitor of CAT, blocked greater than 90% of the choline acetylation without affecting carnitine acetylation. Release of ACh was assayed in a cell culture system utilizing rat striated muscle cells as postsynaptic targets for cholinergic neurons (Puro et al. PNAS 74, 4977: 1977). Synaptic input to myotubes was measured by intracellular recordings one day after addition of trypsin-dissociated retinal cells.

By embryonic day 17 (E-17) ACh synthesis and CAT activity are detected. Spontaneous release of ACh can be demonstrated using E-18 retinal neurons. As CAT activity increases 9 fold between E-17 and E-19, the rate of ACh synthesis rises from 0.29 to 6.88 pmoles/mg protein/hr. These events correlate with formation of the inner plexiform layer and occur more than one week before morphological synapses have been reported. ACh release could be evoked from retinal neurons by glutamate only after E-19. Microiontophoresis of glutamate onto E-19 retinal neurons did not increase the frequency of depolarizations measured in any of the innervated myotubes tested (0/19). When the same assay was done with cells from postnatal day 0 (P-0) retinas, 73% (8/11) of the innervated myotubes showed evoked synaptic input. The basis for this maturation of glutamate-evoked response is uncertain; however, preliminary evidence indicates that glutamate receptors are present on some E-19 cholinergic neurons.

The rate of ACh synthesis increases sharply after P-6. Two factors may contribute to this: 1. a marked increase in CAT activity (from 0.35 to 1.74 nmoles/mg protein/min between P-6 and P-12) and 2. an increase in high affinity choline uptake. When retinal incubations were done in the presence of a low concentration of ^{3}H-choline (0.65µM), and (50µM) HC-3, a specific blocker of high affinity choline uptake, ACh synthesis was reduced approximately 40% in P-9 retinas but by only 25% in P-4 retinas. The development of cholinergic function during the second postnatal week corresponds to the period when morphological synapses appear in the retina.

131.9 INTRAVENTRICULAR NEONATAL 6-OHDA: EFFECTS ON THE ONTOGENY OF SPONTANEOUS MOTOR ACTIVITY AS A FUNCTION OF ENVIRONMENTAL CUES. Sonya K. Sobrian. Dept. of Pharmacology, Howard University College of Medicine, Washington, DC 20059.

Developing rats exhibit a characterist ontogenetic pattern of spontaneous locomotor activity (SMA) when tested in isolation. Activity levels are low at birth, increase to maximal levels at day 15 and then decline to reach adult levels between 25 and 30 days of age. Systemic injections of 6-hydroxydopamine (6-OHDA) on postnatal day 0-3, while producing a selective depletion in NE in brain regions innervated by the ascending dorsal adrenergic system, do not alter the normal ontogenetic pattern of SMA. In contrast to these findings are the alterations in SMA following neonatal intraventricular 6-OHDA.

Sprague-Dawley rat pups were injected in the lateral ventricles with 50 ug of 6-OHDA on postnatal days 1 and 2, and SMA was measured every 5 days from days 10-30. Pups were tested either in isolation (without shavings) or in the presence of shavings from their home cages. Unlike the differential pattern of regional changes seen after neonatal systemic 6-OHDA, intraventricular injections of both NE and DA throughout the brain of the 30 days of rats. Cortical, cerebellar, hippocampal and hypothalamic NE was reduced to 5-60% of control levels; striatal DA was reduced to 5% of control values. Behavioral changes were also more striking. In the isolated condition, intraventricular 6-OHDA altered the levels but not the developmental pattern of SMA. Treated pups inhibited at a significant but transient hyperactivity between 15 and 25 days of age.

The presence of home cage shavings in the testing apparatus markedy altered the development of SMA in control pups. Activity levels remained low and relatively unchanged between 10 and 30 days of age. In contrast, this test situation exaggerated the hyperactivity seen in 6-OHDA treated pups between days 15 and 25. Activity levels were not only significantly increased over control values, but were also higher than the level of drug treated pups tested in isolation. Preliminary data suggests that this enhanced hyperactivity in a familiar environment may reflect an olfactory deficit in pups treated intraventricularly with 6-OHDA. Treated pups exhibited no preference for the odor of home cage shavings at an age (Day 8) when controls spend 90% of their time over this odor. These data indicate that environmental factors can influence the effects of neurochemical changes in modulating developing behavior. (Supported by NSF Grant #BNS-80-26765)

131.10 NALOXONE DURING INFANCY INCREASES OPIATE BINDING WITHOUT ALTERING MONOAMINE SYSTEMS. M.T. Bardo, R.K. Bhatnagar and G.F. Gebhart. Department of Pharmacology, University of Iowa, Iowa City, IA 52242.

We recently reported that chronic administration of naloxone from birth to 21 days of age increases opiate binding in rats. Since strong evidence indicates that at least some opiate receptors are located on monoamine-containing neurons, we hypothesized that naloxone-induced alterations in opiate binding might produce a concomitant alteration in monoamine systems. In the present experiments, we examined the effects of chronic naloxone treatment on levels of norepinephrine, dopamine and serotonin, and on opiate receptor binding during different periods of postnatal development. Sprague-Dawley rat pups were injected subcutaneously with either naloxone hydrochloride (1 mg/kg) or 0.9% NaCl vehicle twice daily at various intervals after birth. In one experiment, animals were injected for one week beginning at either 1, 8, or 15 days of age. These animals were decapitated on the day following the last injection (i.e., day 8, 15 or 22), and the brains and spinal cords were removed; brains were dissected into medulla-pons, midbrain, hypothalamus, striatum and cortex. Opiate receptor assays were performed on homogenized tissue incubated with 1 nM ^{3}H-naloxone in the presence or absence of 100 nM levallorphan. In another experiment, animals were injected with either naloxone or saline from 1 to 21 days of age. On the day following the last injection, each animal was subsequently injected intraperitoneally with either α-methyltyrosine (250 mg/kg), an inhibitor of tyrosine hydroxylase, or saline vehicle. Three hours later, animals were decapitated and the brains regionally dissected as above. Norepinephrine, dopamine and serotonin assays were performed using standard radioenzymatic procedures with ^{3}H-S-adenosyl-methionine. α-methyltyrosine-induced decreases in catecholamine content was used as an index of amine turnover.

Naloxone treatment during the first postnatal week increased ligand binding in spinal cord, hypothalamus and striatum. An increase in ligand binding was also evident following naloxone treatment during the second and third postnatal weeks, although not in striatum. Steady-state levels of catecholamines and serotonin, and turnover of catecholamines, were unaffected by the naloxone treatment. Thus, while opiate receptors may be located on monoamine neurons, these results indicate that changes in opiate receptors do not necessarily produce changes in monoamine systems.

Supported by USPHS grants NS-12121, NS-12114 and MH-15172.

131.11 THE ONTOGENY OF ENKEPHALIN-LIKE IMMUNOREACTIVITY IN THE DEVELOPING AVIAN CILIARY GANGLION AND THE NUCLEUS OF EDINGER-WESTPHAL. Brian M. Davis, Jonathan T. Erichsen and Harvey J. Karten. Dept. of Neurobiology & Behavior, SUNY, Stony Brook, New York 11794.

Leucine-enkephalin-like immunoreactivity (ELI) has been demonstrated in the preganglionic terminal endings upon both ciliary and choroid neurons in the avian ciliary ganglion (Karten et al., Neurosci., submitted). Lesion studies have shown that enkephalinergic neurons in the nucleus of Edinger-Westphal (EW) are the source of these immunoreactive terminals (Erichsen et al., 1981). Since neurons of EW are also known to be the source of cholinergic input to the ciliary ganglion (CG), enkephalin may coexist with acetylcholine and play an ancillary role in synaptic transmission. The present study describes the ontogeny of ELI in both the CG and EW of the chick.

ELI first appears in both EW and the CG at St 25 shortly after cell proliferation ends in the CG (Landmesser & Pilar, 1978). The first functioning synapses in the CG are reported to occur at St 26 (Landmesser & Pilar, 1972).

From St 25 through 36, ELI staining in EW is punctate and diffuse in appearance, revealing no obvious enkephalin-positive cells. Enkephalin-labeled neurons appear in EW at St 37 and continue to show a similar pattern of ELI through St 45, although the number of labeled neurons diminishes after St 40.

In the CG, ELI staining is weblike in appearance between St 25 and St 33 and shows no obvious morphological specializations around individual neurons. By St 35, shortly before enkephalin-positive cells first become evident in EW, delicate enkephalin immunoreactive fibers completely surround most cells in the CG. The first recognizable immunoreactive calyceal-like terminal endings appear at St 37, near the time calyces are known to start forming but before transmission by these synapses is reported (St 39) (Landmesser & Pilar, 1972). By St 41, terminal endings on both choroid (boutons) and ciliary (calyces) cells show ELI in the CG. The pattern of ELI remains essentially the same through St 45.

The development in the pattern of ELI of the preganglionic terminal endings within the CG correlates well with the described sequence of events during synaptogenesis. Significantly, enkephalin appears immediately before the first functioning synapses, and subsequently, recognizable calyces show prominent ELI before they are reported to become synaptically active. These results suggest that enkephalin plays an essential role in synaptogenesis and/or neurotransmission in the CG.

131.12 LOCOMOTOR HYPERACTIVITY IN NEONATAL RATS FOLLOWING LESIONS OF MESOCORTICAL DOPAMINERGIC NEURONS. Alfred Heller, Thomas Heffner, Connie Kotake*, Frederick Miller* and Lewis Seiden. Dept. of Pharmacol. & Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

In neonatal rats, destruction of brain dopamine (DA) neurons by ivt injections of 6-hydroxydopamine (6-HDA) results in locomotor hyperactivity (Shaywitz et al. Sci.191:305,1976; Erinoff et al. Br. Res. 164:195,1979). As an approach to determining which DA projections are responsible for this effect, we examined locomotor development in rats after ablation of either mesocortical or nigrostriatal DA neurons at 4 days of age. A single electrolytic lesion in the medial ventral tegmental area (VTA) or bilateral lesions of the substantia nigra (SN) were made by use of stereotaxic procedures (Heller et al. J. Neurosci. Meth. 1:41, 1979). Locomotion in control rats (measured for 1 hr daily in stabilimeter cages) averaged 38 counts per hr from days 22-24 of life. Rats with lesions placed in the medial VTA displayed a 3-fold increase in locomotion relative to controls during this time whereas rats with lesions placed in the SN displayed no change in locomotion. The VTA lesions depleted DA in frontal cortex (FC) by 45%, septum (S) by 57% and nucleus accumbens (NA) by 29%, but did not alter DA content of the caudate-putamen (CP). The SN lesions reduced DA in the CP by 60% but had less effect on DA within FC (-33%), S(-18%), and NA (-20%). The SN lesions produced substantial bilateral loss of cells within the pars compacta. In rats that displayed hyperactivity following a VTA lesion, the ablated area involved the midline tegmentum immediately dorsal to the interpeduncular nucleus generally extending above the rostral 1/2 to 2/3 of this nucleus. In rats that did not display hyperactivity after a VTA lesion, the lesion spared this midline area. In an attempt to produce less nonspecific destruction of cells other than DA neurons within the medial VTA, 6-HDA (2 µg/0.4 µl) was injected into the midline VTA site in 4 day old rats pretreated with desipramine. These rats displayed a 2-fold increase in locomotion relative to controls during days 22-24 of life. The depletions of DA within the FC (-54%), S(-44%), and NA (-44%) in these rats were similar to those seen in rats that displayed hyperactivity after an electrolytic lesion in the VTA. Although VTA 6-HDA injections produced depletion of DA in the CP (-54%) this depletion did not exceed that seen in rats that failed to display hyperactivity after electrolytic lesions in the SN. These results suggest that destruction of DA cells within the midline VTA results in locomotor hyperactivity in the neonatal rat. Destruction of these cells may account for the hyperactivity seen following ivt 6-HDA injections. Thus, DA cell groups within the medial VTA may be essential for the normal ontogeny of locomotor behavior. (USPHS-12324; MH-10562; MH-14274).

131.13 EFFECTS OF NEONATAL X-IRRADIATION ON SELECTED STROMAL AND PARENCHYMA CELLS IN RAT BRAIN. L.K. Gerbrandt, R.B. Chronister and G.C. Palmer. Neurosci Res. Prog., M.I.T., Boston, MA. 02116 and Univ. So. Ala. Col. Med., Mobile, Alabama 36688.

We have recently shown that neonatal x-irradiation directed to the hippocampus produces not only anatomical alterations (diminution of the granule cell layer), but also subsensitivities of biogenic amine (norepinephrine, dopamine and histamine) receptors coupled to adenylate cyclase. The purpose of the present study is to examine in similar animals, the effects of x-irradiation on cyclic AMP systems and histological changes in other areas of the CNS.

Long-Evans derived hooded rats were given unilateral x-irradiation as follows: 200 rads on neonatal days 2, 3 and 150 rads on alternate days 3-15. Partial schedules were given identically but the procedure was stopped after day 7. Tissue was removed from animals at 3 months of age.

The irradiation produced a marked decrease in the skin pigment of the head and clearly showed the outline of the irradiation. The eye was also smaller, a midline shift of the head was toward the x-irradiated side, and the lacrimal gland was hyperplastic. Histological examination showed striking changes in the retina. The rod and cone nuclei were diminished and occurred in clusters. Several layers of bipolar cells were present. Concomitantly dopamine activation of adenylate cyclase was augmented. The pia overlying the posterior cortex was hyperplastic but the stimulation of adenylate cyclase by norepinephrine (NE) and/or GTP analogs were reduced. Similarly the posterior cortex showed a decrement in NE-adenylate cyclase without remarkable histological change. The capillaries in the posterior cortex were unchanged. The hippocampus displayed again a lessened sensitivity of NE-adenylate cyclase even when the damaged gyrus was removed. The partial irradiation schedule revealed only a slight reduction of NE enzyme sensitivity in the hippocampus.

These findings show that the effects of neonatal x-irradiation are complex, area specific and vary in direction. (Supported by NSF PCM 7911782.)

131.14 THE MONOSODIUM L-GLUTAMATE (MSG) SYNDROME IN MICE DEVELOPS INDEPENDENTLY OF HOUSING CONDITION. June E. Barnhart* and William J. Pizzi. Neuropsychology Lab, Northeastern Ill. Univ., Chicago, Illinois, 60625.

The sequelae of neuroendocrine, somatic, and behavioral events following neonatal MSG treatment has been well documented, including obesity and decreased locomotor activity. Recently, however, Dawson & Lorden (J. Comp. Physiol. Psych., 95: 71,1981; Abstr. Soc. Neurosci., 5: 215, 1979) reported that several features of the MSG syndrome only appear in group-housed animals. While these findings are difficult to reconcile with the existing MSG literature, they could be of theoretical importance if verified. The present studies were designed to systematically explore the effects of housing conditions on the MSG syndrome.

HaICR mice (n=193) were treated with MSG or a control vehicle for 10 days (days 2-11 after birth) according to a dose schedule described by Potts et al. (Amer. J. Ophthalmol., 50: 900, 1960). The dosage ranged from 2.2 mg/g b.w. on day 2 to 4.4 mg/g b.w. on day 11. Animals were assigned to either an individual-housing condition (1 animal/cage)or a group-housing condition (4-6 animals/cage) at weaning (29 days of age). Growth curves were recorded until the mice reached 200 days of age. On day 200 a random sample of group-housed males were switched to the individual-housing condition, and followed for 20 days in order to simulate the conditions of Dawson & Lorden. Male mice in each housing condition were tested for locomotor activity levels between 190 and 200 days of age.

All MSG-treated male and female mice, regardless of housing condition, displayed the extreme obesity typical of the MSG syndrome ($p < 0.001$). Regardless of housing condition, all MSG-treated animals were hypoactive ($p < 0.001$). When the group-housed male mice were switched to individual housing at day 200, they failed to show any disruption in their growth curves.

These findings fail to show any effects of housing condition on the development of the MSG syndrome. In this study animals were assigned to the housing conditions well before any obesity occurred, and no disruption of the growth curve was observed. Animals which became obese in the group-housed condition also failed to show any weight loss when switched to the individually-housed condition. We conclude that housing variables play no role in the production of the MSG syndrome in mice.

131.15 THE PERINATAL DEVELOPMENT OF NEUROTRANSMITTER RECEPTORS STUDIED BY AUTORADIOGRAPHIC METHODS. M. Lewis, J.M. Palacios, J.R. Unnerstall, D.L. Niehoff, M. Molliver and M.J. Kuhar (SPON: W.S. Young, III). Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Using light microscopic autoradiographic techniques for the localization of neurotransmitter receptors after *in vitro* labeling of mounted tissue sections, we have studied the ontogeny of several receptor types, e.g., opiates, dopamine, norepinephrine, serotonin, GABA and benzodiazpines. Goals of this study were to correlate the appearance of receptors with 1) the maturation of particular cell populations, 2) the appearance of responses to agonists and antagonists of these receptors and 3) maturation of the presynaptic input.

The different receptor types exhibit dissimilar patterns of development. Many of the receptors develop mainly during postnatal life, whereas in the fetus, opiate receptors are found in high concentrations in particular regions of the brain. In some cases, receptors were present in young animals in areas where they are absent in the adult. This age-related "elimination" process was observed in several cases: opiates, serotonin and GABA receptors. Association of receptor development with the maturation of some specific cell types was observed. For example, undifferentiated cells in the external granule layer of the cerebellum do not exhibit any receptor binding. But, as these cells mature and migrate to the granule cell layer, a concomitant increase is seen in the density of GABA receptors. However, no clear relationship could be established between the maturation of either cell types or neurotransmitter systems and their receptors. For example, opiate receptors in some areas develop before measurable quantities of enkephalins are found; beta-adrenergic receptors, on the other hand, develop much later than the noradrenergic input. The results indicate that the initial development of specific receptors is, in most cases, not dependent upon the ingrowth of axons that contain the appropriate neurotransmitter. Rather, the pattern of receptor development is an expression of the individuality and the distinctive membrane differentiation of different neuron types. Later in ontogeny a complex process of receptor remodelling leads to the mature receptor profiles of different sets of adult neurons.

131.16 DEVELOPMENT OF ADRENAL MEDULLARY AND CARDIAC RESPONSES TO SYMPATHETIC STIMULATION IN RATS. R. F. Kirby* and R. McCarty. Dept. of Psychol., Univ. of Virginia, Charlottesville, VA 22901.

The ability of the sympathetic nervous system to increase ornithine decarboxylase (ODC, EC 4.1.1.17) activity in the heart and to stimulate catecholamine secretion from the adrenal medulla requires a functional system of innervation to these tissues (Bareis and Slotkin, J. Pharmacol. Exp. Ther., 205: 164, 1978). In the present study, we were interested in determining the age at which functional sympathetic innervation of the adrenal medulla and heart occurs. Insulin was administered to developing rat pups to stimulate a centrally-mediated increase in sympathetic activity and increases in heart ODC activity and depletion of adrenal catecholamines were used as measures of tissue responses to sympathetic stimulation. Litters of Sprague-Dawley rats were reared in our laboratory. At 12±1 days of age, pups were injected with insulin (1, 10, 20 or 30 IU/kg, s.c.) and sacrificed at 1, 3 or 4 hours post-injection to determine the dose of insulin and time of sacrifice which yielded maximal stimulation of heart ODC and maximal depletion of adrenal catecholamines. Heart ODC activity was found to be more sensitive to increases in sympathetic stimulation than the depletion of epinephrine (EPI) from the adrenal medulla. To assess the development of sympathetic responses in heart and adrenal medulla, rat pups (4, 8, 12, 16 days old) were injected with saline or insulin (30 IU/kg, s.c.) and sacrificed 3 hours later. Administration of insulin resulted in a significant increase in heart ODC activity at 12 and 16 days of age (Table 1).

Table 1. Heart ODC Activity (nmoles/g/hr, $\bar{x}$±SE)

Age (days)	4	8	12	16
NaCl	8.17±1.94	8.69±1.63	6.63±1.18	4.41±.80
Insulin	12.22±3.77	11.31±2.98	19.19±3.06*	10.57±2.34*

In contrast, administration of insulin resulted in a significant depletion of EPI from the adrenal medulla as early as 8 days of age (Table 2). At no age was there a significant depletion of norepinephrine.

Table 2. Adrenal Epinephrine (µg/pair, $\bar{x}$±SE)

Age (days)	4	8	12	16
NaCl	.495±.067	1.009±.144	2.390±.233	2.436±.386
Insulin	.526±.055	.615±.096*	.979±.146*	1.201±.241*

These data suggest that the development of functional sympathetic innervation to the adrenal medulla of rats occurs prior to the development of functional sympathetic innervation to the heart.

131.17 DEVELOPMENTAL CHANGES IN CONCENTRATIONS OF BIOGENIC AMINES IN THE BRAINSTEM NUCLEI OF THE RABBIT. M. Colleen McNamara and E.E. Lawson.* University of North Carolina, Chapel Hill, NC 27514.

Neurotransmitter levels were studied in specific brainstem nuclei of postnatal rabbits at various developmental ages (1,3, 7,14, and 21 days). Animals were killed by decapitation; brains were rapidly removed and immediately frozen in ice chilled isopentane at -70°C. Six brainstem regions, zona compacta of the substantia nigra (SN-A_9); nuclei parabrachiales (npb); nucleus raphe dorsalis (dr); locus coeruleus (LC-A_6); nucleus ambiguus (n. Amb.); and the nucleus tractus solitarius (nts-A_2), were removed according to the micropunch technique of Palkovitz (Brain Res., 59:449, 1973). Serotonin (5HT) was measured using the radioenzymatic method outlined by Saavedra, et al. (J. Pharm. Exper. Therap., 186:508, 1976). Dopamine (DA) and norepinephrine (NE) were determined by a modification of the method of Versteeg, et al. (Brain Res., 113:563, 1976).

As in the rat, we found low levels of 5HT at birth in all areas sampled. These concentrations gradually increased, and by day 21 the dr and n. Amb. showed the most dramatic changes, 511% and 468% respectively. Concentrations of DA also were very low at birth, especially so in the pons and medulla (less than 5pg/µg). The highest concentrations were observed in the LC 12pg/µg. By 21 days of age, there were moderate increases in DA, the largest being 366% in the SN.

In contrast, high NE levels were present at birth in the SN 31pg/µg, npb 48pg/µg, the LC 32pg/µg and the nts 23pg/µg; by day 21 the NE had dropped an average of 60%. The largest decrease was 94% in the LC.

These data demonstrate dramatic changes in neurotransmitter concentrations in the brainstem nuclei during postnatal development, and suggest that changes in neurotransmitter synthesis accompany the known changes in brainstem neurologic function. This work thus represents an essential first step in determining the roles and interrelationship of neurotransmitters with the function of neuronal circuits.

131.18 VINBLASTINE INJECTED NEONATALLY PRODUCES A PARTIAL BUT PERSISTENT PERIPHERAL SYMPATHECTOMY IN RATS. G. Jaim-Etcheverry and L. M. Zieher*. Instituto de Biología Celular, Fac. de Medicina, Buenos Aires, Argentina.

The systemic injection of the vinca alkaloid vinblastine (VIN) to adult rodents, seems to destroy the terminal portions of their peripheral sympathetic neurons leaving unaffected the noradrenergic neurons in the brain. The morphological and biochemical alterations in the periphery gradually recover because the cell bodies of the sympathetic neurons are not irreversibly damaged. However, many of these cell bodies are destroyed when VIN is injected to newborn rodents.

To further characterize the alterations produced by VIN in the development of noradrenergic neurons, we studied the long-term effects of a single systemic injection of VIN to rats at 2 days of age (0.25 µg/g, sc) on the concentration of noradrenaline (NA) in the periphery as well as in the brain. Already at 15 days of age, the absolute amount of NA in the superior cervical ganglion (SCG) was depleted but normal values were obtained for NA when expressed per unit weight. This indicates that part of the cells in the SCG were destroyed while those remaining had a normal content of NA. These changes became more evident at 30 and 60 days of age when the content of NA was reduced by 47 %. Marked depletions of NA were found in the heart, salivary glands and spleen at 15 days, an effect that persisted at 60 days when the reduction of peripheral NA was, on average, more than 70 % in comparison with controls. In several brain regions (cortex, brain stem, cerebellum and spinal cord), NA levels were not modified 30 or 60 days after systemic neonatal VIN.

Thus, a single systemic injection of VIN to newborn rats produces a partial but persistent peripheral sympathectomy without affecting noradrenergic neurons in the brain. These seem to be insensitive to the actions of VIN even when the compound is given directly into the brain. Similarities and differences between the effects of VIN and those of neurotoxins that alter the development of central and peripheral noradrenergic neurons, may help to understand the mechanisms involved in this process. (Supported by grants from CONICET, SECYT and Secretaría de Salud Pública, Argentina).

131.19 Neonatal Desmethylimipramine(DMI) and Methysergide(MSG) treatment: Neurochemical responses of serotonergic neurons to L-5-hydroxytryptophan(5-HTP). H. Taub* and D.A.V.Peters*(SPON:R.J.Boegman). Dept. of Pharmacology, Sch. of Med.,Univ. of Ottawa, Ottawa,Ont.

Previous studies in our laboratory showed that several psychoactive drugs as haloperidol, chlorpromazine and lithium alter the development of central 5-hydroxytryptamine(5-HT)-containing neurons in the rat when administered during early postnatal period. In the present study DMI and MSG exposure served as a model with which to investigate further the responses of the brain to potential toxic insults occurring during specified developmental stage.

Newborn Sprague-Dawley rats were given once daily intravenous injections of DMI (15 µg/g), MSG (5 µg/g), or saline (1 µL/g) on days 1 and 2 after birth. No other treatment was given until 21 days of age when subgroups of rats were injected with 5-HTP (30 mg/Kg, i.p.) or its vehicle and killed 60 minutes later. The rat brain was dissected into 8-12 discrete regions and assayed spectrophotofluorometrically for 5-HT and 5-hydroxyindoleacetic acid (5-HIAA).

DMI treatment and to a lesser degree MSG treatment reduced the body growth rate of the offsprings, adrenal, whole brain and cerebellar weights. DMI treatment produced small (20-40%) but significant increases in the 5-hydroxyindole (5-HI) levels in midbrain, thalamus, motor cortex, olfactory tubercle and cerebellum when examined at 3 weeks of age. In contrast, MSG produced small but significant decreases in 5-HI levels of the above regions as well as in the striatum and hippocampus.

To assess the possible adaptive changes in the synthesis of 5-HI following drug exposure, 5-HTP was used. While 5-HTP produced marked elevations in 5-HI levels in all regions examined, the magnitude of the increases were significantly modified by the neonatal drug treatment. The 5-HTP-induced stimulation of 5-HI synthesis was significantly greater (25-127%) in all regions of DMI-exposed rats, and to a lesser extent (29-87%) in several regions of MSG-exposured rats. The data suggests that exposure to DMI and MSG (drugs presumed to differentially modify serotonergic function) during the neonatal period may alter the development of serotonergic neurons differentially. However,it may be tentatively concluded that the underlying enhanced sensitivity of serotonergic neurons may reflect a common mechanism of neurochemical adaptation. One cannot exclude the possibility that DMI and MSG, additionally, modify the development of other central neurotransmitters, i.e. catecholamine-containing neurons, and their possible interaction with serotonergic neurons may be responsible for the observed effects.

131.20 DYNAMICS OF HEAVY METAL CONCENTRATION BY HIPPOCAMPAL MOSSY FIBERS. Richard L. Roth* and John H. Peacock (SPON: D. Kennedy). Hopkins Marine Station of Stanford Univ., Pacific Grove, CA 93950 and Dept. of Medicine, Univ. of Nevada Medical School, Reno, NV 89507.

We have used Timm's sulfide silver method in a semiquantitative way to study postnatal accumulation of heavy metals by hippocampal mossy fibers of laboratory mice. As part of this effort, six logarithmic dilution series of $ZnCl_2$ (range: 9.0-0.001 mM) were mixed with equal volumes of 4% agar and fixed with sulfide-containing formalin. Slices of these zinc standards were processed by Timm's method, and the time required for each specimen to acquire a standard tinctorial quality was recorded. For brain samples, we minimized the influence of factors other than the intended experimental variable by processing the brains of 6-12 animals in tandem, using the same batches of sulfide-containing fixative, buffers and staining solutions.

Over a wide range of concentrations, the time required for visible silvering is related to zinc concentration in an almost perfectly inverse fashion--viz., a doubling of concentration results in an approximate halving of staining time. This stoichiometric relationship permits reliable comparisons of different tissue samples; by concurrent staining of brain slices and zinc standards actual tissue-zinc concentrations can be estimated.

The heavy metal content of mossy fibers is detectable in neonates, increases rapidly between the 5th and 30th postnatal days and continues to increase at a slow rate through at least the 8th postnatal month. Overall there is at least a ten-fold increase in heavy metal content between birth and the 8th month, the most rapid increase occurring between the 5th and 12th postnatal days.

By subcutaneous injection or cardiac perfusion of zinc-containing solutions and by incubation of 0.5 mm brain slices in similar solutions, we have found that the capacity to sequester exogenous zinc is present by the 18th day of gestation, increases slowly over the first 4 postnatal days, increases very rapidly between the 5th and 10th postnatal days and slowly thereafter. Throughout postnatal life hippocampal mossy fibers are capable of taking up several times their normal metal content within 1 min of exposure to 0.75 mM $ZnCl_2$ made up in any of a wide variety of physiological saline solutions.

The energy dependence of heavy metal uptake is indicated by its temperature sensitivity, its diminution by 0.001 mM CCCP and its abolition by 0.01 mM CCCP. 30 mM Ca^{++} modestly inhibits zinc uptake; 4 mM La^{+++} and 0.2 mg% ruthenium red have a strong inhibitory effect, and uptake is abolished by 0.2 mg% verapamil. Mossy fibers appear to be incapable of distinguishing Zn^{++} from many other divalent cations since Cd^{++}, Co^{++}, Cu^{++}, Fe^{++}, Hg^{++}, Mn^{++}, Ni^{++}, Sn^{++}, Sr^{++} and UO_2^{++} are also sequestered.

131.21 BEHAVIORAL TOXICITY OF ETHYLNITROSOUREA AND CORRELATION WITH TRANSPLACENTAL CARCINOGENICITY. S. M. Lasley, R. L. Bornschein*, J. Manson*, and L.S. Rafales*. Kettering Laboratory, University Cincinnati, College of Medicine, Cincinnati, Ohio 45267.

Direct-acting alkylating agents are the most active known transplacental carcinogens, and of these the most potent are the alkylnitrosoureas. Few studies have assessed the developmental and behavioral effects of ethylnitrosourea (ENU) or have compared tissue pathology data to such findings as was done in this work.

On day 16 of pregnancy dams received an i.p. injection of 20 mg/kg ENU dissolved in a trioctanoin oil vehicle or the vehicle alone. Litters were weighed at birth, and individual weights were recorded at days 12 and 22 (weaning), and at other points up to 150 days. Behavioral testing was initiated at 70 days of age and repeated at 4-week intervals--offspring were placed in individual photocell activity cages and responses monitored at 5 minute intervals for 3 hours, the last 2 hours following a 1 mg/kg s.c. dose of D-amphetamine. At death autopsies were performed and major organs retained for gross evaluation. At 9 months of age all remaining animals were sacrificed to obtain a proportion of treated animals that did not display overt toxicity for contrast with animals that had died previously.

At the point of termination of the study 59% of the treated animals had died with a median age at death of 199 days. Neurogenic tumors were localized in the brain (45%) largely related to the trigeminal nerve, and in the spinal cord (43%) almost exclusively in the lumbar region. Analyses of growth curves uncovered treatment effects that differentiated males from females and were more prominent at later ages. Photocell activity measures on animals at 114 days showed that the decline in activity during the 2-hour post-D-amphetamine period was altered in treated animals, and that the activity of males was less than that of females and diminished at a faster rate. Additional analyses showed the decline in activity effect to be present in treated males only. A covariance analysis with body weight as the linear covariate did not alter these findings. The protocol for behavioral testing appears therefore to have value in detecting the neurocarcinogenic effect of ENU before overt toxicity is present.

131.22 DEVELOPMENTAL CHANGES IN PHARMACOLOGICAL RESPONSIVITY OF THE ACOUSTIC STARTLE REFLEX. D.W. Gallager, J.H. Kehne*, and M. Davis. Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508.

Several ontogenic studies have found a general caudal to rostral sequence of neurochemical development of various neurotransmitter systems in the CNS. Data described here using acoustic startle measurements suggests that the pharmacological responsivity of this reflex behavior at different postnatal (P) ages may reflect this caudal to rostral developmental sequence.

In adult rats (P 55 days) systemic administration of the GABA antagonist, picrotoxin (PICRO) produces a dose-related inhibition of acoustic startle. In adult rats intraventricular administration of PICRO produces a marked inhibition of startle. In contrast, intrathecal infusion of PICRO onto the spinal cord enhances acoustic startle. The inhibition of startle observed following the systemic administration of PICRO appears to be a summation of inhibitory supraspinal and excitatory spinal effects of the drug. If caudal systems develop before rostral ones, PICRO should enhance startle responses in the immature rat, reflecting its activity in the spinal cord. To test this, the effects of PICRO were tested at various postnatal ages. At P 15 days, littermates were tested before and after i.p. PICRO or saline. Increases in startle amplitude occurred following 1 mg/kg of PICRO. However, by P 35 days this same dose depressed acoustic startle in the same rats. These data indicate that enhanced startle in immature animals after PICRO probably reflects the spinal actions of the drug.

To test the generality of these findings, comparable studies were done using drugs that act on central 5-HT systems. Recently, different functional effects of 5-HT in rostral and caudal 5-HT systems have been described. In both electrophysiological and acoustic startle experiments 5-HT has inhibitory effects in the forebrain but facilitates transmission in the spinal cord. p-Chloroamphetamine (PCA) releases 5-HT shortly after administration and concomitantly depresses startle in adult rats. If caudal to rostral maturation of the 5-HT system occurs during ontogenesis, increased 5-HT release should activate only the spinal (excitatory) system at ages prior to the completion of forebrain 5-HT synaptogenesis. Consistent with this expectation, 5 mg/kg of PCA increases startle response in P 15 day rats during the 5-HT release period. This effect is completely blocked by pretreatment with the 5-HT synthesis inhibitor PCPA. In contrast this same dose of PCA depresses startle in adult rats during the 5-HT release period, and this effect is blocked by PCPA. Taken together, these results suggest a functional caudal to rostral developmental sequence as measured by pharmacological responsivity of the acoustic startle reflex to drugs acting on two different neurotransmitter systems.

132.1 FIBER ORDER IN THE XENOPUS OPTIC NERVE AFTER QUADRANTIC GRAFTS OF EMBRYONIC RETINA. J.W. Fawcett* and R.M. Gaze* (SPON: S.C. Sharma). National Institute for Medical Research, London NW7 1AA, U.K.

The developing Xenopus eye acquires positional properties, which will later determine the nature of the retinotectal fiber projection, before any axons have grown from the eye rudiment. Shortly afterwards, grafting part of the eye to a different position in another eye has no obvious effect on these properties. Thus fibers from a temporal retinal quadrant will still connect with rostral tectum even when that quadrant has been transplanted elsewhere in the eye. We have been studying the behaviour of fibers from retinal quadrants moved 180° from their original positions.

Xenopus embryos at stages 28 to 31 had ventral, temporal or nasal quadrants removed from their right eyes and grafted in place of the left dorsal, nasal or temporal quadrants of a host of the same age; thus the quadrants were transplanted 180° from their original positions. The animals were grown to metamorphosis, mapped electrophysiologically to check that the implanted fragment was still present, and then had Horseradish peroxidase applied to the implant. Serial sections of the optic nerve and brain were taken and developed with benzidine dihydrochloride to show the course of axons to the tectum.

Fibers from temporal quadrants, transplanted to nasal positions, rotated in the optic nerve relative to the other fibers from the eye and took up a position at the chiasma normally occupied by fibers from temporal retina. Fibers from nasal quadrants, transplanted to temporal positions, in most cases occupied the two areas at the chiasma usually occupied by nasal fibers. However, fibers from ventral quadrants transplanted to dorsal positions showed no consistent behaviour in the optic nerve, often being randomly spread within it at the chiasma. These fibers, however, occupied only the medial brachium of the optic tract. To this extent, at least, they had regained their correct pathways between the chiasma and the tectum.

The optic chiasma must have properties which allow ingrowing fibers from different positions along the nasotemporal dimension of the eye to get to different parts of it. Organization of fibers from different positions along the dorsoventral retinal dimension may occur more centrally in the optic tract.

132.2 VISUALLY GUIDED ORIENTING BEHAVIOR BY RATS WITH EXPANDED IPSILATERAL VISUAL PATHWAYS. G. C. Midgley*(SPON: John P. J. Pinel) Department of Psychology, Univ. of Western Ont., London, Ont. N6A 5C2.

The behavioral and anatomical consequences of neonatal enucleation and subsequent expansion of the intact retinas' ipsilateral visual pathways were examined. The left eye of albino rats (Sprague-Dawley strain) was enucleated on either postnatal day 1 or 21 and their visual behavior made dependent upon the ipsilateral retinal projections by a lesion of the contralateral optic tract as adults. Visually guided orienting behaviors were examined following training to remain motionless for a food reward in a modified perimetry. Slow motion video tapes of the rats orienting behavior to food and other stimuli presented in the four quadrants of the animals' visual field were assessed for accuracy and direction of orienting responses and reaching responses to the food stimuli. The striate cortex ipsilateral to the intact eye was ablated and perimetry testing repeated.

Expansion of the ipsilateral pathway and the extent of the lesion of the contralateral pathway were assessed by injections of [^{3}H] proline in the intact eye and autoradiography. Enucleation on day 1 resulted in significant expansion of the ipsilateral projections while enucleation on day 21 did not. Both the day 1 and day 21 enucleated rats oriented toward and reached for food presented in the upper nasal visual field. The day 1 enculeated rats also oriented and reached for food presented in the lower nasal and lower temporal fields. The initial orienting component of the reaching response was misdirected on most occasions. When the striate cortex ipsilateral to the aberrant retinal projections was ablated the rats enculeated on day 1 made significantly more orienting and reaching responses to food presented in all but the upper temporal field. Misdirected turning was not observed following striate cortex removal. The day 21 enucleated rats did not show this recovery with striate lesions.

Supported by NSERC grants to R. C. Tees(UBC) and NIH grants to R. D. Lund (U. Wash).

132.3 REGENERATION OF A BANDED RETINOTECTAL PROJECTION IN GOLDFISH. S. C. SHARMA and A. D. SPRINGER (SPON: F. E. HORVATH). Depts. of Ophthalmology and Anatomy, New York Med. Coll., Valhalla, N.Y. 10595.

After one tectal lobe is removed in adult goldfish, the severed optic nerve fibers from the contralateral eye regenerate and innervate the remaining ipsilateral tectal lobe. Therefore, the remaining tectal lobe is innervated by both eyes. Initially, efferents from the two eyes are characterized by continuous, overlapping projections over the surface of the tectum. Within 70 days at 30°C these two projections become segregated into alternating "eye-specific" bands oriented rostrocaudally across the tectum. Once the bands have formed, the pattern of banding observed appears to be independent of how long the fish have survived with two eyes innervating one tectal lobe. Segregation of optic fibers into "eye-specific" bands, rather than maintained intermingling of the two sets of retinal fibers, suggests that the retinal fibers of one eye are distinct from the retinal fibers of the opposite eye. Experiments were designed to determine whether the banded retinal projections could impart their differential labels onto tectal cells. Goldfish in which two eyes projected to one tectal lobe for periods ranging from 112-1660 days were used in these experiments. In one group of fish (A), the contralateral optic nerve was crushed and the ipsilateral eye was left intact. In two other groups of fish, the contralateral optic nerve was crushed and the ipsilateral eye was removed at the same time (B), or just before the regenerating fibers reached the tectum (C). The pattern of optic nerve regeneration was examined over a period ranging from 11-70 days post-crush using [^{3}H]proline radioautography. The fish were maintained at 30°C to accelerate regeneration. Regenerating optic nerve fibers in Group A initially formed a continuous projection over the tectum, which later became banded. However, the regenerating optic nerve fibers formed a continuous projection over the tectum at all time points examined in groups B and C. Since a regenerated banded projection was not observed when the ipsilateral eye was removed, it appears that the putative differential retinal labels are not imparted onto the tectal cells.

132.4 FIBER-FIBER INTERACTIONS IN DUALLY INNERVATED TECTA FOLLOWING BILATERAL OPTIC NERVE REGENERATION IN XENOPUS WITH ONE COMPOUND EYE. C. Straznicky and D. Tay* Dept. of Human Morph. Sch. of Med., Flinders Univ. of S.A., Bedford Park, 5042, Australia.

Right compound eyes were formed in Xenopus at stage 32 by the fusion of two nasal (NN) or two temporal (TT) halves of the eye blastema. The left eye was kept intact. Two to four weeks after metamorphosis both the right and the left optic nerves were cut close to the chiasm to facilitate optic fiber regeneration from each eye to both tecta. One to 12 months after bilateral optic nerve sections the retinotectal projections to the dually innervated tecta were assessed anatomically and electrophysiologically. ^{3}H-proline was administered either into the right or left eye of the animal. In a few cases one eye had ^{3}H-proline the other eye had HRP injections. Twenty four to 48 hours after isotope and HRP administration the visual projections from each eye to both tecta were mapped electrophysiologically.

Retinotectal projections from TT eyes, determined autoradiographically and electrophysiologically, failed to cover the entire extent of the contralateral and ipsilateral tecta. The caudomedial area of each tectum (normally receiving nasal retinal fibers) was consistently uninnervated. The NN projection in some of the animals extended across the entire tectum, while in others they were restricted to the caudomedial part which is the normal destination of nasal fibers. The left normal eye projections extended over the entire tecta in all TT and NN eye animals. Both the compound eye and normal eye maps were orderly, projecting retinotopically in a superimposed fashion to the tecta. In areas where the compound eye and the normal eye projections overlapped eye-specific terminations bands were found. Double ^{3}H-proline and HRP labeling revealed mutually exclusive right and left eye termination bands extending in a rostrocaudal direction over part of the tecta. No banding was observed in areas which were innervated only by the left intact eye. The patterns of retinotectal projections were similar in animals with shorter or longer regeneration time.

These observations show that the tectal distribution of fibers from a compound eye is selective and that at least the greater part of the overlapping projections are in register as far as their retinotopic order is concerned. We suggest that the underlying mechanism is fiber-fiber interactions in the forms of recognition of the like fibers and of competition for preferred tectal termination. Supported by an Australian Research Grants Committee grant to CS.

132.5 WHOLE MOUNT VISUALIZATION OF BAND DEVELOPMENT IN THREE-EYED TADPOLES. M. Constantine-Paton, M. I. Law and P. Ferrari-Eastman*. Dept. of Biology, Princeton Univ., Princeton, NJ 08544.

Addition of a third eye primordium to the forebrain region of embryonic frogs (Rana pipiens) causes two retinas to innervate one optic tectum where their terminals segregate into highly sterotyped eye-specific stripes (Constantine-Paton, M. and Law, M. I., Science 202: 639, 1978; Law, M. I. and Constantine-Paton, M., J. Neurosci., in press, 1981). We have studied the development of this pattern in tadpole and young frog brains after horseradish peroxidase (HRP) application to the cut stump of either the normal or the supernumerary optic nerves.

We have used a diaminobenzidine histochemical procedure (Fugisawa, H. et al., Brain Res. 206: 21, 1981) that allows visualization of HRP filled retinal axons and terminals in whole brains. The development of the frog's visual pathway using this method was identical to that reported with 3H-proline autoradiography (Currie, J. and Cowan, W. M., Devel. Biol. 46: 103, 1975). In the earliest brains examined, the retinal projection was restricted to the anterolateral pole of the tectal lobe. It expanded with age in a medial and caudal direction to fill all but a caudomedial strip of the tectal surface by metamorphosis.

Three-eyed tadpoles show the same expansion of retinal projections within their doubly innervated tectal lobes. Supernumerary or "normal" eye projections were distributed as ≃ 200 micron wide stripes in the anterior tectal regions even in the youngest animals examined. These stripes were oriented perpendicular to the expanding edge of the retinal terminal zone but they ended abruptly at its caudomedial border. At higher magnifications, this region showed low densities of uniformly distributed optic fibers. Lack of segregation in such immature tectal areas may be due to low innervation density and to the lack of differentiated tectal cells.

In a few three-eyed animals, a small complement of supernumerary eye fibers entered the second tectal lobe. Banding did not occur in these partial projections at low innervation densities. At high innervation densities, these second tectal lobes showed a few bands. At intermediate levels non-continuous "patches" of supernumerary eye terminals were observed. These patches were arranged in a pattern that had the same orientation and spacing as stripes. Thus, given a certain threshold level of optic nerve fibers, bands seem to progressively form around discrete elements that are probably intrinsic to the optic tectum.

132.6 MORPHOMETRIC EXAMINATION OF COMPETING RETINAL PROJECTIONS IN THREE-EYED FROGS. M. I. Law and M. Constantine-Paton. Dept. of Biology, Princeton University, Princeton, NJ 08544.

The effects of competition were morphometrically examined in the optic tecta and retinas of three-eyed tadpoles. The supernumerary eye in these animals co-innervates one tectal lobe and disrupts the normal eye's continuous projection, producing 200μ wide, eye-specific bands of neuropil (Constantine-Paton and Law, 1979, Science 202: 639-41). Volume measurements indicate that super-innervated tecta are ~ 30% enlarged, with most of the hyperplasia confined to cellular tectal layers. Moreover, volumes of neuropil occupied by either co-innervating retina are reduced by 46-59% relative to the neuropil volume of the singly-innervating optic tract in the same animal (Law and Constantine-Paton, 1981, J. Neurosci., in press). These results suggest that retinal ganglion cells (RGC) of competing eyes must either compress their terminal arbors or die at higher than normal rates.

Cell counts which sampled all three retinas in several frogs revealed fewer RGCs in co-innervating eyes compared to the host's normal retina. A reduction of 9-21% was observed in the competing host eye versus the non-competing eye of the same animal. This contrasts with less than 1% difference in the two normal retinas of an animal whose third optic nerve did not grow into the brain. The RGC reduction in co-innervating eyes is not sufficient to account for the large decrease in the neuropil volume occupied by their terminals. This suggests that some increase in optic fiber density may also be present in doubly innervated lobes.

There are potentially two components of competition in these tecta: competition between compressed fibers of the same projection and competition between similarly-specified axons from the two different eyes. The latter would be expected to occur primarily in areas of overlap between the eye-specific bands. We have now directly measured this overlap by differentially labelling the two projections with ^{3}H-proline autoradiography and HRP. The average area of overlap ranged between 100-800μ^2 in different animals. This represents ~ 5% of any single band's total area.

Overlap values may vary with the relative densities of the two projections or with the visual environment in which the animal is raised. Thus, this information will provide a background necessary to determine if the effects of binocular competition are separate from the effects of binocular segregation in three-eyed frogs.

This was supported by NIH grant EY01872.

132.7 "OCULAR DOMINANCE" COLUMNS IN GOLDFISH, ONTOGENY AND EFFECT OF VISUAL ENVIRONMENT. Ronald . L. Meyer. Dept. Developmental-Cell Biol., Univ. Calif., Irvine, CA 92717.

Fascicles of optic fibers supplying dorsocaudal optic tectum were teased free of surrounding tectum and back to the anterior tectal pole near their exit from the medial brachium of the optic tract. These were then deflected into a large mediolateral incision made across the anterior end of the contralateral "host" tectum. This latter incision also severed the host fibers (cf Meyer, JCN 183: 883, 1979). Regeneration of host and deflected fibers was followed with autoradiography by injecting one eye with tritiated proline at 2 to 12 weeks after surgery. At 2-4 weeks both sets of fibers were spread throughout dorsal tectum, completely overlapping. At 6 weeks deflected fibers began to show local condensations of label and host fibers showed regions of lighter than normal label. By 8 weeks most deflected fibers were restricted to several clumps in dorsocaudal tectum while in this same region host fibers showed gaps in their otherwise continuous distribution of label. Some light label outside the clumps (deflected) or within the gaps (host) persisted but by 12 weeks had decreased to that seen previously at longer intervals (Meyer, ibid.). Thus host and deflected fibers appeared to be largely or completely segregated. These fish had been maintained in diurnal illumination.

To examine the effect of visual stimulation, fish with identical surgery and autoradiography were subjected to three different visual environments. One group was kept in total darkness in a standard aquarium for 2-12 weeks. In two other groups the individual fish were maintained for 8 weeks in 1000 ml round bottom boiling flasks having long necks and turned upside down. Fish lived in the spherical portion and were subjected to one of two environments. In one, the inside of the flask was painted with black polka-dots of various size against a white translucent background. Illumination was continuous. In the other group the flask was carefully made to be a homogeneous translucent white. The sole illumination was an overhead strobe operating at 6 hz. The autoradiographic results from these 3 groups could not be distinguished from that of the diurnal group.

It is concluded that segregation represents active sorting out of left and right optic fibers and that the mechanism is resistant to changes in the pattern of impulse activity and may not be due to impulse activity at all. An underlying left-right neurospecificity of optic fibers should be entertained as a serious possibility. (Supported by PHS Grant NS15381.)

132.8 ALTERATIONS IN THE CROSSED RETINOTECTAL PROJECTION DURING DEVELOPMENT OF THE CHICK. S. C. McLoon. Dept. of Anatomy, Medical University of South Carolina, Charleston, S.C. 29425.

Previous work has shown that a transient ipsilateral retinofugal projection is present during early chick development (McLoon and Lund, '80). This suggested that the visual system may initially develop broadly distributed projections which are subsequently refined to the adult pattern. It was not known whether this early projection was broad only with respect to laterality or if there was also a broad distribution of fibers within a target nucleus as well. This was approached in an earlier study in which partial ablation of an optic cup resulted in no retinal projection to a portion of the contralateral tectum at 18 days of development (Crossland et al., '74). The region of the tectum lacking innervation corresponded topographically to the ablated region of the eye. We have examined embryos at earlier developmental stages which had received similar ablations to determine if transient projections develop from the remaining portion of the eye to inappropriate regions of the tectum. A superior-nasal or inferior-nasal retinal quadrant of embryos was ablated on the third day of incubation. On embryonic day 10, 12, 14 or 16 an injection of horseradish peroxidase (HRP) was made into the partial eye. After an appropriate survival time the embryos' brains were fixed, sectioned and reacted with tetramethyl benzidine and hydrogen peroxide. Based on the distribution of HRP reaction product, a significant projection from the injected eye was identified in the contralateral tectum. For 10 and 12 day embryos the heaviest projection was to portions of the tectum corresponding topographically to the remaining portion of the eye. However, a light projection was also found in the tectal quadrant corresponding to the ablated retinal quadrant. By 14 days of incubation no projections could be identified in the region of the tectum corresponding to the retinal ablation. In another series of 10 and 12 day old embryos the partial eye ablations were made 0, 12 or 24 hours prior to the HRP injection. In these animals a projection was also identified from the remaining retina into areas of the tectum appropriate for the ablated retinal quadrant. These results suggest that during early development of the chick visual system, areas of the retina project broadly across the contralateral tectum. The results from the partial retinal ablations made just prior to the HRP injection suggest that these broad projections are present normally and were not induced by early lesions. Between 12 and 14 days of incubation, the retinotectal projection is refined leaving a tightly ordered topographic map. The broad distribution of retinal fibers on the tectum during early developmental stages suggests that an orderly ingrowth of optic fibers alone is not a sufficient mechanism for establishing the proper topography in the retinotectal system. (Supported by grant EY03314 and EY03713 from the National Institutes of Health)

132.9 DEVELOPMENT OF THE NUCLEUS ISTHMI IN XENOPUS LAEVIS. Susan B. Udin. Div. Neurobiol., State Univ. of NY, Buffalo, NY 14214.

The nucleus isthmi (NI) is a relay for the ipsilateral visuotectal projection in the frog, Xenopus. The nucleus receives retinotopic input from the tectum and projects topographically to both tecta. The topographic pattern of the crossed isthmotectal projection is influenced by visual experience during development; for example, mid-larval eye rotation induces abnormal isthmo-tectal topography (Keating and Udin, 1979, J. Physiol., 300:63P). To help understand how orderly connections between the NI and the tecta arise, the development of the NI in normal Xenopus is being studied.

The NI can be unambiguously identified by stage 53, when it acquires the characteristic structure of a "shell" of cells surrounding a relatively cell-sparse core. There are about 200 cells in the NI at stage 53. By stage 57, there are over 1000, and by the early 60's stage, just prior to metamorphic climax, the adult number of about 2000 cells is reached.

To study cell birthdays, tadpoles of different ages were injected with ^{3}H-thymidine and allowed to survive past metamorphosis. Autoradiographic results show that there is a spatiotemporal gradient of development, with cells born at about stage 29 occupying ventral NI and those born at stage 56 occupying the dorsomedial NI. (Similar results are reported by Tay and Straznicky, 1980, Neurosci. Lett., 16:313.) However, a few cells born between stages 52 and 56, plus many cells born between stages 58 and 62, occupy positions scattered throughout the nucleus. These cells may be glia.

Injections of horseradish peroxidase (HRP) show that there are connections between tectum and NI as early as stage 53. The tecto-isthmic and uncrossed isthmo-tectal projections are quite substantial, but the crossed isthmo-tectal projection is still sparse at this stage. Thus, the anatomical connections for ipsilateral visuatectal activity are present--in limited numbers--well before such activity is first found electrophysiologically, at around stage 60. The first cells which project from the NI to the opposite tectum lie in the ventral NI, the earliest-born region. However, cells in this position do not normally project to the earliest-born parts of the contralateral tectum, and a simple scheme of matching newly-generated NI cells with newly-generated tectal cells during growth cannot be invoked to explain normal connectivity of the crossed isthmotectal projection.

132.10 CHANGES IN RESPONSE PROPERTIES OF SINGLE UNITS IN THE SUPERIOR COLLICULUS OF STROBOSCOPICALLY-REARED RABBITS. Helen E. Pearson and E. Hazel Murphy. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Our laboratory has recently reported that restricting early visual experience to a stroboscopically illuminated environment results in a modification of receptive field properties in the striate cortex of the rabbit with the most striking change being a loss of direction selectivity in orientation selective cells (Pearson, H. E., Berman, N. and Murphy, E. H., Devel. Brain Res. 1981). In the present study, we have investigated the effects of early stroboscopic rearing on receptive fields in the rabbit superior colliculus.

Single unit recordings were made from 194 neurons in the superior colliculus of rabbits raised from birth in a stroboscopically illuminated environment. These data were compared with 265 neurons recorded in the superior colliculus of normal rabbits.

The receptive field properties of strobe reared rabbits were significantly different from those of normals. In strobe reared rabbits there was a profound loss of direction selectivity. There was also an increase in the percentage of units preferring the offset rather than the onset of flashed stationary stimuli, and an increase in receptive field size. In addition, the two groups differed in their responses to stroboscopic stimulation. Compared to normals, the units recorded in strobe reared rabbits showed an increase both in the percentage of units which responded to stroboscopic flashes, and in the percentage of units whose responses to their optimal stimuli were inhibited by the simultaneous presentation of stroboscopic flashes.

Our study indicates that strobe rearing causes a significant alteration of response properties in the rabbit superior colliculus. These changes are strikingly similar to those which we have previously reported (Graham, Berman and Murphy, ARVO Abstr. 1981) in the superior colliculus of the rabbit following ablation of the visual cortex. This suggests that modification of corticotectal influences plays a major role in strobe-induced alterations of rabbit superior colliculus response properties.

132.11 NEONATAL VISUAL CORTICAL ABLATIONS ALTER RETINOTECTAL PROJECTIONS IN HAMSTER. R. W. Rhoades, D. C. Kuo, and J. D. Polcer*. Dept. of Anatomy, CMDNJ-New Jersey School of Osteopathic Medicine and Rutgers Medical School, Piscataway, NJ 08854.

Autoradiography and the anterograde transport of horseradish peroxidase (HRP) were used to examine retinotectal projections in normal hamsters and in animals subjected to ablation of most of the dorsal, posterior neocortex at 1, 3, 6, 10 or 120 days of age. The results obtained from the normals were in good accord with previous reports from this and other laboratories. In both the autoradiographic and HRP material, label was observed throughout the superficial laminae of the colliculus contralateral to the injected eye, and was most dense in the dorsal two-thirds of the stratum griseum superficiale. In the autoradiographic material the ipsilateral projection was restricted to a series of discrete patches in the rostral third of the stratum opticum and a few labelled fibers in the zonal layer. In the tissue processed for HRP the ipsilateral projection appeared much more extensive, and labelled fibers could, in most cases, be traced to the posterior collicular boundary.

The crossed retinocollicular projection in the brain damaged hamsters did not differ markedly from that in the normal animals. A small increase in the density of the labelling in the ventral portion of the stratum griseum superficiale was visible. Very clear differences were observed in the uncrossed retinal projection to the colliculus ipsilateral to the damaged hemisphere. In the autoradiographic material, numerous labelled fibers could now be traced into the posterior one-half of the colliculus, and in many cases such fibers were visible at the caudal limit of the tectum. In sections processed for HRP, the incidence of labelled fibers in the posterior part of the colliculus was much greater than in the tissue from normal hamsters. These changes were most pronounced in the hamsters lesioned on postnatal days 3 and 6, but were clearly visible in material from all of the neonatally brain damaged animals.

In additional experiments, HRP was deposited into the colliculus ipsilateral to the damaged cortex to determine whether or not neonatal cortical ablations altered the distribution of ipsilaterally projecting retinal ganglion cells. Comparison of the resultant data with those from identically treated normal controls indicated that neonatal cortical damage did not alter the distribution of ganglion cells which contributed axons to the ipsilateral retinotectal pathway.

132.12 ANALYSIS OF GOLDFISH OPTIC NERVE SPECIFIC PROTEINS DURING REGENERATION. W. Quitschke* and Nisson Schechter. Departments of Biochemistry, Psychiatry and The Long Island Res. Inst., SUNY-Stony Brook, New York 11794.

The process of axonal growth and synapse formation can be studied in the regenerating retinotectal pathway of goldfish. Previous analysis of proteins from optic nerve and tectum by 2D-gel electrophoresis revealed a cluster of proteins enriched in the retinotectal pathway. Furthermore, specific components of the cluster disappeared or diminished after optic nerve disconnection. Following optic nerve crush their levels are restored to normal concomitant with return of vision (Brain Res., 201, (1980) 347-360). This report is concerned with the in vitro synthesis of these proteins using ^{35}S-met. Pooled control and experimental tissues were removed and incubated in HEPES minimal salt medium in the presence of ^{35}S-met. The tissues were homogenized in 0.5% SDS and acetone extracted. The protein was solubilized in a buffer containing 0.05M Ches buffer pH 9.5, 2% SDS; 1% DTT, 10% Glycerol and 5mM PMSF. Two-dimensional gel electrophoresis was performed as described by O'Farrell. Autoradiograms were obtained by exposing the stained and dried gels to x-ray film for 7 days.

The coomassie blue stained gels of the optic nerve revealed a cluster of four well separated components. Upon optic nerve disconnection two of the four components disappear completely. The same two components are restored to control levels 60 days after optic nerve crush. The other two components remained unchanged after optic nerve disconnection. The cluster is also present in the retina, but at a level barely detectable by coomassie blue staining. The levels of the components in the retina appear unaffected by optic nerve disconnection. Autoradiograms of the optic nerve show that the two components which are unaffected by optic nerve disconnection are labeled whereas the components sensitive to disconnection remain unlabeled. Results from retinal incubations show that the two components which disappear from the nerve after crush are indeed labeled. The synthesis of these components is significantly enhanced after optic nerve crush. The interpretation of these experiments is based on the assumption that protein synthesis does not take place within axons. Consequently, the in vitro synthesis must involve non-neuronal cells of the optic nerve.

It appears that the two components which are unaffected by optic nerve crush and which are also synthesized in the optic nerve are indeed of non-neuronal origin. The components which disappear from the optic tract upon disconnection are labeled in retina, but not in optic nerve. Thus, they are likely to be synthesized by the retinal ganglion cells and localized to the optic nerve axons.

132.13 OPTIC NERVE HYPOPLASIA INDUCED BY KAINIC ACID: A CHICK EMBRYO MODEL. A. Suburo and H. Campaña*. Instituto Multidisciplinario de Biología Celular (CONICET-CIC). CC 403. 1900 La Plata. Argentina.

Optic nerve hypoplasia --as described in human beings-- is characterized by a reduced number of axons in the optic nerve of an eye showing an otherwise normal structure. The developmental mechanisms underlying this defect need further study, both for prevention of the defect and for the understanding of visual pathway morphogenesis. We report here a similar anomaly produced in chick embryos by a neuronal toxic administered at a stage when only a fraction of the total ganglion cell population has developed.

Six day-old embryos received kainic acid (Sigma, 3 mg per embryo) through a window in their shells. Their retinas were dissected after different survival times. Right retinas were flat-mounted and stained with 0.1% cresyl violet and left ones were silver impregnated (Goldberg, S., Stain Technol., 47, 65, 1971). The latter were observed with scanning electron microscopy. Controls received Hank's solution and were processed in the same fashion.

Kainic acid produced lesions in most cells lying in the layer of ganglion cells. After four hours, some cells had been completely destroyed leaving heterochromatic debris. The remaining cells showed nuclear dilatation and loss of cytoplasmic basophilia.

Kainic acid treated retinas reached the same size as control retinas, in marked contrast with the general underdevelopment of the neural tube. The ganglion cell layer of 18 day-old retinas showed a normal structural organization, i.e.: the different morphological classes were distributed in the appropiate central, nasal and temporal patterns. Cell density appeared to be the same, but the bigger ganglion cells did not attain control sizes. On the contrary, there was a marked reduction in the layer of optic fibres, its thick bundles being replaced by an incomplete layer of fibres. All the axons, however, extended in the direction of the nerve-head. The latter had the same length as in controls, but its width was reduced.

Thus, the death of a considerable number of neurons at an early period of development did not change the morphogenetic program of the retina. Besides, it seems that those cells differentiating after the administration of kainic acid were able to find the correct pathway, at least up to the nerve-head.

132.14 REAGGREGATED EMBRYONIC RETINAE DIFFERENTIATE AND FORM CONNECTIONS AFTER TRANSPLANTATION TO HOST RAT BRAIN. L. K. McLoon, R. D. Lund and S. C. McLoon. Dept. of Anatomy, Medical University of South Carolina, Charleston, S.C. 29425.

This study was undertaken to examine the role of initial cell-cell associations in the differentiation and formation of connections by central nervous system during development. Embryonic day 14 neural retinae were dissociated into single cells and reaggregated into pellets. The reaggregated tissue was cut into pieces and transplanted over the left superior colliculus (SC) of newborn rat hosts. One month later the brains of the host were examined. Host SC were injected with HRP, and transplants were examined for labeled cells. In six host rats a lesion was placed in the transplant, and degeneration methods were used to determine the distribution of connections made by the transplant with the host brain.

The reaggregated retinal transplants differentiated in the host brain. All the laminae of intact retinae were discernible and organized as rosettes or sheets. The transplants were located on the anterior surface of the cerebellum, and fiber bundles were grossly discernible coursing from the transplant over the inferior colliculus to the SC. HRP injected into the host SC retrogradely labeled a population of cells in the transplants. The labeled cells were found in the lamina corresponding to the ganglion cell layer and displayed a morphology characteristic of normal ganglion cells. Lesions of the transplants resulted in degeneration along the fiber bundles that exited the transplants. The fiber bundles were traced into the SC where degeneration was distributed throughout the superficial layers. Electron microscopic examination of the host SC confirmed the presence of degenerating synaptic terminals resembling those seen after eye removal in control rats. Degeneration was also traced into the dorsal terminal n., posterior pretectal n., olivary pretectal n. and the caudal portion of the dorsal LGN. These projections are all to nuclei that are normally retinorecipient.

It appears that the disruption of normal cell-cell associations early in retinal development and prior to transplantation did not adversely affect its subsequent ability to differentiate and form appropriate connections with the host brain. (LKM is NEI fellow EY05394. Supported by NEI grant EY03414.)

132.15 A NEW, IMPROVED QUANTITATIVE EM TECHNIQUE FOR DETERMINING THE NUMBER OF SYNAPSES PRESENT IN A VOLUME OF BRAIN TISSUE. J. J. Norden and J. A. Freeman. Dept. of Anatomy, Vanderbilt Univ. School of Medicine, Nashville, TN 37232.

Use of quantitative EM techniques is providing an increasingly definitive insight into the phenomena of synaptic formation, regulation, and plasticity. Common to such studies is the necessity of obtaining accurate counts of the number of synapses present in a given volume of brain tissue. We have compared the following quantitative EM techniques currently in use: 1) direct counting of synapses from photographic montages; 2) morphometric point-counting techniques; and 3) "on-line" counting of synapses at the electron microscope. While each of these methods has advantages, they all tend to be exceedingly time-consuming, especially if large areas or many animals must be sampled. Furthermore, the use of photographic montages for some of these methods is quite costly.

For these reasons, we have developed a new method based on statistical and stereological principles. A pseudo-random sample is made of the number of synapses present in a succession of EM viewing windows. A running tally of the standard error of the mean is computed, and in this way the minimum number of samples is determined necessary to insure a given criteria of accuracy. Additionally, we have derived correction factors to compensate for errors due to finite section thickness, grazing sections, and the overlapping of synaptic profiles in adjacent thin sections. These corrections are necessary before the number of synapses (number per volume) can be estimated from the areal density determined from counting the number of synapses in ultra-thin sections, since the average size of the synapse (as computed from serial reconstructions) is significantly larger than the thickness of the ultra-thin section. Finally, to compute the true number of synapses in a given volume from areal density requires obtaining volume information, for which we have developed a geometric method of general applicability. Volumetric density is then computed from areal density using stereological principles.

Each of the techniques described above were compared in terms of time, cost, reliability, and accuracy, using synaptic counts obtained from the optic tecta of long-term enucleated fish and amphibia. The random sampling method gave far superior results in terms of these criteria. The results of this analysis also clearly showed that without applying correction factors for errors due to finite section thickness, grazing, overlap and volume changes, none of the techniques for counting the number of synapses currently in use can be used to accurately determine the true number of synapses present.

133.1 A COMPARISON OF FUSIMOTOR EFFECTS FROM STATIC AND DYNAMIC GAMMA EFFERENTS OBSERVED WITH INTEGRATED ACTIVITY IN THE MUSCLE NERVE. K. S. K. Murthy, Lorie M. Shapiro* and Chaudhry Saleem*. Div. of Neurosurgery, Univ. of Texas Med. Sch., Houston, Tx. 77030.

Static and dynamic fusimotor actions due to γ efferents are definable with a recording of their effects on a single muscle spindle Ia afferent. However, each γ efferent is known to innervate a number of muscle spindle receptors. It may then be expected that an observation of fusimotor effects on the integrated multiple afferent activity would also help to differentiate the two types of γ efferents. The present study demonstrates a lack of correlation between the effects observed on a single afferent and that on multiple afferents in the case of dynamic γ efferents.

Experiments were performed on cats anesthetized with sodium pentobarbital. In each experiment one of the following muscles was studied - peroneus brevis (4 experiments), peroneus tertius (2 experiments), peroneus longus (2 experiments) and soleus (1 experiment) with the rest of the limb denervated. Dorsal and ventral roots L_7-S_1 were cut close to the cord. Between 4 and 14 Ia muscle spindle afferents in each experiment were isolated in dorsal root filaments and monitored for classification of fusimotor actions with single γ efferents that were isolated in ventral root filaments. Each γ efferent thus isolated and classified was investigated for effects on the multiple afferent activity recorded from the whole muscle nerve. The multiple unit activity in the muscle nerve was processed through a level detector adjusted for recording only the large action potentials from spindle afferents, rectified and integrated with a rate meter (time constant 3 msec). The level detector ensured that the smaller action potentials of the stimulated γ efferent were rejected. In each case, the effects were studied on the afferent response to a standard "ramp and hold" stretch (2mm at 10 mm /sec) and a brief, low amplitude vibration (< 100μ, lasting 20 msec).

A total of 103 static γ efferents and 11 dynamic γ efferents were studied with 91 Ia afferents. Both with large amplitude muscle stretch and the small amplitude vibration the effects of static γ stimulation on the integrated muscle nerve activity were qualitatively similar to the effects observed on a single afferent. The most remarkable difference was that with dynamic γ stimulation the effects on integrated muscle nerve record were different from that observed on a single afferent, but appeared qualitatively similar to static γ effects.

Supported in part by funds from NIH grants # NS-14702 and # NS-15012.

133.2 HISTOCHEMICAL EVIDENCE FOR THE ADEQUACY OF THE PHYSIOLOGICAL TESTS FOR IDENTIFYING FAST-CONDUCTING SKELETOFUSIMOTOR (β) EFFERENTS. W.E. Cameron, W.D. Letbetter, K.S.K. Murthy and J. Petit*. Div. Neurosurgery, Univ. Texas Med. Sch., Houston, TX 77030 & Dept. Anatomy, Emory Univ. Med. Sch., Atlanta, GA 30322.

Fast-conducting skeletofusimotor (β) efferents of the cat hindlimb muscles have been identified by using a combination of four different physiological tests (Jami et al., Neurosci. Abstr. 6:395, 1980). These tests are: 1) the occurrence of "unfused oscillations" in the instantaneous frequency of the afferent when the stimulation frequency was increased beyond the level required for complete fusion of the extrafusal tension; 2) the occurrence of an abrupt increase in afferent discharge in response to a step increase in stimulation frequency of the efferent fiber without a concomitant increase in extrafusal tension; 3) the demonstration of fusimotor action of the efferent during a concurrently applied muscle stretch; and 4) the maintained increased level of afferent discharge in the absence of muscle tension due to failure at the extrafusal endplate resulting from high frequency stimulation. The present study provides histochemical evidence that these tests are more than adequate for establishing the existence of skeletofusimotor (β) innervation and, in fact, that only the first three tests are required.

Experiments were performed on adult cats anesthetized with sodium pentobarbital. Up to eight group Ia muscle spindle afferents from the peroneus tertius muscle were isolated in split dorsal root filaments. Single motor axons with conduction velocities > 90 m/sec were isolated from split ventral root filaments. Those motor axons which caused an increase in the discharge of one or more of the afferents when stimulated with a brief tetanic train were retained for further investigation. In the first experiment, all four criteria were applied to the efferent. In the subsequent three experiments, only the first three criteria were used for identification. The beta efferent from each experiment was classified according to its "fatigue index" and then subjected to a stimulus regime designed to deplete the innervated muscle fibers of their glycogen. At the end of the experiments, the muscle was frozen for histochemical processing. Alternate transverse sections were stained for myosin ATPase and glycogen content.

In each case (N=4), there was evidence of glycogen depletion of extrafusal fibers as well as intrafusal muscle fibers within a number of muscle spindles. It was concluded based on glycogen depletion results that the first three criteria mentioned above were sufficient for identification of fast-conducting skeletofusimotor (β) efferents.

(Supported in part by USPHS grants NS14702 and NS15012.)

133.3 EFFECTS OF ALTERED AFFERENT SIGNALS UPON THE LOAD COMPENSATING RESPONSES AT THE HUMAN WRIST. R.J. Jaeger, G.L. Gottlieb, G.C. Agarwal, and A.J. Tahmoush. Depts. of Physiology and Neurology, Rush Medical College, Chicago IL 60612, and Bioengineering Program, Univ. of Ill., Chicago IL 60680.

A variety of electromyographic (EMG) activity has been described between the latency extremes of a tendon-tap reflex and a visual voluntary reaction time. The exact nature of these responses has been very controversial, especially with regard to their classification as reflex, triggered, or voluntary activity. One aspect of these responses that has not yet been fully clarified is their dependence on afferent input.

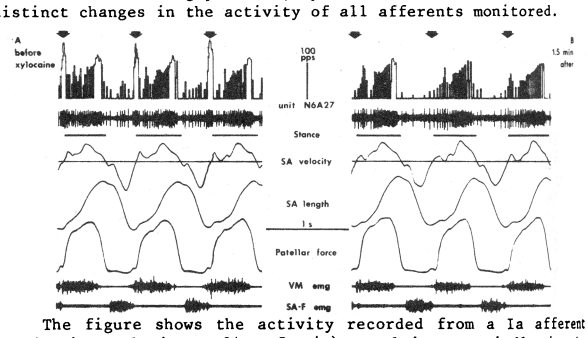
Step torque perturbations were applied to flex or extend the wrists of normal human subjects who were instructed to restore the joint to its initial position as soon as possible. The resulting EMG activity was recorded from the flexor carpi radialis and ulnaris and the extensor carpi radialis. Data were collected under four different conditions: 1) normal, 2) with vibration (50-120 hz) applied to the muscle tendon, 3) with ischemia induced in the forearm, and 4) with a local anaesthetic block of the ulnar nerve at the elbow.

The normal data was subdivided into four intervals: myotatic, late myotatic, postmyotatic, and stabilizing (voluntary) responses; the normal responses are treated in a companion abstract. Vibration reduced the myotatic response to between 10% to 60% of normal; the other responses were unchanged. Ischemia completely abolished the myotatic and late myotatic responses, with subsequent responses enhanced (up to 200% of control) or reduced (down to 25% of control). Ultimately, complete ischemic nerve block was obtained. Local anaesthetic produced varying degrees of block. During complete nerve block, all EMG activity was abolished. During mild nerve block, slight impairment of cutaneous sensations was noted. During moderate nerve block, alterations in cutaneous sensations and differential effects on the EMG were observed. EMG activity before 120 ms was attenuated much more than activity after 120 ms. Also, after complete nerve block by ischemia or local anaesthetic, a differential recovery of the responses was seen.

Evaluating these results in terms of currently accepted actions of the three procedures used and the behavior of the normal responses suggests that each of the load compensating responses has its own unique dependence on afferent information. Since individual motor units have been suggested to participate in one and only one phase of load compensation (Bawa and Tatton, Exp Br Res 37:417, 1979) it is possible that each response is a manifestation of a separate load compensating system. (This work was supported by NSF grant ENG-7608754 and NIH grants NS-00196 and NS-12877)

133.4 EFFECT OF FUSIMOTOR BLOCKADE ON DISCHARGE PATTERNS OF CAT HINDLIMB SPINDLE PRIMARIES DURING WALKING. J.A. Hoffer and G.E. Loeb. Lab. of Neural Control, NINCDS, Bethesda MD 20205.

Conduction in small-diameter nerve fibers can be selectively interrupted by local anesthetic infusion. Using implanted nerve recording cuffs fitted with catheters, we administered 2 ml of 0.3% Xylocaine to the femoral nerve of cats walking on a treadmill. In the next few minutes spindle afferent unit activity (recorded by wire microelectrodes implanted in the fifth lumbar dorsal root ganglion) reflected progressive stages of functional spindle deefferentation. Individual spindle afferents had very characteristic firing patterns; Xylocaine infusion caused marked, distinct changes in the activity of all afferents monitored.



The figure shows the activity recorded from a Ia afferent (conduction velocity = 94 ± 5 m/s) supplying a spindle in the proximal part of sartorius pars medialis (SA-F; hip and knee flexor). Normal activity during walking (A) typically included a few spikes during flexion (in spite of rapid muscle shortening), a sharp burst just prior to foot contact (arrows), and a smooth acceleration during the extension phase of gait. The sharp burst started when the muscle reached minimum length; however, its amplitude was not well correlated with velocity of subsequent stretch. Firing rates during the extension phase appeared to signal primarily muscle length. Xylocaine infusion obliterated the sharp burst (B: arrows) whereas activity during the extension phase appeared unchanged. We infer that during the flexion phase, this spindle was normally under the influence of strong static gamma bias. Dynamic gamma influence appeared slight in this unit.

Spindle afferent activity patterns have so far been too heterogeneous to summarize simply. However, this technique has allowed us to distinguish between activity generated by "passive" stretch and that caused or augmented by fusimotor input.

133.5 CORRELATION ANALYSIS OF MUSCLE SPINDLE AND TENDON ORGAN AFFERENTS IN ACTIVE MUSCLE. Connie E. Osborn and Marc D. Binder. Dept. of Physiol. and Biophys., Univ. of Washington Sch. of Med., Seattle, WA 98195.

While the ensemble behavior of a muscle's tendon organ and spindle populations closely match the parameters of whole muscle activity, individual receptors are more strongly influenced by the state of their local environment. Ia, spindle group II and Ib afferents exhibit their greatest sensitivity in the lowest range of length or tension changes and are each strongly correlated with the activity of a discrete fraction of the muscle's total motor unit populations, presumably those units in the immediate area of the receptor (Binder and Stuart, Prog. Clin. Neurophysiol., 8:72, 1980). Consistent with this view are studies by Windhorst and colleagues which demonstrated that in decerebrate cats Ia afferents innervating neighboring spindles responded to similar tension transients (as measured at the tendon) and showed strong correlations in their discharge. Afferent pairs innervating spindles widely separated in a muscle showed much less, or no correlation at all(Biol. Cyber., 31:71, 1978). We have attempted to test the generality of proximity-dependent correlations by examining the discharge of spindle group II and Ib afferents as well as Ia afferents in both decerebrate cats (N=2) and decapitate cats treated with L-Dopa and nialimide (N=10). Pairs of afferents from medial gastrocnemius were functionally isolated from small dorsal root filaments and the location of the corresponding receptors approximated by gentle probing of the muscle. Tension fluctuations in the muscle occurring either spontaneously or in response to manually or electrically evoked crossed extension, or by electrical stimulation of ventral roots were simultaneously recorded. Of the 49 afferent pairs tested (6 Ia-Ia;7 II-II;8 Ia-Ib;10 Ia-II;12 Ib-II) 14 (28%) showed significant temporal correlations in their discharge pattern. While some of the strongly correlated pairs were in closely apposed areas of muscle, several were not, and in general proximity was a poor predictor of the degree of correlation. We found that tension transients measured at the tendon were sometimes associated with specific patterns of correlated discharge, but not always. Of particular interest were 5 of the 12 Ib-II afferent pairs which displayed negative correlations, suggestive of the "dyad" receptor arrangement described by Marchand et al. (Anat Rec. 169:23, 1971), but again these correlated pairs were not always located close together in the muscle. Our results suggest that even though two receptors may appear to be in close proximity, they may not be responsive to the same set of motor units.(Supported by NINCDS Grants NS 15404 and NS00345, BRS Grant RR 05432 and GM 07108)

133.6 PROJECTIONS OF INDIVIDUAL MEDIAL GASTROCNEMIUS SPINDLE GROUP II AFFERENTS TO TYPE-IDENTIFIED MOTONEURONS. J.E. Zengel, J.B. Munson, J.W. Fleshman and G.W. Sypert. Dept. of Neuroscience, Univ. of Florida, Gainesville, Florida 32610.

Sypert et al (1) have suggested that medial gastrocnemius (MG) group Ia and spindle group II afferents may comprise one continuous functional system, organized in adherance to a size principle. Accordingly, we examined the projections of individual spindle group II afferents to type-identified MG motoneurons using the spike-triggered averaging technique. The results of this study were then compared to those previously described for Ia afferents (2).

Twelve single MG spindle afferent fibers from 9 cats were examined (2). Ninety-five motoneurons were classified into motor types based on muscle unit responses (3): fast twitch, fatigue-sensitive (FF); fast twitch, fatigue-resistant (FR); and slow twitch, fatigue-resistant (S).

Motor unit type:	FF	FR	S	Significance
Connectivity	53%	46%	52%	NS
EPSP amplitude (μV)	22	34	23	NS
Input Resistance (MΩ)	0.6	0.9	1.3	< .001

Mean afferent conduction velocity was 56 m/s. Connectivity was closely related to afferent conduction velocity: fast afferents (> 56 m/s) had high connectivity (66%) while slow afferents (< 56 m/s) had low connectivity (33%), similar to results from a previous study (1). This supports the idea that larger spindle afferents make synaptic contacts with more motoneurons than do smaller afferents. Unlike Ia afferents, the mean amplitude of single fiber EPSPs elicited by spindle group II afferents is unrelated to afferent conduction velocity (25 μV for fast vs. 23 μV for slow afferents), as previously reported (1).

Neither connectivity nor EPSP amplitude appear related to motor unit type, in contrast to Ia-motoneuron projections (2). Furthermore, there was no relation between EPSP amplitude and input resistance (R_N), suggesting an equal density of group II-motoneuron synapses over the range of motoneuron sizes. Overall there was no significant relation between R_N and connectivity; however those cells with the highest R_N (> 1.4 MΩ) had very low connectivity (3/19 = 16%).

The projections of MG Ia and spindle group II afferents to MG motoneurons share many but not all principles of organization.

133.7 DO JOINT RECEPTORS AFFECT MOTONEURONE EXCITABILITY IN MAN? K. Robinson, A.J. McComas and A.Y. Belanger, Department of Neurosciences (Room 4U 7), McMaster University Medical Centre, Hamilton, Ontario L8N 3Z5.

It is known that excitability of human soleus motoneurones, as measured by H-reflex testing, is diminished if the foot is dorsiflexed. Experiments have been undertaken to determine whether this effect is due to altered discharge from receptors in the triceps surae muscle and Achilles tendon, on the one hand, or from those in the joint capsule, on the other. The principle of the method has been to compare the result of ankle dorsiflexion with that of lengthening the muscle by displacing the Achilles tendon towards the tibia, the ankle joint being fixed in mid-position. A needle was inserted into the soleus belly and allowed to tilt in front of a protractor as the Achilles tendon was depressed or as the ankle joint was dorsiflexed. The amounts of dorsiflexion and of tendon depression were adjusted to cause the same change in the inclination of the needle; the elongation of the muscle and the subsequent activation of muscle receptors must have been similar in the two situations. Since the depression of the H-reflex was also similar in the two types of manoeuvre, it would appear that any effect of the joint receptors was relatively minor. Control experiments, including the use of local anaesthesia of the skin overlying the Achilles tendon, served to exclude the possibility that cutaneous mechanoreceptors had contributed significantly to the observed results.

134.1 WALKING BEHAVIOUR OF A ROCK LOBSTER ELICITED BY A DOUBLE TREADMILL. F. Clarac* (SPON: R. R. Almon). Lab. de. Neurobiologie, 33120 Arcachon, France.

In the rock lobster, Jasus lalandii, forward or backward walking can be elicited by a treadmill with separate belts for the left and right legs respectively. Belt speed is controlled by two independent motors which can also be coupled. While walking under these conditions, the animal uses mainly its back legs (3, 4 and 5). EMG's were recorded from the basal muscles of these legs (promotor or remotor, levator or depressor).

When both belts move at the same speed, the two sides stay in absolute coordination. If the two belts move at different speeds, contralateral legs continue to walk at the same or at a slightly different step frequency (relative coordination). If the difference between the belt speeds is too great, however, the two sides of the animal become completely uncoordinated. It is also possible to evoke forward walking on one side and backward walking on the other when the belts move in opposite directions. These contralateral variabilities observed with the treadmill can also be recorded during free walking when the animal is involved in complex motor sequences such as turning or changing the direction of walking.

It can be concluded, therefore, that in the crustacean walking system, although the two sides can operate independently, there must also be functional couplings which maintain a certain degree of bilateral coordination. The main factors involved in this coordination are the durations of returnstroke and powerstroke and the amplitude of the stride.

134.2 INNERVATION OF FLIGHT MUSCLES IN THE TSETSE FLY. David G. King. Dept. of Anatomy, Sch. of Medicine, Southern Illinois University, Carbondale, IL 62901.

Among the best understood aspects of the thoracic nervous system of Muscoid flies are the motor innervation of the dorsal longitudinal muscle and the interneuronal initiation of jumping and flight. The six dorsal longitudinal muscle fibers are innervated by five motor neurons. These neurons are indirectly activated by the giant axon descending in the cervical connective from the brain. This same interneuronal giant axon also activates, by direct electrical connection, the motor neuron which innervates the jump muscle, or tergotrochanteral muscle (Tanouye & Wyman 1980, J. Neurophysiol. 44:405-421). Mutants of Drosophila are now known which affect several aspects of this system (J.B.Thomas 1980, Neurosci. Abs. 6:742). Evolutionary modification of this system in other flies may also be expected.

The similarity of this system in the flies so far studied (including Drosophila, Musca and Calliphora, representing three families) suggests a very conservative evolutionary history. However in the related tsetse fly, Glossina morsitans, previous workers have reported two notable differences: absence of the tergotrochanteral muscle (Smart 1959, Smithson. Misc. Coll. 139: 331-364) and four rather than five large axons in the nerve which innervates the dorsal longitudinal muscle (Anderson 1978, J. Morph. 155:19-34). In the present study the nerve to the dorsal longitudinal muscle was found to contain five distinctly large axons, rather than the four reported by Anderson. Thus in this respect the tsetse is in fact similar to other flies. However, the absence of the tergotrochanteral muscle was confirmed. In mutants of Drosophila which lack this muscle as adults, the muscle nonetheless develops in the pupa and then degenerates; the motor axon which innervated the degenerated muscle remains present in the adult. In contrast the tsetse shows no sign of this muscle ever forming. Furthermore, careful anatomical analysis of serial sections yielded no evidence for any component of the entire giant fiber pathway. Neither the descending cervical giant fiber, the peripherally synapsing interneuron, nor the tergotrochanteral motor axon was found. If any of these neurons is present, it does not display the characteristic defining morphology described by King & Wyman (1980, J. Neurocytol. 9:753-770).

It will be of considerable interest to observe the physiological activation of the dorsal longitudinal muscle in the tsetse fly, which apparently lacks the giant fiber pathway.

(Specimens were provided by the Tsetse Fly Research Laboratory, Langford, Bristol, England.)

134.3 IDENTIFICATION OF FLIGHT NEURONS IN THE COCKROACH PERIPLANETA AMERICANA. R.E. Ritzmann, C.R. Fourtner and A.J. Pollack.* Dept. of Biology, Case Western Reserve Univ., Cleveland, OH 44106 and Department of Biological Sciences, SUNY at Buffalo, Buffalo, N.Y.

Recent studies indicate that flight in P. americana can be reliably initiated by activity in the dorsal giant interneurons (dGIs) (Ritzmann et. al, Science, 210:443, 1980). The identifiable nature of dGIs makes this a potentially advantageous preparation for studying control of oscillatory behaviors. However, we must first increase our understanding of the neural flight apparatus that is involved.

We have begun to identify neurons in the meso and metathoracic ganglia (T_2 and T_3) that are active during flight. Neurons were impaled with glass microelectrodes filled with Lucifer Yellow. Flight was initiated by a brief wind puff or by stimulating a dGI. The flight rhythm was monitored with EMG electrodes placed in known wing muscles (Fourtner and Randall, Neurosci. 6:369, 1980). Neurons displaying depolarizations correlated with the flight rhythm were injected with Lucifer Yellow. The ganglion was then fixed and cleared for observation with a fluorescence microscope.

We have located several flight motor neurons and interneurons in both T_2 and T_3. Cell bodies of motor neurons tend to be located in the anterior region of the ganglion. In most cases axons exit the ganglion in nerves 3a, 4 and 6. Within the neuropile of T_2 and T_3 fibers of flight motor neurons tend to project medially up to but not beyond the midline. Other fibers project into the posterior region of the ganglion. We have also been able to identify the muscles innervated by some of these neurons by dissecting fine branches of motor nerves as they enter known flight muscles, and backfilling these branches with Lucifer Yellow. The resulting filled neurons can then be compared with intracellularly filled neurons. For example, two homologous flight motor neurons have been impaled in T_2 and T_3 from which activity synchronous with wing depressor muscles was recorded. They have been identified in backfills as innervating wing depressor muscles 135c (T_2) and 177c (T_3).

In addition to motor neurons, we have also located several interneurons that are active during flight. Some of these cells are restricted to one ganglion, but most have axons in interganglionic connectives. These may be involved in coordinating flight rhythms between ganglia.

134.4 INTRACELLULAR ANALYSIS OF THE LOCUST FLIGHT SYSTEM. R.M. Robertson and K.G. Pearson, Department of Physiology, University of Alberta, Edmonton, Canada.

The numerous studies by D.M. Wilson and his colleagues during the 1960s on the flight system of the locust played an important part in the development of the concept of central programming of motor activity. More recently, however, there has been little interest in this system due to the apparent difficulty of obtaining information about the cellular events underlying the generation of the flight rhythm. In this presentation, we describe a simple preparation which readily allows intracellular recording from thoracic interneurons and motoneurons during flight, and the identification of interneurons providing some of the synaptic drive to flight motoneurons.

During flight, there are large amplitude oscillations (15 to 25 mV) in the membrane potential in the main neuropile processes of flight motoneurons, but the form of these oscillations is not identical in elevator and depressor motoneurons. The basic flight cycle consists of an elevator-depressor-pause sequence with a rapid depolarization of depressors corresponding to a rapid hyperpolarization of elevators. Depolarization of elevators is relatively slow. Elevator and depressor motoneurons also respond differently to stimuli which initiate and maintain flight (e.g., wind on the head). Elevators are strongly depolarized and most depressors are hyperpolarized.

By simultaneously recording intracellularly from interneurons and flight motoneurons, we have succeeded in identifying interneurons which make monosynaptic connections to the flight motoneurons and provide some of the tonic and phasic synaptic input to these motoneurons during sustained flight. We have also identified a large number (>20) of other interneurons whose activity is strongly modulated during flight but whose output connections remain to be determined. The striking feature of these interneurons is the heterogeneity in their structure and their electrical properties. We conclude that the patterning of locust flight activity involves the interaction of large numbers of interneurons, and is considerably more complex than suggested by all previous models of this system.

134.5 SEGMENTAL DISTRIBUTION OF VENTILATORY CONTROL MECHANISMS IN AN AQUATIC INSECT. S. C. Kinnamon*, G. K. Fitch*, K. L. Bellah* and A. E. Kammer (SPON: P. Kelly). Division of Biology, Kansas State University, Manhattan, KS 66506.

Rhythmic movements involving segmentally arranged groups of muscles are controlled by a series of central oscillators coupled by coordinating interneurons. We expect such serially homologous local oscillators to have similar properties. In Cordylalus cornutus, an insect with 7 pairs of segmentally arranged abdominal gills, this expection is not fulfilled. The abdominal ganglia differ in their ability to generate rhythmic output when isolated and in their responses to stimuli.

Selective cutting experiments show that both segments 2 and 3 possess oscillators that are active in isolation from other segments and in the absence of sensory input. These two oscillators when isolated produce rhythmic bursts of impulses in the motor root supplying the gill retractor muscle, but their frequencies often differ. Under our experimental conditions other ganglia will not generate a rhythm unless connected to ganglion 2 or 3.

Hypoxia (8% O_2) increases ventilatory frequency in an animal with an intact nervous system. This effect is readily reversible upon return to normoxia. When ganglia are isolated by cutting roots and connectives, neither ganglion 2 nor 3 respond to hypoxia. When the ventral nerve cord is cut between 1 and 2, ganglia 2 through 7 fail to respond to hypoxia, but ganglia 1 and 2 isolated together exhibit a hypoxic-mediated frequency increase from 28 to 39 beats/min, similar to that of intact preparations. These results suggest that the ventilatory response to hypoxia is mediated by receptors in ganglion 1 influencing the oscillator in ganglion 2 and perhaps 3.

Frequency modulation by sensory input was examined by stimulating a ventral nerve that contains primarily afferents from the gill. In isolated ganglion 3 or ganglion 3 plus any other ganglia, a single electrical stimulus to the sensory nerve in segment 3 advances the next motor burst in all ganglia connected to 3, and the oscillator in 3 is reset. The rhythm can be driven at a frequency greater than the unstimulated frequency by single pulses delivered rhythmically. Similar stimulation of the homologous sensory nerve in any other segment does not reset the rhythm or modulate its frequency.

Octopamine dramatically increases the ventilatory frequency of preparations with an exposed but intact ventral nerve cord. Preliminary results suggest that octopamine also has different effects on the diverse abdominal ganglia of this insect. These results suggest that various inputs act via different neural pathways and on different oscillators to modulate the ventilatory rhythm. (Supported by NSF Grant BNS 79-23096.)

134.6 INTERACTIONS OF VENTILATORY RHYTHM GENERATORS AND SENSORY MODULATION OF THEIR OUTPUTS. G. K. Fitch* and A. E. Kammer. Division of Biology, Kansas State University, Manhattan, KS 66506.

Abdominal segments 1 through 7 in the aquatic insect Corydalus cornutus have pairs of gills which are retracted in a specific metachronal sequence with a frequency which remains relatively constant over short periods of time. The ventral root on either side of an abdominal ganglion has two anatomically distinct branches, one carrying motor output to the corresponding gill and one carrying sensory information to the ganglion. It has been shown previously that each gill retraction is caused by a burst of spikes which travel to the gill retractor muscle via a single motor neuron in the motor branch of the ventral root. Extracellular recordings from this branch allow monitoring of the patterned output.

Ganglia of abdominal segments 2 and 3 are each capable of generating the ventilatory motor pattern when isolated from all other parts of the CNS. In addition, neither requires sensory input to produce the rhythm. During normal ventilation the oscillator in ganglion 3 is the principal one responsible for motor output. This result is intuitively consistent with the gill retraction sequence, which is segment 3, then 4, 5, 6, 7, 2, and 1.

Electrical stimulation of the sensory branch of ganglion 3 has dramatic effects. A single pulse delivered during the last 70% of the expected interval between motor bursts will advance the next burst. The interburst interval can be halved if the stimulus is properly timed. Stimuli delivered during the first 30% of the expected interburst interval have no effect on the timing of the next burst. The lag between a stimulus and the onset of the burst advanced by it becomes slightly less as the stimulus is delivered later in the expected interburst interval.

Analysis of successive interburst intervals suggests that such stimuli reset the oscillator rather than merely advance one burst in the motor neuron. The rhythm can be driven at frequencies greater than the unstimulated frequency by single pulses delivered in a rhythmic fashion. This effect cannot be produced if the stimulation frequency exceeds the unstimulated ventilation frequency by more than about 20%.

The gills on segments 1 and 2 sometimes miss one beat entirely. Data from this relative coordination between segments can be used to evaluate models of pattern generators, in an effort to clarify the mechanisms by which rhythmic behaviors are coordinated.

134.7 PATTERNED SPIKE TRAIN ANALYSIS AND SPIKE-TRIGGERED AVERAGING OF CRAYFISH POSTURAL MOTONEURON ACTIVITY. W.G. Tatton and S.K. Wernham*, (Spon: J.K. Stevens) Playfair Neuroscience Unit, University of Toronto and Division of Medical Physiology, University of Calgary.

Existing techniques for spike train analysis or spike-triggered averaging treat each action potential in the presynaptic train as an indistinquishable event despite the fact many neurons fire in bursts or other stereotyped patterns of action potentials. We have explored patterned spike train analysis using the motoneurons in the abdominal postural system of the crayfish. Suction electrode recordings were made from the axons of the six flexor motoneurons simultaneously with intracellular recordings from single fibers of the polyinnervated slow postural muscles. Computer programs allowed specific patterns to be extracted from the motoneuron spike trains and specified spikes within the patterns to serve as point events in the analysis.

The EJP's and IJP's for each of the six motoneurons were spike-trigger averaged from the intracellular records in order to determine their magnitude and distribution to individual muscle fibers using conventional techniques. Facilitation in the EJP's generated by the F6 motoneuron was compared for naturally-occurring F6 burst patterns of two to four spikes. Facilitation ratios and the calculation of half wave areas for the EJP's revealed that patterns of four spikes with interspike intervals of 7.0 msec resulted in at least three times the increase in EJP size for the 4th spike as compared to 10.0 msec interspike intervals. The patterned analysis also provided a means of assessing the contribution of temporal summation of EJP's generated by different motoneurons to the apparent facilitation. This was shown to contribute minimally, if at all, to the increase in EJP size. The non-linear increase in EJP size with pattern length and small decreases in interspike intervals was entirely masked by conventional single spike averaging.

Intracellular recordings have established that F6 motoneurons make weak reciprocal excitatory connections with the contralateral F6 in the same ganglion. Due to the bursting patterns of the motoneurons, the firing probability alterations indicative of these connections are not detectable in cross-correlation histograms constructed for F6-F6 extracellular spike trains. Patterned analysis "extracted" the crosscorrelation peak for the F6-F6 connection and showed that the F6 firing was influenced most strongly by the 3rd and 4th spikes in the patterned bursts. These results illustrate that conventional spike train analysis and spike-triggered averaging techniques may fail to accurately reflect the "strength" or even to reveal the existence of neural connections. (Supported by MRC grant 5218)

134.8 INTRACELLULARLY OBSERVED COUPLING AMONG MOTOR NEURONS: A BASIS FOR PATTERN FORMATION. J.H. Koenig and Kazuo Ikeda, City of Hope Research Institute, Duarte, CA. 91010.

A salient characteristic of the in-flight firing pattern produced by the dorsal longitudinal flight muscle (DLM) fibers of Drosophila melanogaster is that no fiber fires immediately after any other. It has been suggested that this "exclusion" phenomenon is due to interactions between the DLM motor neurons (MN) but disagreement exists on what type of interactions might produce this effect. Wyman (1969) proposed that it is caused by mutual inhibition among the motor neurons, while Koenig and Ikeda (1980) suggested that it is due primarily to an "excitatory" effect which synchronizes the firing times of 2 MN's when they should have fired one right after another. In order to resolve this question, intracellular recordings were made from the DLM motor neurons as described below.

In the DLM, a firing pattern among the fibers which is very similar to the output pattern that occurs during flight can be induced by temperature (26°C) in the single-gene mutant, $shibire^{ts1}$ (Koenig and Ikeda, 1980). While monitoring this temperature induced firing pattern by simultaneous intracellular recordings from the DLM fibers, intracellular recordings were made from the motor neurons (which singly innervate these fibers). The motor neuron was identified by its corresponding activity to one of the DLM fibers, and by horseradish peroxidase injection after the recording.

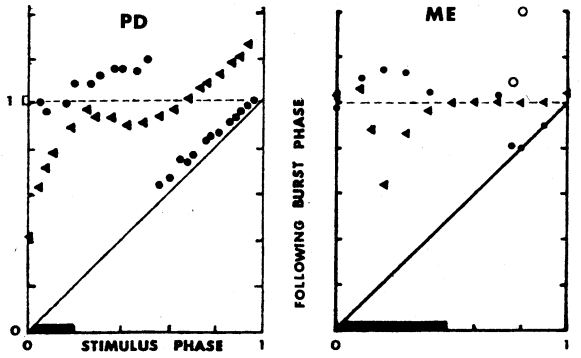
A DLM motor neuron response consisted of a slowly rising prepotential followed by a spike. The motor neuron recording revealed an apparent electrical coupling between the DLM motor neurons. Thus, a spike in another MN (observed at the muscle level) appeared as an attenuated spike in the intracellularly recorded MN. Although the coupling was weak, it was possible to strongly stimulate one DLM motor neuron and cause another DLM motor neuron to fire. This coupling was stronger between certain pairs of neurons.

The data supports the suggestion of Koenig and Ikeda (1980) that a weak electrical coupling between motor neurons whose spikes are preceded by a slowly rising prepotential, could cause the "exclusion" phenomenon observed in the DLM pattern by synchronizing the firing times of 2 MN's which would have fired one right after another. (Supported by USPHS, NIH Grant NS-07442).

134.9 PERTURBATION RESPONSES OF ENDOGENOUS AND NETWORK-DERIVED BURSTING PATTERNS. D. K. Hartline, D. V. Gassie, Jr., and C. D. Sirchia, Bekesy Lab, University of Hawaii, Honolulu, HI.

Responses to perturbations are shown for an endogenously bursting neuron (PD, lobster stomatogastric ganglion) and two computer generated network models, whose bursting is an emergent property of the network (two-cell reciprocal inhibition, RI, and 2-cell mutual excitation, ME). A continuous-output (non-spiking) model was used (Hartline, Roberts & Baker, Neurosci. Abstr. 6: 406, 1980). The figure shows timing of the burst following the perturbation for brief depolarizing (●) and hyperpolarizing (▲) pulses to the PD (left; 5 nA, 50 msec) and ME net (right: perturbation area = 1.5; ρ = 1/3; ξ = .2; γ = .7, Hartline et al. loc. cit.). Moderate depolarizing pulses at early phase (with respect to burst onset) hasten burst terminations and promote earlier occurrence of the next in both models and some PD cases. As stimulus phase increases, a delay followed by an advance is typical. Moderate hyperpolarizing pulses at early phase which "terminate" a burst cause timing advances (otherwise often a delay). In models without "rebound", midphase pulses have little effect, whereas in PD cells and models with rebound a "paradoxical" region of timing advance may intervene before the typical late-phase delay. Similarities are apparent between the two network models and the PD cells, but details vary. Models and burster share other features of a regenerative process, such as an "N"-shaped I-O curve in an "output-clamped" situation.

PD cell responses are similar to those of other endogenous bursters (Pinsker, J. Neurophysiol. 40: 527, 1977). Similarities in responses of the two network models indicate that care is needed in using such behavior to distinguish mechanisms for burst origin. Supported by NIH NS 15314.



134.10 DESCRIPTION OF IDENTIFIED SIPHON MOTONEURON ACTIVITY IN INTACT APLYSIA BY SPIKE TRAIN ANALYSIS. Lewis Eberly and Harold Pinsker, Marine Biomedical Institute, Depts. of Physiology & Psychiatry, UTMB, Galveston, Texas 77550.

We have utilized quantitative techniques to examine neuronal activity accompanying simple behavioral acts in the marine mollusc, Aplysia californica. Using a combined approach involving chronic recordings from freely behaving animals, then intracellular recordings from identified neurons, we have described the activity of identified units in the intact animal under different behavioral conditions.

The experimental approach involves simultaneously monitoring behavioral events in the siphon and neuronal activity in the siphon nerve of intact animals after implantation of a two-channel extracellular cuff electrode. After monitoring spontaneous activity and the responses to stimuli, animals are surgically reduced for intracellular identification of siphon motoneurons. A computerized spike train analysis is used to characterize the population of efferent units in the siphon nerve based on spike amplitudes and conduction velocities. Since the same unitary population can be recognized in the reduced preparation where the intracellular identifications are made, we are able to identify siphon motoneurons in samples from the intact animal.

During spontaneous background activity in the intact animal, the LBS cells typically fire at a low rate, cells LDS1, LDS2 and L7 fire more rapidly and LDS3 is usually silent. Short bursts of neuronal activity, not associated with overt siphon movements, frequently involve firing in only a single neuron. After surgical reduction for intracellular experiments, fewer individual units are spontaneously active. The remaining activity is more homogeneous and rhythmic with fewer short bursts in individual units. Spontaneously occuring Interneuron II (INT II) bursts, normally characterized by a brisk pattern of firing in the intact animal, become frequently prolonged and less intense after dissection. Furthermore, abnormally heightened postimulus activity often occurs in the reduced preparation, far outlasting the stimulus (20-30 sec).

Since the activity of identified neurons in the reduced preparation can be substantially different from that in the intact animal, a neuronal event described in the reduced preparation may not be relevant to the natural behavior in the intact animal. We are currently extending the analysis to describe other stimulus effects, including the involvement of individual neurons in response to stimuli of different intensities and the successive presentation of weak stimuli. (Supported by NSF grants 77-25584 and 80-16421 and NIH grants 16087 and 11255).

134.11 ISOLATION INDUCED CHANGES IN HELISOMA BUCCAL GANGLION NEURONAL ACTIVITY. V.J.Waks* and C.H.F.Rowell (SPON: G.Wesley Davis). Dept. of Zoology, UCB, Berkeley, Cal. 94720.

The effect of isolation on the firing pattern of selected buccal ganglion neurons was examined in the freshwater snail, Helisoma trivolvis. Representative feeding network cells, cell 4 and protractor motorneuron P19 were recorded intracellularly before and after section of the cerebrobuccal connectives (CBCs), nerve trunks connecting the buccal ganglion to both the periphery and the rest of the central nervous system. Firing patterns of the two cells were then examined for changes in interburst interval(IBI), and spike rate(the number of spikes produced/time).

CBC section consistently resulted in a statistically significant decrease in P19 IBI, accompanied by a reduction in variability of IBI values. Reported spontaneous rhythmicity in isolated Helisoma buccal mass preparations is then commensurate with increased burst rate in P19 and more rapid alternation of bursts in protractor/retractor MN pools. The induction of spontaneous rhythmic network output by nerve section suggests that the expression of bursting is regulated or inhibited by descending higher order control elements.While CBC section significantly changed the overall patterning of P19 bursts, this effect was not accompanied by the production of more spikes/time in recorded cells.

The activity of cell 4, which innervates the salivary glands, was unaffected by isolation at the levels of patterning or number of spikes produced/time. The absence of overt change in cell 4 activity does not preclude the existence of subtle, subthreshold responses and supports previous reports of a highly labile functional relationship of this cell within the feeding network.

134.12 ELECTROTONIC STRUCTURE & SYNAPTIC INTEGRATION IN IDENTIFIED NEURONS. D.H. Edwards. Dept. of Zoology, U. Calif., Davis, CA 95616.

The integrative properties of a neuron can only be understood in the context of a description of the electrotonic structure of the cell. My colleagues and I have developed a set of techniques for describing the electrotonic structure of neurons, and I have used these techniques to analyse the synaptic integrative properties of members of a set of identified neurons in the crayfish, the fast flexor motorneurons that mediate the tail flip.

The fast flexor inhibitor motor neuron has a large cell body that is connected by a thin neurite to a large, contralaterally projecting integrating segment. The integrating segment gives rise to ipsilateral and contralateral dendrites, and a large contralateral axon. Analysis of the electrotonic structure of this neuron suggests that the large cell body and the large axon act as current sinks at either end of the integrating segment. The analysis predicts that inputs on dendrites ipsilateral to the soma will evoke large, fast-rising EPSPs in the soma and smaller, more slowly rising EPSPs near the axon. EPSPs arising from inputs on contralateral dendrites will have the opposite relation at the two sites. This prediction has been verified for the responses to identified presynaptic neurons. Another prediction, that the contralateral inputs (which evoke the smaller EPSPs at the soma) will more readily fire the cell, is currently being tested.

A similar analysis for a fast flexor excitor motor neuron predicts that the same input addressed to different dendrites will evoke the same pattern of EPSPs at the soma, integrating segment and axon. In this cell, ipsilateral and contralateral dendrites converge on the same region of the integrating segment. The analysis suggests that synaptic currents will be modified in similar ways during their passage inward along different dendrites, and will thereby give rise to a similar pattern of potentials following convergence at the integrating segment. This prediction is currently being tested.

134.13 EVIDENCE FOR NON-MODULATORY OCTOPAMINERGIC TRANSMISSION MEDIATING LUMINESCENCE IN LARVAL FIREFLIES. T. A. Christensen and A. D. Carlson*. Department of Neurobiology & Behavior, S.U.N.Y., Stony Brook, New York 11794.

The terminal abdominal ganglion (A_8) of larval Photuris versicolor fireflies contains a consistently identifiable cluster of four dorso-medial somata, each approximately 25 μm in diameter. A primary neurite arises from each soma and bifurcates only once within the neuropil sending an axon through both the right and left ventro-lateral nerve roots. The four axon pairs travel within their respective roots to the periphery where they terminate within the photogenic tissue of the paired larval lanterns, located on the lateral margins of the eighth abdominal sternite. The neurons from which these four symmetrical pairs of axons arise therefore fit the description of true dorsal unpaired median (DUM) neurons.

Antidromic stimulation of the DUM neurons through either nerve root causes the lantern innervated by the contralateral root to glow. Moreover, both lanterns glow synchronously in response to intracellular stimulation of a single DUM neuron. In either stimulating condition, a weak single shock stimulus is sufficient to elicit a detectable glow response. However, a brightening of the glow response is always associated with increased firing frequency as recorded from the DUM neurons.

The effect of DUM neuron stimulation is mimicked by superfusion of octopamine (OA) over the lanterns at a threshold concentration between 10^{-5} and 10^{-6} M. Furthermore, the receptors mediating the glow response are optimally sensitive to OA and its N-methylated derivative, synephrine. The receptors resemble those of the α-adrenergic class in that the glow response is blocked by chlorpromazine but not by β-adrenergic antagonists.

Treatment with d-amphetamine, reserpine or denervation of the lanterns two days prior to OA application does not diminish the glow response. Furthermore, high concentrations of the putative insect neurotransmitters glutamate, ACh, 5-HT and GABA are unable to induce glowing.

In a series of preliminary experiments performed in collaboration with R. E. McCaman, whole terminal abdominal ganglia as well as isolated and pooled DUM somata were assayed for their OA content. Between 0.1 and 0.2 pmol of OA was found within each ganglion and at least part of this OA was localized within the DUM somata.

Here we report the identification of four OA-containing DUM neurons that bilaterally innervate the two larval lanterns. This is the first report of octopaminergic DUM neurons in Coleopteran insects, and demonstrates a function for DUM neurons in the direct activation of firefly photogenic tissue.

134.14 GENETIC DISSECTION OF THE DROSOPHILA GIANT AXON PATHWAY. Gadi Benshalom* and Daniel Dagan*. (Spon: Chien-Ping Ko). Section on Functional Neuroanatomy, NINCDS, NIH, Bethesda, MD 20205 and Faculty of Medicine, Technion, Haifa, Israel.

A genetic dissection of the Drosophila giant axon pathway was done to clarify some obscure features of this neural pathway, through which electrical stimulation of the cervical connective evokes electrogenic responses of the thoracic, indirect flight muscles. Gynandromorph flies mosaic for the $para^{ts}$ mutation ($+ w^{vc} +/y\ w\ para^{ts}//y\ w\ para^{ts}/0$), with an external y w mutant phenotype involving only their entire thorax, or a mirror image half of their head, or thorax, or both head and thorax, were selected for study. The recessive, x-linked, temperature-sensitive paralytic mutation, $para^{ts}$ causes paralysis of mutant flies at elevated temperature. A neural conduction block, upon elevation of temperature, was expected only in the neural components of these gynandromorph flies, which originate from mutant, paralytic regions. Intracellular recordings of the neurally-evoked electrical responses of the thoracic indirect flight muscles revealed a functional coupling between the left and right giant axon pathways of the Drosphila: all ipsilateral and contralateral muscle fibers of the dorsolongitudinal muscles (DLMs) of any wild type or $para^{ts}$ fly responded at room temperature to cervical stimulation with a common, sharply-defined excitation threshold; in $para^{ts}$ mutant flies, all the neurally evoked DLM fiber responses were always blocked simultaneously at elevated temperature and recovered simultaneously upon cooling. This functional coupling between the giant axon pathways could not be abolished at restricted temperatures in any of the bilateral gynandromorph flies. On the contrary, the DLM fibers on both sides of each gynandromorph fly always responded uniformly, mostly as in normal but sometimes as in $para^{ts}$ flies. Picrotoxin (10^{-4} M), induces spontaneous activity of neural origin in both DLMs and dorsoventral muscles (DVMs). In addition to the normal response to cervical stimulation, a delayed evoked response is recorded coincidently from fibers of both muscle systems. Analysis of the interaction between these spontaneous and evoked electrogenic responses in wild type flies, supports the notion that both DVMs and DLMs share a common activating pathway. Applying picrotoxin to the gynandromorph flies exposed the existence of additional neuronal elements, that can activate flight muscles in response to cervical stimulation. Intracellular recordings from gynandromorph flies of the $para^{ts}$ mutation exhibited a poor correlation between the mosaic external phenotype of these flies and the genotype of certain neural pathways. Nevertheless, these mosaic flies were found useful to confirm the presence of at least one interneuron in the giant axon pathway activating the DVMs.

135.1 THE ORGANIZATION OF LIMBIC CORTICAL EFFERENTS IN THE ALVEUS-FIMBRIA-FORNIX COMPLEX OF THE MONKEY. Steven Demeter and Gary W. Van Hoesen. Department of Neurology, Division of Behavioral Neurology, and Anatomy, University of Iowa College of Medicine, Iowa City, IA 52242.

Tritium labeled amino acids (leucine, lysine, proline) were injected into the hippocampus, the entorhinal (Brodmann area 28) and posterior parahippocampal (Bonin and Bailey areas TF and TH) cortices and other limbic areas in 17 monkeys (Macaca mulatta). After seven day survivals, the brains were processed in the standard manner for autoradiographic tracing.

Labeled axons arising from allocortical regions coursed through the fimbria to reach the splenium. In contrast, axons from the proisocortical posterior parahippocampal gyrus coursed through the alveus to reach the splenium, mostly without traversing the fimbria. Periallocortical fibers from the entorhinal cortex took an intermediate course, overlapping with adjacent fibers. This relationship was maintained in the splenial portion of the alveus-fimbria-fornix complex. Allocortical fibers from the fimbria assumed the most lateral position. Axons from proisocortical regions coursed most medially. Periallocortical axons maintained their intermediate position.

Surprisingly, few fibers from allocortical and periallocortical regions decussated in the hippocampal commissure. Instead, these fibers crossed the midline throughout the body of fornix. Decussating as well as ipsilateral fibers maintained their relative positions throughout their course in the fornix. The hippocampal commissure was observed to be primarily composed of proisocortical posterior parahippocampal axons, rendering this designation inaccurate.

135.2 FRONTAL LOBE AFFERENT INPUT TO AREA 6 IN THE RHESUS MONKEY. H. Barbas and D.N. Pandya. Harvard Neurol. Unit, Beth Israel Hospital, Boston, and V.A. Medical Center, Bedford, MA.

There are at least two cytoarchitectonically distinguishable subregions within area 6 in the rhesus monkey. A dorsal region lies above the spur of the arcuate sulcus and extends medially to the cingulate sulcus. This region lacks a granular layer IV, and its medium and large size pyramidal cells in layers III and V form a central band. The cells show a columnar arrangement throughout the cortical layers. A ventral area 6 region lies below the spur of the arcuate sulcus. Unlike the dorsal area 6, ventral 6 has incipient layers II and IV, small cells in layer III, only medium size pyramidal cells in layer V, and lacks a columnar organization.

Analysis of the sources of ipsilateral frontal lobe afferents to area 6, studied with horseradish peroxidase (HRP), revealed that the two subregions of area 6 have different afferent connections. Thus ventral 6 receives projections from both cytoarchitectonic subregions of area 6, the ventral half of the precentral gyrus (area 4), the prefrontal cortex (areas 8, 12, 46, 10), the depths of the cingulate sulcus (area 24d), and the frontal operculum. In contrast, the sources of input to dorsal area 6 are more restricted and are confined primarily to dorsal parts of areas 6 and 4. To demonstrate further these differences, the number of HRP labeled cells within a specific frontal cortical region was expressed as a percentage of the total number of labeled cortical cells in the frontal lobe (opercular, motor, premotor, and prefrontal cortices). Of all the neurons in the frontal lobe projecting to ventral area 6, 53% were in ventral, medial, and dorsal parts of area 6, and 17% were in area 4. The remaining HRP labeled neurons were in the prefrontal cortex, in the depths of the cingulate sulcus, and in the frontal operculum. In contrast, 91% of the cells projecting to dorsal area 6 were in adjoining regions of dorsal and medial area 6, and 5% were in area 4. A small percentage (4%) of HRP labeled neurons was in ventral area 6, and in areas 9 and 8.

The results suggest that the two cytoarchitectonic subregions of area 6 also receive input from divergent sources: Dorsal area 6, which lacks a granular layer IV, receives input mostly from neighboring agranular premotor (area 6) and motor cortices. On the other hand, ventral area 6, having incipient layer IV, receives input not only from motor and premotor regions, but also from prefrontal and opercular granular regions.

135.3 THALAMIC PROJECTIONS OF AREA 6 IN THE DOG. S.T. Sakai, D. Tanaka Jr., G.B. Stanton & O.I. Weeks*. Dept. of Anatomy, Michigan State University, East Lansing, Michigan 48824 & Dept. of Anatomy, Howard University, Washington, D.C. 20059.

Based on electrophysiological findings, the medial one-third of the anterior sigmoid gyrus (ASG) in the dog has been identified as the premotor area while the region located immediately lateral to it has been identified as the supplementary motor cortex (MII) (Gorska, 1974). The purpose of this study was to investigate the cytoarchitecture and thalamic connectivity of these two cortical areas. The cytoarchitecture was defined by Nissl stains and thalamic projections were traced with the horseradish peroxidase (HRP) method. Thalamic subdivisions were defined both by Nissl stains and by acetylthiocholinesterase histochemistry.

Based on cytoarchitectonic analysis, two cortical areas were identified on the ASG corresponding to the functional subdivisions defined by Gorska. The cortical region occupying the medial one-third of the ASG most notably contained a wide layer III composed of small and medium pyramidal cells. Further the demarcation between layer IIIc and layer Va was indistinct. This region corresponds cytoarchitectonically to area 6aα of Hassler and Muhs-Clement (1964) in the cat. Following HRP injections confined to this area, clusters of labelled cells were found in a dorsoventral band in the ventral anterior (VA), ventral lateral (VL), ventral medial (VM) and lateral part of the mediodorsal (MD) nuclei. In addition, HRP positive neurons were seen in the central lateral (CL), paracentral (Pc) and central medial (CeM) nuclei. In contrast, the cortical region identified as MII by Gorska was characterized cytoarchitectonically by a clear strip between layers Vb and VI and the presence of large, medium and small pyramidal cells in layer V. Layer III contained medium and small cells loosely arranged in clusters. This area corresponds cytoarchitectonically to area 6a β of Hassler and Muhs-Clement in the cat. After HRP injections into this area, labelled thalamic cells were also distributed in a dorsoventral band but were located more sparsely through VA, VL, VM and lateral MD. It appeared that this band was partially coincident with the HRP labelled band seen following the medial ASG injection. The intralaminar nuclei, CL, Pc and CeM, also contained HRP positive neurons. In summary, the two functional and cytoarchitectonic subdivisions of area 6 in the dog appear to receive afferents arising from similar thalamic nuclei.

135.4 THE FASTIGIO-VENTROMEDIAL THALAMIC-CORTICAL PROJECTION. J.P. Roy*, J. Hada* and M. Steriade, Lab. Neurophysiol., Dept. Physiol., Fac. Med., Laval Univ., Québec, Canada.

The cerebellar inputs and cortical projections of thalamic neurons were investigated in cats acutely prepared under ketamine anesthesia, by recording extracellularly single units in the lateral part of ventralis anterior-ventralis lateralis (VA-VL), medial paralaminar part of the VL (VLpl), centralis lateralis-paracentralis (CL-Pc) and ventralis medialis (VM) nuclei. Out of 137 elements activated orthodromically from one of the three cerebellar nuclei, 86 neurons could also be antidromically invaded from cortical areas 4, 6, 8 & 5. A first component of the cerebello-cortical system originates in the interpositus cerebellar nucleus and is relayed by neurons mainly located in the VL that project to areas 4 and 6. A second component consists of afferents from the dentate nucleus; they activate neurons in both VA-VL and CL-Pc (and, to a lesser degree, VLpl cells) that project to areas 6, 4 & 5. Finally, the majority of fastigio-thalamic axons excite VM cells that project to medial parts of areas 6 and 8.

In addition to the already known cerebello-cortical projections relayed in the VA-VL complex, these data provide evidence at a unitary level of cerebellar inputs to cortically projecting CL-Pc and VM nuclei. In particular, the fastigial → VM → areas 6 & 8 projection seems distinct from the interpositus → VA-VL & CL-Pc → areas 4 & 6 projection: the slower conduction velocity in the VM → cortical path (≃7 m/sec) matches the longer latency of fastigial-evoked discharges in VM neurons (median 2.4 msec) compared to that of interpositus-evoked discharges in VA-VL and CL-Pc neurons (median: 1.7 msec and 1.8 msec, respectively). These differences revealed by electrophysiological analyses are further stressed by the predominant or even exclusive projections from the VM to the cortical layer I of cat, as indicated by our electrophysiological and HRP anterograde labeling experiments (Glenn et al., this volume). The cerebello-cortical operations in motor control and the fastigial diffuse influence on the electrical activity of the neocortex should be viewed by taking into account this superficial fastigio-VM-cortical projection.

Supported by M.R.C. grant MT-3689.

135.5 RECIPROCAL PROJECTIONS BETWEEN THE VENTROMEDIAL THALAMUS AND PRECRUCIATE AREAS 6 AND 8 IN CAT. L.L. Glenn, J. Hada*, J.P. Roy, M. Deschênes*, and M. Steriade, Lab. Neurophysiol., Dept. Physiol., Fac. Med., Laval Univ., Québec, Canada.

Autoradiographic experiments have disclosed that the nucleus ventralis medialis (VM) of the thalamus projects to layer I of almost the entire neocortex in the rat (Herkenham, J. comp. Neurol. 183:487, 1979). We investigated the laminar distribution and spatial extent of the cortical projections of VM in the cat, since we are interested in structures with widespread influences on cortical electrical activity. Horseradish peroxidase (50%, 100 nl) was injected into the VM; the tetramethyl benzidine method was used to reveal transported enzyme 48 h. later. Furthermore, the distribution of field potentials evoked by focal VM stimulation was determined in most of the neocortex.

After HRP injections, an intense retrograde labeling was seen in structures known to provide afference to VM, such as the substantia nigra and fastigial cerebellar nucleus. The anterograde label was situated almost exclusively in a 60-70 μm band in the superficial third of layer I of the ipsilateral anterior neocortex. The highest grain density was in the anterior sygmoid and proreus gyri, which included cytoarchitectonic areas 8, 6, & 4. When present, the layer I label in the postcruciate part of area 4 consisted of only sparse grains, much less dense than that found in the precruciate areas. No projection could be detected posterior to area 4. Retrogradely labeled neurons were found in cortical layer VI and the deep part of layer V. The spatial extent of this band paralleled the anterograde projection to layer I strikingly.

Clear VM-evoked responses could be recorded only in the medial part of precruciate areas 6 & 8. They consisted of a purely surface-negative wave in area 8, but in area 6 this component was preceded by two distinct surface-positive deflections of much smaller amplitude. The surface-negative wave reversed superficially (0.2 - 0.4 mm), indicating a termination in layer I. The initial surface-positive waves reversed more deeply. The superficial nature of the surface-negative wave was tested by superfusing the surface with warmed normal Ringer solution containing either manganese (2mM) to reversibly block synaptic transmission or calcium (2mM) as a control. Manganese selectively reduced or abolished the VM-evoked surface-negative, depth-positive wave.

The anterograde transport and depth profile findings confirm that VM projects almost exclusively to layer I, but indicate that the projection is confined to precruciate areas in the cat.

Supported by M.R.C. Grant MT-3689 and NSF Grant SPI79-14817.

135.6 DISTRIBUTION AND MORPHOLOGY OF PYRAMIDAL TRACT-CELLS VISUALIZED WITH TWO HORSERADISH PEROXIDASE METHODS. M. A. Biedenbach and J. L. DeVito, Dept. of Physiol., Univ. of Texas Health Science Center, San Antonio, Tx. 78284 and Primate Research Center, Univ. of Washington, Seattle, Wash. 98195.

In anesthetized cats horseradish peroxidase (HRP) was applied to all axons in the pyramidal tract (PT), that had been sectioned at the medullary level. The retrogradely transported HRP product in PT cells was visualized with both DAB and TMB histochemistry. All labelled cells in a sample of the brain sections were plotted to establish extent of PT-cortex and PT-cell density in subregions within. Quantitative morphological information was obtained from camera Lucida drawings of labelled PT-cells which were re-traced with a graphic digitizer. The output of the digitizer and alphanumeric data were stored in files of a Minc-11 computer for later analysis. Electron micrographs were taken from thin sections through the medullary pyramid. The outlines of the axons were also traced with the digitizer to determine their size and number.

Results of the TMB method, compared with those of the DAB method, revealed a roughly similar extent of PT-cortex but much greater density of labelled cells visualizing virtually all PT-cells (estimated from the number of axons in the medullary pyramid). With both methods, PT-cells were highly concentrated in the two banks of the cruciate sulcus and in a band of cortex continuing over the anterior sigmoid gyrus into the hidden lateral bank of the presylvian sulcus. PT-cells were less concentrated in surface cortex extending caudally from cruciate sulcus and laterally down to the orbital sulcus; here cell concentration was sparse with DAB, but moderate with TMB.

The TMB-visualized cell population contained a larger fraction of small cells. For each cortical subregion in PT-cortex, frequency distribution histograms of soma diameter and cross-sectional area will be presented. They will be compared with similar histograms obtained from the axons of the medullary pyramid. Most labelled cells were basically pyramidal-shaped with a prominent apical dendrite oriented towards the cortical surface. Other soma shapes occurred among labelled cells throughout PT-cortex but more often in areas where section plane was not perpendicular to the cortical cell layers.

135.7 SURVIVAL TIME PROFOUNDLY AFFECTS THE LAMINAR DISTRIBUTION OF HRP LABELED NEURONS IN CEREBRAL CORTEX. C. L. Pappas and P. L. Strick. Dept. of Internal Medicine. U. South Florida Medical School, Tampa, FL., and Depts. of Physiology and Neurosurgery, Upstate Medical Center, and VA Med. Ctr., Syracuse, NY.

Recently, we reported the results of a study in which the retrograde transport of horseradish peroxidase (HRP) was used to examine patterns of connectivity in the callosal system of cat motor cortex. During that study, we noted that the survival time of the animal following HRP injection seemed to influence the laminar distribution of subsequently labeled neurons. In the present study, we have performed experiments examining this influence in both the cat and primate motor cortex callosal systems.

In 7 cats, survival time following multiple HRP injections into one motor cortex was varied from 26 to 50 hours. Following histochemical processing with TMB, the numbers of labeled neurons in superficial (I-III) and deep (V-VI) layers of homologous regions in the contralateral motor cortex were counted. We sought to normalize the slight variations in staining from animal to animal by converting these numbers into a superficial-to-deep (S/D) ratio. The S/D ratio decreased with increasing survival times. Similar observations were made in the primate.

A decrease in the S/D ratio could be accomplished by either an increase in the number of deep neurons labeled, a decrease in the number of superficial neurons labeled, or both. We found that while the absolute number of deep neurons labeled was rather constant, the number of superficial neurons labeled decreases with increasing survival time.

We found no difference in the size of labeled neurons when the two groups (short vs. long survival) of either superficial or deep neurons were compared.

One interpretation of these results is that neurons in deep and superficial layers either metabolize and/or transport HRP at different rates. It is clear from these results that carefully varied and controlled survival times must be employed in studies using HRP histochemistry in the cerebral cortex.

Supported in part by the VA Medical Research Service and USPHS-NS 02957.

135.8 THALAMOCORTICAL CONNECTIONS TO THE ROSTRAL FORELIMB AREA OF THE RAT MOTOR CORTEX. E.L. Bold* and E.J. Neafsey. Dept. Anatomy, Loyola Univ. Med. Center, Maywood, IL 60153

Two separate forelimb motor areas have recently been described in rat frontal cortex (Neafsey, Neurosci. Abstr. 6:156, 1980). The present study investigated the thalamocortical projections to the rostral forelimb region (RFL) by mapping retrogradely labeled thalamic neurons following injections of HRP or HRP conjugated with wheat germ agglutin (HRP-WGA) into the RFL. The rats were anesthetized with ketamine HCl (100 mg/kg,IP) and placed in a stereotaxic frame. The cisterna magna was opened to prevent cortical swelling and a small piece of bone (5x2mm) was removed just rostral to bregma on one side. The RFL was identified by locating the region where intracortical stimulation (.25 msec pulses, 100 μamps or less, 300 msec train @ 300 Hz) evoked digit or wrist movements rostral to an area where neck movements were elicited. Then .01 to .02 μl of either a 30% solution of HRP (Sigma VI) or a 1% solution of HRP-WGA (Polysciences) in physiological saline was injected into RFL using a 1 μl Hamilton syringe fitted with a 50 μ diameter pipette tip (average diameter of injection=1.5mm). After survival periods of 1-2½ days, the animals were reanesthetized, transcardially perfused with 1.25% glutaraldehyde and 1% paraformaldehyde, and the tissue was processed for HRP histochemistry according to the TMB procedure of Mesulam (J. Histochem. Cytochem. 26: 106-117,1978).

Retrogradely labeled neurons were found in several thalamic nuclei, including the ventromedial (VM), ventrolateral (VL), intralaminar, dorsomedial (DM), and the lateral posterior/posterior (LP/Po) nuclei. A prominent longitudinal column of labeled cells was found throughout VM, except in its most rostral portion where only a few scattered cells were labeled. In VL, labeled cells were found only in the rostral one-third and were situated dorsally, just lateral to the intralaminar nuclei. Within the intralaminar nuclei, labeling seemed to move from ventral to dorsal as one moved caudally, with the heaviest labeling found in paracentral and central lateral nuclei. Sparse labeling was also seen in the lateral portion of DM, where it bordered the intralaminar nuclei. This labeling was restricted to the middle third of DM. LP demonstrated positively labeled cells throughout its extent, again forming a longitudinal column of cells running rostral to caudal and merging with a similar column of cells in the anterior two-thirds of Po.

Thalamocortical projections in the monkey have been shown to arise from longitudinal columns or strips that may cross nuclear boundaries (Kievit and Kuypers, Exp.Brain Res.29, 1977). The present findings suggest such a pattern exists in the rat also.

Supported by NIH grant NS 16146 and BRSG RR05368 from Loyola Univ.

135.9 LIGHT AND ELECTRON MICROSCOPICAL FEATURES OF TWO TYPES OF NEURONS IN THE CAT'S VENTRAL MEDIAL THALAMIC NUCLEUS AS REVEALED WITH HRP INJECTIONS IN THE MOTOR CORTEX. K. Kultas-Ilinsky, S. Warton* and I. Ilinsky. Depts. of Anatomy and Surgery, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

Retrograde HRP transport was used to study the relationships between thalamo-cortical projection neurons (PN) and local circuit neurons (LCN) in the ventral medial nucleus (VM). Injections of 35-50% HRP in 2% DMSO were made in the medial part of the precruciate gyrus in three cats. The animals were sacrificed in 24 hrs by perfusion with 2.0% glutaraldehyde and 0.5% paraformaldehyde in 320 mOsm phosphate buffer. Serial 100 um thick sections were cut on a vibrotome and alternate sections were reacted for HRP according to one of three procedures: Adams (1977), Malmgrem and Olsson (1978), or Itoh et al. (1979). After incubation, disks of tissue 1 mm in diameter were punched out from the VM and processed for EM. The disks embedded in Epon were either sectioned serially at 1 μm for light microscopic analysis and cell counting or cut on an ultramicrotome for EM analysis.

Large numbers of cells were found to contain retrogradely transported HRP granules throughout the anterior-posterior extent of the VM. LM analysis showed that HRP positive cells belonged to a distinct neuronal population which had morphological characteristics quite different from those of unlabelled cells. The former were relatively large (20-30 μm dia.) with angular cell bodies, numerous dendritic processes and large amounts of cytoplasm. The unlabelled cells were small (10-16 μm dia.), with oval or elongated cell bodies, a few dendrites and a larger nuclear-cytoplasmic ratio. None of these small cells were observed to contain HRP. This allowed us to classify the large neurons as being PN and the small cells as LCN.

The ratio of the two types of cells was estimated from maps of complete series of 1 μm plastic sections (from four different tissue disks) prepared using an x-y plotter. The ratio of PN to LCN varied in different parts of the VM. PN tended to be in groups, while LCN were scattered without any recognizable pattern. At the ultrastructural level HRP granules could be traced quite far within the PN dendrites up to the smallest branches. In no case were HRP granules seen within vesicle-containing dendrites providing further evidence for our earlier suggestion that vesicle-containing dendrites belong to LCN. Another feature was that axosomatic synaptic contacts which are usually very rare in the VM are found almost exclusively on the perikarya of the PN and not on the LCN. Furthermore, no synaptic contacts were observed on the axon hillock or initial segment areas of the PN which were easily identifiable due to the presence of HRP granules. Supported by a grant from American Parkinson Disease Association.

135.10 ANTEROGRADE HRP AND AUTORADIOGRAPHIC EVIDENCE FOR COLUMNAR ORGANIZATION IN IPSILATERAL CORTICAL AND CALLOSAL PROJECTIONS OF RAT FRONTAL CORTEX. A. Isseroff, M.L. Schwartz, J.J. Dekker and P.S. Goldman-Rakic, Sect. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT. 06510.

Although columnar organization in the ipsilateral and callosal projections of various cortical areas has been observed in primates, cats and other species, its presence in rats has not been clearly established. Patchy terminations, suggestive of columns, have been noted in the callosal projections of rat somatosensory and posterior neocortex (Cippoloni and Peters, Brain Res. 176:33, 1979; Wise and Jones, J. Comp. Neurol. 168: 313, 1976). However, Akers and Killackey (J. Comp. Neurol. 181: 513, 1978) reported that the pattern of anterograde degeneration of ipsilateral projections from rat somatosensory cortex was homogeneous. Thus, discontinuities in callosal terminations could be attributed solely to intercalation of areas receiving callosal input with cytoarchitectonically and functionally distinct acallosal regions.

Using autoradiographic and HRP tracing methods, we have obtained evidence that the termination of both ipsilateral and callosal projections from rat frontal cortex have a columnar organization similar to that found previously in the rhesus monkey (Goldman and Nauta, Brain Res. 122: 393, 1977). ^{3}H-leucine was injected and acrylamide-bis gel HRP pellets implanted in the motor, premotor and medial prefrontal cortex of adult albino rats. Placement of tracer was verified by observations of labeling in thalamic nuclei. Anterograde labeling of ipsilateral terminations in frontal and somatosensory cortex as well as that from callosal projections to homotopic areas took the form of distinct columns, most of which were 250-500 μ wide in the deeper layers and somewhat wider and more prominent in superficial strata, similar to columns demonstrated in the frontal cortex of rhesus monkeys. Thus, some of the label-free areas in callosal terminations may be cytoarchitectonically distinct acallosal regions; however, columns in ipsilateral projections and within contralateral terminal fields are apparently indicative of the kind of modular parcellation of afferents observed in primate frontal cortex.

A previous study (Bugbee and Goldman, Neurosci. Abs. 6: 822, 1980) demonstrated that the frontal cortico-cortical projections of both rhesus and squirrel monkeys terminate in columns 250-500μ wide. Present data provide further evidence that columnar organization is a pervasive characteristic of mammalian neocortex, and that the vast differences in cortical volume in different species apparently result in differences in the number, but not the width, of the columns. (Supported by NIH Grant NS16666 and NIH Fellowship Awards NS06158, MH08308 and MH 00298).

135.11 HORSERADISH PEROXIDASE DETERMINATION OF POSTERIOR LATERAL HYPOTHALAMIC INNERVATION. S. L. Scharoun, F. C. Barone, M. J. Wayner, R. Guevara-Aguilar and H. U. Aguilar-Baturoni. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210 and Depto de Fisiologia, Facultad de Medicine, U.N.A.M., Mexico.

Horseradish peroxidase (HRP, Sigma Type VI, 13%) was injected into the posterior portion of the lateral hypothalamus-medial forebrain bundle (LH-MFB) of male hooded rats. After 20-24 hr the animals were perfused intracardially with a phosphate buffer plus sucrose wash followed by glutaraldehyde and paraformaldehyde fixative. The whole brain was removed and sectioned at 50 μm. Alternate sections were processed with DAB and counterstained with cresyl violet for the brown reaction and with TMB and counterstained with neutral red for the blue reaction. Sequential sections were examined and positively labeled neurons were identified and photographed through a microscope with both light and dark fields. Labeled neurons and axons rostral to the LH were identified in the zona incerta, internal capsule, and radiatio thalami intermedia. Axons were also identified in the caudate putamen, nucleus ventralis thalami, nucleus reticularis thalami and nucleus dorsomedialis (hypothalami) par ventralis. Soma rostral to the LH were identified in the globus pallidus. Labeled cells and axons in the reticular formation, zona incerta, substantia nigra zona compacta and zona reticulata were also observed. Additional posterior axons were identified in Forel's Field H_1, H_2, nucleus ventralis thalami, nucleus parafascicularis and the nucleus posterior thalami. These results based on the retrograde labeling of neurons following HRP ejection in the posterior LH-MFB indicate a considerable degree of synaptic input to this region from the brain stem, especially from the reticular formation and other MFB associated structures. (Supported by NIH Grant NINCDS USPHS No. 13543.)

135.12 THE DORSAL NUCLEUS PRAEEMINENTIALIS OF A GYMNOTIFORM FISH. A CORRELATIVE GOLGI AND NISSL STUDY. E. Sas and L. Maler. Univ. of Ottawa, Sch. of Med., Ottawa, Ont. K1N 9A9. (SPON: W. Hendelman).

This study was prompted by the lack of information on the cytoarchitecture of this important nucleus in the feedback loop of the electrosensory pathway of the weakly electric fish Eigenmania Viriscens.

The n. praeeminentialis (N.PRAE) is an isthmic structure located dorsolateral to the lateral lemniscus, and anterior to the eminentia granularis - a subdivision of the archicerebellum of fish.

It can be divided into a large dorsal portion, concerned with electroreception and a small ventral portion involved solely with mechanoreception (this is also the case in mormyrids).

In this work the structure of the N.PRAE is examined using both Nissl and Golgi material, and an attempt is made to correlate this information with data from H.R.P. studies (Maler-Sas, unpublished observations) on the afferent and efferent connections of this nucleus.

The N.PRAE consists of three parts: a pars medialis (p.M.), a large pars principalis (p.P.) and a narrow pars lateralis (p.L.). The p.P. presents three zones: a dorsal (Dz), a central (Cz) and a ventral zone (Vz), which are reciprocally and topographically connected with the 3 zones of the posterior lateral line lobe (PLLL); medial PLLL with ventral zone, central PLLL with central zone and lateral PLLL with dorsal zone.

Several types of projection cells are present in the N.PRAE: a) neurons that show preferential orientation of their long dendrites in relation to the afferent fibre systems, b) cells with wide dendritic fields radiating in all directions, and c) cells with small well oriented dendritic fields.

Two small interneurons are also identified, showing different axonal ramifications. A detailed representation of these cells is shown in Golgi as well as diagrams of the afferent fibre systems to the N.PRAE from PLLL, caudal lobe, and torus semicircularis.

The complex processing within this nucleus is reminiscent to the feedback loops in the phylogenetically related auditory system.

135.13 A "NEW" HISTOLOGICAL PROCEDURE FOR USE IN DEVELOPMENTAL STUDIES: THIONIN COUNTERSTAINED-REDUCED SILVER. G.H.Gross* (SPON: J.D. Greenspan). Neurobiol. Prog., Univ. of N.Carolina,Chapel Hill,NC 27514 and Neuroembryol. Lab.,Dorothea Dix Hosp.,Raleigh,NC 27611.

Avian and mammalian embryos and amphibian larvae stained with a Cajal-DeCastro reduced silver technique (Levi-Montalcini,R., J. Comp.Neurol. 91:209-241,1949) were counterstained for Nissl substance with the basic aniline dye, thionin. This simple modification produces highly differentiated histological material at all embryonic ages studied in these species. Early in development the background is pale green, young neurons and glia are blue, cartilage is purple, and fibers, which are relatively unaffected by counterstaining,range from black to gold.As development proceeds, some neurons develop a remarkable burgundy coloration of the soma and dendrites, which is startling against the deepening green background. This coloration may reflect the development of argyrophilia in these neurons, and may be useful as a rapid visual index of maturation.

Thionin Nissl stain reveals cell perikarya several developmental stages before the cytoplasm of young neurons has developed sufficient argyrophilia to be visible in reduced silver preparations. However, use of the combination of stains permits study of relations between young neurons and nerve fibers from early stages when such critical events as cell death occur, up to the later stages of development and synaptogenesis. In addition, since the combination stain shows fibers, nucleoli, and perikarya clearly, it is possible to obtain accurate cell counts during the early development of cell groups which require a fiber stain for consistent delineation of nuclear boundaries in the adult,e.g. avian vestibular complex. Comparisons of cell counts in thionin-, reduced silver-, and combination-stained material suggest that argyrophilia may develop at different rates, and to different degrees even within the boundaries of a conventionally-defined "homogeneous" nuclear group. In counterstained material it is clear that an argyrophilic neuron, evident in reduced silver, may be surrounded by neurons of generally comparable size and morphology which stain only for Nissl substance, and hence could not be detected by reduced silver technique. Consequently, cell counts based on classic reduced silver could be misleading.

The following examples will be given to illustrate the technique: 1.Development of the spoon ending between a vestibular colossal fiber and a n.tangentialis principal cell in chick,pigeon, and finch. 2. Development of primary vs. secondary motoneurons in Rana catesbeiana. 3.Development of dorsal root ganglia. 4.Development of vestibular sensory epithelia.

Supported by an Amelia Earhart Fellowship from Zonta International, USPHS Grant MH 14277, and NSF Grant BNS 7924088.

135.14 CALLOSAL AND ASSOCIATIONAL AXON COLLATERALS OF PREFRONTAL CORTICAL NEURONS IN THE RHESUS MONKEY DEMONSTRATED BY RETROGRADE FLUORESCENT TRACERS. M.L. Schwartz and P.S.Goldman-Rakic. Sect. of Neuroanatomy, Yale Univ. School of Med., New Haven, CT. 06510.

The recent development of double labeling techniques using retrogradely transported fluorescent tracers has made it possible to identify neurons which issue axon collaterals to divergent targets (Kuypers et al., Exp. Brain Res., 40: 383, 1980).In the present study we have used this method to determine the extent to which individual callosal neurons may also have associational projections within the same hemisphere. In order to answer this question, the fluorescent dye Fast Blue (FB) was injected into the posterior bank of the intraparietal sulcus (Brodmann's area 7) of one hemisphere: 8-10 days later, a second dye, Nuclear Yellow (NY) was injected into the principal sulcus (Brodmann's area 9) in the other hemisphere. FB selectively labels the cytoplasm of a cell, while NY labels the cell nucleus. Double labeled neurons display a blue fluorescent cytoplasm and a whitish fluorescent nucleus.

The types and distribution of fluorescing neurons were analyzed in the principal sulcus of the hemisphere ipsilateral to the FB injection and contralateral to the NY injection. This region contained large numbers of retrogradely labeled neurons. Most were single labeled with either Fast Blue or Nuclear Yellow. However, a very small fraction, perhaps less than 1%, were double labeled. The single labeled neurons were present in greatest density within layer 3, where they were frequently intermixed in both the deep and superficial portions of this layer. The small population of double labeled neurons was randomly interspersed among the single-labeled neurons. Double labeled neurons were not confined to the cortex of the principal sulcus but were also observed, for example, in the cingulate cortex. Again, the neurons containing NY + FB were few in number and were scattered among numerous single labeled neurons containing one or the other dye.

The present study indicates that a small fraction of callosal neurons in the primate brain have widely diverging axon collaterals, some of which even project to heterotopic regions across the callosum. Thus, a neuron in the cingulate cortex may project to the principal sulcus in the frontal lobe of one hemisphere and to the parietal cortex of the other. The scarcity of double labeled cells may reflect their rarity in the adult cortex or alternatively a greater number of callosal neurons may have such divergent collaterals but project to areas that were not injected in the present study.

(Supported by NIH Grant NS16666 and Fellowship Awards MH08308 and MH00298).

135.15 SOME FLUORESCENT COUNTERSTAINS FOR NEUROANATOMICAL STUDIES. L.C. Schmued*, L.W. Swanson and P.E. Sawchenko* (SPON: W.M. Cowan). The Salk Institute, La Jolla, California 92037.

An increasing number of methods in neurobiology rely on the detection of fluorescent markers in tissue sections or in culture; these include fluorescence methods for monoamines, immunohistochemical (IHC) methods for the localization of specific antigens, and pathway tracing methods based on the retrograde transport of fluorescent markers. Small amounts of bright fluorochromes can be detected against a dark background, but the dark field is a disadvantage when trying to determine the precise location of labeled cells within specific structures. We have, therefore, screened some 40 fluorescent compounds to determine those best suited for counterstaining 1) IHC labeled cells in tissue sections and in culture, 2) retrogradely transported fluorochromes, and 3) normal material.

There are several requirements for adequate counterstaining of immunofluorescence material. The counterstain should not mask FITC-labeling, it should fluoresce a different color, it should be nearly invisible at wavelengths used to excite fluorescein, it should be effective at neutral or basic pHs, and it should provide a crisp Nissl stain. The compound that meets these criteria best is ethidium bromide. At dilute concentrations (.00001%), it produces a moderately bright red Nissl stain (green excitation), which provides good contrast to the green FITC label (blue excitation). Ethidium bromide may be used with either histological sections or with cells in tissue culture.

We have also found counterstains suitable for localizing cells that are labeled with retrogradely transported fluorescent tracers. Since these markers fluoresce with ultraviolet excitation, a counterstain that is visible only when excited with longer wavelengths is desirable. The acridines (acridine orange and quinacrine) are suitable for this application since they are visible when excited with blue light, but not with ultra violet. Other effective dyes for this purpose include ethidium bromide, neutral red, and astrazone red.

When immunofluorescence and retrograde transport methods are combined to characterize biochemically the cells that project to a particular terminal field, a counterstain is needed that does not mask either FITC or retrograde markers. Ethidium bromide best meets these requirements. It is quite bright when illuminated with green light, moderately visible when examining fluorecein conjugated label with blue light, and barely visible when examining retrogradely transported fluorochromes with ultraviolet light.

Bisbenzimide and nuclear yellow are particularly effective counterstains for normal material at low concentrations. At pH 7.2 both dyes produce a nuclear stain, while at pH 2.0 they produce a brilliant Nissl stain. Neutral red, safranin-0, and astrazone red differentially stain cell bodies and myelineated fibers, producing a fluorescent "Kluver-Barrera" stain.

135.16 COMPARISON OF THE DISTRIBUTION OF MECHANOSENSORY TARGET (MERKEL) CELLS IN MAMMALIAN AND AMPHIBIAN EPIDERMIS USING QUINACRINE FLUORESCENCE AS A MARKER. C.A. Nurse, K.M. Mearow, B. Visheau, M. Holmes and J. Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5.

The Merkel cells are specialized sensory cells located at mechanosensitive spots in the vertebrate epidermis. Following a report that these cells bind the fluorescent dye, quinacrine, (Crowe and Whitear, Cell Tiss. Res. 190: 273-283, 1978) we have adapted the technique to aid visualization of the Merkel cell distribution within whole mounts of epidermis known to contain these cells from electronmicroscopic (E.M.) studies. The tissues (Xenopus tadpole tentacles, salamander skin, rat touch domes and vibrissae) were removed 3 hrs-4 days following injection of 5-15 mg/kg quinacrine dihydrochloride into the tail musculature of the tadpole or intraperitoneally in rat and salamander. The distribution of the quinacrine fluorescent cells (QFC) was viewed under dark field illumination after the tissues were mounted in liquid paraffin and exposed to U.V. light. In the tadpole, many epidermal QFC were arranged 25-40 μm apart in rows along the length (up to ca. 2 cm) of the tentacle. In salamander epidermis, separated mechanically from the dermis following 1 hr incubation in BSS containing 1 mg/ml collagenase, individual QFC were scattered 40-100 μm apart; in a few tests, touch-sensitive spots mapped physiologically on the skin (over an area of about 0.16 mm^2) correlated closely with the QFC-distribution in that skin. Rat touch domes from trunk skin contained scores of QFC at the basal epidermis. Frequently, the QFC were arranged as a flat elliptical annulus surrounding an eccentric tylotrich hair; the QFC tended to concentrate caudal or caudo-lateral to the exit-point of the hair. We are interested in the possibility that this array may be the morphological basis for the directional sensitivity to tylotrich hair displacement reported for the rat touch dome (Smith, J. Comp. Neurol., 1967, 131: 459). The mechanically isolated outer root sheath of the neonatal rat vibrissa contained several hundred QFC periodically arranged in a cylindrical sleeve adjacent to the basement membrane. In all cases, the location, size and shape of the QFC corresponded to that of the Merkel cells as revealed by other light and E.M. studies. We have also enzymically dissociated cells from the quinacrine-labelled outer root sheath for use in other studies in vitro; about 6% of isolated cells were clearly fluorescent within a larger non-fluorescent cell population. We are now confirming directly the Merkel cell identity of the QFC.

135.17 A TECHNIQUE ENABLING THE ELECTRON MICROSCOPIC EXAMINATION OF LUCIFER YELLOW- INJECTED NEURONS. A.R. Maranto. The Biological Laboratories, Harvard Univ., Cambridge, MA 02138.

Because of the ease of microinjection and quick diffusibility of the dye Lucifer Yellow it was of interest to develop a procedure to make cells filled with this dye visible for electron microscopy. The technique reported here is based on the ability of irradiated Lucifer Yellow to sensitize the photo-oxidation of 3,3'- diaminobenzidine (DAB) to an insoluble osmophilic polymer.

To demonstrate the staining obtainable with this technique the S interneuron of the leech was used because of its easily identifiable large axon. S cells were filled with Lucifer Yellow CH by pressure injection or iontophoresis. Ganglia were then allowed to incubate for 20 minutes in a solution of DAB (1mg/ml) in normal leech Ringer's adjusted to pH 7.4. The photooxidation step was performed next with the intense blue light from a fluorescence microscope equipped with a mercury arc lamp and suitable excitation filters. When the dye fluorescence faded below visibility the ganglia were washed in Ringer's, fixed in glutaraldehyde, and post-fixed in OsO_4. After embedding in Spurr's medium, the reaction product could be identified in 1 micron sections by its reddish-brown appearance. In ultra-thin sections the S cell axon was marked by dense granular deposits throughout the cytoplasm and especially along the inner surface of the plasmalemma.

The compatibility of this technique with other intracellular electron dense markers such as metal precipitates and the horseradish peroxidase reaction product suggests its possible value in double marker experiments to establish interactions between neurons at the ultrastructural level.

This work was supported by PHS Grant 1R01NS 15101.

135.18 A COMPUTER SYSTEM FOR NEUROANATOMICAL DATA ACQUISITION, ANALYSIS AND DISPLAY. W.K. Smith, D.S. Schlusselberg and D.J. Woodward, Dept. Cell Biology, Univ. Texas Health Science Ctr., Dallas, TX 75235.

Ongoing anatomical studies in this laboratory on cell topography and connectivity in brain stem nuclei have generated a need for new techniques in anatomical data acquisition and display. In this report we describe progress in development of a general computer-based system for acquiring and viewing neuroanatomical data.

An initial program, MACRO, employs a light microscope drawing tube, an X/Y stepper motor stage and digitizing tablet. After an initial calibration procedure, the operator may digitize fiducial marks, lines to note structural boundaries and points for cell locations. Independent designation of different anatomic components is performed through the use of a 12-character label which may be referenced at later stages of analysis. Convenience features include on-line graphical output of data obtained at any magnification, scaled and transformed from a common file system to a relevant biological coordinate system.

REFINE, the primary data manipulation program, employs a disk-based virtual memory array with 24-bit mantissa floating point elements so that numerical accuracy and memory size are not limiting. Objects for display can be constructed by combining and aligning labeled serial section data from different experiments. Available output devices include a Tektronix graphics terminal, a Versatec matrix printer/plotter and an Ikonas color video frame buffer with microprogrammable processor.

Graphics software includes display of stick frames, contours, labeled cell distributions and surface reconstruction with hidden object removal. Sequential contours are processed by a minimum surface area algorithm which generates an optimum set of triangles spanning the contours. Smooth shaded images in 3-space are constructed after defining an eye position and light source to compute the proper view in perspective. A flexible file system has been developed consisting of strings of four numbers - X, Y and Z coordinates plus a real number CODE. Files are organized as tree structures with a system of pointers from a root to define classes of structures, segments, strips and complex objects. The system is being employed to quantitate and display gross brain surfaces, cytoarchitectural boundaries of brain stem nuclei, cell distributions and objects reconstructed from serial electron microscopy. (Support from NSF BNS77-01174 and the Biological Humanics Foundation.)

135.19 COMPUTER GENERATED THREE DIMENSIONAL RECONSTRUCTION OF SERIALLY SECTIONED TISSUE.

David P. Baker* and Jeanine R. Carithers. Department of Veterinary Anatomy, Iowa State University, College of Veterinary Medicine, Ames, Iowa 50011.

Computer generated 3-dimensional modeling created from 2-dimensional images has been utilized by several investigators in recent years for analysis of neurons and neuronal systems. This technique has required the collaborative efforts of a neuroscientist, a computer scientist, and a digital electronics technician. The results of these efforts have led to a clearer understanding of the gross and microscopic architecture of the nervous system. However, the equipment needed has been prohibitive in cost. Furthermore, a variety of computer systems were used in the early studies, and attempts to replicate these systems have been hampered by hardware and software incompatibilities between devices from different manufacturers. Additional incompatibilities are introduced when system dependent interfacing is required for the input and output of data.

The techniques presented here utilize an Apple II+ computer system, with programs written in BASIC and 6502 machine language, and a Houston Instrument Hi Pad graphics tablet for data entry. Tissue sectioned for light microscopy can be digitized from 2x2 Kodachromes, photographs, or a camera lucida. Data from electron microscopic preparations can be entered from the viewing port of the microscope using an optical accessory, from negatives, or micrographs. The data is entered as a series of x, y coordinates and the z data is relative to the thickness of the tissue sections.

This system provides quantification of neuronal structure and simultaneous morphometric analysis of cytoarchitecture using a small, inexpensive microcomputer instead of a large mainframe computer. Different pathways or structures can be highlighted in up to 16 colors with complete 360 degree rotation. The method presented here is limited only by the magnification limitations available from the input devices. It could be used equally well to reconstruct images of organs from gross anatomical material or computer assisted tomography images.

136.1 MORPHOMETRIC DETERMINATION OF AXON DIAMETER AND MYELIN SHEATH THICKNESS IN NEURONS MYELINATED BY BOTH SCHWANN CELLS AND OLIGODENDROCYTES. J.K. Donnelly and J.P.H. Wyse, Dept. Anat., Faculty of Medicine, Univ. of Calgary, Calgary, Alberta, Canada T2N 1N4.

Myelin sheath thickness (m) increases concomitantly with axon diameter (d) in both central (CNS) (Hildebrand & Hahn, J. Neurol. Sci. 38: 421, 1978) and peripheral (PNS) (Williams & Wendell-Smith, J. Anat. 109: 505, 1971) nervous systems. The relationship between myelin sheath thickness and axon diameter is frequently described as the g-ratio (i.e. the ratio of axon diameter to total fiber diameter). The purpose of the present study was to examine the relationship between fiber thickness and axon diameter in a population of CNS axons myelinated by ectopic Schwann cells and to determine if the relationship is similar to that present in either peripheral nerves or central tracts. The model system used in this study was the Bmn-wys (BW) strain of rat. These animals are affected by several coinherited neurological defects including a dopaminergic abnormality which is manifest in the retina, hypothalamus and nigrostriatal system as well as an unusual Schwann cell myelination of axons in the retinal nerve fiber layer (Wyse, J. Neurocytol. 9: 107, 1980). Since the latter axons are sequentially myelinated first by Schwann cells in the retina and then by oligodendrocytes in the optic nerve, this model system provides the opportunity to determine whether myelin sheath thickness differs for the two populations of myelinating cells when the neuronal population is constant. Measurements of axon diameter and sheath thickness were made from electron micrographs of myelinated axons in retinae, optic nerves, and sciatic nerves of one year old BW rats as well as in sciatic nerves of control animals. Myelinated axons in retinae and optic nerves ranged up to 4 μm in diameter. Sheath thickness increased significantly ($p < 0.01$) in retina, optic nerve and sciatic nerve samples as axons increased from 1 to 2 and from 2 to 3 μm in diameter. In all samples, values of g ($g = d/D$; $D = d + 2m$) increased rapidly over the smaller range of axon diameters with transition to a more linear relationship as axon diameter continued to increase. Average g-values ($\bar{X} \pm SD$) for the largest ensheathed axons ($d = 2.5$ to 4 μm) in both the retina (0.83 ± 0.02) and optic nerve (0.81 ± 0.06) were significantly greater than the g ratios of axons of comparable diameter in both BW (0.71 ± 0.05) and control (0.71 ± 0.05) sciatic nerves. These data suggest either that g-ratios are higher in CNS than in PNS or that special sensory neurons have higher g-values than do motor neurons of comparable diameter. Furthermore, since the maximal values of g in the retina were the same as those in optic nerves, it may be inferred that myelin sheath thickness is more dependent upon the neuron than on the type of ensheathing cell.

136.2 QUANTITATIVE MORPHOLOGICAL ANALYSES OF MOTONEURONS. M. D. Egger and L. D. Egger*. Department of Anatomy, CMDNJ-Rutgers Medical School, Piscataway, New Jersey 08854.

Horseradish peroxidase (HRP) was injected intracellularly into motoneurons responding to cutaneous stimulation of the central foot pad of the hind limb in cats (Egger et al., J. Physiol. (Lond.), 306: 349-363 (1980)). Three motoneurons were selected for further analysis: two excited by foot pad stimulation, sectioned transversely (ET) and horizontally (EH). The third, sectioned transversely, was inhibited postsynaptically by foot pad stimulation (IT). Dendritic lengths and areal measurements should be considered lower limits: dendritic segments broken from their main stems were excluded, and some segments may not have filled completely with HRP. Cell bodies of EH and IT were about 0.4 mm from the lateral border of the ventral horn in S1 segment; that of ET, also in S1, was within 50 μm of the dorsolateral ventral horn border. Major and minor diameters of cell bodies were 96.4 X 66.7 μm (ET), 73.0 X 61.2 μm (EH), 59.4 X 43.9 μm (IT). The overall lengths of the dendritic trees were 15.8 mm (ET), 15.2 mm (EH) and 20.4 mm (IT). Total surface areas were 0.185 mm^2 (ET), 0.161 mm^2 (EH), 0.173 mm^2 (IT). The highest order of branching for ET and EH was VIth; for IT, it was VIIth. ET had 9 primary dendrites of 69 dendritic branches; for EH, it was 8 of 80; and for IT, 14 of 136. ET had 39 terminal dendrites, 31% > 0.8 mm from soma to tip; 4 > 1.4 mm. EH had 44 terminal dendrites, 20% > 0.8 mm; 4 > 1.0 mm. IT had 76 terminal dendrites, 12% > 0.8 mm; 1 > 1.0 mm. Using published values for R_m and R_a, and assuming uniformity throughout the dendritic tree, electrotonic lengths of terminal dendrites were estimated. The means were 1.3±1.1 (ET), 28% > 2.0; 1.3±0.8 (EH), 18% > 2.0; 1.2±0.7 (IT), 13% > 2.0. 75.2% of the total dendritic length of ET was accounted for by branches of 3 of its 9 primary dendrites; for EH, 69.1% by 3 of 8; and for IT, 47.9% by 3 of 14. However, for each motoneuron, when the lengths of dendrites were analyzed by order of branching, dendritic branches of orders II-V each included > 15% of overall dendritic lengths. Four patterns of dendritic branching were observed: 1) one daughter ≤ 50% of its sister's diameter; 2) the sum of the diameters of the daughters ≤ the diameter of the parent, & one daughter > 50% of its larger sister; 3) diameters of parent and two daughters about equal; 4) all others. The means of the quantity $\{(d_{d1}^{3/2} + d_{d2}^{3/2}) / d_p^{3/2}\}$ were calculated: 1.3±0.5 (ET); 1.1±0.9 (EH); 1.4±0.6 (IT). Means for ET and IT were significantly different from 1.0 ($P < 0.01$). However, the means of this quantity for branches of category "4)" were close to 1.0: 1.1±0.1 (ET); 0.9±0.2 (EH); 1.1±0.2 (IT).

136.3 The hypothalamic suprachiasmatic nucleus of rat: quantitative stereological assessment of neuropil and perikarya. Anthony N. van den Pol, Richard Bucholz*, and Rania Baik*. Section Neurosurgery, Yale Univ. Sch. Med., New Haven, Ct. 06510.

To further examine the organization of the suprachiasmatic nucleus (SCN) (JCN 191: 661-702), we have undertaken a stereological analysis of ultrastructural components. Four inbred male adult Fischer rats were perfused with a cacodylate-buffered 2.5% glutaraldehyde, 2.5% paraformaldehyde fixative. Silver thin sections from the SCN were saved on 300 mesh grids. Photomicrographs with a final magnification of 17,080, 37,950, and 75,900 were studied with a Bit Pad Digitizer interfaced with a Horizon microprocessor, and with the dot superimposition and line intersection methods described by Weibel (1973). Over four hundred 11 by 14 inch micrographs were quantitatively studied.

The synapse analysis included measurement of the area, synaptic membrane specialization, size of postsynaptic structure, number of vesicles, and size and number of mitochondria in 790 synapsing boutons from four different areas of the nucleus (anterior, ventrolateral, dorsomedial, and posterior). The mean bouton area in thin sections was 0.65 um^2 ± 0.41 um^2 (SD)(range: <0.1 to 2.7 um^2). The mean length of the synaptic membrane specialization was 0.43 um ± 0.18 um (SD) (range: <0.1 to 1.8 um). The mean number of vesicles per bouton was 48 ± 30 (range: 4 to 283). These data are based on two-dimensional data and are therefore underestimates of the true size. Statistically reliable differences were found between some of the characteristics of the synapses of the four SCN loci studied.

By examining a total of 21,818 regularly spaced points superimposed over photomicrographs magnified 17,080X, the volume compartments of different stuctures within the SCN could be determined. In the ventrolateral SCN, which receives afferent input from the retina, ventral lateral geniculate, and raphe, neuropil accounted for 76%, neuron somata 14%, glial cell bodies 2%, and cellular nuclei for 8% of the total SCN volume. Relative membrane lengths were determined by their intersections with 10,829 two cm regularly spaced straight line segments. Neuronal perikaryal membrane accounted for 903 intersections, glia soma for 129, and nuclear membrane for 615 intersections.

These and additional data will be examined relative to metabolism, structure, and intercellular communication in the suprachiasmatic nucleus. Some of the data support the emerging picture that regional morphological differences exist with the SCN.

Support provided by NIH NS16296.

136.4 THREE-DIMENSIONAL SCANNING ELECTRON MICROSCOPY OF HIPPOCAMPUS. T.J. Teyler, J. Gilliam* and D. Ayers*. N.E. Ohio College of Medicine, Rootstown, OH 44272.

Scanning electron microscopy (SEM) permits the visualization of relatively large areas of neural tissue (as compared to transmission electron microscopy) at greater resolution than is possible with light microscopy. This permits a consideration of neural geometry not readily achieved by other approaches. When combined with the ability of SEM to provide three-dimensional, stereoscopic images, the result provides an informative and beautiful view of central nervous system architecture.

The hippocampus of rat was employed for these pictures. To enhance the surface imaging capabilities of the SEM, we dissected free the fixed hippocampus and mechanically split it along the lamellar plane and at various other orientations. We found that the fixative employed contributed greatly to the quality and usefulness of the imaged specimen. Best results were obtained with standard formalin fixation of hippocampus. The amount of time in formalin fixative determined the degree of rigidity of the tissue and the degree to which it could split to yeild an interesting surface. Unlike freeze-fracture techniques, formalin-split tissue largely preserves cell and process integrity. Following fixation and splitting, specimens were critical point dried and sputter-coated with gold.

The images produced by SEM of formalin-split hippocampal tissue, clearly indicate such pronounced features as the cell body layers, dentritic tree orientations and the lamellar organization of the tissue. Higher resolution, three-dimensional images show the proximity of neighboring somata, the fiber terminations in the dentritic tree and details of the synaptic contacts in the hippocampal neuropil.

136.5 COMPLEX RAMIFICATIONS OF HIPPOCAMPAL CA1 PYRAMIDAL CELL AXONS DEMONSTRATED BY LUCIFER YELLOW *IN VITRO*. W. Douglas Knowles and Philip A. Schwartzkroin. Dept. of Neurological Surgery, University of Washington, Seattle, WA 98195.

Intracellular injections of Lucifer Yellow into CA1 pyramidal cells of the *in vitro* guinea pig hippocampal slice enabled us to examine in detail the morphology of the axons of these neurons. We found that many of these axons bifurcate in the alveus with the major branch projecting caudally towards the subiculum and the second, thinner branch projecting rostrally towards the fimbria. Either axon may further bifurcate to produce several axon branches which follow parallel paths in the alveus. These axons also have local collaterals which project into strata oriens and pyramidale. In addition, a very fine plexus of axonal processes was observed in stratum oriens located largely within the basal dendritic field of the parent cell. The local axonal elaborations may be involved in recurrent pathways mediating feedback inhibition and/or excitation. It is possible that the synchronization of neural activity seen during epileptiform activity may be mediated by these axonal processes.

136.6 MORPHOLOGY OF VISUAL PRETECTAL NUCLEI IN THE CAT: A GOLGI STUDY. K.M. Gregory. Dept. of Biology, CSU Long Beach, CA 90815.

The pretectal complex in the cat was studied using the Golgi-Cox impregnation procedure. The olivary pretectal nucleus (PO) is characterized by cells with a fusiform or crescent shaped body with 1 or 2 dendrites emanating from each end. The dendrites branch repeatedly to form a bushy plexus of spiny dendrites which are confined to the central area of the nucleus. The nucleus of the optic tract (NTO) contains large and medium sized multipolar cells with moderately spiny robust branching dendrites which extend out for 300-500 μm and which are predominately oriented in a plane perpendicular to the path of the brachium. Neurons of the anterior pretactal nucleus (PA) have 5-6 main dendrites which branch into 2-3 secondary dendrites at varying distances from the cell body. Cells of the posterior pretectal nucleus (PP) possess 5-6 long (300-500 μm) thin dendrites of which 1 or 2 may branch about midway. The neurons of the PA and PP do not appear to have any specific dendritic orientation in transverse sections. Except for the PO, there is a lack of distinct nuclear boundaries due to dentritic overlap. The PA and PP are especially difficult to demarcate from each other due to the similarily of neuron morphology. There are no distinct ventral boundaries to the PA or PP nuclei.

136.7 EFFERENT PROJECTIONS FROM THE ENTORHINAL AREA TO THE BASAL FOREBRAIN AND FRONTAL CORTEX ORIGINATE IN LAYER IV. Ch. Köhler*and L. Eriksson(SPON:R.S.Schmidt) ASTRA Research Laboratories,Dept. of Neuropharmacology,Södertälje,Sweden.

Microinjections of 3H-leucine/proline(5uCi;50nl) into the rat entorhinal area(EA)resulted in anterograde axonal transport to several forebrain structures in addition to the perforant path projection: the septum(SEPT),the nucleus accumbens(AC),the piriform(PIR) and the frontal cortex(FC).In order to determine the exact localization of the cells that give rise to these extrahippocampal projections of the EA,small injections of either HRP(40%;100nl) or granular blue(GB,5%;100 nl) were made into each brain area of individual rats.After survival periods ranging between 2-5 days retrogradely labelled cells were found almost exclusively in layer IV of the medial and lateral EA.Comparisons between the HRP and fluorochrome methods indicated that GB was a more sensitive marker of retrograde transport than HRP in the present system.A small population of retrogradely labelled cells were always found in layer III of the most ventral parts of the lateral EA and in layer IV of the contralateral EA after all injections.Analysis of serial horzontal sections through the entire EA revealed that cells projecting to the various brain regions of the forebrain occupies different but partly overlapping levels of the EA.Thus,cells which project to the SEPT and AC are found at all levels of the EA,while cells innervating the FC and the PIR are concentrated predominantly at middle and ventral levels, respectively.Studies using double retrograde fluorescent tracing where propidium iodide(3%;100 nl) was injected into the PIR and GB into the SEPT,AC and FC,respectively,showed that some cells in layer IV of the EA have branching projections to the PIR and the SEPT or AC.Evidence for such simultaneous innervation by these cells of the PIR and the FC could not be obtained.The present results link the EA closely to several forebrain structures and suggest that the EA may directly influence the neural activity not only in the hippocampus via cells in layers II and III but also in several regions of the basal forebrain through cells in layer IV.

136.8 AN ELECTRON MICROSCOPIC STUDY OF HORSERADISH PEROXIDASE LABELLED NEURONS IN THE PHRENIC NUCLEUS OF THE ADULT ALBINO RAT. H. G. Goshgarian and J. A. Rafols. Department of Anatomy, Wayne State University School of Medicine, Detroit, Michigan 48201.

Phrenic motor neurons in the rat spinal cord were labelled by the retrograde transport of horseradish peroxidase (HRP) after the enzyme was applied to the central stump of the transected phrenic nerve in the neck. Forth-eight hours after the application of the enzyme the animals were perfused transcardially using conventional methods for electron microscopy. One hundred micron thick frontal and sagittal sections from the C3-C5 levels of the spinal cord were obtained with a tissue chopper. The sections were reacted for peroxidase activity using diaminobenzidine as the substrate. Labelled phrenic neurons were identified under the light microscope, trimmed from their surrounding tissue, osmicated and embedded in Araldite blocks. One μm sections were cut from the blocks and stained with toludine blue for light microscopy. Ultrathin sections were obtained from those blocks which yielded heavily labelled neurons in the 1 μm thick sections. In order to confirm the presence of HRP electron dense granules, unstained ultrathin sections as well as sections stained with lead citrate and uranyl acetate were studied with the EM. Cell body and dendritic profiles of phrenic neurons contained HRP reaction granules in membrane bound vesicles, cisternae of smooth endoplasmic reticulum, Golgi apparatus, lysosomes, and multivesicular bodies. Phrenic perikarya were characterized by the presence of coarse Nissl granules, numerous cisternae of rough endoplasmic reticulum, ribosomal rosettes and other organelles. The labelled somata and proximal dendrites were contacted by four different types of presynaptic endings. Type I endings contained flattened synaptic vesicles, had an electron lucent matrix and formed symmetrical synapses. Type II endings contained round synaptic vesicles, also had an electron lucent matrix and had some microtubules and neurofilaments. The endings formed asymetric synapses and were often associated with wide extracellular clefts which were filled with a granular or fibrillar material. Type III endings had an electron dense matrix, contained flattened, plieomorphic synaptic vesicles, microtubules, neurofilaments, and numerous mitochondria. These endings formed symmetrical synapses. Type IV endings were similar to type III endings except that they contained round synaptic vesicles. Axoaxonic and serial synapses were also observed in association with labelled phrenic profiles. In the neuropil immediately adjacent to labelled profiles, dendrites were commonly separated by astroglial processes. Direct apposition of dendritic membranes seldomly occurred.

136.9 SENSORY CELLS AROUND THE MOUTH OF HYDRA: ULTRASTRUCTURAL CORRELATES OF MOUTH OPENING BEHAVIOR. J. C. Kinnamon and J. A. Westfall. Department of Anatomy and Physiology, Kansas State University, Manhattan, Kansas 66506.

Previous work in our laboratory has established that sensory cells are concentrated in the top 120 μm of the hypostome of Hydra littoralis. Using transmission electron microscopy of 0.1 μm thick serial sections of Epon-Araldite embedded specimens of Hydra we have determined the patterns of synaptic connectivity of sensory cells in the circumoral region.

Neurons at the apex of the hypostome are arranged in two layers, with sensory cells in the superficial region of the epidermis. Their sensory cell papillae protrude through the cuticle into the environment. Below the sensory cells, ganglion cells form a second layer of neurons. In a previous study on the tentacle, we found an average of only one sensory cell per epitheliomuscular cell. In the present study, however, we found sensory cells to be abundant at the apex of the hypostome, especially in the rosette of epitheliomuscular cells surrounding the mouth. In this region up to four sensory cells are enveloped by a single epitheliomuscular cell, and the basal portions of these sensory cells are in direct contact with each other. They form sensory cell-sensory cell synapses, including reciprocal synapses between two sensory cells. Sensory cells around the mouth also have synapses with ganglion cells and epitheliomuscular cells similar to those previously observed in the tentacle and the hypostome-tentacle junction.

Ultrastructural characteristics and patterns of synaptic connectivity indicate that these cells are sensory in nature; their circumoral location suggests a function associated with feeding behavior. We propose that adequate stimuli (mechanical and/or chemical) to oral sensory cells can initiate direct responses and also indirectly affect adjacent sensory cells and ganglion cells. Reciprocal synapses may modulate the threshold levels between sensory cells and sensory cell-neuro-epitheliomuscular cell junctions might initiate local contractions of the oral musculature. Sensory cell-ganglion cell synaptic pathways may be used to transmit impulses to epitheliomuscular cells throughout the oral region. The end result of this activity would be opening of the mouth, swallowing, and associated feeding movements involving oral musculature. We have provided ultrastructural evidence for the neuronal substrates underlying one of the more complicated behaviors coordinated by this simple nervous system.
(Supported by NIH grant NS 10264).

136.10 LAMINAR DIFFERENCES IN THE MORPHOLOGY OF LATERAL GENICULATE NUCLEUS CELLS IN GALAGO. E. Birecree* and V.A. Casagrande. Depts. of Anat. & Psych., Vanderbilt Univ., Nashville, TN. 37232

The lateral geniculate nucleus (LGN)of Galago consists of six layers which can be divided into three cell size pairs. The first pair (1&2) contain magnocellular cells, the second pair (3&6) contain medium size cells equivalent to the parvocellular layers of monkeys, and the third pair contain small size cells (Casagrande & Joseph,'80). Analysis of receptive field properties has shown that different LGN cell size pairs contain functionally different neuronal classes. Thus, medium and large size layer pairs have X-like and Y-like units, while the layers with small cells have a mixture of unit types some of which have W-like properties (Norton & Casagrande, '80; '81). In the present study we used Golgi preparations to determine if the physiologic and cell size differences seen in LGN laminae of Galago could be correlated with differences in cell morphology. Our material reveals four basic cell types, three of which correlate with cell size layer of origin. In the magnocellular layers, the majority of cells have large somata (400-600um^2), 4-8 thick primary dendrites that tend to branch repeatedly forming a complex network extending in a radially symmetric pattern around the soma. The latter closely resemble the Class 1 cells described by Guillery ('66) in cat LGN. In contrast, cells in layers 3 & 6 have medium size somata (200-400um^2) with asymmetrically grouped dendrites that are elongated either perpendicular or parallel to the plane of the layers. These cells have from 1-4 main dendritic groups but in all cases at least one group is oriented with its main axis perpendicular to the layers. Cells in the small cell layers can be distinguished from the other two types by their soma area (100-200um^2) and very simple dendritic organization consisting of only one or two thin primary dendrites with few branches. In each of the above three cell classes, subtypes can be distinguished according to the distribution, shape, and arrangement of dendritic appendages and the tendency of dendrites to cross laminar borders. The latter features do not, however, appear to correlate with cell size. In addition to the three classes described, a fourth category of very small cells (50-70um^2) exists that resembles the smallest squirrel monkey LGN cells described by Wong-Riley ('72). These stellate cells have very small thin dendrites that project in a radially symmetric pattern for a short distance around the cell body and are not confined to particular LGN laminae. From the above results we conclude that several morphologic features of Galago LGN cells can be correlated with cell-size layer origin and thus function. In several respects these distinguishing features resemble those described for X, Y, and W cells by Friedlander et.al. ('81) for the cat. Supported by EY01778, 1K07-EY00-061, BRSG-RR-05424-17.

136.11 ULTRASTRUCTURAL LOCALIZATION OF PHOTORECEPTOR ANTIGENS IN RAT. D. M. Fekete* and C. J. Barnstable (SPON: R. H. Masland). Depts. of Anatomy and Neurobiology, Harvard Med. Sch., Boston, MA 02115.

A number of monoclonal antibodies have been produced which react with vertebrate photoreceptor cells (Barnstable, C.J., Nature, 286: 231, 1980). Initial localization of antigens was carried out at the light microscopic level using indirect immunofluorescent labeling of fixed tissue sections. Antibody RET-P1 labeled the cell bodies, inner segments and outer segments of rods, but not cones. Antibody RET-P2 labeled only the photoreceptor outer segments. An antibody against the photopigment rhodopsin (a gift of M. Applebury) labeled the photoreceptor outer segments strongly and the inner segments weakly.

An electron microscopic study was undertaken to determine with greater resolution the distribution of the photoreceptor antigens. All antibodies in these experiments were diluted in a phosphate-buffered saline solution containing 1% bovine serum albumin, 1% goat serum and 0.05% Triton X-100. Vibratome sections of fixed rat retinas (Long Evans strain) were incubated overnight in the monoclonal antibodies. Control tissue was incubated in the buffer solution alone and subsequently processed exactly as the experimental tissue. The following day, one group of sections was placed into a ferritin-conjugated goat anti-mouse IgG antibody solution. A second group was incubated in goat anti-mouse IgG antibody followed by a mouse peroxidase-anti-peroxidase incubation. The sections were then reacted with diaminobenzidine. Tissue from both groups was then osmicated and processed for electron microscopy.

RET-P1 antigen was shown to be associated with the plasma membrane of both the inner and outer segments. The ferritin labeling technique showed that RET-P1 was distributed on both the outside face of the plasma membrane and the inside face of the discs. In suitable sections, RET-P1 could be localized within the membrane folds at the base of the outer segment, the area from which discs are assumed to be formed. It was not possible to localize RET-P1 on the photoreceptor cell bodies, as was seen with fluorescence, presumably because diffusion was limited by the tightly packed arrangement of cells in the outer nuclear layer. The labeling pattern for RET-P2 will be compared with that for RET-P1.

The particular anti-rhodopsin antibody used was shown to react with that portion of the molecule on the exterior of the plasma membrane. Rhodopsin was also found on the inner segment plasma membrane; this tends to support the suggestion that outer segment membrane is first inserted in the inner segment rather than flowing up through the connecting cilium and then being inserted. (Supported by grants NS13126, NS17309 and EY03735).

136.12 THE TRIDIMENSIONAL ASPECT OF THE "STATUS SPONGIOSUS" IN A CASE OF JACOB-CREUTZFELDT DISEASE, AS IS SHOWN BY THE GOLGI METHOD. J.P. Machado-Salas.Div. Neurocien cias, Neuromorfología, ENEP, Iztacala, UNAM, y Div. de Patología, Depto.Inv.Cient.CMN IMSS.México, D.F. MEX.

In this communication it is shown, by the first time, some interesting morphological changes that were observed in dendrites and axones from the frontal cere bral cortex of a young adult, who was clinically and histológically diagnosed as a case of Jacob-Creutzfeldt.Long time ago,it was learned that the nervous tissue from these cases, showed some "holes" or perforations, which,in some time, were regarded as artifacts. More recently, they were demonstrated with the E/M, and thereafter considered as a substantial feature of this neurological disease.It is the purpose of this presentation to provide further structural knowledge obtained in a cortical biopsy impregnated with the Golgi method.

The overview of the Golgi-stained material, showed a generalized decrement in the size of neurons, as well as in the number of spines and dendrites.Nevertheless, the remaining dendrites and axones showed a rather normal aspect, even though some appeared thinner.When these structures were studied at higher magnification, it became clear the presence of spherules along the neuronal branches.In general, each process bears 2 or 3 of them (dendrites).Ocassionally they were seen at the level of the neuronal somata.Those in the axones were more numerous.On the other hand,those of dendritic origin were less spherical.It is important to emphasize, that the Golgi-impregnated material did not show any "holes" or perforations, as it was expected to do.

These findings allow to state that in the spongiform status, there is a segmentary and well defined process of dilation in dendrites and axones, which apparently never ends with rupture of membranes, but it parallels the decline of neural function.

136.13 ULTRASTRUCTURE OF CULTURED OLIGODENDROCYTES. R.L.Wollmann and S.Szuchet:Dept. of Neurology, University of Chicago,950 E. 59th St.,Chicago, Illinois 60637:

The presence of junctional complexes between oligodendrocytes in vivo has been documented.(Mugnaini,E.&Walberg,F.Rev.Anat. Embrol.&Cell Biol.37,194,1964;Dermietzel et al.,Cell&Tissue Res. 193,61(1978). Here we report that oligodendrocytes maintained in vitro also develop specialized junctions. Oligodendrocytes were isolated from ovine white matter and were maintained in Dulbecco's modified MEM supplemented with 20% horse serum and 20mM glutamine(Szuchet et al.,Brain Res.200:151,1980). We have followed the ultrastructural changes accompanying the initial seeding and further development of oligodendrocytes in culture, using transmission electron microscopy. Fourteen hours after being plated on plastic culture dishes most cells have formed floating aggregates; these take several days to attach. The ultrastructure of clustered cells, unlike the cells fixed immediately after isolation, revealed an electron lucent cytoplasm, no clumping of nuclear chromatin and abundance of intracellular organelles. These cells resembled the light oligodendrocytes described by Mori and Leblond(J.Comp.Neurol;139,1,1970). The cells in clusters were in close apposition to each other. The apposed plasma membranes exhibited intense osmiophilia which at high magnification appeared as septilamellar structures approximately 21nm in thickness. In some sections, the two inner lamellae were seen to be bridged in a regular fashion by filaments or tubules. These junctional complexes were reminiscent of gap junctions. After 4 to 5 days in culture, most cells had attached to the culture dishes but a certain proportion remained as floating clusters. Examination of the latter showed the disappearance of the "gap"junctions but now short complexes resembling zonula adherens were found. The cells that adhered to the culture plates did not differ significantly in their cytoplasmic constituents from the floating cells. Attached cells extended long membranous processes which contained large numbers of microtubules,filaments,polyribosomes, and an occasional mitochondrion. In established cultures the membranous sheets became highly complex and organelles such as cisternae of endoplasmic reticulum,membrane bound vesicles, lipid droplets and mitochondria were in abundance. Oligodendrocytes isolated from young lambs are able to express in vitro, properties associated with these cells in the intact organism. Hence, cultured oligodendrocytes should prove useful for studying interactions between oligodendrocytes and between these cells, neurons and astrocytes, and thus, enhance our understanding of myelin synthesis and maintenance.

Supported by Grant #RG1223-B3 from the Natl. Mult. Sclerosis Soc.

136.14 DEVELOPMENT OF TANYCYTES IN THE RAT THORACIC SPINAL CORD FROM DAY 14 OF GESTATION TO ADULTHOOD-A LIGHT MICROSCOPIC STUDY.
J. P. Cummings* (SPON: D. Czech). Program in Physical Therapy, Marquette University, Milwaukee, WI 53233.

Ependymal tanycytes lining the cerebro-ventricular system and the central canal of the spinal cord have been implicated in a number of processes including: 1) neuroendocrine regulation, 2) the absorption and transport of CSF-borne substances, 3) neural migration and 4) axonal guidance. Using a modified Golgi-Cox stain this study was undertaken to further explore the ontogeny of spinal cord tanycytes in the rat thoracic spinal cord from day 14 of gestation to adulthood.

At day 14 of gestation the length of the somata, which either border the central canal or are located within the deep layers of the ependyma, ranged between 15 and 40µm. The somata often gave rise to one or more cilia-like processes that projected 2-8µm into the central canal. The necks of the cell bodies ranged from 10-30µm in length and often had mound-like varicose enlargements giving rise to long (4-12µm) filopodial-like processes. The tanycyte shafts, extending to the pial surface, also had similar intermittent mound-like varicosities from which filopodial-like (often bifid) processes 6-10µm in length protruded into the neuropil. These mound-like enlargements were most numerous on the distal one-third of the shafts. The proximal one-third of the shafts had scattered barbed spines 1-3µm in length while the middle one-third of the shafts was usually quite smooth, but did have either an occasional short spine or mound-like varicosity with a filopodial-like process. The shafts often branched and contacted cerebral vasculature and neural elements as they coursed through the neuropil prior to terminating in small (4-8µm long) swollen end-feet on the pial surface of the spinal cord.

At birth the tanycyte somata and necks remained similar to those described at day 14 of gestation. However, by birth the shafts had bead-like enlargements from which an occasional short (.5-1µm) spine protruded. Otherwise, the necks and shafts were virtually spine-free. The pial end-feet continued to enlarge (20-40µm in length), and there was an increase in the number of long (6-10µm) filopodial-like process arising from the end-feet.

By adulthood (60 days of age) the tanycytes arising from the lateral aspects of the central canal had stubby necks and very short (20-40µm) shafts that exhibited occasional short (.5-2µm) spines. The pial end-feet had continued to enlarge (40-80µm in length) with most of the filopodial processes having been replaced by longer and thicker dendrite-like processes. These "differentiated" pial end-feet resembled sub-pial astrocytes.

136.15 SCANNING ELECTRON MICROSCOPY (SEM) OF THE MIDLINE FLOOR OF THE FOURTH VENTRICLE OF THE RABBIT. B.T. Burnett*, V.H. Gattone*, B.A. Connors*, A.P. Evan*, and D.L. Felten. Department of Anatomy, Indiana University School of Medicine, 1100 W. Michigan St., Indianapolis, IN 46223.

Recently we have shown tanycytes on the floor of the fourth ventricle in the rabbit brain with shafts entering raphe dendrite bundles (J. Comp. Neur., 183:1-24; Neurosci. Lett., 16:275-280). In order to assess the possible functional roles of these cells, we examined their surface ultrastructure with SEM. The midline floor of the fourth ventricle contains clusters of tanycytes adjacent to nuclei raphe obscurus and dorsalis, demonstrating tight junctions between the lateral tanycyte surfaces. With SEM, differences were noted in the pattern and density of cilia, microvilli, and supraependymal elements and fibers on the midline (25-75 um) floor, including scant clusters of cilia with preterminal and terminal bullae, prominent single cilia, a dense and relatively uniform mat of clavate and filiform microvilli, and occasional areas of smooth ependymal surface apparently devoid of microvilli and cilia. A threadlike reticular network of fibers was found on nearly all of the midline ventricular surface, consisting of fine (0.3 um or less) strands which intertwined and possessed bullous and fusiform varicosities approximately 1.0 um long at 2-4 um intervals. This reticular network often converged in a radiating pattern in areas relatively devoid of microvilli which possessed multiple globoid 2-4 um swellings. Portions of the reticular network coursed through the microvillous cover of the surface, disappearing into the clusters of cilia. Supraependymal smooth spherical elements (0.3-0.6 um) occurred singly, in clusters of 50-80, or intermixed with clusters of cilia at their base. Some single elevated projections (0.5-1.5 um) were covered with microvilli. Two cell-like supraependymal structures were noted in the midline. Small (4 um dia.) ovoid cells possessed a single bifurcating process near the soma, which disappeared into the ependymal surface. Large (15-20 um dia.) tear-drop shaped unipolar cells sent a tapering, spiraling process across the ependymal surface, where it disappeared into the ependyma within 40 um of the soma. We suggest that the prominent microvillous cover serves an absorptive function for tanycytes. The smooth globoid structures and areas of cilia may serve a secretory function. The supraependymal cell-like structures and the reticular fibrous network may represent a supraependymal neuronal network of connections. The present SEM findings are consistent with an active absorptive and secretory role for tanycytes on the midline floor of the fourth ventricle.

136.16 ORTHOGONAL ARRAYS IN GLIA OF THE MEDIAN EMINENCE. James D. Hatton and Mark H. Ellisman, Department of Neurosciences, U. Calif. at San Diego, La Jolla, CA 92093

The distribution of orthogonal arrays of particles and their relationships to gap and tight junctions has been studied in the glia of the freeze-fractured rat median eminence (ME). These rectilinear clusters of intramembrane particles are thought to represent trans-membrane channels for ions or metabolites. Analysis of the cellular distribution of these structures may aid in understanding their function. These orthogonal arrays were found to be densely packed on the membranous laminations of the pial-glial limitans forming the ventral border of the ME. Arrays were found to be present on all of the perivascular glial end-feet examined, surrounding either fenestrated or non-fenestrated capillaries. Two classes of end-feet were distinguished by their relative densities of orthogonal arrays. End-feet displaying low densities of arrays occurred more frequently in the internal zone, while end-feet displaying high densities occurred more often in the external zone. Similar distinctions based on orthogonal array density could be made in membranes from other regions of the cell as well. Cross-fractures revealing the cytoplasm underlying these array-poor membranes often exposed lipid inclusion bodies, suggesting that membranes containing few arrays belong to tanycytes or to "astrocyte-like" tanycytes. Such inclusion bodies were not found where cross-fractures exposed cytoplasm beneath array-replete membranes. The distribution of arrays appeared to be unrelated to the distribution of gap junctions in the membranes of astrocytes, tanycytes, and "astrocyte-like" tanycytes of the ME, appearing near to and far from gap junctions with approximately equal frequency. Orthogonal arrays were absent from glial membranes near synaptic profiles in the ME. Arrays were also absent from the microvillous membranes of the apical surfaces of ependymal cells, from the cytoplasmic protrusions into the CSF of tanycytes, and from the vicinity of the tight and complex junctions linking the tanycyte and ependymal cell lateral membranes near their apical poles. These results suggest that there is a gradient of array density for most glia of the ME, increasing from ventricular to pial surface. Furthermore, it is apparent that orthogonal arrays are present on glial end-feet surrounding capillaries in an organ lacking the traditional blood-brain barrier, suggesting that arrays are not functionally involved therein.

136.17 LIGHT- AND EM ANALYSIS OF THE PROLIFERATING GLIAL CELLS IN A PARTIALLY DENERVATED NEUROPIL AT EARLY POSTLESION STAGES. C.Avendaño. Dept. Morfología, Fac. Medicina, U. Autónoma, Madrid 34, SPAIN.

Substantial controversy exists about the nature of the non-neuronal cells that react in the nervous tissue in response to an insult. The kind of cellular response appears to depend largely on the degree of inflammation produced by the lesion (Vaughn & Pease, '70): stab wounds or inflammatory diseases clearly elicit an invasion of the lesioned area by circulating phagocytes, while the participation of these cells in wallerian or retrograde degeneration processes, if any, is controverted. In the latter processes some agreement exists that the cells that proliferate and turn into phagocytes resemble morphologically either microglia or undifferentiated "stem cells". Moreover, well differentiated oligodendrocytes, perivascular elements and astrocytes have been described to proliferate in some cases. While there is a good deal of information on the proliferative glial response to wallerian degeneration in myelinated fiber tracts, little is known of this response in the gray matter, perticularly in areas in which no retrograde degeneration of neurons is involved. The rat dentate gyrus (FD) is a well-suited model for studying the glial reaction to denervations of controlled intensity. Avendaño & Cowan ('79) have shown that the cells that proliferate after interrupting the commissural connections of FD (which presumably elicits no noticeable inflammation in FD) do not exhibit typical features of microglia at LM. Here, using the same ^{3}H-thymidine-treated, plastic-embedded material, a direct correlation was made between the LM and EM appearance of the cells labeled at the peak of the proliferative period (6 h after an injection of ^{3}H-thymidine given 30-36 h after lesion). The technique used was similar to Kaplan & Hinds' ('77) procedure of re-embedding and thin-cutting 2 µm-thick sections which had been previously coated with photographic emulsion, exposed and revealed for autoradiography. At LM the labeled nuclei appeared to be fairly large (6-8 µm larger diameter), ovoid or elongated, sometimes markedly indented, with chromatin clumps standing out against a relatively light nucleoplasm. The cytoplasm, scanty, weakly stained and usually devoid of dense inclusions, was sometimes seen to accumulate or to send a broad process at one side of the nucleus. The most relevant features at EM were: well-developed Golgi complex, abundant polisomes, few and short cisternae of granular ER with a moderately electron dense content, multivesicular bodies, absence of filaments and scarcity of microtubules and inclusion bodies. The surrounding extracellular space appeared sometimes moderately enlarged. These findings suggest that most of these proliferating cells correspond to poorly-differentiated microglia-like cells in a reactive state.

136.18 ALTERATIONS OF ASTROCYTIC PLASMA MEMBRANES AFTER EXPOSURE TO HIGH CO_2 IN VITRO. J. J. Anders and M. W. Brightman. (Spon. David I. Rubin). NINCDS/LNNS, National Institutes of Health, Bethesda, MD 20205.

Distinct aggregates (assemblies) of small (6-7 nm) particles characterize the P-face of frozen, cleaved and replicated astrocytic membranes. In mammals, assemblies increase with the age and reactivity of the astrocytes. Astrocytes in primary cultures of dissociated cerebral cortex from 7 day old rats have assemblies, but they are fewer than in in vivo astrocytes of a comparable age. The longer astrocytes remain in vitro, the fewer the assemblies within their membranes. For this reason, astrocytes 14 days in vitro were used in all experiments. We have reported that assemblies are affected by the protein inhibitor cycloheximide (10^{-4}M, 3 hrs) and protein denaturants, guanidine HCl (2M, 30, 60 min) and urea (5M). Distribution of assemblies in astrocytic membranes is also differentially altered by cytochalasin B (5×10^{-5}M, 60 min) and colchicine (10^{-4}M, 30, 60 min). With cytochalasin B, intramembranous particles, including assemblies, clump, while with colchicine, the assemblies selectively form "cap-like" aggregates. These changes suggest that the distribution of assemblies is associated with cytoplasmic contractile proteins. Since assembly/disassembly of cytoplasmic proteins is related to pH, CO_2 was chosen to alter the intracellular pH of the astrocytes. Primary cultures were subjected to 100% CO_2 at 37°C until the medium was saturated (pH of medium, 5.5). The cultures were then fixed with 5% glutaraldehyde after 5, 15 and 30 minutes. The cells were frozen, fractured and replicated by standard procedures. By 15 minutes, some astrocytic membranes had clumped intramembranous particles resembling the distribution seen after cytochalasin B treatment. After 30 minutes, the number of assemblies increased in the majority of astrocytes, while in others, the assemblies were clumped. Most of these assemblies were small, consisting of only a few particles, and resembled those in astrocytic membranes of fetal and newborn rats where assemblies are added. The cap-like formations caused by colchicine were not seen after CO_2 treatment. Cultures exposed to hydrochloric acid at low pH (2,4,6) had no effect on the membranes. We are currently determining whether the increase in assemblies is due purely to anoxia or acidification of the cytoplasm. Evidence is increasing which suggests that intracellular pH is an important factor in cytoskeletal regulation. Thus, decreases in pH which occur in the brain during seizures and ischemia may cause a change in intracellular pH affecting not only the astrocytic cytoskeleton but also its membrane morphology.

137.1 ^{3}H-RAUWOLSCINE BINDING TO α_2-ADRENERGIC RECEPTORS IN BOVINE BRAIN
B. D. Perry* and D. C. U'Prichard (SPON:E. Silinsky). Dept. of Pharmacology, Northwestern Univ. Med. Sch., Chicago, Ill. 60611

α_2-Adrenergic receptors (R) have been labeled in central and peripheral tissues with ^{3}H-catecholamine and ^{3}H-imidazoline agonist ligands. ^{3}H-Agonists label brain α_2-R in the high affinity (agonist binding) state. It is unclear whether ^{3}H-agonist sites represent the total brain α_2-R population. This question may be addressed by examining the binding characteristics of a selective α_2-antagonist ligand. ^{3}H-Yohimbine (YOH) has been used to characterize α_2-R in platelets and neuroblastoma X glioma cells; in brain, however, the mixed α-adrenergic R population and the moderate α_2-selectivity of YOH complicate characterization. Recently it has been established that rauwolscine (RAUW, α-yohimbine) is a more potent and selective antagonist than YOH at central α_2-R (Hedler et al., Eur.J.Pharm., 70:43-52. 1981), indicating that ^{3}H-RAUW may be a more suitable ligand for examining α_2-R in tissues containing a mixed population of adrenergic R. ^{3}H-RAUW (80-90 Ci/mmol) binding was examined in bovine cortex membranes. Norepinephrine (NE)-displaceable ^{3}H-RAUW (1.0 nM) binding was 75-80 % of total binding. Binding was optimal in 50 mM Na-K phosphate buffer (pH=7.4) at 4^{o}C. Association and dissociation kinetics revealed a single order of sites with k_1/k_{+1} = 1.2 nM. ^{3}H-RAUW binding was saturable, and again monophasic, with an apparent K_D of 1.0-3.0 nM, in good agreement with the kinetic K_D. Agonists and antagonists inhibited ^{3}H-RAUW binding in a manner suggesting α_2-R interactions: K_i values for (-)-epinephrine (EPI), (-)-α-Me-NE, (-)-NE, (+)-NE, (-)-isoproterenol, p-aminoclonidine, and oxymetazoline were 150; 200; 500; 4600; 40,000; 2.0 and 2.0 nM, respectively. Agonist competition curves were shallow (n_H = 0.6-0.8). For antagonists, yohimbine (4 nM) was 1000 times more potent than prazosin (4 μM). Antagonists had high (0.9-1.0) n_H values. In contrast, prazosin inhibited cortex ^{3}H-YOH binding with greater potency and in a heterogeneous manner. (-)-EPI K_i values, in 4^{o}C conditions, were increased 5-fold by 100 μM GTP alone and 2-fold by GTP in combination with 60 mM Na^+. GTP increased agonist n_H values to about 1.0. In contrast, Na^+ increased (-)-EPI K_i values 4-fold but did not increase the n_H values. Regional distribution of ^{3}H-RAUW sites (30 bovine brain regions) was consistent with prior studies with ^{3}H-α_2-agonists. The areas of highest ^{3}H-RAUW binding included frontal cortex, anterior hypothalamus, and cerebellum. ^{3}H-RAUW saturation in 5 brain areas revealed similar K_D values. The results indicate that ^{3}H-RAUW binds with high affinity and selectivity to a single population of brain α_2-adrenergic R. ^{3}H-RAUW should prove a useful implement to further analysis of α_2-R function. Supported by USPHS grant NS 15595.

137.2 VIPOXIN: A SNAKE VENOM PROTEIN LIGAND FOR BIOGENIC AMINE RECEPTORS.
Jonathan E. Freedman and Solomon H. Snyder. Depts. of Neuroscience, Pharmacology and Psychiatry, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Vipoxin (VPX) is a small, highly basic protein, molecular weight 13,000, which we have purified to apparent homogeneity from the venom of Russell's viper (Vipera russelli). VPX inhibits in a dose-dependent manner the binding of ^{3}H-ligands to biogenic amine receptors, with apparent Ki values of 3 nM at alpha$_1$-adrenergic receptors, 5 nM at alpha$_2$-adrenergic receptors, 15 nM at dopamine receptors, and 32 nM at serotonin receptors. VPX up to 1 μM is inactive at beta-adrenergic, histamine, nicotinic cholinergic, muscarinic cholinergic, adenosine, GABA, benzodiazepine, and opiate receptors. The inhibition of alpha-adrenergic receptor binding is essentially irreversible over a 20-hour period, but can be protected against by 100 μM norepinephrine. VPX also possesses phospholipase A_2 activity, which appears not to account for its actions because VPX is active in 1 mM $CoSO_4$, which completely and selectively inhibits the phospholipase activity.

We have studied the physiological actions of VPX at alpha-adrenergic receptors in the rat vas deferens. At alpha$_2$-adrenergic receptors, VPX is an agonist. Its response is blocked by yohimbine and piperoxan selectively, and is of slow onset and extremely slow recovery. VPX is over an order of magnitude more potent than norepinephrine itself. VPX is neither a simple agonist nor an antagonist at alpha$_1$-adrenergic receptors, but potently and selectively potentiates the actions of norepinephrine. It is unexpected for a venom protein to have agonist-like actions, and it is particularly interesting that an agonist should have phospholipase activity.

We have recently prepared ^{125}I-VPX to a specific radioactivity of 4000 Ci/mmole, with at least partial retention of pharmacologic activity. We are beginning binding studies in brain and peripheral tissues, and expect VPX to be a useful ligand for receptor binding, as well as a valuable tool for the purification and biochemical characterization of receptors.

137.3 COMPETITION BY ESTROGENS FOR CATECHOLAMINE RECEPTOR BINDING IN VITRO.
C. M. Paden, L. Snyder*, V. DeGroff* and B. S. McEwen. The Rockefeller University, New York, New York 10021.

Estrogens with hydroxyl groups on either the 2 or 4 carbon atoms of the A ring are referred to as catechol estrogens, and these compounds can be formed by hydroxylation of estrogens in neural tissue. Catechol estrogens have been shown to inhibit catecholaminergic enzymes and to displace ^{3}H-spiperone from anterior pituitary dopamine receptors. These reports have led us to investigate the interactions of catechol estrogens as well as other steroid hormones with a variety of catecholaminergic receptor sites in the rat brain.

Female Sprague-Dawley rats were ovariectomized at least one week prior to use. Membrane binding assays were performed using published procedures with 28,000 x g pellets centrifuged and resuspended twice in tris buffers. Incubations were performed at 25^o C for 30 min. and bound ligand separated by rapid filtration over Whatman GF/B filters. Dopamine receptors in striatum and pituitary were assayed using ^{3}H-spiperone; specific binding was that suppressed by 1 μM d-butaclamol. Beta noradrenergic receptors in cortex were assayed using ^{3}H-dihydroalprenolol; specific binding was that suppressed by 1 μM propranolol. Alpha noradrenergic receptors were assayed using 2,6-dimethoxy ethyl amino methylbenzo-1,4-dioxan (^{3}H-WB4101) or ^{3}H-prazosin (α_1) and ^{3}H-yohimbine (α_2); specific binding was that suppressed by 1 μM phentolamine. The α_2 agonist ^{3}H-clonidine was also used, and specific binding was that suppressed by 100 μM norepinephrine.

An initial survey utilized six steroids added to incubations at a final concentration of 100 μM; 2-hydroxy estradiol (2OHE$_2$), estradiol-17β (E$_2\beta$), estradiol-17α (E$_2\alpha$), progesterone, testosterone and corticosterone. Only the 17β estrogens, 2OHE$_2$ and E$_2\beta$, were effective and only binding of ^{3}H-spiperone in striatum and pituitary and ^{3}H-WB4101 and ^{3}H-prazosin in cortex were reduced. Thus only putative dopaminergic and α_1 noradrenergic sites appear to recognize estrogens. Further experiments varying steriod and ^{3}H-ligand concentrations independently revealed that estrogens were competitive inhibitors of ^{3}H-prazosin binding. The IC_{50} of the most potent estrogen, 2OHE$_2$, was 32 μM, comparable to that of norepinephrine (13 μM). In both striatum and pituitary, 2OHE$_2$ was again the most potent estrogen, but it was far less effective than dopamine itself in displacing ^{3}H-spiperone, with IC_{50}'s of 160 μM and 1 mM in striatum and pituitary, respectively, compared to 12 μM and 5 μM for dopamine. These results show that there is specificity of steroid interactions with catecholamine receptors, both in terms of steroid structure and receptor type. However, the physiological relevance of these effects remains to be established.

137.4 ADRENERGIC RECEPTOR SUBTYPES IN AUTONOMIC TISSUES: RADIOLIGAND BINDING TO RABBIT IRIS-CILIARY BODY MEMBRANES.
Tom Mittag*. (SPON: S.D. Glick) Pharmacology Dept. Mount Sinai Sch. of Med., New York, N.Y. 10029.

Receptor subclasses in iris-ciliary body were determined by direct binding of radioactive dihydroalprenolol (DHA), yohimbine (YOH), WB-4101 (WB) and prazosin (PRZ), classified respectively as β_1 + β_2, α_2, α_1, and α_1 subtype selective ligands (based on binding to brain adrenergic receptors). Rabbit iris-ciliary body membrane fragments in 50 mM phosphate buffer, pH 7.4, 5 mM $MgCl_2$, 0.1 mM GTP and ascorbic acid (0.5 -.025%) were used in glass fiber filter binding assays. Specific binding was defined by competition with appropriate unlabelled agonist and antagonist in each case. Binding data was analysed by use of library programs of the PROPHET computer system.

Binding parameters for the labelled ligands were determined from 4 or more complete binding isotherms as follows: K_d in nM, B_{max} in fmoles/mg protein; DHA = 0.675 $\pm$ .024, 132 $\pm$ 4.9. YOH = 12.48 $\pm$ 1.8, 256 $\pm$ 27.8. WB = 1.33 $\pm$ 0.45, 152 $\pm$ 9.6. PRZ = 0.552 $\pm$ .174, 51.8 $\pm$ 5.9. The Hill coeffs. were close to unity in all cases.

Subclass specificity was also determined by binding competition of the labelled ligand (at a 3-10 fold K_d concentration) with increasing concentrations of cold agonist or antagonist. Cold ligand binding parameters were obtained from Dixon and Scatchard plots. Hill coeffs. for agonists were in the range 0.7 - 0.9, and for antagonists 0.8 - 1.1, except as noted.

For β receptors (determined against DHA) K_d for norepinephrine = 8.54 μM and K_d for epinephrine = 1.07 μM. The ratio of affinities (8 - 15) classify the DHA binding receptors as >80% β_2 subtype.

For β receptors subtype specificity of binding ligands could not be defined. Clonidine (classified as α_2 specific) had similar K_d for PRZ, WB and YOH (0.47, 0.38, 0.50 μM respectively). The K_d's (nM) for cold competing antagonists were determined as follows: Against labelled PRZ, cold WB = >1000, cold PRZ = 0.73; against labelled WB, cold WB = 1.16, cold PRZ = >1000, cold YOH = 50.4 (Hill coeff. 0.5); against labelled YOH, cold WB = 58.7 (Hill coeff. 0.5), cold YOH = 7.1.

Adrenergic receptor density of iris-ciliary body is $\pm$ 600 fmoles/mg protein of which 20-25% are primarily β_2 receptors. Three distinct subpopulations of α-receptors, 10%, 25% and 40-45%, bind PRZ, WB and YOH respectively, each with high specificity for its corresponding ligand but with 10-1000 fold lower specificity for the other two ligands. (Supported by Grant EY-02619 from the National Institutes of Health).

137.5 THE EFFECTS OF MICROINJECTION OF 6-HYDROXYDOPAMINE INTO THE LOCUS COERULEUS OR THE LATERAL RETICULAR NUCLEUS ON ALPHA$_1$-RECEPTORS AND NOREPINEPHRINE CONCENTRATIONS WITHIN THE VENTRAL HORN OF CAT CERVICAL SPINAL CORD. C.H. Park*, J.P.Suyderhoud*, and V.J.Massard Dept. Pharmacol., Howard U., Col. of Med., Washington, DC 20059.

Experiments are in progress to determine the quantitative contribution of two "bulbospinal" noradrenergic (NE) nuclei to measured levels of NE within individual lamina of each segment of the spinal cord. It was also of interest to determine the normal distribution of alpha$_1$ adrenergic receptors in specific laminae of the spinal cord, and to investigate if these receptors could be manipulated pharmacologically. Two groups of cats received a bilateral sterotaxic injection of the NE neurotoxin 6-hydroxydopamine (4μG/μL)into either the locus coeruleus (A$_6$)or the lateral reticular nucleus (A$_1$). A control group was operated upon, but not injected. All animals were sacrificed 10 days after surgery and the entire central nervous system was rapidly removed and frozen on dry ice. Correct lesion placement was verified histologically. The spinal cord was cut in a cryostat alternately into 660μ slabs and 60μ sections. The thin sections were stained and used as a guide to the microdissection. NE concentration was determined in Lamina IX for each segment of the cervical enlargement of the spinal cord i.e.,C$_6$,C$_7$,C$_8$,and T$_1$. Alpha$_1$ receptor binding was measured in a pooled aliquot from the same tissues. Alpha$_1$ receptor binding was estimated using the specific alpha$_1$ receptor antagonist Prazosin-H^3 as a ligand. In control cats,NE concentration in Lamina IX did not vary significantly from segment to segment in the cervical enlargement. A$_6$ lesions caused a uniform and statistically significant 62±5% (X̄±S.E.M.)reduction in NE in all these segments. However A$_1$ lesions caused a significant 56±8% reduction of NE only in segment C$_7$. A$_1$ lesions did not effect ^{3}H-Prazosin binding to alpha$_1$ receptors. A$_6$ lesions, however, caused a 20% increase in binding which just missed statistical significance ($p<.06$). These data show that the quantitative contribution of the A$_1$ nucleus to measured levels of NE in discrete laminar areas of the spinal cord varies from segment to segment. Previous data suggested that A$_1$ projects only to the dorsal horn of the spinal cord. The present results indicate that A$_1$ also has a NE terminal projection to Lamina IX of the ventral horn in segment C$_7$. Within this segment, it also appears that almost all the NE terminal input may come from the A$_1$ and A$_6$ neuclei Lesions of A$_1$ caused relatively little decline in NE levels in Lamina IX of the entire cervical enlargement. Correspondingly,no effect was seen on alpha$_1$ receptor binding. On the other hand A$_6$ lesions, which caused a substantial decrease in NE throughout this area,caused a slight increase in Prazosin binding,which may reflect the onset of denervation supersensitivity.

Supt. NSF7923451.

137.7 REGULATION OF α_2-ADRENERGIC RECEPTOR SITES IN NEUROBLASTOMA X GLIOMA HYBRID CELLS. D.J.Kahn and D.C.U'Prichard. Department of Pharmacology, Northwestern University Medical School, Chicago, IL., 60611.

We have examined the regulation of rodent neuroblastoma x glioma, NG 108-15, α_2-receptors (R) using the antagonist radioligand, ^{3}H-yohimbine (YOH, mean K_D 8 nM), the partial agonist, ^{3}H-p-aminoclonidine (PAC, K_D 1.8 nM) and the full agonist ^{3}H-epinephrine (EPI, K_D 11 nM), along with the coupled biochemical response of a GTP-dependent inhibition of adenylate cyclase(AC). We have previously shown that agonists preferentially label a high-affinity form of the α_2-R in NG 108-15 cells, α_2(H), while ^{3}H-YOH recognizes α_2(H) and a low affinity form, α_2(L), with equal affinity. In order to examine regulation of α_2-R, NG 108-15 cells were grown for 1-16 hours in the presence of (-)-EPI. Results indicate that in NG 108-15 cell α_2-R down-regulation, uncoupling precedes receptor loss. That is, after 1-4 hours of EPI incubation there was no change in the total receptor number labeled by any of the radioligands, but the number of high-affinity sites labeled by ^{3}H-EPI or ^{3}H-PAC was increased. This corresponded to an observed decrease in the potency of EPI for AC inhibition, while the affinity of YOH for reversing AC inhibition or the maximal EPI response were unchanged. Longer incubation times increased basal and stimulated AC, but there was no observed tolerance to the α_2-R AC response. However, following 8-16 hours of EPI incubation there was a progressive loss of receptor sites. By 16 hours the B_{max} of ^{3}H-YOH was decreased by 60% with no change in K_D, while ^{3}H-EPI and ^{3}H-PAC binding were similarly reduced in extent (60-70%) with an accompanying increase in K_D for both agonists (EPI K_D from 8 to 17 nM, PAC K_D from 1.9 to 6.6 nM). The results indicate that NG 108-15 α_2-R are able to be regulated and that down-regulation involves two phases. An earlier phase may be uncoupling of the α_2-R from AC, represented by a shift from low to high affinity states but no receptor loss, and a decrease in EPI potency for AC inhibition. A second phase observed after longer agonist incubation periods is represented by significant loss of α_2-R from NG 108-15 cell membranes, along with a steadily increasing basal AC activity. Agonist and antagonist radioligand binding data suggest that high affinity (α_2(H)) states are preferentially lost in the second phase of α_2-R down-regulation. Studies are in progress to examine agonist-induced loss of different α_2-R states in more detail, and to correlate regulation of binding sites and the adenylate cyclase response.

Supported in part by USPHS grants DA 02763 and NS 15595, and a Scottish Rite Schizophrenia Research Fellowship (D.J.K.).

137.6 REGULATION OF ADRENERGIC RECEPTORS ON RAT CORTEX NEURONS BY CONGENITAL NORADRENERGIC HYPERINNERVATION AND SUBSEQUENT DENERVATION C. H. Wang and D. C. U'Prichard. Dept. of Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Bilateral lesion of noradrenergic (NA) bundles, or intracerebroventricular (i.c.v.) 6-hydroxydopamine (6-OHDA) treatment, causes increases in rat cortical β-, α_1- and α_2-adrenergic receptors (Adr-R)(U'Prichard et al. 1979, 1980). It is not known however if different cortical Adr-R subtypes can be down-regulated to the same extent by increasing the amount of presynaptic NA inputs. In this study, we examined pharmacologically-induced fetal NA hyperinnervation, and subsequent NA lesion with 6-OHDA, as a means of modulating presynaptic NA input to rat cortical neurons, and we measured subsequent alterations in different Adr-R subtypes labeled with both agonist and antagonist ligands. Pregnant female rats injected with the antimitotic agent methylazoxymethanol acetate (MAM) on gestation day 15 gave birth to offspring with microencephaly and cortical NA hyperinnervation. Previously Johnston and Coyle (Brain Res. 170:135,1979) reported MAM-induced reductions in β-receptor binding per mg cortex prot. We found significant decreases in B_{max} (fmole/mg prot.) for all cortical Adr-R subtypes in 10-16 wk old male or female progeny of MAM-treated rats:β-R (-28%, ^{3}H-dihydroalprenolol, DHA);α_1-R (-19%, ^{3}H-prazosin);α_2-R (-40%, ^{3}H-yohimbine, YOH; -27%, ^{3}H-p-aminoclonidine,PAC) Radioligand K_D values were not significantly altered. In control cortex, catecholamine agonist competition curves at β- and α_2-R labeled with antagonist radioligands are shallow, indicating multiple R affinity states ((-)-isoproterenol vs. DHA: IC_{50}=41 nM, n_H=0.72); (-)-epinephrine vs. YOH: IC_{50}=130 nM, n_H=0.79).Residual β- and α_2-R after MAM treatment were further characterized by examining agonist competition profiles. No changes were observed in either IC_{50} or n_H values for (-)-isoproterenol vs. DHA or (-)-epinephrine vs. YOH, between MAM and control groups. Thus there is no preferential loss of high-affinity states of β- or α_2-R as a result of MAM treatment. Bilateral i.c.v. 6-OHDA treatment of 16 wk old MAM rats increased B_{max} values 80% for cortex PAC binding, but only 18% for YOH binding. No change was seen in ligand K_D values. These increases in α_2-R densities were significantly greater than increases observed after i.c.v. 6-OHDA in control rats. The results indicate that different cortical Adr-R subtypes can be reduced in total number by increasing presynaptic NA input, with no change in other R characteristics. Differential effects of 6-OHDA lesions in control and MAM rats indicate that denervation-induced increases in Adr-R number on cortical neurons may depend on the density of NA input prior to denervation.

Supported in part by USPHS grant NS 15595.

137.8 IDENTIFICATION OF β-ADRENERGIC RECEPTOR (β-AR) SUBTYPE ON RAT ASTROGLIA AND OLIGODENDROGLIA. K.D. McCarthy and T.K. Harden (Spon: R.B. Mailman) Dept. Pharmacology, Univ. North Carolina School of Medicine, Chapel Hill, NC 27514.

Membrane preparations from rat cerebral cortex and cerebellum express very different ratios of β_1-AR to β_2-AR (81:19 in cerebral cortex, 15:85 in cerebellum; Minneman et al, Mol. Pharmacol. 16:34, 1979). The cellular localization of these receptor subtypes is not known. However, indirect studies using drug-induced alterations in noradrenergic input suggest that it is the β_1-subtype that receives endogenous innervation by norepinephrine-containing neurons (Minneman et al, Science 204:866, 1979). The present study was undertaken to identify the β-AR subtype that exists on glial cells. Astroglia and oligodendroglia were purified from rat cerebral cortical cultures. Astroglia were also purified from rat cerebellum cultures. ^{125}I-hydroxybenzylpindolol (^{125}IHYP) was utilized to identify β-AR in membrane preparations obtained from these cells. ^{125}IHYP bound with a similar Kd (20-35 pM) to receptors of cultured astroglia, oligodendroglia, C6BD12 glioma, and 132INI astrocytoma cells. Similar affinities for ^{125}IHYP were also obtained using membranes from rat heart, lung, and cerebral cortex. Competition binding curves were generated with the β_2-AR selective drugs, zinterol and ICI 118,551, and the β_1-AR selective drug, practolol. The following K_i values (nM) were obtained (n = 2-6):

Tissue	Zinterol	ICI 118,551	Practolol
heart	364±25	48±13	669±116
lung	42±3	2±0.4	13,214±3004
cerebellum astroglia	309±77	67±15	1004±178
cerebral cortex astroglia	800±203	101±32	780±70
cerebral cortex oligodendroglia	375	118	
C6 BD12 glioma	480±50	42±2	
132INI astrocytoma	47±7	2±1	

Hofstee plots of competition binding curves with these three drugs using membranes from cultured astroglia and oligodendroglia as well as membranes from C6 BD12 glioma and 132INI astrocytoma cells were fit by a single line suggesting that ^{125}IHYP interacts with a single receptor subtype. In contrast, Hofstee analysis of competition curves with membranes from adult rat cerebral cortex and heart were nonlinear suggesting the presence of two binding components. Our data are consistent with the conclusion that a single subtype of β-adrenergic receptor exists on astroglia from rat cerebral cortex and cerebellum and oligodendroglia from rat cerebral cortex. This receptor is of the β_1-subtype. Supported by NS 16992.

137.9 REMOVAL OF CHAOTROPIC AGENTS ELIMINATES THE ENHANCEMENT OF BICUCULLINE INHIBITION OF HIGH AFFINITY GABA BINDING IN BOVINE RETINAL MEMBRANES. Lynn Churchill and Dianna A. Redburn, Dept. of Neurobiol. & Anat., Univ. of Texas Med. Sch., Houston, TX 77025.

The chaotropic agent, ammonium thiocyanate, enhanced bicuculline inhibition of high affinity binding of γ-aminobutyric acid (GABA) to rat forebrain membranes (Enna and Snyder (1977) Mol. Pharmacol. 13, 442) and the chaotropic agent, sodium perchlorate, was used to assay both agonist (GABA) and antagonist (bicuculline) binding under the same conditions in rat cerebellum (Mohler (1979) In: GABA-Biochemistry and CNS Functions (Mandel and DeFeudis, eds) Plenum Press, N.Y., p. 355). We have examined bicuculline inhibition of high affinity (10 nM) GABA binding in synaptosomal fractions from bovine retina and found a similar enhancement of bicuculline inhibition in the presence of both ammonium thiocyanate and Tris perchlorate. The 50% displacement (IC_{50}) of high affinity GABA binding with bicuculline was 0.2 μM in the presence of 100 mM ammonium thiocyanate in comparison with 2 μM for the same tissue in the presence of 100 mM ammonium chloride as a control. Likewise, the IC_{50} in the presence of 100 mM Tris perchlorate was 0.5 μM compared with 6 μM for Tris chloride as the control. Since solubilization of a component blocking the receptor binding site or a regulatory component has been proposed as an explanation for the action of chaotropic agents, we tested this hypothesis by removing the chaotropic agent and testing to determine if the enhancement of bicuculline inhibition is still present after removal. After removing the chaotropic agents by centrifugation through 0.32 M sucrose, the IC_{50} for bicuculline was 1-3 μM for all of the membranes whether treated with chaotropic agents or control solutions prior to the centrifugation. The additional washing decreased the IC_{50} for the controls and removal of the chaotropic agents increased the IC_{50} values to the same values as the control. This data indicates that the presence of the chaotropic agent is necessary for the enhancement of bicuculline inhibition and strongly suggests that solubilization and removal of a component blocking or regulating the receptor site is not a reasonable explanation for enhancement of bicuculline inhibition.

137.10 SOLUBILIZATION AND CHARACTERIZATION OF NEUROLEPTIC-RECEPTOR BINDING SITES FROM RAT STRIATAL MEMBRANES. J.Y. Lew*, J.C. Fong* and Menek Goldstein. Neurochemistry Lab., New York University Medical Center, Dept. of Psychiatry, New York, N.Y. 10016.

To determine the molecular properties of dopamine (DA) receptors with high affinity for DA antagonists (neuroleptic receptors), we have solubilized and characterized the receptor from rat striatal membranes. Among a number of tested detergents, only the recently described one, CHAPS (zwitterionic acid of cholic acid) (L.M. Hjelmeland, Proc. Natl. Acad. Sci., 77, 6368, 1980) was found to have the ability to solubilize active neuroleptic receptors. The neuroleptic receptors were solubilized by incubation of membranes in 0.05M Tris-HCl buffer, pH 7.4, containing 2mM dithiothreitol (Tris buffer) and 10mM CHAPS for 20 min at 0°C. At the end of the incubation period, the mixture was centrifuged at 100.000xg for 30 min. and aliquots of the supernatant were used for assay. The receptor assay mixture contained 0.2 ml of supernatant solution (solubilized proteins from 10 mg striatum), 0.05 ml of ^{3}H-Spi (Sp. act. 35.9 Ci/mmol) and 0.7 ml of Tris buffer. Haloperidol and (+) butaclamol, but not (-) butaclamol, displaces ^{3}H-Spi from the soluble receptor at nanomolar concentrations. Apomorphine (Apo) and DA displace ^{3}H-Spi only at μmolar concentrations. The displacement of ^{3}H-Spi by Apo is not affected by GTP, indicating that the soluble receptor is not coupled to the GTP sensitive component. Scatchard plot analysis revealed that ^{3}H-Spi binds to a low affinity site (K_D = 0.16nM, B_{Max} = 2.5 pmole/g tissue) and to a low affinity site (K_D = 1.25nM, B_{Max} = 11.2 pmoles/g tissue). Thus, the binding characteristics of ^{3}H-Spi for the soluble receptor are similar to those reported for the membrane bound receptors. In some experiments, the detergent was removed after centrifugation by passing the protein solution through a Bio-Beads SM-2, 20-50 mesh (Bio-Rad) column. The neuroleptic receptor remained active even after removal of the detergent. The molecular weight of the soluble receptor complex is now being determined by gel filtration on a calibrated Sepharose 6-B column. This study was supported by NINDS Grant 06801 and NIMH Grant 02717.

137.11 IN VITRO AND IN VIVO INTERACTION OF NORHARMAN (BETA CARBOLINE) WITH THE BENZODIAZEPINE RECEPTOR. A.M. Morin*, I.A. Tanaka*, C.G. Wasterlain* (SPON. A.S. Kling) Neurology and Epilepsy Res. Labs., V.A. Medical Center, Sepulveda, CA 91343 and Dept. Neurology, U.C.L.A., Los Angles, CA 90024.

Norharman (β-carboline) has been described as an in vitro competitive inhibitor of [^{3}H]-diazepam binding in mouse forebrain (Morin and Wasterlain, Life Sci. 28(20)2257-2263, 1981; Trans. Amer. Soc. Neurochem 12(1)128, 1981). This unsubstituted β-carboline along with other structurally related β-carbolines appears to antagonize the action of diazepam (Skolnick et al. Eur. J. Pharmacol. 69:525-527, 1981; Braestrup et al., PNAS 77 (4)2288-2292, 1980; Nielsen et al., J. Neurochem. 36(1):276-285, 1981). Binding data in mouse brain areas indicate linear Scatchard plots unlike the curvilinear Scatchard plot obtained with β-carboline-3-carboxylate in rat brain (Braestrup et al., PNAS 77(4):2288-2292, 1980). EC_{50} values are in the 3-6μM range. The profile of this compound along with other β-carbolines indicate that in vitro norharman binds to the same site as benzodiazepines and in a similar manner.

The in vivo administration of norharman produces profound behavioral effects. Mice become ataxic within 5 minutes of receiving an i.p. dose (50 mg/kg). Animals remain sedate and lose the ability to right themselves when placed on their sides. They exhibit tremors and a stiffness in limbs. Diazepam (3.5 mg) prolongs the sedation, reduces the stiffness and stops tremors. Unlike the benzodiazepines, norharman has no anti-convulsant activity. Given prior to pentylenetetrazol (70 mg/kg) or bicuculline (6 mg/kg), norharman (50 mg/kg) reduced the latency time (50% to 75%) to seizures (P<.05). In vivo brain concentrations of norharman peak within 5-10 min. of an i.p. dose (50-100 mg/kg). Determination of in vivo concentrations in various brain areas (cortex, hippocampus, striatum and cerebellum) indicate that behavioral responses to norharman occur at brain concentrations in the range of 0.20 μM. Levels of inhibition of in vitro [^{3}H]-diazepam binding measured in whole homogenate in these areas showed regional differences with 29.3±3.4% in cortex; 47.4±5.4% in cerebellum; 16.2±3.5% in hippocampus and 18.9±5.0% in striatum. It seems likely that if norharman exerts some effects in vivo through the benzodiazepine receptor, it does so by binding with a higher affinity than that observed in vitro and perhaps through greater binding to receptors in a specific area (i.e. cerebellum).

137.12 TEMPERATURE-DEPENDENT BINDING TO THE BENZODIAZEPINE RECEPTOR. R.L. Kochman and J.D. Hirsch. Dept. Biol. Res., G.D. Searle & Co., Chicago, IL 60680.

Recently, several non-benzodiazepines have been found to antagonize some of the effects of diazepam (DZ). In an attempt to find a biochemical means of distinguishing these compounds from benzodiazepine-like drugs, we investigated the temperature dependence of their in vitro binding to the benzodiazepine receptor.

Approximately 0.5mg of protein from a 1000xg supernatant prepared from whole rat brain homogenate was preincubated with various concentrations of test compounds and 50mM Na-K phosphate buffer containing 0.2M NaCl for 15 minutes at 0°,10°,20°, or 30°C. Binding was initiated by adding ^{3}H-DZ (final concentration 4nM). Incubation was continued at the appropriate temperature for 30 minutes, then samples were filtered under vacuum pressure through Whatman GF/C papers and rinsed with 8mls of 0.15M NaCl. The IC50 value for each compound was determined by log-logit analysis of the displacement of ^{3}H-DZ binding by the compound, and the related K_I value obtained using the Cheng-Prusoff equation. Saturation binding of ^{3}H-DZ and ^{3}H-β-carboline-3-carboxylic acid propyl ester (βCPE) were analysed by Woolf plots to obtain affinity constants (K_D). The K_I and K_D values were then used to calculate the thermodynamic parameters of binding for each compound (Weiland et al., Nature 281:114, 1979).

The apparent K_Is of DZ, βCPE, β-carboline-3-carboxylic acid ethyl ester (βCEE), flunitrazepam, chlordiazepoxide, alprazolam (A), zopiclone (Z), and irazepine all decreased with increasing temperature. To the contrary, the K_Is of triazolam (T) and SC-35195 (SC), a pyridobenzothiazinol which also appears to antagonize DZ, were enhanced with increasing temperature. Thermodynamic analysis indicated that for all compounds binding was an entropy-driven process, with entropy values (ΔS^o) ranging from 5 entropy units (e.u.) for A to 72 e.u. for T. Enthalpy values (ΔH^o) ranged from -6kcal/mol for Z to -8kcal/mol for DZ, while T and SC binding were endothermic (approx. 6kcal/mol).

Preliminary results using a washed P_2 homogenate and 50mM Tris·HCl indicate ΔH^o and ΔS^o values similar to those above. However, whereas DZ binding is stimulated by both GABA and $NiCl_2$, βCPE, βCEE, and SC are differentially affected. Also, GABA stimulation increases, while stimulation by $NiCl_2$ decreases, with increasing temperature.

137.13 FLUORESCENT PROBE STUDIES OF MOUSE BRAIN BENZODIAZEPINE RECEPTORS. James D. Hirsch, Dept. Biol. Res., G.D. Searle and Co., Chicago, IL 60680.

The membrane events associated with and subsequent to ligand binding to the brain benzodiazepine receptor (BDZR) are largely unknown. In order to go beyond measuring only ligand-BDZR recognition and to begin examining these events in more detail, the anionic fluorescent dye 8-anilino-1-naphthalene sulfonic acid (ANS) was used to probe various loci in mouse brain membranes. Upon excitation at 380nm, ANS fluorescence in membranes was greatly enhanced and blue-shifted with an emission maximum at 490nm. This baseline fluorescence was enhanced further by Triton X-100 (EC_{50} 0.03% v/v), ethanol, halogen anions (Cl > Br > F > I), monovalent cations (Li > Na > K > NH_4), divalent cations (Hg, Cu, Mn, Ni, Mg, Ca, Zn), and Al^{+3}. Fe^{+2} and DMSO decreased fluorescence. DMSO caused a red shift in emission as well. ANS binding measured by fluorescence was saturable and the K_m (45-55 µM) was similar in membranes from whole brain, cerebellum, frontal cortex and olfactory bulbs. However, cerebellum membranes contained 25% more ANS sites than other regions. In all brain regions, 100mM NaCl enhanced ANS fluorescence by increasing the B_{max} by about 70% with no change in K_m. Two binding sites for Cl^- and I^- ions were detected. Pretreatment of membranes for 30 min at 30° with 100 µM diisothiocyanostilbene disulfonic acid (DIDS), an irreversible anion channel blocker, decreased the number of Cl^- sites with no change in K_m. Tetrodotoxin (100nM) obliterated a high affinity Na^+ site (K_m=25mM) but had no effect on a low affinity site (K_m=200mM). The H_2O-soluble BDZ's chlordiazepoxide, flurazepam, and chlorazepate (5-10000nM) decreased ANS fluorescence emission at 490nm in a concentration-dependent fashion. Irreversible occupation of the BDZR by irazepine (200nM, 30 min, 4°) and avermectin B1a (10µM, 60 min, 4°) caused a 25% decrease in ANS fluorescence due solely to a decrease in dye K_m. Photoaffinity inactivation of the BDZR with UV light and flunitrazepam (20nM, 4 hr. U.V., 4°) had the same effect. Administration of 50 mg/kg chlordiazepoxide i.p. to mice followed 30 min later by fluorescence measurements in brain membranes from treated animals also resulted in decreases in ANS fluorescence emission. These data suggest that ANS binds to the Cl^- and Na^+ channels and to the brain BDZR. Occupation of the receptor by BDZ's and other ligands in vitro and in vivo quenches receptor-bound probe fluorescence. This may be due to ligand-induced conformational changes in the receptor that lead to decreased hydrophobicity in the probe's microenvironment. Ligand-induced perturbation of the BDZR structure might be the first step in the ligand-receptor-signal transmission process.

137.14 BRAIN MONOAMINE RECEPTOR CHANGES ASSOCIATED WITH CATECHOLAMINE DEPLETION AND HYPOTENSION DURING CONTINUOUS α-METHYLDOPA INFUSION D.C.U'Prichard, C.H.Wang and C.R.Freed. Dept. of Pharmacology, Northwestern Univ.Med.Sch.,Chicago,IL 60611, and Depts. of Medicine and Pharmacology, Univ.Colorado Med.Ctr., Denver, CO 80262.

The antihypertensive drug α-methylDOPA (α-MeDOPA) has been shown to deplete central stores of norepinephrine (NE) and dopamine (DA). The hypotensive effect of α-MeDOPA may be due to interaction of its metabolites α-MeNE and α-MeDA with presynaptic catecholamine (CA), especially α_2-adrenergic, receptors (R); however it is unclear which metabolite is more important in mediating hypertension, and whether other R may also be secondary sites of action. In studies designed to compare effects of α-MeDOPA and other antihypertensive α_2-agonists, we examined central monoamine R changes after continuous i.v. αMeDOPA infusion and correlated R changes with depletion of endogenous CA and steady-state levels of α-MeDOPA metabolites. Conscious male Sprague Dawley rats (200-300 g) under mild restraint were infused via jugular vein cannula with α-MeDOPA (0,5 or 20 mg/kg/hr) plus the decarboxylase inhibitor Carbidopa (2.5 mg/kg/hr) for 72 hr. Blood pressure (BP) was measured before and after 72 hr infusion via an indwelling aortic catheter below the level of the renal arteries. After infusion, brains were hemisected and one half used to measure CA and α-MeDOPA metabolite levels by HPLC electrochemical detection. In the other half, monoamine R levels in cerebral cortex,corpus striatum and rest of brain were assayed as follows (R, ligand, blank): β-R ^{3}H-dihydroalprenolol (DHA), 0.2 µM (-)-propranolol; α_1-R, ^{3}H-prazosin (PRAZ), 100 µM NE; α_2-R, ^{3}H-p-aminoclonidine (PAC),10 µM NE and ^{3}H-rauwolscine (RAUW), 100 µM NE; DA-R, ^{3}H-spiroperidol (SPIRO), 1.0 µM (+)-butaclamol; 5HT1-R, ^{3}H-5HT, 1.0 µM 5HT;5HT2-R SPIRO, 1.0 µM cinanserin. 0,5 and 20 mg/kg/hr α-MeDOPA infusion caused dose-dependent decreases in BP (-1,-2,-17 mm Hg), decreases in hypothalamic DA (2.5, 1.7, 0.5 nmole/g) and increases in α-MeDA (0, 3.8, 11.5 nmole/g). Depletion of hypothalamic NE and appearance of α-MeNE was not dose-dependent; maximal effects were observed at 5 mg/kg/hr α-MeDOPA. 72 hr α-MeDOPA infusion caused dose-dependent reductions in cortex α_2-R and increases in cortex α_1-R and striatal DA-R: PAC (max. -54%), RAUW (max. -33%), PRAZ (max. +19%), SPIRO (max. +58%). Cortex β-R and 5HT-R were not changed. α_1-R and α_2-R changes in rest of brain were similar but less extensive. The results show that α-MeDOPA metabolites directly down-regulate brain α_2-R, and also up-regulate α_1-R and DA-R, either by CA depletion or reducing CA release via presynaptic R interactions A strong correlation was observed between DA depletion, α-MeDA appearance and R changes, suggesting that R changes are mediated primarily by α-MeDA, which achieves a brain concentration sufficient to interact at α_2-R.

137.15 ADENOSINE RECEPTOR HETEROGENEITY. Kenneth M.M. Murphy and Solomon H. Snyder., Johns Hopkins University, School of Medicine, Dept. of Neuroscience, Pharmacology and Psychiatry, Baltimore, MD 21205.

The existence of multiple receptors for individual neurotransmitters has implications for developing drugs with therapeutic selectivity. Adenosine's actions upon neuronal and non-neuronal systems involve at least two distinct receptors. Reduction of adenylate cyclase activity involves A_1 receptors which respond to nanomolar adenosine while micromolar adenosine is required to stimulate adenylate cyclase at A_2 receptors. ^{3}H-N^6-cyclohexyladenosine (^{3}H-CHA) at 25°C labels A_1 adenosine receptors in membranes of bovine, guinea pig, rat, rabbit and human brains. The xanthine antagonist ^{3}H-1, 3-diethyl-8-phenyl-xanthine (^{3}H-DPX) at 0°C labels typical A_1 adenosine receptors in bovine, rat and rabbit brain. In guniea pig membranes, ^{3}H-DPX at 0°C labels sites which have micromolar affinities for adenosine analogs and other properties suggesting interactions with A_2 receptors (Bruns, Daly, Snyder, Proc. Natl. Acad. Sci., USA, 77:5547-5551, 1980). Thermodynamics of adenosine receptor interactions vary considerably among species and differ for agonists and antogonists. Agonists become less potent with reduced temperature at A_1 receptors, while antagonists generally become more potent. Between 25°C and 0°C, agonist affinities fall 5-10 fold in bovine brain, 10-20 fold in rat and rabbit, while a much greater decline in agonist affinities occurs for guinea pig brain. Accordingly, the weak competition by agonists for ^{3}H-DPX binding to guinea pig brain at 0°C, resembling A_2 receptors, may reflect one end of a continuum of temperature-dependent agonist affinities at A_1 receptors. Besides these temperature variations, drug potencies vary markedly at ^{3}H-CHA binding sites in various species. Thus, the K_i for inhibition at 25°C of ^{3}H-CHA binding by DPX is 10 nM, 100 nM, 150 nM and 500 nM in bovine, rat, rabbit and guinea pig brain membranes, respectively. These data suggest a considerable heterogeneity of adenosine receptors. For a substance which influences a wide range of physiological processes, such as adenosine, clarification of receptor heterogeneity may facilitate the design of tissue specific drugs.

137.16 SOLUBILIZATION, PHOTOAFFINITY-LABELLING AND INITIAL PURIFICATION OF THE GLYCINE RECEPTOR IN RAT SPINAL CORD. H. Betz*, D. Graham* and F. Pfeiffer*. (SPON: R. Nowakowski). Max-Planck-Institute for Psychiatry, Dept. of Neurochemistry, D-8033 Martinsried, Federal Republic of Germany.

Glycine is a major inhibitory neurotransmitter in mammalian spinal cord. The hyperpolarizing action of this amino acid can be selectively antagonized by the alkaloid strychnine, the latter being a highly specific ligand for the postsynaptic glycine receptor. Here we report the solubilisation, photoaffinity-labelling and purification of the glycine receptor from membrane preparations of rat spinal cord.

High-affinity binding sites for ^{3}H-strychnine were solubilized from rat spinal cord membranes by using Triton X 100, and were subsequently detected by a polyethylene glycol precipitation assay. Scatchard analysis of ^{3}H-strychnine binding data showed a single class of binding sites with dissociation constants of 11 nM and 20 nM, for membrane-bound and solubilized receptor, respectively. For both preparations, similar concencrations of glycine, ß-alanine and taurine were needed to produce half-maximal inhibition of ^{3}H-strychnine binding. The solubilized receptor exhibited a stokes radius of 73 Å upon Sepharose 6B gel exclusion chromatography and gave a sedimentation coefficient of 8.5 S on sucrose density gradients.

Incubation of the membrane fractions with ^{3}H-strychnine in the presence of UV light led to an irreversible binding of the alkaloid to a membrane protein which exhibited a molecular weight of 48,000 ± 2,800 (n=3) on 10 % SDS polyacrylamide gels. The labelling of this protein was specifically inhibited by the addition of either glycine or unlabelled strychnine to the incubation mixture.

The solubilized receptor was retained on concanavalin A - and wheat germ agglutinin - sepharose, and thus is a glycoprotein. Affinity chromatography on strychnine-derivatised agarose beads gave approx. a 500-fold purification of the glycine receptor.

137.17 GLUCOCORTICOID BINDING BY SOLUBLE FRACTIONS FROM RAT SUPERIOR CERVICAL GANGLIA. A. C. Towle* and P. Y. Sze (SPON: S. C. Maxson). Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT 06268.

Several investigators have suggested that the sympathetic nervous system may be a target organ for adrenal glucocorticoids. We have investigated glucocorticoid binding capacity in the soluble fractions (100,000 g supernatants) of the adult rat superior cervical ganglia. A remarkably high level of ^{3}H-corticosterone binding (2150 femtomoles/mg protein) was found in the ganglion preparations. However, there was no detectable binding for ^{3}H-dexamethasone. The ^{3}H-corticosterone binding protein was characterized as a transcortin-like protein by various biochemical criteria, including isoelectric focusing and chromatograph on DEAE-cellulose and DNA-cellulose. The transcortin-like protein found in the ganglia was not from contaminating blood, as shown by the complete clearance of intravenously injected ^{14}C-inulin following extensive perfusion of the animal. When the sheath was removed from the whole ganglion, 20% of the ^{3}H-corticosterone binding capacity remained in the desheathed ganglion; the other 80% was found in the interstitial fluid. Our data indicate that a binding protein with glucocorticoid receptor-like characteristics is not present in the ganglia. This raises a question about the mechanism of action of dexamethasone, which has been commonly used to elicit biochemical effects in the ganglia.

137.18 REGULATION OF ^{3}H-DOPAMINE BINDING TO RAT STRIATAL MEMBRANES BY GUANINE NUCLEOTIDES AND CATIONS. Mark W. Hamblin, Stuart E. Leff and Ian Creese, Dept. Neurosciences, Univ. Calif. San Diego, La Jolla, CA 92093.

Both guanine nucleotides and physiological cations are known to regulate radioligand binding to a variety of different neurotransmitter receptors. Guanine nucleotides have previously been shown to lower the Kd for the binding of the dopaminergic agonist ligand ^{3}H-apomorphine without affecting the Bmax, and to lower agonist affinity for dopamine (DA) receptors labeled by ^{3}H-spiroperidol. Conversely, divalent cations have been shown to enhance binding of ^{3}H-apomorphine. No such studies have previously been made with ^{3}H-dopamine itself, nor has the interaction of guanine nucleotides and ions in the regulation of dopaminergic ^{3}H-agonist binding been described. We have now characterized these effects using fresh rat striatal membranes.

Little specific ^{3}H-DA binding to well washed membranes can be detected in the absence of added metal cations or chelating agents. Addition of Ca^{++} or Mg^{++} produces a dose dependent increase in Bmax to maximum values of approximately 20 pm/g tissue, with no change in Kd (2 nM). EC50's for both ions are approximately 100 µM. EDTA (0.01 mM to 10 mM), as reported previously, also increases the Bmax, although only to a level half that obtainable with Ca^{++} or Mg^{++}. Maximal effects of the divalent cations or of the ions and EDTA are not additive. This high affinity ^{3}H-DA specific binding is partially eliminated by nigral 6-OHDA lesions, consistent with both pre- and postsynaptic locations for these sites.

Na^{+} (10-300 mM) and GTP (300 µM) have no effect on specific binding in the absence of other added metal cations or EDTA. Na^{+}, GTP, GDP and the stable GTP analogue GppNHp, however, reverse the effects of divalent cations or EDTA on Bmax, again without affecting Kd. GMP and ATP are ineffective. 300 mM Na^{+} or 300 µM GTP reduce specific binding in the presence of 1 mM Ca^{++} or 1 mM EDTA to control levels.

These results may reflect the existence of two interconverting states of the ^{3}H-dopamine binding site. The presence of Ca^{++} or Mg^{++} appears to favor the formation of the high affinity state, whereas Na^{+} and GTP favor the formation of a low affinity state not labeled by ^{3}H-DA in filtration assays. These results also indicate that the comparison of absolute numbers of various dopamine receptor subtypes labeled by different ^{3}H-ligands is invalid unless optimum ionic conditions are employed. (Supported by GM07198 and MH32990)

138.1 EFFECTS OF SOMATOSTATIN ON CORTICAL NEURONS IN CULTURE: MEMBRANE EFFECTS WITH UNUSUAL DOSE-RESPONSE CHARACTERISTICS. John R. Delfs and Marc A. Dichter (SPON: Howard W. Blume). Dept. of Neurology, Children's Hospital Medical Center, Boston, MA 02115.

Previous reports from our laboratory have described that somatostatin causes increased synaptic activity when applied to rat cortical neurons in cell culture. This effect was blocked by simultaneous perfusion with tetrodotoxin, suggesting an unobserved direct membrane effect.

We have now applied known concentrations of somatostatin by local miniperfusion to over 150 neurons during intracellular recordings. The following additional points can be made about the effects of somatostatin on rat cortical neurons in culture:

1. Somatostatin depolarizes a subpopulation of the neurons. This depolarization is usually small (6 +/- 4 mV), but is often associated with an increased generation of action potentials (APs) by the depolarized neuron. The effect of somatostatin to increase the frequency of PSPs is likely due to depolarization and excitation of one or more neurons in a particular neuronal circuit.

2 The observed effect of somatostatin, whether to increase PSP frequency or to depolarize, is greatest with the initial application of somatostatin. A rapid decrement in the amplitude of the response was seen with repeated applications.

3. An especially remarkable finding was a dose-response relationship in which lower concentrations of somatostatin (high pM or low nM) caused larger or more predictable responses than did higher concentrations (high nM or low uM). Application of a higher concentration often resulted in no observable response, while the application of a lower concentration to the same neuron would often result in a significant depolarization or an increase in synaptic activity. These dose-response characteristics suggest similarities with other agents known to have biphasic dose-response characteristics and have major implications for an understanding of the physiologic role of somatostatin in the central nervous system.

4. In some neurons a low concentration of somatostatin caused an increase in the frequency of spontaneous or stimulus-evoked APs, while a higher concentration inhibited action potential generation in the same neuron. This may suggest the existence of at least two receptor sites of different affinities for somatostatin on cortical neurons, one mediating an excitatory and the other an inhibitory response.

138.2 SOMATOSTATIN HAS EXCITATORY ACTIONS ON MURINE SPINAL CORD NEURONS IN PRIMARY DISSOCIATED CELL CULTURE. R.L. Macdonald and L.M. Nowak. Department of Neurology, The University of Michigan, Ann Arbor, MI 48109.

Somatostatin (Somatotropin release inhibiting factor; SRIF) is a putative neurotransmitter of small diameter primary afferents. We have investigated SRIF actions in cell culture and report that this tetradecapeptide depolarized some multipolar spinal cord neurons and decreased membrane potassium conductance (g_K).

Spinal cords and attached dorsal root ganglia (DRGs) were dissected from 12-13.5 day old fetal mice. Cells were mechanically dissociated, plated on 35 mm collagen-coated dishes and grown in culture at 35° for 4-10 weeks prior to electrophysiological investigation. Intracelllar recordings were made with high impedance (30-40 MΩ) 4M KAc-filled or 3M KCl-filled micropipettes from neurons bathed in buffered saline on the modified, heated (35-36°) stage of an inverted phase contrast microscope. Single electrode voltage-clamp recordings (3 KHz switching frequency; 50% duty cycle) were made with low impedance (10-20 MΩ) KCl-filled micropipettes which were shielded (to 1-2 mm of tips) with conductive paint and insulated from the recording medium with nail enamel. SRIF (Sigma, St. Louis; Bachem, Torrence; Peninsula, Belmont) were dissolved in 0.02 M ammonium acetate-acetic acid buffer (pH 4-4.8) with 0.1% BSA, split into aliquots and stored at -27°C. Peptides were diluted in recording medium and applied directly to the neuronal surface by pressure pulses (1 sec at .25-3.0 psi) from blunt glass micropipettes (2-10 μm tips).

SRIF produce dose-dependent (3-300 nM), slow (4-8 sec to peak), reversible depolarizations and decreased membrane conductance. SRIF-responses (current or voltage) increased when membrane potential was held at depolarized potentials and decreased at hyperpolarized holding potentials. Extrapolated reversal potentials were more negative than resting membrane potential. SRIF evoked inward current at resting membrane potential, suggesting that it decreased either g_K or g_{Cl}.

Thus, we have demonstrated that SRIF, a putative primary afferent neurotransmitter, had excitatory actions in primary dissociated cell culture and produced membrane depolarization by decreasing membrane conductance.

138.3 PEPTIDES FROM NEURONS R3-R14 AFFECT FIRING PATTERNS OF OTHER NEURONS IN APLYSIA. D.G. Gibson*, C.Y. Lin*, and D.J. McAdoo. Marine Biomedical Inst., Univ. Texas Medical Branch, Galveston, TX, 77550.

We are investigating the possibility that the peptides synthesized by cells R3-R14 in the Aplysia parietovisceral ganglion (PVG) have hormonal effects.

Our test preparations were the buccal ganglion of Aplysia, PVG parabolic burster R15, and PVG left upper quadrant cells L3 to L6. All have previously been shown to respond to peptides secreted by the bag cells of the PVG, and none are synaptically connected to R3-R14. We utilized A. californica and A. brasiliana.

R3-R14 cell bodies and processes were dissected in sucrose-PMSF solution to inhibit proteolysis. Whole-cell homogenates were made in physiological solution and tested immediately; homogenates were also fractionated based on molecular weight on a Sephadex G-50 column. Dosages were equivalent to 10% to 100% of the material from one animal. Most tests were carried out in artificial seawater with elevated magnesium (4.5X normal) and zero calcium to eliminate synaptic components from the recorded responses.

Whole-cell homogenates evoked pacemaking discharges in previously quiescent third buccal nerves of both species, an effect similar to results obtained with egg-laying hormone (ELH) (Stuart and Strumwasser, 1980. J. Neurophysiol. 43:499-519). Onset of effect required up to 10 minutes, and did not persist as long as the effect of ELH.

The fraction of cell body material weighing from 2000 to 4000 Daltons, presumably peptides, increased burst duration and decreased interburst intervals in the PVG burster R15. Intracellular records indicate that pattern changes were mediated by baseline depolarizations of 5 to 10 mV. These effects differ from those of ELH in that burst intensity (max. spike rate) is not increased, bursts occur more frequently, and the effect is washed out more readily. Left upper quadrant neurons (L3 through L6), reportedly inhibited by bag cell activity (Mayeri et al., 1979. J. Neurophysiol. 35:202-219), showed no consistent response to R3-R14 products.

The response of R15 and the buccal ganglion to the test materials supports the idea that cells R3-R14 may release both peptides and glycine (Sawada et al., 1981. Br. Res. 207:486-490) as neurochemical messengers.

138.4 VASOACTIVE INTESTINAL POLYPEPTIDE EXCITES DORSAL HORN INTERNEURONS IN THE CAT SPINAL CORD. M. Randić and S. Jeftinija* (Spon: K. Sikora-VanMeter). Dept. of Vet. Physiol. Pharmacol., Iowa State University, Ames, IA 50011.

Vasoactive intestinal polypeptide (VIP) has been reported to be present in small sensory ganglion cells and in high concentration in the superficial parts of the spinal dorsal horn, the area where primary afferent fibers are known to terminate. Since the functional role of VIP in the spinal cord is at present unknown, it was of interest to study the central effects of synthetic VIP (1.5 mM, pH 4.7) by applying it iontophoretically onto functionally identified dorsal horn neurons.

We found that VIP caused a strong but slow excitation of a majority of the tested dorsal horn interneurons in laminae I-V. Excitation was observed as initiation of firing in a previously quiescent unit, or as an increase in the rate of spontaneous and/or evoked firing. In general, excitation began at a latency of 10-15 sec following the onset of VIP ejection and outlasted application for several minutes. VIP appeared to possess an excitatory action in all categories of neurons recognized in spinal preparations of cats in this area on the basis of their excitability to different kinds of afferent input.

These results indicate that VIP should also be added to the ever growing list of peptides having possible functional roles as transmitters or modulators in the dorsal horn of the cat spinal cord. (Supported by NSF grant BNS 23871 and the U.S. Dept. of Agriculture).

138.5 VASOPRESSIN ENHANCES SPONTANEOUS NEURAL ACTIVITY IN HIPPOCAMPAL SLICES. M. Mühlethaler* and J.J. Dreifuss. Dept of Physiol., Univ. of Geneva Med. Sch., Geneva, 1211 Switzerland.

Vasopressin administered intracranially has been shown to affect memory storage and retrieval (De Wied, Proc.R.Soc. B210:183, 1980) To investigate a possible mechanism for this effect, we have applied vasopressin and analogs to hippocampal slices obtained from adult rats while monitoring the spontaneous firing activity of neurones located in the pyramidal layer of the CA1 region. Since the posterior hippocampus is known to receive axon terminals which react with vasopressin antisera (Buijs, J.Histochem.Cytochem. 28:357, 1980), posterior hippocampal slices were prepared conventionally and placed on a nylon grid at the medium-oxygen interface at 37°C. Substances to be tested were dissolved in Yamamoto medium containing 0.8-1.0 mM $CaCl_2$ and bath-applied at a rate of 2.0 ml/min.

Stable extracellular recordings were obtained from cells which displayed short, intermittent bursts of activity. Arginine-vasopressin (AVP) and lysine-vasopressin (LVP) produced a dose-dependent (10^{-8}-10^{-5} M), sustained but reversible increase in the mean firing of 16/19 cells in 12 slices and prolonged the burst duration. The antidiuretic analog DDAVP had a much weaker action. Inhibitory effects were not observed. The vasopressor antagonist d(CH_2)$_5$Tyr(Me)AVP (Kruszynski et al., J.Med.Chem. 23:364, 1980) applied at 10^{-6}M in 5 slices had no effect per se on neuronal firing. However in 4/4 cells it totally and reversibly blocked the stimulatory effect of 10^{-6} M AVP. In slices trimmed to contain only the CA1 region, AVP was as effective as in normal slices. Intracellular recordings with KCl-filled electrodes in 23 slices perifused with Yamamoto medium containing 2 mM $CaCl_2$ confirmed that LVP and AVP excited a majority of responsive hippocampal neurones (15 cells) but weak inhibitory effects were also occasionally observed (9 cells). The peptides produced at times a slight membrane depolarization and a small increase in membrane conductance.

The results, which showed a predominant excitatory effect of vasopressin in the hippocampus, suggest moreover that hippocampal neurones possess vasopressin receptors resembling those of the V_2 category shown to be present on smooth muscle cells and on liver cells.

138.6 ADRENOCORTICOTROPIN ALTERS MOTOR UNIT SIZE AND EFFICIENCY FOLLOWING DENERVATION OF RAT EXTENSOR DIGITORUM LONGUS MUSCLE. C. Saint-Come* and F.L. Strand. Dept. of Biology, New York Univ., New York 10003

Daily intraperitoneal administration (0.2U) of Adrenocorticotropin (ACTH 1-39) to male rats (180-200g) during recovery from crush denervation of the extensor digitorum longus (EDL) muscle improves the recovery of neuromuscular efficiency as measured by a ratio of maximum tension recorded from peroneal nerve stimulation to that obtained from direct massive stimulation of the muscle. In addition, ACTH 1-39 appears to increase the size and activity of regenerating motor units. Motor unit size and activity were monitored by delivering finely graded stimuli (0.05ms. duration) to the peroneal nerve by means of a pair of platinum electrodes at one minute intervals. Muscle action potentials were recorded by means of a fluid electrode system that permits simultaneous recording of isometric tension. Alternate proximal and distal stimulation of the peroneal nerve allowed calculation of the motor conduction velocity. While the indirectly evoked action potential and isometric contraction amplitude are both increased by peptide treatment, no other parameters of the electrical response (conduction velocity and duration) or of the contractile response (contraction time and half relaxation time) of the denervated muscle are affected. ACTH 1-39 does not alter any of the parameters of the contractile response of the EDL when the muscle is directly stimulated, supporting other evidence from this laboratory that the enhancement of neuromuscular function by ACTH is a neurogenic, not a myogenic phenomenon.

138.7 SPECIFIC ANTAGONISM OF SUBSTANCE P INDUCED EXCITATION OF LOCUS COERULEUS NEURONS BY (D-Pro^2, D-Trp^{7,9})-SP. G. Engberg, T.H. Svensson*, S. Rosell* and K. Folkers* (SPON: S. Grillner). Depts of Pharmacology, University of Göteborg and Karolinska Institute, Stockholm, Sweden and Institute for Biochemical Research, University of Texas, Austin, USA.

Several lines of evidence suggest that Substance P (SP) participates in synaptic transmission in the brain. Recent immunocytochemical studies have shown several brain nuclei, including the noradrenergic locus coeruleus (LC) which innervates almost the entire neuroaxis, to be enriched in SP-containing fibers. In addition, a great majority of LC neurons have been found to be specifically excited by microiontophoretically applied SP. A major drawback in SP research has been the unavailability of a specific SP-antagonist. However, recently (D-Pro^2, D-Trp^{7,9})-SP has been synthetized and this agent was found to block peripheral effects of SP. Here single cell recording techniques and microiontophoresis were used to establish whether this compound would antagonize the excitatory effect of SP on rat brain noradrenaline (NA) neurons in the LC. When microiontophoretically applied at low ejection currents SP consistently caused a rapidly increased firing rate of the LC neurons. Total recovery of base-line activity was seen within 30 sec after termination of ejection. The simultaneous iontophoretic application of (D-Pro^2, D-Trp^{7,9})-SP completely antagonized the SP-induced excitation of the NA cells, but did not affect the excitation of the LC neurons by glutamate or acetylcholine . When applied alone the SP-antagonist did not affect the spontaneous firing of the cells. Thus, (D-Pro^2, D-Trp^{7,9})-SP seems to be an effective and specific SP-antagonist in a brain nucleus, the LC, which receives a prominent SP-input. This input is probably not critical for maintenance of the spontaneous activity of the NA cells. (Supported by the Swedish Medical Research Council, project nos. 4747 and 4495)

138.8 AUTORADIOGRAPHIC LOCALIZATION OF CHOLECYSTOKININ RECEPTORS IN GUINEA PIG BRAIN. R.B. Innis, M.A. Zarbin, J.K. Wamsley, S.H. Snyder and M.J. Kuhar. Dept. Neuroscience, Johns Hopkins School of Medicine, Baltimore, Maryland 21205.

Cholecystokinin triacontatriapeptide (CCK-33) or its COOH-terminal derivative peptides are putative neurotransmitters in the mammalian central nervous system. Data which are compatible with this hypothesis are as follows. CCK-33 and its COOH-terminal octapeptide (CCK-8), as measured by radioimmunoassay, are present in high concentrations in the brain. The predominant form of cholecystokinin (CCK) in the brain appears to be CCK-8. Moreover, immunohistofluorescence studies indicate that CCK-like immunoreactivity is localized to neuronal perikarya and processes within the CNS. Recently, specific high affinity CCK receptors were detected in mammalian brain and pancreas with in vitro biochemical techniques. In an attempt to further analyze this peptide's role in neurotransmission, we have determined the distribution of CCK receptors within the CNS at the level of resolution of light microscopy. This in vitro autoradiographic method of receptor localization is quantitative and allows the labeling of receptors with a high degree of specificity.

Cholecystokinin receptors were found widely distributed throughout the central nervous system with enrichment in limbic, visual, and cortical areas. In the limbic system, relatively high densities of receptors are found in the medial and lateral mammillary nuclei, in the stratum lacunosum-moleculare of the hippocampus, in the polymorphic layer of the dentate gyrus, and in other areas. Within the visual system, receptors are found in the ganglion cell layer of the retina, in the optic tract, in pretectal areas, and in the superficial layer of the superior colliculus. In the cerebral cortex, CCK receptors have a distinct laminar distribution with particularly high densities over laminae IV and VI. Laminae II, III, and V have a lower density of receptors while lamina I has a negligible density of receptors. In cingulate cortex, a dense band of grains overlies the anatomically indistinguishable laminae II, III, and IV. An even higher density of autoradiographic grains is localized to lamina VI of cingulate cortex while a negligible density of grains is present in laminae I and V.

138.9 BRADYKININ AS A PEPTIDE TRANSMITTER: CHARACTERIZATION OF ^{3}H-BRADYKININ RECEPTOR BINDING. Donald C. Manning, Robert B. Innis and Solomon H. Snyder. Johns Hopkins University, Sch. of Medicine, Dept. of Neuroscience, Pharmacology and Psychiatry, Baltimore, Maryland 21205.

Bradykinin (BK), a nonapeptide well known to be one of the most potent algesic substances, has been postulated to be one of the primary stimuli for pain resulting from tissue damage. A role for BK as a central neurotransmitter is suggested by the existence of immunoreactive BK in specific neuronal systems in the brain (Proc. Natl. Acad. Sci., USA., 76:1489-1493, 1979) and the hypotensive, analgesic and hypothermic effects elicited by BK injections in the brain. Bradykinin may also act peripherally where it is known to stimulate both vagal and sympathetic chemosensitive A delta and C fibres in the heart and is proposed to function in mediating the pain associated with myocardial ischemia. Classically, BK is known to have very potent effects on smooth muscle of the guinea pig ileum and estrous rat uterus. It is in these tissues with the greatest receptor density where we have chosen to characerize BK binding initially.

We have used ^{3}H-bradykinin (^{3}H-BK) as a physiologic ligand, the newest batch having a specific activity of 65 Ci/mmole. In the guinea pig ileum ^{3}H-BK exhibits saturable binding to membrane homogenates having a K_D value of approximately 0.4 nM and a B_{max} of 25 pmoles/g tissue wet weight. Incubations were done in 25 mM TES buffer pH 6.5 containing 0.2% BSA, 1 mM DTT, 0.1 µM Captopril (SQ 14225) and 100 µM Bacitracin for 30 mins at 4° C. Membrane bound ^{3}H-BK was separated from unbound ^{3}H-BK by centrifugation.

We have initiated in vitro receptor autoradiography studies and preliminary data show binding as expected in the muscle layers of the guinea pig ileum but surprisingly we have found binding in the mucosal layers also. This mucosal binding is an intriguing and unexpected finding indicating some unknown function of BK in the villi possibly involving ion flux modulation.

Another unusual finding of this study is the inhibition of receptor binding by divalent cations. This is contrary to every other agonist investigated in this lab where divalent cations usually increase agonist binding. Calcium was the most potent of the divalent cations studied so far causing 50% inhibition of specific binding at approximately 1 mM, Mg was less potent. Bradykinin's influence on the contraction of smooth muscle and calcium's unusual potency at affecting BK receptor binding suggests a possible link between the receptor and the calcium conductance channel.

138.10 SOMATOSTATIN RECEPTORS IN BRAIN AND PANCREAS: DIFFERENT PHARMACOLOGICAL PROPERTIES, Jean-Claude Reubi*, Jean Rivier*, Marilyn Perrin*, Marvin Brown and Wylie Vale. Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Saturable and high affinity binding has been obtained for a somatostatin-28 (SS-28) analog, [Leu^8,D-Trp^{22},Tyr^{25}]-SS-28 in 2 different organ preparations likely to be rich in SS receptors: the rat brain (cortex) and the hamster insulinoma, the latter primarily composed of pancreatic β-cells. In both preparations, the specific binding is more than 65% of the total binding and is maximal after 1 hr incubation at 22° C. The K_D for SS-28 is in both cases approximately 1 nM; the number of binding sites correspond to 260 fmols/mg protein in rat cortex and 80 fmols/mg protein in hamster insulinoma. SS binding sites in the brain show a strong regional distribution: Hippocampus > amygdala > cortex > spinal cord > hypothalamus > cerebellum. Pharmacological specificity is present in both preparations since bombesin, LRF or des-Trp^8-SS-14, an SS analog inactive in all SS bioassays, are all inactive at 100 nM, whereas [D-Trp^8]-SS-14 or [D-Trp^{22}]-SS-28, two very potent analogs in SS bioassays, completely displace the radioligand. The following pharmacological differences exist however between both binding sites: whereas SS-14 is approximately equipotent with SS-28 in the brain, it is less potent in the insulinoma despite a similar degradation rate. SS-analogs which selectively inhibit pancreatic insulin release (i.e. Des-Asn^5[D-Trp^8,D-Ser^{13}]-SS-14 are more potent in insulinoma than brain. In contrast, [5-D-F-Trp^8]-SS, which is potent in inhibiting growth hormone release, is more potent in brain than in insulinoma. These results suggest that SS receptors in brain, where SS possibly subserves a neurotransmitter or neuromodulator role, are pharmacologically different from SS receptors located on pancreatic β-cells, which control insulin release.

The successful use of a SS-28 analog as radioligand together with the high binding affinity, particularly in insulinoma, of SS-28 and SS-28 analogs, is in agreement with in vivo bioassay data showing high potency of SS-28 in pancreas and brain, and raises the question whether SS-28 is a possible endogenous ligand for SS receptors.

138.11 CHOLECYSTOKININ RECEPTORS ARE REDUCED IN CEREBRAL CORTEX AND BASAL GANGLIA OF HUNTINGTON'S DISEASE. S. E. Hays*, and S. M. Paul*. (SPON: J. Daly). Clinical Psychobiology Branch, NIMH, Bethesda, MD 20205.

Accumulating evidence indicates that cholecystokinin (CCK) functions as a neurotransmitter or neuromodulator. This evidence includes the presence of specific CCK receptors which we and others have identified in rodent brain. We now have demonstrated the presence of CCK receptors in human brain, and have found that patients with Huntington's chorea have a marked reduction in receptor number, not only in basal ganglia (the region of major neuropathology in Huntington's disease), but in cerebral cortex as well.

Post-mortem tissue was obtained from brains of 8 patients with Huntington's disease and 8 controls matched for age, sex and autolysis time. Specific (displaceable) binding of $^{125}CCK_{33}$ was 62% lower in basal ganglia of Huntington's patients as compared with controls, and 33% lower in cerebral cortex of Huntington's vs. controls. Scatchard analysis demonstrated that these differences reflected reduced receptor number (B_{max}) while the apparent affinity (K_D) was not significantly different from controls.

Reduced CCK receptors in Huntington's basal ganglia indicate that CCK receptors are localized predominately to neuronal elements, and suggest a role for CCK in the regulation of motor function. The reduced cortical CCK receptors suggest that CCK also may be important in cognitive function, which frequently is impaired in Huntington's patients.

138.12 SUBSTANCE P RECEPTORS ON ADRENAL CHROMAFFIN CELLS. P. Boksa*, S. St. Pierre* and B.G. Livett (SPON: Barry S. Layton). Division of Neurology, The Montreal General Hospital, Montreal, Quebec, Canada.

We have previously shown that the undecapeptide substance P (SP) inhibits nicotine- or ACh-induced release of catecholamines from cultured bovine adrenal chromaffin cells. In order to further characterize the site at which SP exerts this action, we have now compared, in chromaffin cell cultures, the inhibitory actions of SP, SP-free acid and a series of SP analogues in which each amino acid of SP is replaced by L-alanine. Chromaffin cells were isolated by retrograde perfusion of adrenal medullae with collagenase, purified on Percoll, and maintained as monolayer cultures as described previously (Livett, B.G. et al., Nature 278: 256, 1977). On the day of the experiment, cultures were pre-loaded with (^{3}H)l-norepinephrine ((^{3}H)NE, 10^{-7}M), washed free of unbound radioactivity, and the nicotine ($5x10^{-6}$)-induced release of (^{3}H)NE was measured in the presence and absence of SP or its analogues. All of the analogues tested inhibited nicotine-induced NE release and their ID_{50}'s are shown in the following Table, where the analogues are listed according to their rank order of potency.

	ID_{50}		ID_{50}
1) (Ala^5)-SP	7.1×10^{-7}	7) (Ala^1)-SP	5.1×10^{-6}
2) SP	1.4×10^{-6}	8) (Ala^{11})-SP	7.3×10^{-6}
3) (Ala^2)-SP	1.6×10^{-6}	9) (Ala^8)-SP	8.0×10^{-6}
4) (Ala^6)-SP	2.2×10^{-6}	10) (Ala^{10})-SP	1.7×10^{-5}
5) (Ala^4)-SP	2.3×10^{-6}	11) (Ala^7)-SP	2.0×10^{-5}
6) (Ala^3)-SP	4.1×10^{-6}	12) SP-COOH	2.2×10^{-5}

These data indicate that the most important groups for conferring inhibition of NE release from chromaffin cells are the C-terminal amide and amino acids in positions 7,10,8 and 11; substitution of amino acids 1 to 6 led to less loss of activity. Similar results have been obtained with these analogues in other SP-responsive tissues including the guinea pig ileum, rabbit mesenteric vein and rat vas deferens (Couture, R. et al., Can. J. Physiol. Pharmacol. 57: 1427, 1979). We conclude that a specific SP receptor exists on adrenal chromaffin cells and that the binding site of this receptor shares similar structural requirements with the SP receptor found in other tissues.

138.13 **CHARACTERIZATION OF CENTRAL INSULIN RECEPTORS.** Nancy R. Zahniser. Dept. Pharmacology, UCHSC, Denver, CO 80262.

Both insulin immunoreactivity and specific binding sites for ^{125}I-insulin have been identified in the mammalian brain. Although the function of insulin in the brain remains to be determined, it has been suggested that insulin is a neuromodulator or a neurotransmitter. This study was carried out to determine the localization of ^{125}I-insulin binding in rat cerebral cortex. Results from binding assays using crude nuclear and nonnuclear (synaptic/mitochondrial) membrane fractions of rat cerebral cortex were compared to those obtained using purified plasma membranes from rat liver. Studies of the inhibition of radiolabelled insulin binding by unlabelled insulin or glucagon were carried out over a concentration range of 170 fM - 17 μM unlabelled polypeptide. ^{125}I-Insulin binding to membranes from both brain and liver was inhibited by low concentrations (<0.15 nM) of insulin but was not inhibited by glucagon. Based on these experiments, specific binding of ^{125}I-insulin binding was defined as the difference in the amount of radioligand bound in the absence and presence of 1.7 μM insulin; it constituted approximately 60% of total binding to cortical membranes and 95% of total binding to hepatic membranes. In both brain and liver membrane preparations, specific ^{125}I-insulin (350 nM) binding reached equilibrium within 75 min at 15° and remained stable for at least 150 min. Routinely, membranes were incubated with ^{125}I-insulin for 90 min at 15° and binding reactions were terminated by rapid centrifugation of the membranes through 0.32 M sucrose. The IC_{50} values for insulin inhibition of ^{125}I-insulin binding were similar in both cortical synaptic membranes (5.7 ± 2.8 nM) and hepatic membranes (2.0 ± 1.1 nM). The Hill coefficients were less than one in both cases (synaptic membranes: 0.42 ± 0.04; hepatic membranes: 0.50 ± 0.03). These low Hill coefficients may indicate negative cooperativity, multiple binding sites or a two-step binding reaction. In the same series of experiments similar results were obtained with membranes from the nuclear fraction of the rat cortex. In this tissue the IC_{50} value for insulin was 8.7 ± 4.4 nM and the Hill coefficient was 0.32 ± 0.02. Scatchard plots of ^{125}I-insulin binding appeared curvilinear in all three membrane preparations. The density of insulin receptors in liver membranes was at least three-fold greater than that measured in either the cortical synaptic or nuclear membrane fractions. These results indicate that by using an iodinated ligand of high specific activity and a large amount of rat brain membrane protein (0.4 - 0.8 mg), specific ^{125}I-insulin binding sites can be measured and characterized in the brain. As previously reported (Havrankova et al., Nature 272: 827, 1978), the affinity of the receptors for insulin in the brain appears to be similar to that measured in the liver. The results also indicate that ^{125}I-insulin binding sites in rat cerebral cortex are rather uniformly distributed and are not restricted to synaptic membranes. Studies are currently being conducted to determine the function of these central insulin receptors.

139.1 THE EFFECTS OF HYPOPHYSECTOMY ON MULTIPLE OPIATE RECEPTORS. E. Young,* J. Lewis, J. Leibeskind and H. Akil (SPON: M. Gnegy). Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109.

The existence of at least two subtypes of opiate receptors, the μ and δ receptors which preferentially bind alkaloid and opiate peptides, is supported by much data. However, no one has been able to selectively alter these receptor subtypes differentially. There is an old and complex literature on the effects of hypophysectomy and adrenalectomy on opiate analgesia. We have looked at the effects of hypophysectomy on ^{3}H morphine and ^{3}H D-Ala-D-leu enkephalin (DADL) binding, μ and δ receptor ligands respectively, across multiple brain regions.

Male albino hypophysectomized and sham operated control rats were obtained from Charles River laboratories. After ten days of adaptation, the animals were decapitated, their brains rapidly removed and dissected into the following brain regions: hippocampus, striatum, frontal cortex, midbrain medulla-pons, and thalamus. Opiate receptor binding assays were done on each brain region of hypophysectomized and control animals simultaneously with both ^{3}H morphine and ^{3}H DADL enkephalin. Scatchard plot analysis were done for each ligand for each brain region.

The results showed: 1) a decrease in μ receptor number in hypophysectomized rats in the following regions: striatum, hippocampus, medulla-pons and thalamus; 2) an increase in the affinity of the μ receptor for morphine in the following brain regions: hippocampus, medulla-pons and thalamus; 3) no change was found in μ receptor number or affinity in the cortex or midbrain; 4) no significant change in δ receptor affinity or number in any of the brain regions. Thus, hypophysectomy produces selective change in one subtype of opiate receptors (μ) varying across brain regions. We are currently investigating the effects of adrenalectomy to see if similar findings emerge.

139.2 REGULATION OF OPIATE RECEPTORS IN NEUROBLASTOMA X GLIMOA HYBRID CELLS IN TISSUE CULTURE, S. F. Atweh. Dept. of Neurology, Univ. of Chicago, Chicago, IL 60637.

Neuroblastoma X Glioma Hybrid (NG) cells grown in tissue culture bind opiate ligands. This binding satisfies pharmacological criteria characteristic of opiate receptors. Opiates inhibit the synthesis of cyclic-AMP by NG cells in response to stimulation by prostaglandin E_1. This inhibition exhibits time-related tolerance to the opiates. The phenomenon of tolerance, however, is not associated with changes in opiate receptor binding. The present study demonstrates some factors that regulate receptor binding in NG cells in culture.

NG cells were grown in a culture medium consisting of Dulbecco modified Eagles' medium supplemented with hypoxanthine, aminopterin, thymidine and 10% fetal bovine serum. Cells were washed and harvested from the flasks at various intervals after plating and sonicated in Tris-HCl buffer. Opiate receptor binding was measured by incubating the homogenate or the membrane fraction with ^{3}H-Etorphine for 30 minutes at 22°C. Memberanes and bound ligand were isolated by rapid filteration on GF/B filters using a suction machine and washed three times with cold buffer to minimize non-specific binding. Specific binding of ^{3}H-Etorphine was calculated by subtracting non-specific binding in the presence of saturating concentrations of Naloxone. Under these conditions NG cells from confluent flasks (12-15 days after plating) exhibited maximal binding of 12.6×10^4 ligand molecules per cell with a Kd of 0.7 nM. Receptor binding exhibited marked variations with the age of the cultured cells. Three days after plating NG cells exhibited very little specific binding; thereafter binding per cell increased with the age of the culture and plateaued after day 12. Increased binding related to the increasing density of the cells. Scatchard analysis revealed that this change was due to an increase in the number of receptor sites per cell with no change in affinty to Etorphine. Culturing the cells in the presence of 0.5 mM Dibutyrl Cyclic-AMP slowed their growth and increased the activity of choline acetyltransferase. The density of opiate receptors did not show a comparable increase, but remained a function of cell density. NG cells, 4 days after plating, were incubated in "conditioned" medium obtained from 10-day old flasks containing 15-20 million NG cells. Cells incubated in the "conditioned" medium for 24 hours exhibited twice as many opiate receptors as those culture in "fresh" medium.

These results suggest that NG cells in tissue culture can regulate their opiate receptors by secreting a factor into the medium which stimulates receptor formation and/or expression.

139.3 OPIATE RECEPTOR HETEROGENEITY IN HUMAN BRAIN REGIONS. K.A. Bonnet*, J. Groth*, H. Mermelstein*, M. Cortes*and E.J.Simon Depts. Psychiatr. and Pharmacol. NYU Med. Ctr. New York, N.Y. 10016.

Evidence for the existence of several sub-classes of opiate receptors has been reported for the CNS and other tissues of several animal species. Cross-competition for receptor binding between enkephalins and opiate alkaloids has led to the postulation of μ (opiate-preferring) and δ (enkephalin-preferring) receptors. Differential distribution of these receptor sub-types between brain regions has been reported by us and others. We now report that a similar heterogeneity and differential distribution of opiate receptors exists in human brain regions. Four brain regions (thalamus, amygdala, striatum and frontal cortex) were dissected from brains obtained at autopsy from the Office of the Chief Medical Examiner of New York. Competition for receptor binding of unlabeled naloxone and D-ala^{2}D-leu^5 enkephalin (DADL) against tritiated naloxone and DADL was studied in each brain region. As in rat and guinea pig brain,naloxone was found to be considerably more effective (4-10 times) against [^{3}H]naloxone than against [^{3}H]DADL,and the reverse was true for DADL (10-20-fold better against [^{3}H]DADL). An interesting exception is the thalamus where naloxone is more effective against [^{3}H]DADL than against [^{3}H]naloxone, in fact, 10 times more potent against [^{3}H]DADL than in the other regions. These findings are in very good agreement with our results in rat brain. They suggest the existence of μ and δ receptors in human brain and their differential distribution, the thalamus showing a considerable preponderance of μ receptors. This is the first evidence for receptor heterogeneity in human brain. An understanding of the nature and distribution of opiate receptor sub-types may ultimately have considerable importance in clinical pharmacology, including drug addiction and pain management. (Supported by grant DA-00017 from the National Institute on Drug Abuse).

139.4 OPIOID RECEPTORS IN THE MONKEY BRAIN, PITUITARY AND RETINA: LOCALIZATION BY LIGHT MICROSCOPIC AUTORADIOGRAPHY. J.K. Wamsley, M.A. Zarbin*, W.S. Young, III and M.J. Kuhar. Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Opioid receptors were localized in the monkey brain, pituitary and retina by using both in vivo (Atweh and Kuhar, Brain Res., 124:53, 1977) and in vitro (Young and Kuhar, Brain Res., 179:255, 1979) labeling techniques of autoradiography. The tissues of three male cynomolgus monkeys (Macaca fasicicularis) were prepared and the opioid receptors were labeled with [^{3}H]-diprenorphine.

High concentrations of autoradiographic grains, associated with opioid receptors, were found in the substantia gelatinosa of the spinal cord. This high density extended out into the dorsal root. Only moderate grain densities were found in lamina III and IV (of Rexed), but the entire gray matter of the spinal cord (including the ventral horn) showed concentrations of grains greater than background. High densities of grains were also found in the spinal trigeminal nucleus, nucleus tractus solitarius and the lateral parabrachial nucleus (with fewer grains in the ventral parabrachial nucleus). The substantia grisea centralis of the periaqueductal gray matter had high grain densities near its rostral extent, just ventral to the posterior commissure. The medial nuclei of the thalamus, many nuclei of the hypothalamus, the substantia innominata and the amygdaloid complex also showed high grain concentrations. In the cortical areas examined there were marked differences in the grain concentrations between regions with the highest density occurring in the deep laminae of the cingulate gyrus.

In the monkey pituitary gland, high densities of autoradiographic grains were associated with the neurohypophysis with only background levels of grains occurring over the adenohypophysis and intermediate lobe. The nuclei of the hypothalamus associated with the neurohypophysis, the supraoptic and paraventricular nuclei, also had moderate to high grain densities. In the monkey retina, autoradiographic grains were associated with the ganglion cell layer and significant grain densities were identified in the optic nerve. Presumably, some of the latter are undergoing axonal flow.

These opioid binding sites correlate well with those observed in autoradiographic studies of the rat brain, although there are a few notable differences. Many of the opioid receptor distributions can also be correlated with anatomical loci of brain functions known to be influenced by administration of opiate compounds.

139.5 EFFECTS OF GUANINE NUCLEOTIDES ON MULTIPLE OPIATE RECEPTOR BINDING SITES. S. R. Childers, J. Vagovic* and J. Jessup*. Dept. of Pharmacology, Univ. of Florida College of Med., Gainesville, Fla. 32610.

Guanine nucleotides, especially GTP, decrease binding of agonists to opiate receptors in brain and membranes. Multiple (μ and δ) opiate receptors have been identified in brain, but it is not clear that these different agonist sites are differentially regulated by GTP. C. B. Pert et al identified multiple Type 1 and Type 2 receptors distinguished by the presence and absence of GTP regulation. To further explore these concepts we compared GTP effects on the binding of a μ ligand, ^{3}H-morphine and a δ ligand, ^{3}H-D-Ala$_2$ D-Met$_5$ enkephalin (DADLE), to rat brain membranes. GTP effectively reduced the binding of both agonists, with slightly greater inhibition seen with ^{3}H-morphine (48% max inhibition) than with ^{3}H-DADLE (39% max inhibition) binding. The IC_{50} values for both GTP and Gpp(NH)p were similar in inhibiting both ^{3}H-ligands. Analysis of 10 regions of porcine brain with different concentrations of Gpp(NH)p inhibiting both ^{3}H-morphine and ^{3}H-DADLE binding revealed similar IC_{50} values and max inhibition values of Gpp(NH)p in all regions studied. Scatchard analyses showed that the effect of 50 μM GTP on ^{3}H-morphine was primarily to decrease the affinity, but not the number, of high affinity sites with little effect on low affinity sites. However, the effect of GTP on ^{3}H-DADLE was to decrease the number of high affinity sites by 40% without affecting affinity, while decreasing affinity of low affinity DADLE sites by 50%.

In other neurotransmitter systems, divalent cations antagonize the actions of GTP. In brain membranes, addition of either Ca^{++}, Mg^{++} or Mn^{++} had very little effect on the inhibition of ^{3}H-morphine binding by Gpp(NH)p. However, if membranes were first stripped of divalent cations by pre-incubation with 1 mM EDTA, the potency of Gpp(NH)p was increased compared with non-treated membranes, with a 2-3 fold decrease in Gpp(NH)p IC_{50} values and no change in max inhibition by Gpp(NH)p. The effect of EDTA was not duplicated by EGTA. In EDTA-treated membranes, the Hill slope of Gpp(NH)p inhibition of ^{3}H-morphine binding was dramatically reduced to 0.5 (compared with 0.9 in control membranes). These results suggest that GTP may exhibit different potency profiles in the absence of divalent cations, but may bind to a single lower affinity state in the presence of cations.

139.6 The Binding and Analgesic Properties of a Sigma Opiate: SKF 10,047 K. Spiegel*, M. Buatti*, and G.W. Pasternak (SPON: R. Price). Cotzias Lab. of Neuro-Oncology, Sloan Kettering Institute and Cornell University Medical College.

Martin et al (JPET 197:517, 1976) classified opiates into three categories on the basis of their pharmacological properties and postulated a different receptor for each: mu (morphine), kappa (ketocyclazocine) and sigma (SKF 10,047 or N-allylnormetazocine). We have investigated the receptor binding and analgesia of the prototypic sigma opiate, SKF 10,047. ^{3}H-SKF 10,047 binds specifically and saturably to rat brain membranes. Unlabeled SKF 10,047 at low concentrations (IC_{50} 5 nM) inhibits ^{3}H-SKF 10,047 binding but at 1 μM does not inhibit binding to a greater extent than levallorphan, morphine or naloxone, also at 1 μM. Computer analysis of saturation experiments demonstrates two components: a high affinity site (K_D 0.3 nM) present at low levels in rat brain and a low affinity site (K_D 6 nM) present at far greater levels. ^{3}H-SKF 10,047 binding is quite sensitive to low concentrations of the proteolytic enzymes trypsin and chymotrypsin and the reagents N-ethylmaleimide and iodoacetamide. Like other opiates, sodium ions lower binding in a dose-dependent manner and this inhibition is substantially reversed by the addition of manganese ions. Naloxazone in vivo and in vitro irreversibly blocks high affinity ^{3}H-SKF 10,047 binding, suggesting that SKF 10,047, morphine, ethylketocyclazocine and the enkephalins bind with highest affinity to the same site. Competitive displacement of specific ^{3}H-SKF-10,047 binding by morphine, levallorphan, naloxone and ketocyclazocine is biphasic, suggesting multiple binding sites. Dextrallorphan is inactive. Blockade of the high affinity site by naloxazone results in the loss of morphine's ability to displace binding at low concentrations. The remaining binding, corresponding to the low affinity site, is far less sensitive to morphine (IC_{50} 40-70 nM compared to <1 nM for the high affinity site). In contrast, the low affinity binding remains quite sensitive to displacement with unlabeled SKF 10,047, suggesting that this low affinity site binds sigma opiates better than mu drugs and may represent the sigma receptor postulated by Martin et al. SKF 10,047 is a potent analgesic in the writhing assay (ED_{50} 0.55 $\pm$ 0.12 mg/kg) with a slope parallel to morphine (ED_{50} 0.23 $\pm$ 0.1 mg/kg). Naloxone (1mg/kg) blocks both morphine and SKF 10,047 analgesia equally well. Blockade of high affinity sites by naloxazone in vivo lowers the analgesic potency of SKF 10,047 5-fold in a manner similar to the decrease in morphine, enkephalin, ketocyclazocine and beta-endorphin analgesia, implying a single analgesic receptor for them all.

139.7 SULFHYDRYL-GROUP INVOLVEMENT IN OPIATE RECEPTOR LIGAND SELECTIVITY SHIFTS: IS THE "μ" CONFORMATION THE DESENSITIZED STATE OF THE "δ" CONFORMATION? W. D. Bowen* and C. B. Pert (SPON: J. Rosenblatt). Section on Biochemistry and Pharmacology, Biological Psychiatry Branch, NIMH, Bethesda, MD 20205.

We have recently reported (Bowen et al., Proc. Nat. Acad. Sci. USA, in press) that the ligand selectivity of opiate receptors in rat striatal patches can be shifted by the presence of allosteric effectors in the incubation medium: sodium ion, divalent cations and GTP shift the μ-like, alkaloid-preferring selectivity to a δ-like, enkephalin-preferring selectivity while promoting the coupling of opiate receptors to adenylate cyclase. Comparison of the striatal slice binding of the prototype μ-agonist, [^{3}H]dihydromorphine (DHM), with that of the prototype δ-agonist, [^{3}H]D-Ala^2-D-Leu^5-enkephalin (DENK), in the presence of various ions and sulfhydryl effectors was performed. When tissue slices are pre-incubated for 15 min at 25°C (50 mM Tris, pH 7.4), sodium chloride (100 mM) increases DENK (+32 ±5%) while reducing DHM (-52 ±7%); manganese ion (3 mM) enhances DHM (+14 ±3%) and does not significantly alter DENK; Na and Mn ions in combination appear synergistic, markedly enhancing (+72 ±9%) DENK while restoring DHM to control levels. Pretreatment of tissue slices with N-ethylmaleimide (NEM) (.05 mM) strikingly alters this pattern, causing sodium ion to inhibit DENK binding as well as DHM binding. Dithiothreitol (DTT) (3 mM) also perturbs this pattern [e.g., enhancing DENK (+46 ±5%) and inhibiting DHM (-10 ±3%) in the absence of added ions]. Hydrogen peroxide (10 mM) preincubation, which promotes disulfide formation, abolishes the effects of sodium ion on DENK; subsequent pre-incubation with DTT, which reduces disulfide bonds, reverses the effects of H_2O_2, restoring the normal ion effects. Thus, NEM, DTT and H_2O_2, all of which perturb the sulfhydryl-disulfide status of proteins, appear able in vitro to shift the ion-regulated equilibrium between μ- and δ-opiate receptor conformations. Striatal slices taken from rats subjected to a 5-min ice-water swim, a highly stressful manipulation that causes massive endorphin release into cerebrospinal fluid and concomitant endorphin depletion at several brain loci, reduces DENK binding (-18%) and increases DHM binding (+15%) compared to control rats ($p < 0.05$). The physiological significance of the μ/δ opiate receptor equilibrium may thus be related to the sensitivity state of opiate receptors in vivo, a state which may be regulated by a mechanism involving sulfhydryl groups.

139.8 CHARACTERIZATION AND VISUALIZATION OF THE "κ" OPIATE RECEPTOR IN RAT BRAIN. R. Quirion, M. Herkenham and C.B. Pert (SPON: M. Murphy). Section on Biochemistry and Pharmacology, Biological Psychiatry Branch and Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205

Recent analyses of the binding of radiolabeled ethylketocyclazocine, a prototype "κ" agonist (in Martin's classification scheme) have been interpreted as supportive biochemical evidence for the existence of yet another unique opiate receptor (Kosterlitz and Patterson, Proc. R. Soc. Lond. 210:113-122, 1980; Woods et al., Eur. J. Pharmacol., in press). Indeed, specific [^{3}H]ethylketocyclazocine binding to 25 μ striatal slices of unfixed rat brain thaw-mounted onto slides cannot be readily displaced by morphine, endorphins, or enkephalins, while naloxone, etorphine and two benzomorphans with "κ" pharmacological properties, MR2034, MR2266, and ethylketocyclazocine itself, are potent displacers. Optimal (75-80%) specific binding of [^{3}H]ethylketocyclazocine (K_D = 2.6 nM; B_{max} = 0.13 pmoles/slice) is obtained at 4°C in the presence of sodium chloride (100 mM), incubation conditions which promote opiate antagonist binding (Creese et al., Life Sci. 16:1837-1842, 1975) and reduce the binding of [^{3}H]dihydromorphine and [^{3}H]D-Ala^2-D-Leu-enkephalinamide to undetectable levels. Visualization of these binding sites with tritum-sensitive film (LKB) reveals a striking, highly discrete brain distribution pattern (e.g., striatal patches, habenular stripe) which is indistinguishable from that of [^{3}H]naloxone (Herkenham and Pert, Proc. Nat. Acad. Sci. USA, 77:5532-5536, 1980). Our interpretation of these data is that "κ" receptors like "μ" and "δ" opiate receptors (Bowen et al., Proc. Nat. Acad. Sci. USA, in press) are different conformations of the GTP-sensitive Type 1 allosteric opiate receptor complex which can assume the "κ" ligand selectivity pattern.

139.9 SUBCELLULAR DISTRIBUTION OF CALMODULIN AND OPIATE RECEPTORS IN CULTURED-NEURONAL CELLS - EFFECT OF OPIATES: D.Baram* and R. Simantov. Dept. of Genetics, Weizmann Institute of Science, Rehovot 76100, Israel.

The antagonism between Ca^{++} ions and the in vivo analgesic action of morphine was extensively studied by Harris, Loh and Way, J.Pharm.Exp.Ther. 195: 488, 1976, and conceivably reflects the profound effect of morphine on the regional and subcellular localization of Ca^{++} in the brain. However, this antagonism seems to take place in sites which are distal to the opiate receptors themselves since Ca^{++} ions increase, rather than antagonize, the binding of opiate agonists-alkaloids or enkephalins- to the brain opiate receptors. The recent findings that many, if not most, of the Ca^{++} activities in mammalian cells take place via interaction of Ca^{++} with the polypeptide calmodulin, prompted us to study the localization and the possibility of receptor-mediated regulation of calmodulin by opiates. Cultured neuroblastoma-glioma cell hybrids were chosen since they possess high density of functional opiate receptors. Calmodulin activity was monitored by a two-steps enzymatic assay, using a purified rat brain phosphodiesterase and crotalus adamanteus 5'-nucleotidase. Binding studies with ^{3}H-D-ala^2-met-enkephalinamide at 0.5-10.0 nM were performed to determine the affinity and the number of opiate receptors. After differential centrifugation of the lyzed cells, the nuclear (P_1), mitochondrial-membrane (P_2), microsomal (P_3) and the cytosol (S) fractions were isolated and tested for calmodulin and opiate receptors. Calmodulin activity was detectable in the concentration order of $S>P_2>P_3>P_1$, whereas opiate receptors were enriched in the P_2 and P_3 fractions. Treatment of the cells with 10^{-5} M morphine sulfate for 48 hours had no effect on calmodulin levels of P_1, P_2, P_3, or S. No changes in the fractions were also observed after treatment with the opiate antagonist naloxone. The mitochondrial-membrane (P_2) fraction was further purified on a gradient of 0.4, 0.8 and 1.2 M sucrose. Five layers and the mitochondrial pellets that were obtained showed an uneven distribution of calmodulin and opiate receptors. Two layers (3 and 4) were the richest in opiate receptors, with one of them (4) being twice as rich as the other. However, calmodulin was highly enriched in layer 4 but was undetectable or in a very low concentration in layer 3. This shows that neuroblastoma-glioma cells contain opiate receptors which are located on membranes that are separable into two types according to the membrane size and/or density. That these two layers contain different amounts of calmodulin deserved further experiments aimed at elucidating whether the biochemical and pharmacological effects of morphine are associated with selective effects on calmodulin or opiate receptors localized in specific cell structures.

139.10 THE USE OF THIOL-SEPHAROSE AND DEAE-SEPHADEX BEADS FOR PURIFICATION OF SOLUBLE OPIATE RECEPTORS. M. Dornay* and R. Simantov (Spon: M. Hershkowitz). Department of Genetics, Weizmann Institute of Science, Rehovot, Israel.

Sulphydryl blocking compounds inhibit the interaction between opiate alkaloids or peptides and the membrane-bound rat brain opiate receptors. Selective protection of the opiate receptors by opiate ligands from SH agents was indicated by Kosterlitz's, Simon's and Snyder's groups. It was of interest, therefore, to study whether thiol-Sepharose B4 beads, that bind covalently compounds that contain SH groups, can be used for purification of opiate receptors. Membranes prepared from the whole rat brain, the hypothalamus-thalamus of the rat (mostly μ receptors) or the neuroblastoma-glioma cell hybrids (apparent δ receptors) were labled with ^{3}H-D-Ala^2-met-enkephalinamide and solubilized by Brij 36T. The solubilization was conducted in the presence of 4 different protease inhibitors to minimize proteolysis. The free ligand was removed by chromatography through Sephadex G-75 column and the void volume that contained the receptor-^{3}H-enkephalin macromolecule was partially purified on a Sepharose B6 column. Three peaks of radioactivity were observed in the effluent, two of them contained proteins and one was free ligand. One of these peaks had a stock radius of about 59Å and was indicated by additional experiments as the specific opiate receptor. This peak was loaded on thiol-Sepharose column in phosphate buffer, washed with the same buffer to remove the non-bound compounds and then eluted by a gradient of 0-50 mM dithiothreitol (DTT). That the radioactive material eluted from the columns was bound to macromolecular proteins was tested by ammonium sulfate precipitation and rapid filtration, a technique developed to separate between free and receptor-bound ligand. The percentage of receptor-^{3}H-enkephalin bound to thiol-Sepharose column and eluted by DTT was 4%, 35% and 34% for opiate receptors solubilized from neuroblastoma-glioma, whole rat brain minus cerebellum and the rat hypothalamus-thalamus, respectively. Thiol-Sepharose beads therefore bind a very small portion of the opiate receptors of neuroblastoma-glioma cells as compared to those prepared from rat brain. Similar experiments with DEAE-Sephadex A50 columns, eluted with 1 M KCl, also showed higher binding of opiate receptors solubilized from the whole rat brain or the hypothalamus-thalamus as compared to neuroblastoma-glioma receptors. Experiments are being carried out to observe whether soluble and active opiate receptors preserve their selective interaction with thiol-Sepharose or DEAE-Sephadex beads and whether this selectivity correlates with differential binding properties to opiate alkaloids and peptides.

139.11 MULTIPLE BENZOMORPHAN BINDING SITES ON NCB20 HYBRID CELL LINE. R.E. West, Jr.*, R.W. McLawhon*, G. Dawson*, and R.J. Miller*. (SPON: D.R. Brown) Depts. Pharmacology, Biochemistry, and Pediatrics, University of Chicago, Chicago, IL 60637.

D-ala^2-D-leu^5-enkephalin (DADL) and ethylketocyclazocine (EKC) bind to a single site on the NG108-15 and N4TG1 clonal cell lines. Specific binding of either compound is totally displaceable by the other. On the NCB20 cell line DADL binds to a single site (K_D=1nM, B_{max}=350 fm/mg prot). EKC binds to two sites on these cells (K_D=3nM, B_{max}=500 fm/mg; K_D=15nM, B_{max}=1400 fm/mg). In competition binding assays, DADL competes for only part of the EKC binding. Scatchard analysis of EKC binding in the presence of 10^{-5} M DADL yields a single low affinity EKC site (K_D=19nM, B_{max}=1250 fm/mg). Thus, it is the high affinity EKC site for which DADL competes. In its pharmacologic profile and in the effects of ions and nucleotides on it this site resembles the δ-opiate receptor described in the nervous system and on the other cell lines.

The lower affinity EKC site displays an unusual pharmacologic profile. Of the drugs and neurotransmitters so far tested, benzomorphans bind with highest affinity. Morphine, etorphine, and naloxone, as well as DADL do not compete for this site. PCP and ketamine compete with μM affinities. Stereoselectivity is the reverse of what might be expected. Mn and Mg inhibit binding to this site, while EDTA, but not EGTA, increases binding. Nucleotides have no effect.

Preliminary studies of basal and PGE_1-stimulated adenylate cyclase activity indicate that benzomorphans may be more efficacious than DADL, morphine or etorphine as inhibitors of adenylate cyclase in these cells.

139.12 EXPOSURE OF OPIATE BINDING SITES ON GLIOMA CELL LINE. J. Shorr,*G.Korner,* U.Bachrach* and O.Abramsky, Lab. of Neuroimmunology, Dept.Neurology and the Dept. Biochemistry, Hebrew University-Hadassah Med. Center, Jerusalem, Israel.

Cultured neuroblastoma-glioma hybrid cells (strain NG108-15) and neuroblastoma cells (N4TG1) contain large numbers of opiate receptors: 100000 and 20000 Enk-binding sites per cell respectively (W.A. Klee and M.Nirenberg, P.N.A.S. USA 71: 3474, 1974). The neuroblastoma-glioma hybrid cell line NG-108-15 has been a result of hybridization between mouse neuroblastoma N18TG-2 and rat glioma C6BU-1. Both parental cell lines were poor in opiate receptor sites on their plasma membrane (W. A. Klee and M. Nirenberg, P.N.A.S. USA 71: 3474, 1974).

In general, hybrid cells display parental properties despite the increase in the number of chromosomes. On the other hand, there are cases in which cells display properties which are not detectable in either parents (J. A. Paterson and M. C. Weiss, P.N.A.S. USA 69: 571, 1972).

The question rises whether the binding of opiates to the hybrid cells is a novel property or whether it originates (in a latent stage) in one of the parental cell lines. To answer this question, Sendai Virus (which is used for the formation of hybrid lines) was added to cultured glioma cells, neuroblastoma and the hybrid of neuroblastoma and glioma cells. Hybridization was performed according to the method of S. K. Sharma, M. Nirenberg and W.A. Klee (P.N.A.S. USA 72: 590, 1975). Opiate binding assays were carried out by binding (^{3}H)naloxone (NEN) to the cells in 50 mM Tris buffer pH 7.4. For fusion experiments one-day-old cells (young) or five-day-old cells (old) were employed. These cells were obtained by splitting confluent culture in a ratio of 1:13. We found that in the old fused cells the binding capacity increased by more than 50% compared to the now fused controls. The maximal increase in the binding of the tritiated ligand to the cells was apparent 30 min after fusion. In young glioma cells the basal specific binding activity was higher than in old glioma cells; moreover fusion did not increase the binding activity compared with non-fused young cells. Neither fused neuroblastoma cells nor the hybrids of neuroblastoma and glioma increased their specific binding after incubation with the virus. These findings suggest that young glioma cells exhibit opiate binding. This property which is lost with age can be recovered by treating old cells with Sendai Virus.

139.13 OPIATE RECEPTOR DISTRIBUTION IN MAMMALIAN CORTEX: A COMPARATIVE AUTORADIOGRAPHIC STUDY. M. Herkenham, S. Moon Edley* and C. B. Pert. Laboratory of Neurophysiology and Biological Psychiatry Branch, NIMH Bethesda, MD 20205.

The method of opiate receptor localization by in vitro autoradiography (Herkenham and Pert, PNAS, 1980, 77, 5532) can be applied to human tissue, since receptor labeling by incubation of fresh, unfixed cryostat-cut brain sections is performed postmortem on glass slides. In this fashion, sections from the brains of human, squirrel monkey, cat and rat were incubated at 4°C in a pH 7.4 solution containing ^{3}H-naloxone, 100 mM NaCl and .05 M Tris buffer. They were subsequently rinsed in sequential dishes of 4°C phosphate-buffered saline, dried under a stream of air, fixed in hot paraformaldehyde vapors and defatted in xylene and alcohol rinses. Autoradiography by dipping into Kodak NTB-2 emulsion or apposition to LKB Ultrofilm in x-ray cassettes gave similar results, but the film, when analyzed by computerized densitometry, facilitates quantitative analysis of large brains and widespread cortical distributions.

In the mammals studied, ^{3}H-naloxone-labeled opiate receptors are found throughout all cortical areas, though differences in density between areas, laminae and species are noticeable. In both rat and cat, medial and orbital frontal, temporal and insular areas show dense ^{3}H-naloxone binding, while primary sensory areas are sparsely labeled. In the squirrel monkey, areas displaying a prominent granular layer IV are the more densely labeled, while limbic areas are relatively more sparsely labeled. Species differences in laminar distributions are very striking. Opiate receptors throughout most of the rat cortex have peak densities in layers I, III or upper V, and deep VI (Lewis et al., this mtg). In the cat, layer I binding is prominent only in frontal, cingulate and retrosplenial areas. There and elswhere, layer VI is densely labeled, though this deep band is only very striking in insular, temporal and parahippocampal areas. In the squirrel monkey, a receptor-dense band in upper layer V predominates in all granular cortical areas and is continuous with a broader and sparser layer V band in limbic temporal and midline areas. In the portions of human cortex examined (frontal and anterior temporal), peak labeling is found in layers II and IV. For all animals, sections incubated in ^{3}H-dihydromorphine show the same pattern as ^{3}H-naloxone labeling but those incubated in ^{3}H-D-ala-D-leu-enkephalin display diffuse, specific binding throughout all cortical areas and laminae. The widespread but laminated appearance of alkaloid binding may mark receptors postsynaptic to intrinsic cortical or extrinsic thalamic "opiatergic" neurons, while the ubiquitous peptide binding represents a functionally mysterious opiate receptor subtype.

139.14 ASSAY OF SOLUBILIZED OPIATE RECEPTORS BY ADSORPTION TO DEAE PAPER. I.F. James*. (SPON: A. Goldstein). Addiction Res. Fdn., 701 Welch Rd., Palo Alto, CA 94304.

Recently, Ruegg et al. reported the solubilization of opiate receptors from the toad, Bufo marinus (Eur. J. Pharmacol. 64:367, 1980). We now describe a rapid and convenient assay for solubilized receptors from toad brain, which is adapted from a method used previously in the study of acetylcholine receptors (Schmidt and Raftery, Anal. Biochem., 52:349, 1973).

Washed brain membranes were extracted with 0.5% (w/v) digitonin and insoluble material was removed by centrifugation ($_{2}$10 000g, 1 hour). The supernatant was then incubated with [^{3}H] etorphine (1 hour, 22°C) and binding to solubilized receptors measured by adsorption of ligand/receptor complex to DEAE paper.

Between 5% and 20% of stereospecific etorphine binding sites on washed brain membranes were solubilized by digitonin. Binding of etorphine to these sites was proportional to the concentration of solubilized protein up to 0.4 mg/ml and had a pH optimum of 7.2. Etorphine (1nM) could be displaced from solubilized binding sites by 1μM levallorphan, but not 1μM dextrallorphan, indicating that stereoselectivity of receptors was maintained.

Experiments are in progress to characterize toad brain opiate receptors before and after solubilization.

139.15 REGULATION OF OPIATE RECEPTORS BY GONADAL HORMONES: POSSIBLE SPECIES DIFFERENCES? David L. Roberts and James A. Diez. School of Biology, Georgia Institute of Technology, Atlanta, GA 30332

It has been previously reported by Hahn and Fischman (Biochem. Biophys. Res. Comm. 90:819, 1979) that brain opiate receptor concentrations in adult male rats increase almost 100% after castration. This finding seems particularly intriguing in that it may provide a link in the mechanism of feedback control of gonadal steroids since with testosterone replacement therapy, receptor number in castrates was found to equal intact controls. We hypothesized that this finding would be generalizable to females as well as males in a related species, but we found no evidence for a major effect of gonadal hormones in controlling opiate receptors in male or female mouse brain.

Opiate receptors were assayed by incubating washed or unwashed membrane fragments from whole mouse brain(minus cerebellum)with 0.27-9.0 nM tritiated met-enkephalin or naloxone, for 1 hr at 22° or 3 hr at 4°. Non-radioactive morphine or met-enkephalin was used for determination of non-specific binding. The assay was conducted in a total volume of 1.2 ml with about 1 mg of protein per tube, well within the linear range for total binding at equillibrium. Data were analyzed by Scatchard plots and the kinetic constants (Kd, Bmax) for high and low affinity binding obtained were comparable to values in the literature.

In some experiments, gonadectomized mice were compared with sham-operated and intact controls; in other experiments, male and female mice were injected with estradiol benzoate and testosterone propionate(200 ug/kg, s.c.)and compared with vehicle and uninjected controls. Treatment times varied from 3 wks to 3 months for gonadectomy, and from 1-2 wks for hormone administration. Unlike the published work with rats cited above, none of the groups of mice used in our experiments showed differences in binding (Kd or Bmax) which appeared interesting or meaningful; differences in group means were typically less than 15%, a value similar to within-group individual variation. We are currently evaluating the effect of castration in male and female rats, with the aim of determining whether our findings represent a true species difference. Supported by a Biomedical Research Support Grant.

140.1 POSSIBLE SIGNIFICANCE OF BINOMIAL PARAMETERS n, p AND q AT A CENTRAL INHIBITORY SYNAPSE. H. Korn, D.S. Faber, A. Mallet* and A. Triller*, INSERM U3 and U194, CHU Pitié-Salpêtrière, 75013 Paris, France and SUNYAB, Buffalo, N.Y. 14214, USA.

The characteristics of transmitter release were studied at the level of the goldfish Mauthner cell's (M-cell) inhibitory synapses. This system allows simultaneous recordings from single pre and postsynaptic neurons and a statistical treatment of fluctuating postsynaptic potentials (Korn and Faber, Science, 194: 1166-1169, 1976). Electrodes filled respectively with KCl and with HRP were inserted in the M-cell soma and in interneurons belonging to either this neuron's collateral network or to a class of commissural second order vestibular cells, all being identified as mediating chemical inhibition of the M-cell given the presence of a Passive Hyperpolarizing Potential (Faber and Korn, Science, 179: 577-578, 1973; Korn and Faber, J. Neurophysiol. 38: 452-471, 1975). As recently reported (Korn, Triller, Mallet and Faber, Science, 1981, in press) we found that computer calculated binomial predictions provide a better description of the observed fluctuating inhibitory postsynaptic potentials (IPSPs) than did the Poisson model. Furthermore there is a one to one correspondence between the binomial parameter n and the total number of presynaptic terminal boutons established by the reconstructed HRP stained interneurons. This series of experiments included 19 cells and the number of boutons varied from 3 to 30. Thus, the binomial quantal unit represents the amount of transmitter emitted at each terminal by a single and evidently all or none releasing bouton. Two sets of evidence favour the hypothesis that such a quantal unit equals the content of only one presynaptic vesicle rather than a larger relatively fixed number of vesicles 1) with basic assumptions that one vesicle opens 2.000 channels, that a single channel conductance is of 20 pS and that the input resistance of the M-cell is of about 200 KΩ, calculations indicate that the effect of one released vesicle is a unitary IPSP amounting to .08% of the equilibrium potential. For a binomial product np of 5, the average unitary IPSP would then be 4% of the IPSP equilibrium potential, which is exactly in the range of those observed experimentally. 2) Presynaptic stimulations of increased frequencies (from 1 to 50 per sec) produce smaller IPSPs indicating a reduced mean quantal content. However and as expected, since the number of synaptic boutons is invariant, binomial n remains constant; in contrast, during the same synaptic depression the parameter p of the binomial equations, i.e. the probability of release at each terminal fell drastically in several cells while q, which defines the value of one quantum was left relatively unchanged.

140.2 MECHANISM FOR PRESYNAPTIC INHIBITION IN CRAYFISH CLAW OPENER MUSCLE. Douglas A. Baxter and George D. Bittner. Dept. of Zoology, The Univ. of Tex., Austin, TX. 78712.

Crayfish (P. simulans) opener muscle fibers are innervated by a single excitor axon and a single inhibitor axon. The inhibitor axon makes synapses not only on opener muscle fibers, but also the terminals of the excitor axon, thus providing both post- and presynaptic inhibition. We have made intracellular recordings from the excitor motor axon as it branches over the ventral surface of the opener muscle within a single space constant of the inhibitory axo-axonal synapses. Both hyper-and depolarizing presynaptic inhibitory potentials (PIPs) were recorded from different excitor axons during inhibitory stimulation. The sign and amplitude of the PIPs in different excitor axons varied with the resting membrane potential (Em) so that the apparent reversal potential of the PIPs was -70.5 mv.

The amplitude of the action potential in 25 excitor axons was 93±4 mv (mean ± s.d.), over-shooting the -74±7 mv resting potential. The spike was followed by a depolarizing after potential (DAP) of 10±2 mv at 2 msec after the rising phase of the spike, and a DAP duration of 30-50 msec. Excitatory action potentials were reduced in amplitude by 6.0±1.2 mv during presynaptic inhibition. Small alterations (1-3 msec) of the optimum delay between the inhibitor spike and the excitor spike produced less presynaptic inhibition and much less reduction of excitor spike amplitude. The reduction in excitor spike amplitude was independent of the amplitude and sign of the PIPs. These and other data suggest that the brief conductance change associated with presynaptic inhibition shunts the excitatory spike amplitude, and is the primary cellular mechanism responsible for presynaptic inhibition.

Finally, bath application of 0.5 mM gamma-aminobutyric acid (GABA) was found to shift the resting Em (ΔE_{GABA}) and reduce the amplitudes of the spike and DAP at all points along the excitor axon. The sign and amplitude of ΔE_{GABA} in different excitor axons varied with the resting Em so that the apparent GABA reversal potential was -68.8 mv. Bath application of GABA reduced the amplitude of the excitor spike by 10-20 mv (mean = 15 mv). In addition, GABA shifted the Em and reduced spike amplitude in the inhibitor axon by a similar amount. The extrajunctional GABA receptors were blocked by picrotoxin and appeared to increase the membrane permeability to chloride ion. Thus, the excitor and inhibitor axons appear to have similar GABA receptors distributed over their entire length.

140.3 SOMATOSTATIN AND GLUTAMIC ACID INCREASE EXCITABILITY OF SINGLE CUTANEOUS PRIMARY AFFERENT C- AND Aδ-FIBERS IN THE CAT SPINAL CORD. S. Jeftinija* and M. Randić. Dept. of Vet. Physiol. Pharmacol., Iowa State University, Ames, IA 50011.

Somatostatin and glutamic acid are present in the superficial laminae of the dorsal horn, the area where primary afferent fibers are known to terminate. While some dorsal horn neurons can be inhibited by a postsynaptic action of somatostatin, glutamate has the potent excitant effect on dorsal horn cells. In addition, amphibian dorsal roots and mammalian muscle afferent terminals are depolarized by glutamate. To determine whether somatostatin and glutamate exert a presynaptic action on the primary afferent fibers we measured the electrical excitability changes of intraspinal portions of single cutaneous afferent C- and Aδ-fibers during local application of these compounds.

In spinalized cats, small filaments of the sural nerve were prepared for recording and thresholds for antidromic activation of single afferent fibers were measured during intraspinal stimulation with a fine platinum microelectrode positioned within laminae I-III of the dorsal horn. Somatostatin (3.1 mM, pH 5.5) and L-glutamate (1.0 M, pH 7.0) were iontophoretically ejected through glass micropipettes glued to a stimulating electrode (intertip distance < 15 μm).

Out of 21 C-fibers tested, somatostatin (25-100 nA for 3 min) decreased threshold (to 67-95% of control) in a reversible and dose-dependent manner in 9 fibers, and increased threshold (to 109-124% of control) in 2 fibers. Decrease in threshold was also observed in 5 of 9 Aδ-fibers tested with somatostatin. L-glutamate (25-100 nA for 3 min) decreased threshold (to 67-93% of control) in 14 of 27 C-fibers and 5 of 8 Aδ-fibers.

Our data indicate that, in addition to previously demonstrated postsynaptic actions in the cat dorsal horn, somatostatin and L-glutamate have presynaptic actions to increase excitability in some cutaneous primary afferent C- and Aδ-fibers. Supported by NSF grant BNS 23871 and U.S. Dept. of Agriculture.

140.4 ELECTROGENIC MECHANISM OF PRIMARY AFFERENT DEPOLARIZATION T. Hashiguchi and A.L. Padjen. Department of Pharmacology and Therapeutics, McGill University, Montreal, Quebec.

The objective of this study was to analyse the ionic mechanism of primary afferent depolarization (PAD) by intra-fibre recording (microelectrodes filled with 3M KCl, 30-50 MΩ resistance) in the isolated hemisected frog spinal cord. Preparation was superfused with Ringer solution at 10°C. Membrane characteristics were determined by means of standard current clamp technique with pulses of 1.5 sec. Stable recordings (1-2 hrs) were obtained from more than 50 fibres with resting membrane potential -71.0 ± 6 mV (Mean ± S.D., n=49) and action potentials, evoked by root stimulation or direct current injection, of 97 ± 12 mV (n=51). All fibres were impaled at the dorsal root (DR) entry of 9th or 10th segment and had conduction velocity of >15 m/sec. I-V curves at steady state showed linear relationship in hyperpolarizing range of membrane potential (effective resistance, R_e=38 MΩ ± 16, n=11). Depolarizing pulses however revealed strong delayed rectification in all fibers studied. Adjacent DR stimulation (supramaximal for A fibres) evoked PAD (5.6 ± 3.2 mV, n=21) but ventral root stimulation evoked much smaller PAD only in some fibres. Most of the fibres showed spontaneous slow depolarizations often as large as evoked PADs. Linear part of I-V curves during PAD indicated a net decrease in R_e (to 68% ± 9 of control, n=11). Amplitude of PAD was dependent on membrane potential (increasing with hyperpolarization) but no reversal of PAD was obtained presumably because of delayed rectification. Extrapolation of the linear part of I-V relationship indicated an apparent reversal potential (E_r) of -45 ± 11 mV (n=11). PAD amplitude did not change when K sulfate (instead of KCl) filled microelectrodes were used but extrapolated E_r became more negative (-52 ± 8 mV, n=9).

These results are consistent with the idea that PAD results from an increase in primary afferents permeability to chloride ions.

140.5 THE EFFECT OF BURST PATTERNED STIMULATION ON POST-TETANIC HYPERPOLARIZATION OF MAMMALIAN C-FIBERS. R. Siegel* and R.I. Birks, Physiology Department, McGill University, Montreal, Canada.

The effect of physiological modes of burst patterned stimulation on post-tetanic hyperpolarization (PTHP) of rabbit vagus nerve bathed in isethionate-Locke solution at 35°C was studied using the sucrose-gap technique and method of analysis of Rang and Ritchie (J. Physiol. 196, 183-222, 1968). Stimulation with 0.5 sec bursts at 20 and 40 Hz every 8 sec was compared to stimulation with equally spaced pulses at 1.25 and 2.5 Hz respectively. Single control bursts at 30 Hz for 5 sec were used to estimate maximum Na pump activity. In 20 trials in 10 experiments the amplitude of PTHP following each successive burst at 40 Hz increased during the first 90±15 sec (Mean ± S.D.) of burst patterned stimulation to a steady-state hyperpolarization 2.6± 0.4 times that in response to the first burst. The steady-state hyperpolarization was 46±5% that in response to a control 5 sec 30 Hz tetanus. A significantly smaller ($P < 0.01$) hyperpolarization occurred during stimulation at 2.5 Hz: the increase over 2 min was to a steady-state value 71±9% of that during the 40 Hz burst patterned stimulation. When the intraburst frequency was reduced from 40 to 20 Hz the hyperpolarization was reduced; but it was over twice that found in comparison trials at 1.25 Hz. Thus burst-patterning of this form produces a greater increase in electrogenic Na pump activity than occurs when the pulses are equally spaced at the same average frequency.

Burst patterned stimulation of preganglionic fibers to the cat superior cervical ganglion has been shown to increase acetylcholine release and synthesis at the unmyelinated terminals by as much as three times that found when the stimulation is with equally spaced pulses at the same average frequency (Birks, J. Physiol. 295, 51-52P, 1979). Indirect evidence indicated the increase in synthesis to be related to accelerated pump activity and the increase in release to increased $[Na^+]_i$. The present results indicate that the increase in sodium pump activity of small unmyelinated fibers is indeed greater when the stimulation is burst patterned. Furthermore, the amplitude of PTHP can be taken as an index of sodium load provided pump activity is proportional to $[Na^+]_i$ and both membrane resistance and pump ratio remain unchanged. On this basis the results also support the hypothesis of increased $[Na^+]_i$ during burst patterned activity.

140.6 FREQUENCY DEPENDENCE OF IA-MOTONEURON EPSPs, W.F. Collins III* and L.M. Mendell, Dept. Neurobiology and Behavior, SUNY, Stony Brook, N.Y. 11794.

EPSPs recorded from medial gastrocnemius (MG) motoneurons during stretch evoked and electrical stimulation of single MG group Ia fibers have been analyzed in an effort to characterize the central properties of Ia fibers and their terminals. Anesthetized cats whose spinal cords had been acutely transected at T13 were used since the resulting enlarged Ia EPSPs (Nelson, et al., J. Neurophysiol. 42, 1979) can be resolved without averaging. Electrical stimulation of single fibers was achieved by stimulating dissected dorsal root filaments shown by impulse discharge to contain only a single MG Ia fiber. The synaptic action of a single Ia fiber was confirmed either by the similarity of the spike triggered and the electrically evoked average EPSPs (1 afferent, 3 motoneurons) or by observing that the EPSP was all or none and unaffected by increasing stimulus intensity (1 afferent, 1 motoneuron). The rate of stimulation varied between $1Hz$ and $500Hz$. Both successive individual EPSPs and the same data averaged over several blocks of n stimuli (e.g. n=5;33) were analyzed. Several clear trends emerged in the course of these initial experiments. At higher repetition rates (e.g. $>40Hz$ at some connections, but varying from connection to connection) the EPSP declined over time with much of the decrease occurring within the first few (5-20) stimuli. After a variable interval a new stable mean amplitude level was achieved. During this period EPSP amplitude fluctuated from trial to trial. These fluctuations occurred in a random manner as analyzed by turning points and phase lengths (Mieri & Rahaminoff, J. Physiol. 278, 1976). The final EPSP average amplitude was highly dependent on the frequency of stimulation with high repetition rates being associated with smaller EPSP amplitudes. There was also a noticeable increase in the proportion of "failures" at high repetition rates as well as a decrease in the number of large EPSPs. At repetition rates up to $200Hz$ there was no measurable change in the latency or rise time of the EPSP averaged during the final portion of the train despite a considerable decrease in amplitude. At higher frequencies a small increase in latency ($< 100\mu sec$) and rise time ($< 200\mu sec$) was noted. However, these may be less reliable because the continued decline in EPSP amplitude results in a smaller signal to noise ratio. The mechanism of this decrease in Ia-motoneuron EPSP amplitude remains unclear. Continuing studies should help to determine whether alterations in impulse conduction at branch points, Ia terminal invasion and/or transmitter release at individual synaptic sites contribute to the observed frequency dependent amplitude decrease. (Supported by NIH grants NS 16996-01 and NS 06407-01.)

140.7 POST-TETANIC POTENTIATION OF Ia EPSPs: DIFFERENTIAL DISTRIBUTION AND POSSIBLE MECHANISMS. A. Lev-Tov*, M. J. Pinter* and R. E. Burke. Lab. Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Post-tetanic potentiation (PTP) of Ia EPSPs has been reported to vary inversely with motoneuron input resistance (R_N; Lüscher et al., Nature 282:859, 1979). We studied 55 medial gastrocnemius (MG) motoneurons in pentobarbital-anesthetized cats with ventral roots cut. A conditioning train of pulses to the MG nerve at 500 Hz for 20 sec was followed by test pulses at 0.5-1.0 Hz. The largest sequential EPSPs during a 10 sec post- tetanus epoch were averaged (V_p) and normalized by control EPSPs (V_c). Despite considerable scatter, we found a negative linear correlation between PTP magnitude (V_p/V_c) and V_c ($r= -0.50$, $p<0.001$, 2-tailed test) and a weaker correlation between V_p/V_c and R_N ($r= -0.33$, $0.02>p>0.01$), implying a tendency for differential distribution of PTP. A complicating factor is the presence of significant depression after prolonged tetani. We found a strong positive correlation ($r= 0.74$; $p<0.001$) between normalized amplitude of the first post-tetanus EPSP (often smaller than control) and V_p/V_c. The observed PTP curve reflects depression as well as potentiation phenomena; both can affect the "peak" and either (or both) could cause differential effects. We found no clear correlations between "pure" synaptic depression (i.e., dependent on quantal release from individual boutons, tested by EPSP pairs at 250 ms interval) and either V_c or R_N. However, this synaptic depression was markedly enhanced during PTP, indicating increased transmitter release per bouton. There was no evidence that failure of action potential invasion contributes to post-tetanic depression since, in most cases, amplitudes of Ia prepotentials in the ventral horn, and of cord dorsum Ia volleys, were maximal immediately post-tetanus. Other possible sources of differential depression remain to be excluded. During PTP, the rise time and half-width of most EPSPs increased but there was no systematic relation between shape changes and V_p/V_c. The correlations between V_p/V_c and V_c or R_N may simply reflect differential scaling of non-linear voltage summation at Ia synapses, which terminate mainly on motoneuron dendrites. With PTP-enhanced transmitter release, non-linear summation would vary directly with local EPSP amplitudes and local input resistances, which are large in dendritic sites and are likely to scale inversely with motoneuron size. Supporting this notion, we found that the summation of MG and lateral gastrocnemius EPSPs was consideraly more non-linear when both were potentiated, as compared to control conditions. The relatively weak differential distribution of PTP in MG motoneurons seems compatible with conventional notions of augmented transmitter release during PTP.

140.8 FIBERS IN THE RIGHT VISCEROPLEURAL CONNECTIVE CAN ACCELERATE THE DECAY OF PTP OF SYNAPSE RC1-R15 OF APLYSIA CALIFORNICA. Jacques P. Tremblay and Gilles Grenon*, (Dept of Anatomy, Laval Univ, Quebec, P.Q. Canada)

A synapse called RC1-R15 can be activated by threshold stimulation of the right visceropleural connective (RC) of Aplysia californica. The activity of this synapse is recorded in cell R15 of the abdominal ganglion. Repeated stimulation of this synapse at 1 to 2 Hz produces successively a reduction of the RC1-R15 EPSPs (synaptic depression), an increase to a sustained plateau (frequency facilitation) and when the rate of stimulation is reduced a rapid increase followed by an exponential decay (posttetanic potentiation). In this poster, we show that stimulation of the RC 50% or 100% above the threshold for activating the fiber making the RC1-R15 synapse can accelerate the decay of PTP of synapse RC1-R15. This suprathreshold stimulation does not modify the synaptic depression and the frequency facilitation phenomena, nor does it affect the membrane resistance and potential of cell R15. Stimulation of RC below the threshold of synapse RC1-R15 can also reduce the PTP of synapse RC1-R15. High frequency (5 Hz) subthreshold stimulation of RC can also reduce the synaptic depression. However the subthreshold stimulation has no effect on frequency facilitation of RC1-R15. The effect of subthreshold stimulation on PTP is often correlated with the recording of a very small EPSP (sEPSP) in cell R15. This sEPSP is barely detected at the beginning of the subthreshold train of stimuli and has a long latency. The effects obtained with subthreshold and suprathreshold stimulation of the RC are abolished in sea water with a high concentration of Ca^{++} and of Mg^{++}. Both types of effects are attributed to the activation of fibers in the RC (called modulating fibers) which by the intermediary of one or several interneurons modulate presynaptically the transmission of synapse RC1-R15. The presence of these modulating fibers in the RC does introduce some noise in the study of PTP of synapse RC1-R15. The acceleration of PTP decay by these RC fibers does not however invalidate the main conclusions of our previous parametric studies of PTP at this synapse. These conclusions were: 1) PTP increases when the frequency of stimulation of RC1-R15 increases, 2) PTP increases when the number of stimuli increases, 3) PTP decays exponentially, 4) PTP decays more slowly following a train with a larger number of stimuli and 5) PTP decays more slowly following a train at an higher frequency of stimulation (Schlapfer et al., Brain Res. 109, 1-20, 1976). All these conclusions have been reached despite the acceleration of PTP decay by the RC fibers. The possible interactions of the modulating fibers of RC with pharmacological studies made at RC1-R15 will be discussed. Researchers are also caution about the possibility of undetected presynaptic modulating effects even in model systems where the synaptic activity is studied between two identified neurons.

140.9 POTASSIUM CURRENT (I_K) IN APLYSIA NEURON L_{10}: RELATIONSHIP TO SPIKE-AFTER-HYPERPOLARIZATION AND TO TRANSMITTER RELEASE. Dick Mooney* and Rafiq Waziri. Dept. of Psychiatry, Univ. of Iowa, Iowa City, IA 52242.

Interneuron L_{10} was voltage clamped in situ with recording and current-passing electrodes in the perikaryon. Monosynaptic IPSPs produced by L_{10} spikes were recorded in one of several follower cells with conventional double barreled electrodes. There are two principal K-conductances in L_{10}. The main one produces a delayed rectifying current; it is suppressed by intracellular or extracellular exposure to TEA, and by extracellular application of 4-aminopyridine or Ba^{++} ions. It is activated by depolarizing pulses and exhibits an expotential decay to brief pulses. Secondly, there is a smaller Ca^{++}-activated I_K which is apparent after somewhat longer depolarizing pulses, and which is suppressed by Co^{++} or Mn^{++} ions. There is a small residual outward I_K after both intracellular TEA and extracellular Co^{++} application. There is no appreciable "A current" activated by depolarizing pulses from hyperpolarized holding potentials, as there is in neuron R_{15}. The after hyperpolarization of the spike has the combined properties of the two principal I_Ks. The delayed rectifying current, measured after brief depolarizing pulses and prior to transmitter release, is correlated with transmitter release, notably under conditions where membrane potential is varied or when L_{10} repeatedly fires. The significance of this correlation is yet unknown.

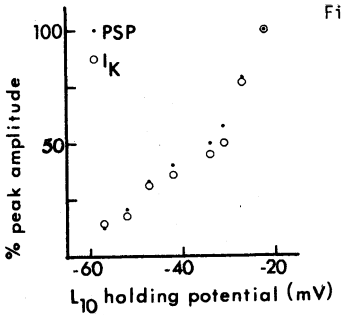

Fig. 1 Normalized PSP and I_K (tail current) amplitudes show a similar dependence on the steady holding potential which preceded and followed a 5 msec. depolarizing pulse.

140.10 TETANUS TOXIN PRODUCES BLOCKADE OF SYNAPTIC TRANSMISSION IN MOUSE SPINAL CORD NEURONS IN CULTURE. G.K.Bergey, P.G.Nelson R.L.Macdonald and W.H.Habig*. Lab. of Devel. Neurobiol., NICHD and Bact. Toxins Br., Bureau of Biologics, Bethesda, MD 20205.

The effects of tetanus toxin on synaptic transmission were investigated using fetal mouse spinal cord neurons grown in dissociated cell cultures. Spinal cord cultures were prepared and maintained in 10% horse serum and Eagle's minimal essential medium (MEM) for four to ten weeks. Prior to addition of tetanus toxin for experiments the cultures were washed X3 and placed in 1% fetal calf serum in MEM. Tetanus toxin (final conc. 10^{-5} to 10^{-9} g/ml) in 1% FCS-MEM was added to the cultures and intracellular recordings were made at various times using 4M KAc filled microelectrodes and a conventional bridge circuit. Spinal cord neurons in this culture system demonstrate prominent synaptic activity; over 80% reveal evidence of spontaneous PSPs.

Intracellular recordings from spinal cord neurons in the above concentrations of tetanus toxin revealed increased excitation manifest by paroxysmal depolarizing events (PDE) in the early hours of toxin exposure (Macdonald, Bergey and Habig, Neurology 29:588, 1979). Continued recording revealed diminished frequency of PDEs after several hours. Recordings from spinal cord neurons after 6 hr to 4 days of toxin treatment revealed an absence of spontaneous synaptic activity. No EPSPs or IPSPs were demonstrable in these chronically treated neurons (n=85). No morphological changes were apparent; membrane potentials and excitability were not affected. Reponses to iontophoretically applied glutamate, GABA and glycine were readily elicited at iontophoretic currents comparable to control situations.

An assay of evoked synaptic activity demonstrated 11 evoked monosynaptic connections in 20 control cell pairs. In contrast, after 24 hrs of tetanus toxin treatment (10^{-7} g/ml) no synaptic connections could be evoked by intracellular stimulation of 21 cell pairs (sig. to <.001 by corrected Chi square).

Neurons remained synaptically quiescent after tetanus toxin treatment despite removal of exogenous toxin and subsequent periods of up to 24 days in medium with antitoxin.

To examine whether the toxin-induced synaptic blockade was a result of effects upon calcium mechanisms, the effects of tetanus toxin on the calcium component of the spinal cord neuron action potential (Heyer, et.al. Br. Res. in press) were examined in the presence of 10 μM TTX, 25 mM TEA and 10 mM calcium. Neither the dV/dt nor the maximum duration of the calcium spike was significantly affected by 24 hr treatment with tetanus toxin.

The apparent presynaptic locus for tetanus toxin blockade of synaptic transmission in spinal cord neurons may involve mechanisms distinct from those mediating calcium flux.

140.11 EFFECTS OF VARIATIONS OF EXTRACELLULAR POTASSIUM ACTIVITY ($[K^+]_o$) ON SYNAPTIC TRANSMISSION AND $[Ca^{2+}]$ RESPONSES IN HIPPOCAMPAL TISSUE IN VITRO. G.L. King and G.G. Somjen. Dept. of Physiology Duke University Medical Center, Durham, NC 27710.

Extracellular recordings were made from the stratum radiatum (SR) and the stratum pyramidale (SP) of the CA1 region of rat hippocampal slices maintained in vitro. Responses were evoked by focal microstimulation of afferent fibers in SR. "Output", expressed as the amplitude of either the compound EPSP or the compound postsynaptic spike, were plotted as a function of "input" (presynaptic compound spike) or of stimulating pulse intensity. $[K^+]_o$ was monitored with ion-selective microelectrodes in the tissue. Either lowering or raising $[K^+]_o$ from the control level (3.0 mM) enhanced the field EPSP (detected as an increased slope of the input-output curve), which suggested increased transmitter release per presynaptic impulse. Raised or lowered $[K^+]_o$ did not affect the input-output curves in a linear manner; no prediction could be made from measured $[K^+]_o$ as to the magnitude of increased transmitter release. The excitability of presynaptic fibers was also increased when $[K^+]_o$ was raised. At 9.0 mM $[K^+]_o$ and above, spontaneous seizure-like discharges were observed. We also measured $[Ca^{2+}]_o$ with ion-selective microelectrodes. Repetitive stimulation of presynaptic fibers causes a decrease of $[Ca^{2+}]_o$ in hippocampal slices (Benninger et al., Brain Res.187:165, 1980). These stimulus-evoked $[Ca^{2+}]_o$ responses were larger in SP than in SR. $\Delta[Ca^{2+}]_o$ became detectable only when the stimulation was of sufficient intensity to evoke a postsynaptic action potential. Raising $[K^+]_o$ greatly enhanced the $\Delta[Ca^{2+}]_o$ evoked by afferent stimulation. In contrast, lowering $[K^+]_o$ reduced the $\Delta[Ca^{2+}]_o$ evoked by afferent stimulation, in spite of the enhanced EPSP, but concordant with the diminished spike discharge. We conclude: (1) That, besides its well-known action on electrical excitability, $[K^+]_o$ also has an important role in regulating transmitter release (see also: Cooke and Quastel, J. Physiol. 228:435, 1973). (2) That, in CA1 region, the quantitatively most important process contributing to the lowering of $[Ca^{2+}]_o$ during stimulation is the action potential discharge of cell bodies and/or proximal dendrites. (3) That the 5 mM $[K^+]_o$ and 2 mM $[Ca^{2+}]_o$ customarily used in bathing media for in vitro CNS tissue significantly alter synaptic transmission compared to the physiological 3 mM $[K^+]_o$ and 1.2 mM $[Ca^{2+}]_o$ (see also: Dingledine & Somjen, Brain Res. 207:218,1981). Supported by Grant#NS 11933 of the NINCDS.

140.12 LEPTINOTARSIN ACTIVATES TWO MECHANISMS OF QUANTAL RELEASE AT THE RAT NEUROMUSCULAR JUNCTION. J. R. Stimers. Dept. Biological Sciences, University of Southern California, Los Angeles, CA 90007.

Leptinotarsin (LPT) causes a biphasic increase in MEPP frequency, followed by a total cessation of release. In the present study, LPT was found to act during the first phase of release by opening Ca channels in a voltage-independent manner, activating the normal Ca-dependent release mechanism. During phase two, release occurs by a mechanism which does not have the normal Ca^{2+} or voltage dependence.

When the external Ca^{2+} concentration is lowered, the peak MEPP frequency of phase one diminishes and is not distinguishable from control at Ca^{2+} concentrations less than 10^{-5}M. The peak MEPP frequency of phase two is first reduced at less than 10^{-6}M Ca^{2+} and is still above control frequency at 10^{-9}M. Cd^{2+} added to normal Ringer gives results similar to 10^{-9}M Ca^{2+}. Furthermore, increasing Ca^{2+} to 20mM enhances phase one, while depressing phase two to low levels.

Using electrotonic polarization of the endplate, in the presence of TTX, the MEPP frequency during phase one of the LPT response is enhanced by depolarization and unaffected by hyperpolarization, even though the release rate is very high. Phase two, however, shows no change in MEPP frequency with either hyperpolarization or depolarization, even when higher currents are used. Application of 50mM K^+ before phase one increases MEPP frequency which is quickly followed by a vigorous LPT response. The same solution applied between phases one and two does not increase MEPP frequency and the expected phase two increase is inhibited. In the same experiment, if K^+ is returned to the normal value (5mM), MEPP frequency increases to the usual phase two level.

These data indicate that depolarization of the endplate is not solely responsible for the biphasic increase in MEPP frequency elicited by LPT. Furthermore, phase one has properties similar to those seen with normal Ca-dependent release. Therefore, it is concluded that LPT acts during phase one by inducing a Ca conductance in the presynaptic membrane. Since this conductance is blocked by Cd^{2+}, Ca^{2+} may be passing through the normal Ca channels. Phase two, however, is inhibited by depolarization with K^+ and has only micromolar dependence upon external Ca^{2+}.

140.13 NON-QUANTAL ACH RELEASE IN THE MOUSE DIAPHRAGM: EFFECTS OF DENERVATION AND BOTULINUM TOXIN. E.F. Stanley, & D.B. Drachman, Dept. of Neurology, Johns Hopkins Sch. of Med., Baltimore, MD 21205.

The spontaneous release of acetylcholine (ACh) from motor nerve terminals is now thought to occur by two mechanisms: a) quantal release, giving rise to mepps; and b) non-quantal release (Katz & Miledi, Proc. Roy. Soc. Lond. B 196:156-172, 1977).

We have studied the effects of denervation and botulinum toxin on these 2 forms of spontaneous ACh release in the mouse diaphragm by a sensitive visual method. This method is based on the observation that ACh can produce structural changes at the neuromuscular junction (see also O'Brien et al., J. Physiol. 295:92p, 1979). The mouse diaphragm is removed whole, and is incubated in oxygenated Ringer's solution with DFP, 1.5 x 10^{-4} - a potent cholinesterase inhibitor - (and tetrodotoxin 0.5 µg/ml, to prevent nerve firing) for 12 to 15 min, and then fixed in 5% glutaraldehyde. The endplate "swellings" are readily seen with the stereomicroscope, or even with the naked eye. We have confirmed the specific role of ACh in producing the swellings, since they do not form: a) in the presence of curare, or b) after prolonged denervation. Moreover, the addition of ACh to denervated diaphragms produces identical swellings. Thus, we have been able to use the occurrence of endplate swellings as an indicator of spontaneous ACh release.

Our findings show that:

1) Botulinum toxin blocks quantal ACh release nearly completely. However, swellings still occur, which can be attributed to persisting non-quantal ACh release.

2) Following denervation ACh release continues for up to 9 hrs, which correlates with mepp activity and hence quantal ACh release. However, non-quantal ACh release ceases far sooner, at 3 1/2 hrs.

These findings fit well with our previous observations suggesting an important role for non-quantal ACh release in the neural regulation of the resting membrane potential and extrajunctional ACh receptors of skeletal muscle (Stanley et al., Soc. Neurosci. Abstr. 6:384, 1980; Pestronk et al., Exp. Neurol. 70, 690-696, 1980.)

140.14 EVIDENCE THAT DECREASES IN INTRACELLULAR pH RAPIDLY INHIBIT TRANSMISSION IN THE GUINEA-PIG HIPPOCAMPAL SLICE. Peter Lipton and Donna Korol* Dept. of Physiology, Univ. of Wisconsin, Madison,Wisc. 53706

Decreases in intracellular pH (pHi) accompany states of compromised energy metabolism,increased neural activity and hypercapnia in brain tissue. We have been studying possible effects of dec reased pHi on monosynaptic transmission in the guinea-pig hippocampal slice. Slices are maintained at 37° by superfusion with a bicarbonate buffer at pH 7.4; the perforant path is stimulated and the evoked response is recorded in the dentate granule cell layer. The size of the population spike is monitored.

Decreasing extracellular pH by .4 units was accomplished either by increasing CO_2 concentration x3.5 (from 5% to 18%) or by decreasing buffer HCO_3^- concentration x 3.5 (from 26 to 7.5mM). Both of these changes produced identical effects on the evoked response; the population spike was reduced to about 55% of its control level with a half-time between 30 and 60 seconds. The decreases in pH did not affect the anti-dromic response in the dentate granule cells within 5 minutes. After this time there was a small (10-20 percent) decrease. Thus the action of the decreased pH seems to be on small neuronal elements. Other workers have studied effects of decreasing extracellular pH on synaptic transmission and have concluded that inhibition probably results from an extracellular, rather than intracellular action of the acidity. We tried to distinguish between these two sites of action.

Elevating both buffer CO_2 and HCO_3^- by x 3.5 decreases pH_i by .35 units (Whittingham and Lipton, unpublished) without changing extracellular pH. This buffer reduced the population spike by 60% with a half-time of 60 secs.

Increasing HCO_3^- may signifigantly lower buffer free Ca^{2+} (Schaer,Pflug. Archiv.,347:249) and we find that a 50% reduction in buffer Ca^{2+} from its normal 2.4 mM rapidly inhibits transmission. However, we find that the elevated CO_2/HCO_3^- buffer has an identical effect on transmission even if buffer Ca is raised to 5mM. (Reducing buffer Ca from 5 to 2.4mM does not affect transmission). In further control studies we found that simply substituting another anion (isethionate) for Cl^- has only a very small effect on transmission.

Thus, decreasing pHi by .35 units appears to significantly attenuate neural transmission. The fact that increasing CO_2 alone similarly inhibited transmission is consistent with this conclusion and suggests that decreasing extracellular pH does not affect transmission. We conclude that decreasing pH by lowering HCO_3^- rapidly lowers pHi. This will be tested.

140.15 STIMULATION OF CHOLINERGIC SYNAPTIC VESICLE Ca^{2+}/Mg^{2+} ATPase ACTIVITY BY BICARBONATE. Joan E. Rothlein and Stanley M. Parsons. Dept. of Chemistry, Univ. of California, Santa Barbara CA 93106.

The Ca^{2+}/Mg^{2+} ATPase associated with cholinergic synaptic vesicles from Torpedo californica is stimulated by several anions, of which bicarbonate is the most effective. Since Torpedo vesicles have been shown to specifically take up exogenous acetylcholine by a process stimulated by bicarbonate and either MgATP or CaATP (Parsons, S.M. and Koenigsberger, R. (1980), PNAS 77,6234-6238), additional studies exploring the mechanism of bicarbonate stimulation of the vesicular ATPase were performed. Basal Mg^{2+} and Ca^{2+} ATPase activities were stimulated by bicarbonate in a saturable manner with an apparent dissociation constant of 5mM for a two-fold maximal stimulation. In the absence of bicarbonate the double reciprocal plot of ATPase activity versus ATP concentration was biphasic with Michaelis constants of 0.048 mM and 0.58mM and maximum rates of 40 and 135 nmoles ATP hydrolyzed/min/mg protein. The double reciprocal plot became nearly linear in the presence of bicarbonate with a Michaelis constant of 0.06mM and a maximum rate of 250 nmoles ATP hydrolyzed/min/mg protein. Basal and bicarbonate stimulated activities were maximal at pH 7.0 and unaffected by sulfhydryl reagents. Classic ATPase inhibitors, NBD-Cl and DCCD, and anion-channel blockers, SITS and DIDS, were more effective in inhibiting bicarbonate stimulated ATPase activities than basal activities.

The vesicle ATPase was stimulated 3-4 fold by several non-ionic detergents and solubilized by 1.6% Lubrol WX or Igepal DM 710. The solubilized vesicle protein contained up to 90% of the total ATPase activity. The solubilized ATPase activity was stimulated by bicarbonate, stabilized by ATP, and appeared as a single broad band in equilibrium buoyant density centrifugation. Thus, bicarbonate binds directly to the ATPase to stimulate its activity.

140.16 KINETIC ANALYSIS OF Ca^{++} EFFLUX FROM SYNAPTOSOMES. S.M. Shreeve* and D.H. Ross (SPON: A. Modak). Div. Molec. Pharmacol., Univ. Tx. Hlth. Sci. Ctr., San Antonio, TX 78284.

Ca^{++} efflux from synaptosomes has been believed to occur primarily via Na^+-Ca^{++} exchange. Recent studies have demonstrated the existence of a high affinity ATPase along the inner portion of synaptic membranes. This enzyme is stimulated by low concentration of Ca^{++} (0.1 - 5.0 µM) and is believed activated by both cytosolic ATP and Ca^{++}. Our interest in studying Ca^{++} efflux was to determine whether or not a portion of the Ca^{++} efflux was ATP-dependent, as has previously been shown in squid axon (Nature 278: 271, 1979). Synaptosomes were isolated from brain homogenates by sucrose gradient centrifugation. Synaptosomes were loaded for two minutes with $^{45}Ca^{++}$ under a depolarizing concentration of K^+ (55 mM) at 37°C, pH 7.4. Efflux was started by the addition of buffer containing 132 mM Na^+, 5 mM K^+, 3 mM EGTA and physiologic concentration of standard components. $^{45}Ca^{++}$ efflux was measured at regular intervals, from 5 sec to 300 sec. Nonspecifically bound Ca^{++} was corrected for by loading the synaptosomes at 0°C and performing the efflux experiments at the appropriate temperature. Efflux of Ca^{++} occurred in three distinct phases, to which rate constants were assigned: K_1 (fast), K_2 (intermediate) and K_3 (slow). The time course for these phases were: K_1, 0-10 sec; K_2, 10-50 sec and K_3,> 50 sec. 65% of Ca^{++} efflux occurred during K_1, while 10% was seen at K_2 and 25% at K_3.

Efflux was studied after choline substitution, glucose deprivation and sodium azide (Na^+N_3) treatment. K_1 efflux was seen to be Na^+- and glucose-dependent, but was unaffected by Na^+N_3. K_2 efflux was Na^+-dependent, glucose independent and inhibited by Na^+N_3. K_3 efflux was unaffected by any treatment. Efflux at 0°C eliminated K_1 and K_2 but not K_3. The results suggest K_1 efflux may be ATP-dependent while K_2 is Na^+-dependent. K_3 was unaffected by any treatment and may reflect osmotic leak of Ca^{++}. These studies support the contention that Ca^{++} efflux from synaptosomes may involve a high affinity Ca^{++}-dependent ATPase.

140.17 PHOSPHORYLATION OF SYNAPSIN I (PROTEIN I) IN HIGHLY PURIFIED SYNAPTIC VESICLES AND OTHER SUBCELLULAR FRACTIONS FROM RAT BRAIN. W. B. Huttner, P. De Camilli*, W. Schiebler* and P. Greengard. Department of Pharmacology and Section of Cell Biology, Yale University School of Medicine, New Haven, CT 06510.

Synapsin I, previously referred to as Protein I, is a neuron-specific protein, present in most, and possibly in all, axon terminals, where it appears to be associated primarily with neurotransmitter vesicles (De Camilli et al.; Huttner et al., manuscripts in preparation). Synapsin I has been shown to be phosphorylated by calcium/calmodulin-dependent protein kinases in three distinct sites (sites 1, 2, 3) and by cAMP-dependent protein kinase in one site (site 1) (Proc. Natl. Acad. Sci. U.S.A., 76, 5402-5406, 1979; J. Biol. Chem., 256, 1482-1488, 1981). In the present study, the phosphorylation of Synapsin I in these sites was investigated in various subcellular fractions from rat brain including a highly purified synaptic vesicle fraction obtained after chromatography on controlled pore glass. During subcellular fractionation the enrichment of Synapsin I paralleled the enrichment of synaptic vesicles. Synapsin I in the highly pure synaptic vesicles could not be phosphorylated at site 1 by either calcium/calmodulin-dependent or cAMP-dependent protein kinases, in contrast to Synapsin I recovered in more crude synaptic membrane fractions. We are currently investigating the silent nature of site 1 of Synapsin I recovered in the synaptic vesicle fraction, to see if it reflects some physiological process occurring in vivo. The silent nature of the phosphorylation of this site 1 does not seem to result from limited proteolysis or presence of a protein kinase inhibitor and is unaffected by prior treatment of vesicle-associated Synapsin I with purified phosphatase.

Synapsin I could be released from isolated synaptic vesicles under appropriate experimental conditions by moderate increases of ionic strength. This effect of ionic strength was potentiated when sites 2 and 3 were in the phosphorylated form.

140.18 THE EFFECT OF REPEATED AMPHETAMINE ADMINISTRATION ON STEREOTYPED BEHAVIOR AND RESPONSE TO APOMORPHINE. P. G. Conway* and N. J. Uretsky. Division of Pharmacology, Ohio State University College of Pharmacy, Columbus, Ohio 43210.

The repeated administration of amphetamine has been shown to induce psychotic behavior in humans and to enhance, rather than diminish, stereotyped behavior in rats. The mechanism of this paradoxical "reverse tolerant" effect is at present unclear, but could be explained by amphetamine-induced subsensitivity of autoreceptors on dopaminergic nerve terminals. To test this hypothesis, rats were pretreated with amphetamine (5.0 mg/kg, i.p.) or saline (0.1 ml/100 g) twice daily at various rate schedules (5 days, 2 day withdrawal; 5 days, 9 day withdrawal; 10 days, 4 day withdrawal). After the withdrawal period, all animals were challenged with various doses of amphetamine (1.0, 3.0, 5.0 or 10.0, mg/kg, i.p.) and stereotypy was monitored for 90 minutes. At all doses and rate schedules studied, involving daily amphetamine administration, the amphetamine pretreated rats exhibited enhanced stereotypy compared to saline pretreated rats. However several injections of amphetamine in one day did not produce this effect after a withdrawal period of 6 days. If this enhancement of stereotypy were due to dopaminergic autoreceptor subsensitivity, then apomorphine's ability to stimulate these receptors and produce a decrease in striatal content of 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) as well as a decrease in locomotor activity should be reduced. Indeed, blocking dopaminergic presynaptic receptors with the neuroleptic molindone (1.0 mg/kg, i.p.) inhibited the apomorphine-induced decrease in striatal content of DOPAC and HVA. In contrast, a low dose of apomorphine (50 µg/kg s.c.) decreased locomotor activity and reduced DOPAC and HVA striatal content comparably in both saline and amphetamine pretreated animals. Also it would be expected that apomorphine's ability to inhibit γ-butyrolactone (GBL)-induced dihydroxyphenylalanine (DOPA) accumulation be reduced in amphetamine pretreated animals. However apomorphine, in a dose related manner, reduced striatal GBL stimulated DOPA accumulation by the same extent in saline and amphetamine pretreated animals. Based on these studies, amphetamine-induced behavioral facilitation does not appear to be mediated by an alteration in striatal dopaminergic presynaptic receptors. Supported by NS grant 13888.

140.19 EFFECT OF THE COMMON FOOD DYE, ERYTHROSIN B (F, D & C RED NO.3), ON TRANSMITTER RELEASE FROM MAMMALIAN CEREBRAL CORTICAL TISSUE. Patricia D. Wade and Philip Siekevitz. Rockefeller University, 1230 York Avenue, New York, NY 10021.

Erythrosin B is a tetraiodinated derivative of fluorescein which is used in food as a coloring agent. We find it to cause release of the transmitters examined, GABA and norepinephrine, from an in vitro cerebral cortical preparation. A mixture of coloring agents including Erythrosin B exacerbates learning defects in children having the hyperactivity syndrome (Science 1980, 207:1485), and, significantly, induces at moderate doses behavioral hyperactivity in certain children with no previous pathology (Science 1980, 207:1487). Erythrosin B at 10µM or greater causes an increase in miniature endplate potential frequency at the frog neuromuscular junction (Science 1980, 207:1489), and is reportedly taken up into brain from the circulation nearly (.82X) as well as water (PNAS 1977, 74:2914).

After preincubation with [^{3}H]norepinephrine or [^{3}H]GABA, and subsequent rinsing of the tissue slices, 9 minutes exposure to 100µM Erythrosin B caused peak release which is estimated to be 3X (norepinephrine) or 10X (GABA) above baseline (Procedure as described for other compounds in Wade, Fritz and Siekevitz, Brain Res. in press.). The parent compound fluorescein did not appear to cause release at 1mM at the sensitivity of the assay. Other derivatives of fluorescein, Eosin YS (tetrabrominated fluorescein) and phloxine B (tetrabrominated, tetrachlorinated fluorescein), were found to cause GABA release at 100µM. Thus the halogen substitutions appear to be important for the property of release. The release was found to occur equally well in the absence of added Ca^{++} (studied for GABA only) and could not be blocked by 10^{-6}M tetrodotoxin, both of which results suggest that the induction of release is not via voltage-dependent Na^+ channels. Erythrosin B is apparently similar to black widow spider venom and the sulfhydryl-oxidizing agent diamide in not requiring Ca^{++} for release and presumably in not requiring Na^+ channel-related depolarization. To summarize, the release effect of Erythrosin B in central nervous system is not transmitter-specific, and, it could be argued, occurs in the estimated dose range in which peripheral physiological and hyperactivity effects are observed.

140.20 BIPHASIC DOPAMINE RELEASE FROM STRIATAL SYNAPTOSOMES PARALLELS Ca ENTRY. P. Drapeau* and M.P. Blaustein. Dept. of Physiology, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

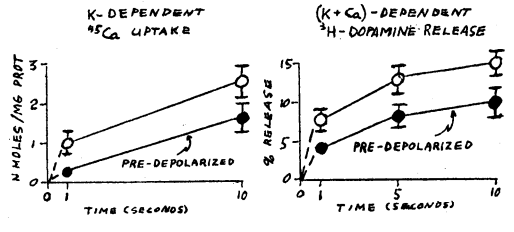
Ca uptake and dopamine release from rat striatal synaptosomes were examined over a 10 sec interval. Synaptosomes were loaded with ^{3}H-dopamine by incubation in 0.1 µM ^{3}H-dopamine solution. Release was subsequently evoked by incubation in K-rich media. Both high K-stimulated ^{45}Ca uptake and ^{3}H-dopamine release occurred in two phases (see figure below): i) a "fast" phase, which showed voltage-sensitive inactivation within one sec, and ii) a "slow" phase, which lasted for 10 sec. The rate constants for release were about 0.08 s^{-1} for the fast phase, 0.01 s^{-1} for the slow phase (averaged between 1 and 10 sec), and 0.001 s^{-1} for the basal efflux of ^{3}H-dopamine.

The evoked release of dopamine was blocked by the Ca channel antagonists Ni, Mg, Mn, Co, and Cd; Sr and Ba substituted for Ca in supporting K-stimulated release. These divalent cations have been shown to have similar effects on Ca entry into rat forebrain synaptosomes (Nachshen and Blaustein, J. Gen. Physiol. 76: 709-728, 1980).

The two phases of evoked dopamine release increased in magnitude as K was increased from 5 to 75mM, and had a $K_{0.5}$ for Ca of 0.2-0.7mM. Similar effects of varying K and Ca on both phases of Ca entry have been observed in rat forebrain synaptosomes.

The data indicate that Ca entry is rate-limiting for dopamine release; however, the kinetics of Ca entry and dopamine release are not linearly related.

Supported by NIH grant NS-16106. PD is a recipient of a MRC of Canada Fellowship.



140.21 PRESYNAPTIC CALCIUM CHANNEL INACTIVATION AT THE SQUID GIANT SYNAPSE. G. Augustine, R. Eckert and R. Zucker, Catalina Winter Squid Program; Department of Biology, UCLA; and Department of Physiology-Anatomy, UC, Berkeley.

Voltage-gated calcium channels inactivate in neuronal soma membranes. Because of the importance of Ca currents in regulating transmitter release, we attempted to determine if Ca channels in a presynaptic terminal also inactivate. Experiments were performed on the giant synapse of the Pacific squid Loligo opalescens. Standard procedures were used to record from pre- and postsynaptic elements, with the preterminal voltage clamped using either 2 or 3 microelectrode techniques. External TTX (2 x 10^{-7} g/ml), 3-,4-diaminopyridine (2 mM) and injected TEA were used to block sodium and potassium currents.

Depolarizing pulses to approximately 0 mV from a holding potential (V_h) of -65 or -70 mV elicited inward currents. These currents were presumably carried by Ca ions, because they were eliminated by 2mM $CdCl_2$. During prolonged depolarizations the Ca current relaxed exponentially, with a time constant of approximately 0.1s. Two lines of evidence indicate that the relaxation is due primarily to Ca channel inactivation, rather than concurrent activation of an outward (potassium) current. First, no outward current was seen in these preparations after treatment with cadmium, which blocks Ca currents while sparing voltage-gated potassium current. Second, Ca 'tail' currents recorded at the end of depolarizing pulses with $V_h = E_K$ decreased in amplitude as pulse duration increased. These tail currents were blocked by cadmium, and had time constants of 1 ms or less.

Inactivation was also observed with other procedures. A decrease in amplitude of the inward current occurred if the test pulse was preceded by a depolarizing prepulse. This inactivation increased monotonically as the amplitude or duration of the prepulse increased (and decreased as the interval between the two pulses was increased). Inactivation was also seen when V_h was lowered. The Ca current was maximal with V_h = -70 mV, was reduced at -50 mV, and was nearly eliminated at V_h = -30 mV.

Thus, Ca channels of the presynaptic terminal of the squid giant synapse appear to inactivate, as do most other voltage-gated Ca channels that have been investigated. Inactivation is not likely to affect transmitter released from this synapse during a single impulse, due to the brief duration of the action potential compared to the time course of inactivation, but may play a role in decreasing transmitter release during prolonged trains of presynaptic impulses.

140.22 THE EFFECT OF ANTIPSYCHOTIC AGENTS ON TRANSMISSION AT THE NEUROMUSCULAR JUNCTION OF THE FROG. N. Stockbridge* and J.W. Moore. Dept. of Physiology, Duke University Medical Center, Durham, NC 27710.

Many studies of transmission at the frog neuromuscular junction have shown calcium to play a key role in the release of the chemical messenger. In low calcium solutions, the amount of transmitter released is proportional to about the fourth power of the external calcium concentration (Dodge & Rahamimoff, 1967; Andreu & Barrett, 1981). This fourth power relationship suggested to us that calmodulin, the ubiquitous intracellular calcium-binding protein with its four calcium binding sites, might be involved in the process of transmitter release.

Experiments have been conducted to test this hypothesis of calmodulin involvement in transmitter release. Trifluoperazine is an antipsychotic which binds to calmodulin and prevents its participation in *in vitro* reactions (Levin & Weiss, 1977). At the frog neuromuscular junction, trifluoperazine (20-30 uM) reversibly decreases the observed endplate potential response to nerve stimuli. This action of trifluoperazine does not appear to be due to a decrease in the sensitivity of the postsynaptic membrane to the transmitter substance, since miniature endplate potentials are undiminished in amplitude by trifluoperazine concentrations several-fold higher than that necessary to block evoked release. Nor does trifluoperazine appear to block of the propagation of action potentials in the presynaptic motor fiber, since extracellular recordings of the nerve terminal potential are unaffected by these concentrations of the drug. At a concentration of 200 uM, trifluoperazine sulfoxide, a derivative of trifluoperazine with much decreased affinity for calmodulin, has no affect on transmission. Other calmodulin-binding drugs also have effects on transmission generally consistent with expectations based upon their *in vitro* behavior.

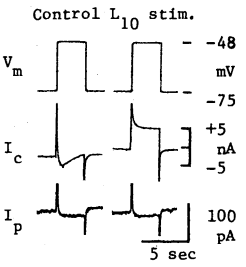
141.2 PATCH CLAMP ANALYSIS OF SOMATIC CURRENTS IN MOLLUSCAN BURSTING PACEMAKER NEURONS: RESPONSES TO NEUROTRANSMITTER AND SLOW SYNAPTIC INPUT. William W. Anderson and Wilkie A. Wilson*. Epilepsy Center, V.A. Hospital, Durham, NC 27705.

Voltage clamp analysis of molluscan bursting pacemaker neurons indicates that certain neurotransmitters and slow synaptic inputs inactivate slow inward currents at depolarized voltages (Wilson and Wachtel, Science, 202:772, 1978). Because the transmitters were iontophoresed into the neuropil, because molluscan somata usually do not have synaptic contacts, and because molluscan soma membrane has slow inward currents, W & W suggested that synaptic and neurotransmitter inactivation of inward currents measured from the whole cell could be due to either inactivation of inward current channels at subsynaptic neuropil sites, or to the inactivation of these channels throughout the cell, including in the soma membrane, by the spread of an intracellular messenger.

We are investigating these possibilities by voltage clamping Aplysia neurons with two intrasomatic microelectrodes and measuring soma membrane currents with a 50-100 uM patch electrode connected to a virtual ground operational amplifier. Dopamine was iontophoresed onto neuropil processes of R_{15}, and slow synaptic input was produced in L_3 by stimulating the presynaptic cell L_{10}.

Short duration stimulation (ca. 20 sec) of L_{10}, which is sufficient to change the whole cell current (I_c) of L_3 from inward to outward during a depolarizing clamp pulse, causes at most only a slight change in the L_3 somatic patch current (I_p), which remains inward (see figure). In these cases, synaptic inactivation of the inward current measured from the whole cell is thus primarily due to the inactivation of nonsomatic, neuropil currents. Possible changes in somatic patch currents with longer periods of synaptic stimulation is under investigation.

Iontophoresis of dopamine onto R_{15} processes in the neuropil does cause clear changes in somatic patch current. Patch current goes from inward to outward for a -50 to -10 mV clamp pulse. Dopamine receptors are not thought to be located on the soma membrane of R_{15}. Whether dopamine was stimulating neuropil receptors and changing soma conductances via an intracellular messenger, or was leaking under the patch and stimulating previously undetected somatic dopamine receptors is not known, but is under study.



Supported by a NIH Postdoctoral Fellowship to WWA, and NIH Grant 15212 and a grant from the VA to WAW.

141.3 CA DEPENDENCY OF ACETYLCHOLINE (ACH) INDUCED K RESPONSES. A.M. Williamson and D.O. Carpenter. Div. of Laboratories and Research, NYS Dept. of Health, Albany, New York 12201.

In Aplysia neurons, there are three kinds of responses to Ach due to conductance increases to Na, Cl, and K. Although the Na and Cl responses are similar in time course, the K response shows a delay in its onset which cannot be explained by an unusual placement of receptors within membrane invaginations or by restrictions in the diffusion path to the receptors. The time to peak of the K response is longer (8-10 sec.) than for the Na or Cl responses (1-2 sec.). The K responses are also sensitive to cooling, being abolished at 8°C. The slow time course and temperature sensitivity are suggestive of a second messenger and/or metabolic dependency, although there is no evidence that cyclic nucleotides are involved in the response. Another possibility is that the K response is mediated by Ca accumulation within the cell or by its release from internal stores. Ca-activated K currents were first discovered by Meech and have since been seen in other systems.

We conducted experiments on the K response to iontophoretically applied Ach on medial cells of the pleural ganglia of Aplysia in order to evaluate the involvement of Ca in the response. The cells were bathed in artificial sea water (ASW) at or near room temperature, and recordings were made under current or voltage clamp conditions. We have previously shown that $MgCl_2$- mannitol sea water blocked the K response. Since Mg is known to block Ca dependent processes we examined the effect of other Ca blockers. The addition of 1-3 mM Cd ions to ASW produced virtually complete but reversible inhibition of the response. The addition of 25 mM Co ions which are known to block voltage dependent Ca currents in Aplysia reversibly reduced the K current by 50%. Manipulations in the Ca concentration from .1 to 10X normal did not produce any significant change in the response. Ca-free solutions with .1 mM EGTA, a potenet Ca chelator, produced little change on the magnitide of the response, but did lengthen the time course. Intracellular injection of EGTA did not alter the response.

The results obtained with Mg, Cd, and Co ions suggest that there is Ca dependency to the K response. Those divalent ions are known to block Ca entry through the membrane. However, the mechanism does not appear to involve a simple Ca-activated K conductance since varying the Ca concentration, and/or adding EGTA had no effect, and no inward current was observed. It is possible that those divalent ions displace Ca from a binding site on the receptor or in the membrane and prevent receptor activation. A less likely possibility is that those ions block the K channel.

141.4 BIOCHEMICAL, PHARMACOLOGICAL AND ELECTROPHYSIOLOGICAL STUDIES ON ISOLATED HORIZONTAL CELLS FROM THE TELEOST RETINA. J. E. Dowling, E. M. Lasater, R. Van Buskirk*, K. J. Watling* and M. Zeldin*. The Biological Laboratories, Harvard University, Cambridge, MA

One of the major challenges of current neuroscience research is to correlate biochemical and physiological processes at the level of single neurons. We are currently approaching this problem using preparations of horizontal cells isolated from the teleost retina.

Carp retinal neurons are dissociated by a combination of enzymic and mechanical means, and horizontal cells are isolated by velocity sedimentation in a Ficoll gradient at unit gravity. Electron microscopy shows the cells are intact with no impinging presynaptic terminals.

When incubated with 2 mM IBMX, the isolated horizontal cells demonstrate dopamine-dependent cyclic AMP accumulation. Cyclic AMP levels are routinely raised 20-40 times over basal levels by 100 μM dopamine. The response (EC50~ 10 μM) is potently blocked by haloperidol, fluphenazine or (+) butaclamol.

Dopamine also induces changes in protein phosphorylation in isolated horizontal cells. The incorporation of ^{32}Pi into various phosphoproteins was examined by SDS polyacrylamide gel electrophoresis. Cells incubated in the absence of dopamine demonstrate two major phosphoproteins, one (A) with a molecular size of approximately 300 KD, and a second (B) with a size of approximately 68 KD. Exposure of the cells to 10-100 μM dopamine results in the appearance of component C with a molecular size greater than 400 KD and the disappearance of phosphoproteins A and B. Haloperidol blocks the dopamine dependent disappearance of A and appearance of C.

Other neurotransmitters were examined for their ability to increase cyclic AMP levels in isolated horizontal cells. Of these only vasoactive intestinal peptide (VIP) is effective. The VIP and dopamine responses are not additive, but haloperidol does not block the VIP response. This suggests the presence of separate VIP and dopamine receptors on isolated horizontal cells associated with a common adenylate cyclase pool.

Finally, intracellular recordings from isolated horizontal cells maintained in tissue culture for 2-4 days show that about one-quarter of the cells are responsive to dopamine. Dopamine increases membrane resistance, and most often hyperpolarizes the cell. L-Glutamate, on the other hand, depolarizes virtually all cultured horizontal cells while D-glutamate, GABA and glycine are without effects.

141.5 INTRACELLULAR MEASUREMENTS OF CHLORIDE ACTIVITY ON THE HORIZONTAL CELLS OF THE VERTEBRATE (FISH) RETINA.
M.B.A. Djamgoz*and P.J. Laming* (SPON: E.M. Lasater). Dept. of Pure and Applied Biology, Imperial College, London SW72BB England.

Ionic substitution experiments have shown that both sodium and chloride ions might be required for the generation of light-evoked horizontal cell responses (S-potentials) in vertebrate retinae (Kaneko, A. & Shimazaki, H., J. Physiol. Lond., 252:509-522, 1975; Waloga, G. & Pak, W.L., J. Gen. Physiol., 71:69-92, 1978; Miller, R.F. & Dacheux, R.F., J. Gen. Physiol., 67:639-659, 1976). In the present study, the role of chloride ions was investigated by measuring intracellular and extracellular ionic activities in L- and C-type horizontal cells.

Isolated cyprinid (roach) retinae were placed receptor side upwards in a transparent recording chamber and maintained in moist air. Retinae were specifically not treated with physiological salines so 'normal' ionic activity values could be measured. Horizontal cells were impaled with double-barrelled chloride sensitive microelectrodes based on the Corning liquid ion-exchanger 477315. The light stimulus comprised a 1.5 mm spot of continuously variable wavelength and intensity. Ion-sensitive microelectrodes were calibrated in a series of solutions of constant ionic strength both before and after an experiment, and data were considered only when the two calibrations did not differ by more than 5 mV. Results were obtained from 78 red-sensitive L_1-units and 9 biphasic C-units in 11 retinae.

The average extracellular chloride activity was 112 mM and this was constant throughout the retina. Intracellular chloride activities in both types of unit were consistently less : 60 mM for L_1-units and 54 mM for C-units. The calculated chloride equilibrium potentials (E_{Cl}'s) were -19 mV and -20 mV; the corresponding dark membrane potentials (E_m's) of these units were -34 mV and -35 mV averaged, respectively. In both types of unit, therefore, the chloride ions are not in equilibrium with the membrane potentials (E_{Cl} is more positive than E_m by 15 mV), and can potentially contribute to the synaptic generation of S-potentials.

141.6 EXTERNAL CALCIUM INFLUENCES THE CHARACTERISTICS OF FAST SYNAPTIC CURRENTS AT THE SYMPATHETIC GANGLION. Elizabeth A. Connor* and Rodney L. Parsons (SPON: G. Webb), Depts. of Physiol. and Biophysics and Anatomy and Neurobiol., Univ. of Vermont, Burlington, Vermont 05405.

Calcium has been reported to influence the timecourse of the nicotinic fast excitatory postsynaptic current (EPSC) decay in sympathetic ganglion cells in addition to its critical presynaptic role in transmitter release (Kuba and Nishi, 1979). In preliminary experiments we noted that calcium not only prolonged fast EPSC timecourse, but in many cells exposed to elevated calcium, the EPSC no longer decayed as a single exponential. In these cells, the decay had two distinct exponential components; one faster and one slower than the control rate of decay. In the present study, we have investigated the alteration of fast EPSCs by calcium (0.9mM to 9.0mM) in more detail. Fast EPSCs were recorded from voltage-clamped B cells (-100 to +30mV) in the IX and X sympathetic ganglia of the bullfrog, Rana catesbeiana, maintained in a HEPES-buffered solution at 21-23°C. Peak EPSC size and decay τ increased with an elevation of external calcium in the concentration range 0.9 to 5.4mM. No further increase in EPSC size occurred with increase in calcium from 5.4 to 9.0mM as reported previously (Kuba and Nishi, 1979). The EPSC decay was a single exponential function in all cells maintained in 0.9 to 1.8mM calcium, but at concentrations $\geq$ 3.6mM calcium, an increasing percentage of cells had EPSCs exhibiting a double exponential decay. Prolongation of the decay timecourse in high calcium can not be attributed simply to the increase in peak EPSC size as EPSCs potentiated 2-5 fold by preganglionic stimulation at 30Hz for 4 seconds decayed as a single exponential with the time constant value similar prior to and after the period of stimulation. A similar alteration in fast EPSC decay occurred in cells exposed to 1.8mM calcium and 8.0mM strontium. In these cells, peak EPSC size was not significantly different from controls but the decay was either markedly prolonged when the EPSC decayed as a single exponential or was comprised of two exponential components, one faster and one slower than control rate of decay. In the strontium-treated cells, the slow component time constant, but not the fast, appeared to increase with hyperpolarization. The complex decay in high calcium or strontium was not due to an increased voltage deviation in these cells or an increased transmitter release, but may represent a direct action of these divalent cations on kinetics of the fast EPSC decay.
(Supported by NIH Grant NS-14552)

141.7 NONCHOLINERGIC "LATE-SLOW"-EPSP IN MAMMALIAN SYMPATHETIC GANGLION. John H. Ashe and B. Libet. Department of Physiology, School of Medicine, University of California, San Francisco, CA. 94143.

Orthodromic input, during cholinergic blockade by d-tubocurarine (50 µM) plus quinuclinidyl benzilate (QNB, 0.05 µM) can elicit a relatively large, slow depolarization, recorded extracellularly as a "late-late-negative" (LLN) response of the superior cervical ganglion of rabbit. LLN is also unaffected by adrenergic antagonists (phenoxybenzamine 10 µM, or sotalol, 10 µM). LLN is a graded response, with latencies of 1 to 3 sec and durations up to 20 min or more. That LLN represents a neuronal PSP is indicated by a) the ineffectiveness of antidromic stimulation of postganglionic axons; b) the absence of LLN in presynaptic recordings (electrodes on ganglion and preganglionic nerve); c) the decrement of LLN along postganglionic nerve, with a length constant the same as for the known PSP's. LLN clearly represents an equivalent of the "late-s-EPSP" described for frog paravertebral (Nishi and Koketsu, 1968) and guinea pig inferior mesenteric (Neild, 1978) ganglion cells; we propose the name "slow-slow" or "ss-EPSP".

The major determinant of both amplitude and duration of LLN is the total number of stimulus pulses (applied to cervical sympathetic nerve). Indeed, pulse frequencies as low as 1 pps can elicit almost as large a response as higher frequencies (20-40 pps), if a sufficiently long train containing an equal number of pulses is applied. However, latency and rise-time are shorter with higher stimulus pulse frequency.

The ss-EPSP features, including effectiveness of low frequency orthodromic volleys and amplitudes estimated to reach 25-50% of the action potential, indicate that this very slow noncholinergic PSP could play a significant role in normal ganglionic functions. (Supported by U.S.P.H.S. research grant NS-00884.)

141.8 The ionic mechanism of the non-cholinergic excitatory potential in mammalian sympathetic ganglion cells. Z. G. Jiang*, N. J. Dun and M. A. Simmons. Dept. of Pharmacol. Loyola Univ., Maywood, Il 60153.

Repetitive preganglionic nerve stimulation (10-30 Hz 2-8 sec) of the inferior mesenteric ganglia of the guinea pig elicited a slow excitatory potential which was not blocked by nicotinic (d-tubocurarine, 0.1 mM) and muscarinic (atropine, 1 µM) antagonists. The amplitude and duration of the non-cholinergic excitatory potential ranged from 2 to 15 mV, and 20 sec to 3 min, respectively. In many instances, spontaneous spike discharges occurred during the generation of non-cholinergic potential; the spontaneous discharges were not blocked by cholinergic antagonists, but readily abolished by membrane hyperpolarization. In a portion of the neurons tested, the input resistance showed a biphasic change: an initial decrease was followed by a more prolonged increase. This biphasic membrane resistance change could also be demonstrated when the membrane potential was clamped at rest manually. In the remaining neurons, the non-cholinergic excitatory potential was associated with either a monophasic increase of input resistance or no detectable change in both unclamped and clamped conditions. The amplitude of the non-cholinergic potential was augmented upon membrane hyperpolarization to the level of K equilibrium potential; the extrapolated equilibrium potential was about -40 mV. In a few neurons, the non-cholinergic response was either not significantly altered or diminished upon conditioning hyperpolarization. In high K (10-15 mM)Krebs solution, the amplitude of non-cholinergic potential was reduced, however, the respone was increased upon membrane hyperpolarization. When the concentration of Na in the perfusing Krebs solution was reduced to 1/3, the non-cholinergic potential was attenuated, whereas, it was not appreciably affected in a low Cl solution. Our results indicate that the ionic mechanism underlying the non-cholinergic potential may be similar to that of the membrane depolarization induced by substance P on these neurons, i.e. a combined mechanism of G_{Na} activation and G_K inactivation. (Supported by NS15848).

141.9 POSTSYNAPTIC HYPERPOLARIZATION DOES NOT AFFECT LONG-TERM ENHANCEMENT OF CA1 SYNAPSES. B.L. McNaughton, C.A. Barnes, H. Wigström*. Dept. Anatomy and Embryology Univ. College London, and Dept. Physiology, Univ. of Göteborg, Sweden.

The long-term enhancement of synaptic efficacy which follows high frequency activation of certain hippocampal synapses has been suggested to constitute a workable neural substrate for associative memory. Aside from the long lasting (although not permanent) nature of this process, one of the major grounds for the assertion that it models associative memory is that it appears to require the association of afferent fibre activity for its generation (McNaughton, Douglas & Goddard, B. Res. 157, 277-293, 1978; Levy & Steward, B. Res. 175, 233-245, 1979).

Virtually all workable neural models for associative memory postulate that some form of postsynaptic integration process must regulate the synaptic change by which information is to be stored. Although the co-operative nature of the enhancement process suggests that postsynaptic integration is required, this has not been demonstrated and viable presynaptic explanations remain.

We have examined, in CA1 pyramidal cells recorded from intracellularly in vitro, the effect of 1.0 nA hyperpolarizing current applied during high frequency activation of fibres in Stratum Radiatum. A non-overlapping set of fibres in the same layer received the identical stimulation without membrane hyperpolarization. Thus, each cell served as its own control.

The hyperpolarizing current, which was sufficient to cause a significant shift in membrane potential at the site of synaptic input, and to reduce or abolish cell discharge during the stimulus train, had no effect whatsoever on the magnitude of the synaptic enhancement observed 15 minutes later. Thus, if postsynaptic integration is involved in the control of enhancement, the signals integrated are likely to be chemical rather than electrical.

141.10 AMMONIA AND POSTSYNAPTIC INHIBITION. W. Raabe and S. Lin*. Depts. Neurology, VA Med. Ctr., Univ. of Minnesota 55417.

Ammonia intoxication has been shown to inactivate the extrusion of Cl^- from central neurons, thus shifting the equilibrium potential of the IPSP, E_{IPSP}, to the level of the resting membrane potential. This effect of ammonia abolishes the hyperpolarizing action of postsynaptic inhibition as well as its potency to suppress neuronal excitation. We measured the concentrations of ammonia, glutamate and glutamine associated with ammonia induced shifts of the E_{IPSP} to the resting membrane potential.

Cats were anesthetized with pentobarbital and respirated artificially. Mono- or polysynaptic IPSPs were recorded from spinal mononeurons. Ammonium acetate was given slowly i.v. until the E_{IPSP} shifted to the level of the resting membrane potential. The administration of ammonium acetate was then terminated. The recovery of the E_{IPSP} occurred as an average after 35 min. The average dose of ammonium acetate required to shift the E_{IPSP} was 2.75 mmol/kg. The resting membrane potential showed no significant changes during ammonia administration. The shift of the E_{IPSP} to the resting membrane potential was not associated with changes of the slope of IPSP size vs. membrane potential during applied current steps. The lumbar spinal cord was frozen in situ with liquid nitrogen before, during and after recovery of the changes in the E_{IPSP}.

With the shift of the E_{IPSP} to the resting membrane potential ammonia concentrations increased from 0.64 $\pm$ 0.02 µM/g (N=5) to 2.32 $\pm$ 0.42 µM/g (N=4), $p < 0.02$; glutamine increased from 5.26 $\pm$ 0.55 µM/g to 8.27 $\pm$ 0.87 µM/g, $p < 0.02$. With recovery of the E_{IPSP} ammonia decreased to 1.60 $\pm$ 0.07 µM/g (N=4); glutamine remained high 7.52 $\pm$ 0.93 µM/g. Glutamate did not change with the shifts of E_{IPSP}; control: 6.62 $\pm$ 0.56, E_{IPSP} shifted: 5.07 $\pm$ 0.48, E_{IPSP} recovery: 5.45 $\pm$ 0.42 µM/g.

An increase of tissue ammonia concentrations to 360% of normal inactivates the extrusion of Cl^- from neurons and thus abolishes hyperpolarizing postsynaptic inhibition. The changes of ammonia concentrations affecting inhibition in the spinal cord correspond qualitatively and quantitatively to those observed to affect postsynaptic inhibition in the cerebral cortex (Brain Res. 210: 311, 1981). It is concluded that in encephalopathies which increase ammonia in the CNS beyond 350% of normal, e.g. severe hypoxia, severe hypoglycemia, portacaval shunting, the effect of ammonia on postsynaptic inhibition contributes to the neurological abnormalities observed.

141.11 METHYLTRANSFERASE INHIBITION AND ACETYLCHOLINE-INDUCED MUSCLE CONTRACTION. G. Magilen, L. Ziskind-Conhaim, I. Diamond, and A.S. Gordon. Depts. of Neurology, Physiology, and Pharmacology. Univ. of Calif., San Francisco, CA 94143. 141.11

It has been suggested that methyltransferase (MT) enzymes play a role in chemotaxis, mitogenesis, hormone responsiveness and neurotransmission. We have investigated the possibility that MT activity is involved in acetylcholine (ACh)-induced myotube depolarization and contraction. In this study we have used primary myotubes grown from chick embryo thigh muscles cultured for 5-7 days. Muscle contraction was evoked when 1M ACh was applied focally by pressure injection from a micropipet. The role of MT reactions in ACh-evoked depolarization and contraction was determined by using a mixture of 0.1mM erythro-9-(2-hydroxy-3-nonyl) adenine, 0.1mM homocysteine thiolactone, and 1.0mM adenosine which together inhibit the activity of methyltransferases. ACh-induced muscle contraction was inhibited within 10 minutes after application of the inhibitor mixture. However, muscle contraction produced by mechanical stimulation was not affected by the inhibition mixture. The inhibition of contraction was not due to desensitization or a change of the resting membrane potential. Intracellular recordings showed that neither ACh-induced subthreshold depolarizations produced by injection of 1mM ACh nor action potentials were affected by the inhibitor mixture. The ACh-induced contraction was restored after washing out the inhibitors.

If the inhibition of contraction was caused by inhibition of MT activity, then the washing procedure which restores ACh-induced contraction should also restore the MT activity. We found that carboxy-MT and lipid-MT activities were decreased 93% and 92% respectively by the mixture of compounds. In contrast to the reversible inhibition of contraction, the inhibition of MT activity was not reversible. Therefore, the inhibition of contraction was not due to the inhibition of either carboxy-MT or lipid-MT activities.

From our results we conclude that the primary function of the acetylcholine receptor is not affected by inhibition of MT activity. Moreover, carboxy-MT and lipid-MT activities are not involved in the inhibition of ACh-induced muscle contraction caused by this mixture of compounds. Therefore, these compounds must be inhibiting contraction by acting on some other process.

141.12 PHYSIOLOGICAL REGULATION OF GLUTAMATE RECEPTOR BINDING. Baudry, M., Halpain, S.*, Arst, D.*, Smith, E.*, and Lynch, G. Department of Psychobiology, University of Calif., Irvine, Ca. 92717

The hippocampus exhibits various forms of physiological plasticity among which is long-term potentiation (LTP) of synaptic transmission following brief bursts of high-frequency stimulation of various pathways. An increasing body of evidence suggests that glutamate (or a closely related compound) is the neurotransmitter used by the pathways exhibiting the LTP phenomenon. Hippocampal synaptic membranes possess a high-affinity Na-independent ^{3}H-glutamate binding site which has properties expected of a postsynaptic glutamate receptor. We previously showed that micromolar concentration of calcium ions are able to increase the number of glutamate binding sites possibly by stimulating a membrane-bound Ca++-dependent proteinase (Baudry et al., Science, 1981, in press) and proposed that this could be the mechanism underlying LTP. We now report changes in glutamate receptor binding under various physiological or quasi-physiological situations.

First, using a new version of the hippocampal slice preparation in which only the CA_1 field is dissected and incubated in the recording chamber, we were able to replicate the finding that high-frequency stimulation results in an increased (+30%) ^{3}H-glutamate binding to hippocampal membranes. This increased binding reflects an increase in the maximal number of sites without changes in their affinity for the ligand. This effect is not found after low-frequency stimulation or when the high-frequency stimulation is performed in low calcium medium, two conditions which are not accompanied by LTP.

Second, incubation of hippocampal slices in the presence of low concentrations of glutamate (0.5 mM) or of various glutamate agonists also induced an increase in the maximal number of binding sites to synaptic membranes without changes in their affinity for the ligand. Finally, ^{3}H-glutamate binding increases progressively as a function of age; in this case, also, the increased binding represents an increased number of sites without changes in their affinity for glutamate. Moreover, in these latter two conditions, the binding measured in the presence of a saturating concentration of calcium (250 µM) does not exhibit the increased binding and this does not result from a qualitative difference in the ability of calcium to stimulate ^{3}H-glutamate binding. These data support the idea that there may exist in hippocampal membranes a fixed amount of glutamate receptors, only a fraction of them being available at any time, and that certainforms of synaptic activity are able to modify this fraction.

Supported by Grant NIMH-MH19793-10 and NIA-AG000538-05.

141.13 CHARACTERISTICS OF A CALCIUM-STIMULATED PROTEASE FROM SYNAPTIC MEMBRANES. M. Bundman, M. Baudry, E. Smith*, D. Heck* and G. Lynch, Dept. of Psychobiology, Univ. of Ca., Irvine, Ca. 92717.

Previous studies have established that calcium (~10μM) increases the number of sodium-independent binding sites for glutamate in several regions of the rat forebrain and that this effect is blocked by inhibitors of certain classes of proteases. Subsequent studies revealed that micromolar levels of calcium induced the degradation of a high molecular weight doublet protein and again, this effect was blocked by protease inhibitors. These results suggested that some neuronal membranes contain a protease which is involved in the regulation of receptors and which is activted by calcium in concentration ranges not far removed from those which might occur under physiological conditions. The experiments to be described intended to test the correlation between calcium induced proteolysis and calcium induced stimulation of glutamate binding by comparing the effects of several manipulations on these two processes.

Time course studies indicated that Ca^{2+} (100 μM) induces a a maximal effect after 15 minutes of incubation at 30°C. The proteolytic process is extremely temperature-sensitive with essentially no activity at 20°C and maximal activity at approximately 30°C; similarly Ca^{2+}-stimulation of glutamate binding is virtually absent at 20°C. The effects of several divalent cations were also tested on this proteolytic activity. Mn^{2+} (1mM) induces a 40-45% decrease in the amount of the substrate doublet protein, an effect similar to that of Ca^{2+} (0.1mM); Sr^{2+} (1mM) also substitutes for Ca^{2+} whereas Mg^{2+}, Ba^{2+}, Co^{2+}, Cu^{2+}, Ni^{2+}, and Zn^{2+} are ineffective at concentrations up to 1 mM. Comparable results have been found with the stimulation of glutamate binding. The Ca^{2+}-stimulation of both the proteolytic process and the glutamate binding are inhibited by the thiol protease inhibitors leupeptin and N-ethylmaleimide (0.1mM).

These data indicate that these two calcium-dependent processes, the stimulation of glutamate binding and the proteolytic activity, share a number of properties, including similar dependencies on divalent cations, inhibitors and temperature. Therefore, they add further support to our hypothesis that the calcium-induced increase in the number of glutamate receptors results from the proteolysis of a specific membrane protein. The precise identification of the protease and its substrate should provide a better understanding of the mechanisms by which calcium ions participate in the regulation of cell surface receptors and the role that this effect might play in synaptic physiology.

141.14 EFFECTS OF LINCOSAMIDE ANALOGS ON ENDPLATE CHANNELS: CORRELATION WITH LIPID SOLUBILITY. J. F. Fiekers, I. G. Marshall*, and R. L. Parsons. Department of Anatomy and Neurobiology, Univ. of Vermont, College of Medicine, Burlington, VT 05405, and Dept. Physiol. and Pharmacol., Univ. of Strathclyde, Glasgow Scotland.

The lincosamide antibiotics, lincomycin and clindamycin, differ in molecular structure by the respective chemical substituent in position 7: lincomycin-hydroxyl, clindamycin-chloride. This chemical modification markedly influences the characteristics of MEPC decay and the shape of the power spectra obtained from noise analysis. Lincomycin splits MEPC decay into an initial rapid phase followed by a prolonged phase. Clindamycin increases the rate of MEPC decay without measurably altering its exponential nature. For each antibiotic the cut-off frequency of each spectral component is predicted by the rate of the corresponding constituent of the MEPC decay. Previously, we have shown (Fiekers, et.al., Fed. Proc. 40: 1981) that the postsynaptic block produced by lincomycin can be described by a sequential kinetic blocking model in which lincomycin interacts with the open state of the endplate channel complex. The present experiments were undertaken to explore the importance of chemical substitution at position 7 on endplate currents. The effects of two lincosamide analogs, epilincomycin and deoxylincomycin on the amplitude and kinetics of MEPCs and ACh-induced EPC fluctuations were studied in voltage-clamped snake costocutaneous neuromuscular junctions. These analogs split the MEPC decay into two components, one faster and one slower than the control decay rate. Either increasing the concentration of each analog or membrane hyperpolarization increased the decay rate of the fast component and decreased the rate of the slow component. The ratio of the respective amplitudes of each component (I_f/I_s) increased with hyperpolarization. On the basis of the electrophysiological analysis of the component rates and amplitudes the compounds could be arranged in the following sequence

lincomycin < epilincomycin << deoxylincomycin < clindamycin

The decay of currents recorded in deoxylincomycin, therefore, consisted primarily of a fast decay component and a small, slow tail component. Currents recorded in lincomycin consisted of a slow current component comprising a greater portion of the total current decay. Analysis of the lipid solubility using thin layer chromatographic techniques resulted in an identical sequence (clindamycin being the most lipophilic). The correlation between lipid solubility and the results on endplate current kinetics suggests that hydrophobic interactions with the endplate membrane may be important in the action of the lincosamide group of antibiotics. 141.15 A CONSTRAINT ON SYNAPTIC ACTION IN APLYSIA: IMPLICATIONS FOR NERVOUS SYSTEM ORGANIZATION. Michael M. Segal and John Koester. Center for Neurobiology & Behavior, Physiology Dept., College of Physicians & Surgeons, Columbia University, N.Y., N.Y.

What constraints limit the types of synapses that can form in a nervous system? It is known that a postsynaptic neuron can have two types of receptors to the same neurotransmitter and the neuron can receive inputs from different cells using that neurotransmitter. In such a case, can one presynaptic cell depolarize and the other hyperpolarize, each by selectively activating one type of postsynaptic receptor? In other words, when a postsynaptic neuron concentrates receptors at synapses, does it concentrate one type of receptor to a particular transmitter at one synapse and a different type of receptor to the same transmitter at another synapse? To approach this question we have investigated neurons in the abdominal ganglion of Aplysia californica that receive inputs from two or more of the cholinergic neurons L10, L16, L24, Int XIII and Int XX.

For any given postsynaptic cell, we found that different cholinergic inputs converging onto the cell all produce the same type of synaptic action. This is true even for cells with more than one ACh receptor type. Cell L7 has both excitatory (E) and inhibitory (I) ACh receptors, and the 4 cholinergic neurons synapsing onto L7 all activate both receptor types, producing conjoint E-I synaptic potentials. Cells RD_{G} and LD_{G2} have two types of inhibitory ACh receptors, and each cell receives two cholinergic synaptic inputs, with each input activating both types of inhibitory ACh receptors.

If all cholinergic inputs to a given cell produce the same type of synaptic action, one would predict that all synaptic actions of different types are produced by non-cholinergic cells. Consequently we examined 3 neurons (L28, L32, LE) that elicit pure E responses in L7. We found that these presynaptic cells are all non-cholinergic.

These data lead to the hypothesis that a postsynaptic cell does not segregate one type of ACh receptor to one synapse and a different ACh receptor type to other synapses. If this hypothesis holds generally, it could, taken together with Dale's principle, provide insights into two organizational principles of nervous systems: (1) If a cholinergic interneuron excites a cell that another interneuron inhibits, the other interneuron must use a second transmitter. If each of these two interneurons produces an action on any other cell that differs from that produced by a third interneuron, then that interneuron must use a third transmitter; (2) If two cells use the same transmitter and influence a particular postsynaptic neuron in different ways, one would expect that at least one of the connections will be polysynaptic, involving an interneuron with a different transmitter. Thus, the constraint on synaptic action we have observed could explain a need for many neurotransmitters and a need for certain interneurons found in neural circuits. Supported by NIH grants GM 07367 and NS 14385.

144 SYMPOSIUM

MEMORY AND BRAIN MECHANISMS. L.R. Squire (Chairman; VA Medical Center, UCSD), B.A. Milner (Montreal Neurological Institute), D.S. Olton (John Hopkins Univ.), M. Mishkin (NIMH), E. Tulving* (Univ. of Toronto).

Brain mechanisms involved in mammalian memory functions will be considered from the point of view of neuropsychological studies of rats, non-human primates, and humans. Dr. Milner will discuss the role of medial temporal lobe structures in human memory based on a review of the early findings and a presentation of the most recent work in this area. Dr. Olton will discuss the effects of hippocampal lesions in rats, reviewing efforts to find parallels between the experimental animal and human literature. Dr. Mishkin will discuss cortico-limbic interaction and memory in non-human primates, reviewing efforts to establish a monkey model of human global amnesia. Dr. Squire will discuss amnesia in human and non-human primates, reviewing how the facts of amnesia have elucidated the organization of memory and its neural substrate. Dr. Tulving will discuss memory and brain mechanisms from the perspective of cognitive psychology, emphasizing the useful interaction that can occur between the experimental study of normal memory and the neuropsychological study of amnesia.

145 SYMPOSIUM

APPROACHES TO STUDYING GENE EXPRESSION AND REGULATION DURING NEURONAL DIFFERENTIATION AND FUNCTIONING. P.H. O'Lague (Chairman; UCLA); L. Greene* (New York Univ. Med. Ctr.); T. Joh* (Cornell Med. School); J. Roberts* (College of Physicians and Surgeons, Columbia Univ.).

The overall objective of this symposium is to present an introduction to several model systems and several current molecular biological approaches that appear useful in studying various aspects of neuronal differentiation and neuronal functioning at the level of the genome.

Determining the role of nerve growth factor (NGF), a presumed trophic substance, in the regulation of the growth and differentiation of its target neurons is an intensive area of current neurobiological research. L. Greene will describe short-term transcription-independent events and long-term transcription-dependent events both mediated by NGF and both of biological significance to neuronal development. The regulation and properties of catecholamine synthesizing enzymes will be discussed by T. Joh who will present biochemical and molecular biological evidence including peptide analysis, antibody cross-reactivity, and cDNA cloning for a common ancestral gene for the enzymes tyrosine hydroxylase, dopamine- -hydroxylase, and phenyl-N-methyltransferase. Molecular techniques have recently become available for quantitating gene expression in the brain and J. Roberts will describe the current methods for this quantitation by using as an illustrative example his work with peptide hormones such as ACTH, vasopressin, GnRH, among others. The production of large cells by chemically-induced fusion of cells sensitive to NGF has recently proven useful in studying aspects of neuronal differentiation. P. O'Lague will discuss the use of large clonal (PC-12) cells in studying the effects of intracellular injection of macromolecules, including NGF among others, on the acquisition of neuron-like properties and the effect of multiple nuclei on NGF-induced growth.

146 WORKSHOP

THALAMIC MECHANISMS OF PAIN SENSATION K.J. Berkley, (Chairman, Fl. St. Univ.), H.J. Ralston, III (UCSF), W.D. Willis, Jr. (Univ. Tx. Med. Br., Galveston), L. Kruger (UCLA), D. Albe-Fessard* (Univ. P. & M. Curie, Paris).

This workshop is designed to provide an overall view of what is currently known (and unknown) about thalamic mechanisms of pain sensation and to relate this information to what is known about such mechanisms in other parts of the central nervous system. Each speaker will address a different aspect of the topic by summarizing current knowledge and by describing some of the relevant problem areas under investigation in the speaker's own laboratory. A general discussion period will follow each lecture, and, if time permits, there will be another period for general discussion at the conclusion of the workshop.

Following some brief introductory remarks on the general status of the field by K.J. Berkley, H.J. Ralston, III will review our current knowledge of connective arrangements within the thalamus as they relate to "pain pathways". In the context of this review, he will also describe some of his recent ultrastructural work (involving intracellular injections of HRP) on local neuronal circuits in some of these thalamic regions. Next, W.D. Willis, Jr. will review our current knowledge of the pain-related response properties of neurons in somatic sensory portions of the thalamus. Included in this review, he will describe some recent electrophysiological findings on the responses of neurons located in both the lateral and medial thalamus of primates to noxious mechanical and thermal cutaneous stimuli. Next, L. Kruger will review our current knowledge of the thalamic mechanisms of pain that are specific to the trigeminal system. He will bring into this discussion some recent anatomical and electrophysiological work that is related to these mechanisms in cats and rats. Next, D. Albe-Fessard will review current ideas of pain mechanisms in the thalamus as they have been derived from clinical findings in humans and from electrophysiological and behavioral studies in animals. She will also discuss some of her relevant new findings on animal models of desafferentation pain and on inhibitory and facilitatory controls acting at thalamic levels. K.J. Berkley will conclude the session by summarizing the proceedings and discussing new directions for further research.

147.1 INHIBITION IN THE HIPPOCAMPAL SLICE IS REDUCED BY PHENCYCLIDINE. G. W. Bourne, Y. Theoret*, B. Esplin and R. Capek. Dept. of Pharmacology & Therapeutics, McGill University, Montreal, Quebec.

The frequently abused general anesthetic and psychotomimetic drug phencyclidine (PCP) can induce numerous signs of excessive stimulation of the central nervous system including convulsions when administered in high doses. The hippocampus may be the major locus of PCP evoked seizure activity because this structure has a low seizure threshold, contains large concentrations of stereospecific PCP binding sites (Vincent et al., Proc. Nat. Acad. Sci. 76, 4678) and responds by large increases in energy metabolism to PCP administration (Meiback et al., Nature, 282, 625). Therefore the possibility that PCP, as numerous convulsants, induces seizures by depression of inhibition was examined in the hippocampal slice in vitro preparation.

The hippocampus of male Sprague Dawley rats was sliced in transverse sections to a thickness of 425 µM. The slices were placed on a nylon mesh, were perfused at a rate of 1-2 ml/min with a 95% O_2 and 5% CO_2 saturated Krebs solution and were maintained at 36°C. Field potentials were recorded extracellularly by a 3 M NaCl filled glass micropipette. The population spikes were elicited orthodromically by stimulation of the Schaffer collaterals or antidromically by stimulation of the alveus. Inhibition of the orthodromic response was produced by a conditioning orthodromic or antidromic stimulus 5 to 40 ms prior to the stimulus evoking the test response.

Bath applied PCP in concentrations of 5 to 50 µM did not significantly alter the orthodromic or antidromic evoked responses in CA1 cells. However, these concentrations of PCP markedly reduced inhibition produced by orthodromic or antidromic stimulation at all time intervals tested. The reduction of inhibition commenced 15 minutes after PCP application. This effect was fully reversible, after a 60 minute washout period with Krebs solution the inhibition was returned to control levels. The inhibition reduced by PCP was restored by diazepam (50 µM), despite the continued presence of PCP in the perfusion medium.

These results indicate that decrease in inhibition may be responsible for PCP induced seizure activity. Since PCP did not interfere with responses elicited by iontophoretic administration of γ-aminobutyric acid (GABA) (Raja, S.N. & Guyenet, P.G., 1980, Neurosci. Abst. 270, 1) it is likely that depression of GABA release either by a direct action on the GABA release mechanism or through a depressant action on the recurrent inhibitory pathway may be the underlying mechanism of this action of PCP.
(Supported by the Medical Research Council of Canada).

147.2 EFFECTS OF PHENCYCLIDINE AND KETAMINE ON THE HIPPOCAMPUS. S.N. Raja*, J.L. Stringer* and P.G. Guyenet. Univ. Virginia School of Med., Dept. of Pharmacol., Charlottesville, VA 22908.

The effects of phencyclidine (PCP) and ketamine (K) on synaptic transmission were investigated at the level of two excitatory connections of the hippocampal formation: the interhippocampal projection from contralateral CA3 (cCA3) to CA1 and the entorhino-dentate pathway.

In urethane-anesthetized rats, PCP i.v. decreased by 16-40% the population EPSP elicited in the stratum radiatum of CA1 by cCA3 stimulation and reduced the amplitude of the corresponding population spike recorded at the level of the CA1 pyramidal (P) cell bodies by up to 97% (ED_{50}: 1.83 mg/kg).

Single-unit analysis of CA1 P-cell discharges indicated that i.v. PCP (0.5-3 mg/kg) reduced their spontaneous firing, their orthodromic activation by cCA3 stimulation and their excitation by iontophoretically applied glutamate and ACh but did not alter the size of the extracellular action potentials.

Similar effects on both field potentials and single-unit activity in the CA1 area were also observed following the administration of larger i.v. doses of K (ED_{50}: 7.2 mg/kg) but the effects of the latter drug were of considerably shorter duration than those of PCP.

The maintained activity of CA1 P-cells and the discharges induced by iontophoretically applied ACh and Glu were also decreased following iontophoretic administration of PCP and K in doses which did not produce any alteration in spike size.

PCP i.v. also decreased neurotransmission in the entorhinodentate pathway as evidenced by a reduction of both the rate of rise of the population EPSP and of the size of the population spike recorded in the dorsal granule cell layer of the dentate gyrus. The linear relationship between these two parameters was not affected by the drug, suggesting that the decrease in the evoked discharges of granule cells was mainly due to a reduction in dendritic depolarization.

In conclusion, PCP was shown to powerfully depress excitatory transmission in the hippocampus when administered in a dose range identical to that previously used to demonstrate behavioral alterations in the same species. The effects of PCP were similar to those of K but the former drug was both more powerful and longer acting. The effects of both PCP and K are presumably due in large part to a direct postsynaptic action. (DA 02310).

147.3 Δ^9-TETRAHYDROCANNABINOL (THC) INDUCED CHANGES IN BASAL AND NOREPINEPHRINE-STIMULATED ADENYLATE CYCLASE ACTIVITIES IN MOUSE CEREBRAL CORTEX. Cecilia J. Hillard and Alan S. Bloom. Department of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226.

We have previously reported that two psychoactive cannabinoids, THC and 11-OH-THC, increased the binding of ^{3}H-dihydroalprenolol (^{3}H-DHA) to beta-adrenergic receptors of mouse cerebral cortical homogenates (Kiernan, CJ and Bloom, AS, Fed. Proc., 39:849, 1980). This increase in in vitro ^{3}H-DHA binding was found to be due to an increase in affinity with no change in the total density (Bmax) of binding sites. Conversely, cannabidiol, a cannabinoid devoid of THC-like psychoactivity, had no effect on ^{3}H-DHA binding. We have now investigated the effects of THC in vitro on both basal and norepinephrine-stimulated adenylate cyclase activities in mouse cerebral cortical homogenates.

Male ICR mice were used in these studies. The animals were sacrificed and cerebral cortices were removed and homogenized. Homogenates were incubated with drug, 0.75 mM ATP and 0.1 mM GTP for 2.5 minutes at 30°C. The cAMP produced during the incubation was measured using the competitive protein binding method of Brown (Brown et al., In: Advances in Cyclic Nucleotide Research, Vol. 2, ed. by P. Greengard and G.A. Robinson, p. 25-40, Raven Press, N.Y., 1972). THC was administered using an emulphor-ethanol-buffer vehicle.

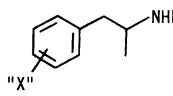
Mean basal adenylate cyclase activity in the absence of drug was 33.77 pmol/mg protein/min. THC at concentrations of 10 µM-30 µM increased basal adenylate cyclase activity to 140-170% of vehicle control, with the increase at 30 µM being statistically significant. The increase was biphasic, both lower and higher concentrations of THC had no effect on basal adenylate cyclase activity. The increase in basal adenylate cyclase activity could not be blocked by 10 µM dl-propranolol.

Mean adenylate cyclase activity in the presence of 10 µM l-norepinephrine was 48.51 pmol/mg protein/min, an increase of 43.6% over basal activity. At concentrations of 1 µM-30 µM, THC appeared to abolish the norepinephrine-stimulated component of adenylate cyclase activity since no additional increase over the change in basal adenylate cyclase activity was seen. At 100 µM THC, adenylate cyclase activity returned to control values. These results indicate that THC has effects on both basal and norepinephrine-stimulated adenylate cyclase activities that may be independent of the drug's effect on binding to the beta-adrenergic receptor. (Supported by USPHS grant DA-00124).

147.4 EFFECTS OF CERTAIN HALLUCINOGENIC AMPHETAMINE ANALOGUES ON THE RELEASE OF ^{3}H-5-HT FROM RAT BRAIN SYNAPTOSOMES. D.E. Nichols, D.H. Lloyd*, M.B. Nichols*, and G.K.W. Yim, Depts of Medicinal Chemistry and Pharmacognosy and Pharmacology and Toxicology, Purdue University, West Lafayette, Indiana 47907

It is generally believed that the mechanism of action for hallucinogenic amphetamines involves direct interaction with central serotonin receptors. However, some compounds have been shown to release endogenous transmitter. The extent to which this is a significant component of the action is unclear. PMA and MDA are two widely-abused hallucinogens which have been implicated in several overdose deaths. The former compound has been shown to be a powerful in vivo releaser of central 5-HT and peripheral NE. MDA has been shown both to release peripheral NE and to block reuptake of NE into synaptosomes.

The behavioral effects of hallucinogenic amphetamines are selectively elicited by the R-(-) enantiomer. It was therefore intriguing that N-methylation of MDA reverses this selectivity. That is, it is the S-(+) isomer of N-methyl MDA which is active. The object of this work was to study the effect of R and S MDA, R and S N-methyl MDA (MDMA), R and S PMA and some related compounds on the release of ^{3}H-5-HT or ^{3}H-DA from rat brain synaptosomes. Synaptosomes were prepared by the method of Whittaker and Barker. Following incubation with ^{3}H-5-HT, synaptosomes were placed into a superfusion apparatus as described by Raiteri et al. Amount of released transmitter in aliquots of superfusate was measured and rates of release were determined. The results of the studies with ^{3}H-5-HT are shown below, expressed as percent increase in release rate, as compared with controls.



R=H, X=3,4-OCH_2O- R and S MDA
R=CH_3, X=3,4-OCH_2O- R and S MDMA
R-H, X=4-OCH_3 R and S PMA

Percent Increase in ^{3}H-5-HT Efflux rate

Cmpd type	Substitution "X"		
	3,4-OCH_2O-	4-OCH_3	3,4-OCH_2O-, N-CH_3
R-amphetamine	99	86	75
S-amphetamine	86	76	75
α,α-dimethyl phenethylamine	9	6	6

This work was supported, in part, by Pharmacol. Toxicol. Training grant GM-709504 and USPHS grant DA-02189.

147.5 CHARACTERIZATION AND VISUALIZATION OF (^{3}H)Brom-LSD BINDING TO RAT BRAIN CORONAL SLICES. S. G. Beck, R. C. Meibach, S. Maayani, and J. P. Green. Dept. of Pharmacology, Mount Sinai School of Medicine, N. Y., N. Y. 10029.

Binding of (^{3}H)brom-LSD (i.e.,(^{3}H)BOL, 47 Ci/mmole) to rat brain coronal slices (32μ) taken from the level of striatum was characterized in respect to K_D, kinetics and dissociation. The (^{3}H)BOL was prepared by the Research Triangle Institute of NIH by bromination of (^{3}H)LSD and purified by reversed phase (C18) HPLC. Specific binding was determined in the presence of D-LSD (10^{-6}M). Incubations were carried out at room temperature (23 ± 2^{o}C) in 300 mOsmolar Tris Maleate, pH 7.4 and rinsed three times in the same ice cold (4 ± 1^{o}C, pH 7.4) buffer for 10 minutes each, after which the slices were wiped with GF/C filters and the radioactivity counted. For two determinations the K_D was found to be 6 and 10 nM with a B_{max} of 187 and 278 fmole/slice. Binding appeared to be maximal at 90 min. No specific binding was found to boiled slices.

In vitro radioautographic analysis was conducted by the technique described by Young and Kuhar (Brain Res., 1979, 179, 255) and by fixing the slices in paraformaldehyde fumes after incubation and directly dipping the fixed slices in emulsion (M. Herkenham, personal communication). Coronal rat brain slices were incubated for 90 min. in (^{3}H)BOL (6 nM, 11 Ci/mmole). Alternate sections were incubated with the same concentration of (^{3}H)BOL plus unlabeled BOL (10^{-7}M), unlabeled D-LSD (10^{-7}M) or unlabeled 5-HT (10^{-6}M). The concentrations of the masking ligands were determined from competition experiments on slices taken from the level of the striatum. Like LSD, (^{3}H)BOL binding sites were found in all layers of the cortex, with a dense band in layer 4, in the septal nucleus, caudate, superior colliculus, raphe, substantia nigra, and interpeduncular nucleus. Label was also found in the hippocampus. As with 5-HT, grains were also found in the subiculum. LSD appeared to mask most of the binding of (^{3}H)BOL, except in isolated areas. In contrast, 5-HT did not mask (^{3}H)BOL binding sites when used at a concentration which had previously been shown to mask (^{3}H)LSD binding sites (Meibach, et.al., Eur. J. of Pharm., 1980, 67, 371). Supported by NIDA DA-01875 and NIDA DA-07135.

147.6 DIFFERENTIAL TOLERANCE TO ANALGESIC AND PHYSIOLOGICAL EFFECTS OF HALLUCINOGENS IN RATS. D.A. Gorelick# and A.B. Hine+. Depts. of Pharmacol. and Psychiatry, Albert Einstein Col. of Med., Bronx, N.Y. 10461, and N.Y.U. Sch. of Med., N.Y., N.Y. 10026.

Roughly equipotent doses (μmoles/kg i.p.) of the hallucinogens mescaline (80), 2,5-dimethoxy-4-methylamphetamine (DOM) (80), N,N-dimethyltryptamine (DMT) (80), and LSD (0.080) were given to adult, male Sprague-Dawley rats. Analgesia was measured by the tail flick method of D'Amour and Smith, heart rate by subcutaneous wire electrodes in the chest, body temperature by electronic tele-thermometer probe inserted into the rectum, and locomotor activity by placing subjects for 10 minutes in an annular photocell activity chamber. Measurements were made immediately prior to injection (baseline) and 20 minutes later. A control group received saline injection. Tolerance was studied by testing some subjects after 5 days of daily drug injection. Data were analyzed in terms of % change from baseline.

All drugs produced analgesia, bradycardia, hypothermia, and decreased locomotor activity when given acutely. When mescaline and DOM were given chronically, a differential pattern of tolerance was found. There was no tolerance to the bradycardic effect of mescaline and DOM, nor to DOM's effect of decreasing locomotor activity. There was complete tolerance to mescaline's hypothermic effect, and partial tolerance to DOM's analgesic effect. These results are consistent with previous reports of differential tolerance to behavioral effects of hallucinogens in rats.

147.7 COMPARISON OF CENTRAL AND PERIPHERAL BINDING SITES FOR COCAINE, M.E.A. Reith*, H. Sershen* and A. Lajtha. Center for Neurochemistry, Rockland Research Institute, Ward's Island, New York, New York 10035.

We have shown previously that mouse brain contains membrane-associated binding sites that are relatively specific for cocaine. Analogs of cocaine are available, some with potent central stimulatory activity and others with only local anesthetic activity. Only the analogs with central activity appreciably compete with cocaine for its bindings sites on brain membranes; both the central effect and the binding show stereospecificity.

The present work indicates that preparations of membranes from mouse liver also bind cocaine in a saturable manner. However, the affinity of the binding is approximately 8-fold lower than that observed in brain. In comparison with those in brain, the binding sites in liver have only moderate stereospecificity, and they discriminate less between the centrally active compounds and the centrally inert analogs. The binding sites in liver may be enzymes involved in the metabolism of cocaine, although after incubation of (^{3}H)cocaine with liver membranes more than 82% of the radioactivity of free and membrane-bound (^{3}H)cocaine cochromatographed with (^{3}H) cocaine itself in various solvents. It is unlikely that the binding sites for cocaine in liver represent uptake sites, since 1) we found no active transport system for cocaine in liver slices, 2) the binding appeared to be Na^+ - independent, and 3) frozen/thawed membranes did not show diminished binding capacities.

Since low binding affinites, as observed in binding of cocaine to liver membranes, may result from fast dissociation rates, we investigated the possibility that bound radioactivity had been released during the separation of bound and free ligand in the filtration method by comparing filtration with centrifugation techniques. Equilibrium binding experiments on liver membranes indicated, with filtration: K_d=5.0± 0.7μM (average ± SEM), B_{max}= 31.8 ± 7.2 pmol/mg of protein, and with centrifugation: K_d=5.2 ± 1.0 μM, B_{max}=57.6 ± 5.2 pmol/mg of protein. Therefore, although both methods give identical values for the affinity constants, there is 45% loss of bound radioactivity upon filtration.

In conclusion, liver membranes have saturable binding sites for cocaine and there is no correlation between the potencies of cocaine analogs in inhibiting the liver binding and their central activities. The function of peripheral receptors for centrally active drugs such as cocaine remains unclear, but is reminiscent of the finding of peripheral sites for benzodiazepines and phencyclidines.

148.1 HUMAN VISUAL EVOKED POTENTIAL AUGMENTING-REDUCING AT THE OCCIPUT AND VERTEX. J. H. Lukas. US Army Human Engineering Laboratory, Aberdeen Proving Ground, MD 21005.

Lukas and Siegel (Science, 198, 73, 1977) reported a significant relationship between cortical augmenting-reducing (A-R) recorded from paralyzed cats and their previously recorded behavioral reactions to novel or aversive stimuli. Reducers were not as emotional or aggressive as the augmenters and demonstrated cortical inhibition during intense sensory stimulation or reticular activation. The present study examined human A-R to changes in luminance utilizing rigorous stimulus control and adequate recording procedures to minimize artifactual sources of variance in the visual evoked potential (VEP) amplitude (Tepas, et al., EEG & Clin. Neurophysiol., 36, 533, 1974).

Ten subjects observed with the right eye, 50 msec light flashes presented 1/sec by a Maxwellian-view optical system. A fixation point was provided within the center of the 22° light beam which was carefully aligned to pass within the pupil. Intensity was varied across a 5 log range in 1.0 log unit steps from a maximum of 599,000 trolands by interposing appropriate neutral density filters. Following 5 minutes dark adaptation, the flashes were presented in counterbalanced ascending-descending intensity series. The VEPs recorded from O_z and C_z (right ear reference) were tape recorded (1-100 Hz) and signal averaged in groups of 100 artifact free sweeps. Linear regression analyses were computed for the latency and amplitude of the first major O_z component (N70-P100) and the C_z component typically measured in human A-R studies (P100-N200).

Latency for the O_z and C_z components decreased with increasing light intensity. Pooled latency data provided correlations of -.96 and -.94 and slopes of -9.1 and -8.4 msec/log. The main effects for cortical area and intensity were statistically significant; whereas, the interaction term was not significant, indicating that the slope functions for latency did not differ at O_z and C_z. The amplitude data from O_z and C_z were positively correlated with intensity. Pooled amplitude data provide correlations of .96 and .95 and slopes of 1.3 and .7 uV/log. The main effects for cortical area, intensity and their interaction were all significant. Although the O_z and C_z data were recorded simultaneously, the C_z slope was less than half that of the O_z slope in 7 subjects. VEP amplitude variability tended to increase at O_z and decrease at C_z with increasing luminance. However, with one exception at O_z, VEP variability was not significantly correlated with intensity. Therefore, different A-R slopes recorded at C_z cannot be accounted for solely by inadequate stimulus control or VEP variability, and may represent true alterations in cortical functioning.

148.2 HUMAN EVOKED SPINAL CORD DORSUM POTENTIALS RECORDED DURING NEUROSURGERY. J. Ovelmen Levitt*, R. Sharpe*, and B. S. Nashold. Div. of Neurosurgery, Duke Univ. Med. Ctr., Durham, N. C. 27710.

Subdural electrical potentials have been recorded, using monopolar platinum electrodes, from the cervical spinal cord in 8 patients undergoing a neurosurgical spinal cord operation to relieve intractable pain. The evoked responses were recorded to assess the functional capacity of the spinal cord before, during and after the surgery. The responses from the intact side are the subject of this report. Stimuli were applied percutaneously or transcutaneously to peripheral nerves or directly to the spinal cord itself. The radial, median and ulnar nerves were alternately, supramaximally, stimulated (10-12 mamp, .5 msec, 7-19 Hz) and recordings were made at cervical levels C5, C6, C7 C8 for each nerve. The potentials were amplified by means of Grass P15 preamplifiers, and averaged 128 to 1024 times using a Nicolet 1170 signal averager. The duration, amplitude and morphology of the potentials were noted. The place of maximal response depended on the peripheral nerve stimulated with radial representation being the most rostral, and the ulnar the most caudal. The amplitudes varied from 30 uV to 180 uV. The morphology and duration of the evoked potentials was similar to that obtained from primates (McCouch, Austin, Lee and Lee, 1958), with components which could be related to primary afferent conduction and to dorsal horn neuronal activity. Conducted responses after tibial nerve stimulation were also recorded from the spinal cord surface over the posterior columns. The conduction distance, latency and velocity of all potentials were determined. Average conduction velocity for arm nerves was 65.8 M/sec. The spinal cord conduction through the operative area was also monitored by stimulating the cord directly at C8 and recording with a bipolar lead at C5. The techniques for recording and evaluating evoked electrical potentials in order to monitor the functional capacity of the human spinal cord are available and interpretation is facilitated through reference to the results of animal experimentation.

148.3 INTERHEMISPHERIC EVOKED POTENTIALS IN THE RAT: RELATION TO BEHAVIOR AND EFFECTS OF ATROPINE AND RESERPINE. G.C. Harvey*, L.S. Leung and C.H. Vanderwolf. Dept. Psychol., Univ. Western Ontario, London, Ontario, Canada N6A 5C2

Cathodal stimulus pulses applied 1 mm below the surface of the rat parietal cortex produced an interhemispheric response (IHR) in the contralateral cortex. In surface records the IHR consisted of 3 components: a) a negative component peaking at a latency of 10-20 msec; b) a positive component; and c) a long-lasting second negative component peaking at 50-100 msec. Records from 1 mm below the surface revealed a negative component peaking at 10-20 msec, followed by a large positive component peaking at 50-100 msec. The IHR is known to vary in relation to behavior (Racine, R., Tuff, L., & Zaide, J. Canad. J. Neurol. Sci. 2: 395-405, 1975). A frame-by-frame video analysis showed that the late component (LC) at 50-100 msec, recorded bipolarly, was maximal during alert immobility, but was strongly suppressed during Type 1 behavior (spontaneous walking, head movement, struggling when held). Type 2 behavior (rotary forepaw movement during face-washing, licking the paws, chewing food, drinking water) was associated with very little suppression of the LC. Using averaged evoked responses we observed a behavior-related suppression of the peak amplitude of the LC which varied with stimulus current. The suppression ranged from 100% at 1.5 x threshold to 48% at 5.5 x threshold. The degree of suppression was measured by comparing the IHR during struggling versus immobility. Atropine SO_4 (50 mg/kg i.p.) reduced the behavior-related suppression of the LC and increased the amplitude of the early component at 10-20 msec. There was little change in the LC amplitude during immobility. Reserpine (10 mg/kg i.p.) alone had little effect on the behavior-related suppression of the LC. Combining reserpine and atropine eliminated the suppression completely; even during struggling the IHR resembled that of an undrugged immobile rat. Cholinergic and aminergic reticulocortical pathways may modulate the IHR in relation to behavior.

Supported by grant A0118 from the Natural Sciences and Engineering Research Council.

148.4 EFFECTS OF STIMULATION OF NUCLEUS TRACTUS SOLITARIUS WITH NALOXONE UPON MORPHINE-INDUCED EEG SYNCHRONIZATION IN THE RAT+. M. L. Kelly*, J. D. Bronzino, C. Cordova*, N. Oley (SPON: D. Adams). Depts. of Engineering and Psychology, Trinity College, Hartford, CT 06106.

There is no doubt that the enkephalins and a number of other opioid peptides are highly concentrated in specific regions within the brain and spinal cord (Wall and Woolf, Nature, 1980, 287, 185-186). The region of the nucleus tractus solitarius (NTS) has been included among these opiate receptor areas (Atweh and Kuhar, Brain Res., 1977, 124, 63-67). This region has also been implicated in the establishment and maintenance of EEG synchronization (Bronzino, et al., Am. J. Physiol. , 1972, 223, 376-383). To study the role of these NTS opiate receptors we have investigated the effect of intracerebral administration of naloxone, an opiate receptor antagonist, upon the analgesia and EEG synchronization induced by systemic administration of morphine.

Fourteen male albino rats were chronically implanted with bipolar recording electrodes in the parietal cortex and hippocampus, as well as a chemical stimulating cannula in the region of the NTS. After recovery from surgery all animals were exposed to each of the following treatments: (1) 30 mg/kg of morphine (i.p.); (2) 10 µg naloxone (i.c.) plus 30 mg/kg morphine (i.p.) (3) 30 µg naloxone (i.c.) plus 30 mg/kg morphine (i.p.) and (4) Ringer's (i.c.) plus 30 mg/kg morphine (i.p.). Treatments were given one week apart. The order of naloxone doses was reversed in several animals to control for morphine tolerance, and the volume of the intracerebral injections was held constant at 0.25 µl. Following injections, 4 hrs of EEG activity were recorded. EEG records were evaluated using visual scoring, as well as amplitude (Bronzino et al., Proc. IEEE-GMEB, 1980, 186-189) and spectral analysis techniques.

Intracerebral injections of naloxone 5 mins prior to systemic administration of morphine significantly reduced the total amount of time spent in EEG synchrony (i.e., high voltage, low frequency (HVLF) activity). The percentage of animals reaching HVLF activity was also significantly reduced. These results indicate that the region of the NTS mediates the production of specific changes in the EEG (i.e., HVLF activity) following systemic administration of morphine. The ability of intracerebral naloxone to reduce rather than to abolish morphine-produced EEG synchronization suggests the the region of the NTS is only one part of the total pathway responsible for this synchronization.

+Supported by NIGMS grant #27226-01.

148.5 HIPPOCAMPAL THETA RHYTHM: PHASE-RELATIONS OF NEURON FIRING AND CONDUCTANCE IN URETHANIZED RATS. S. Wolfson, S.E. Fox and J.B. Ranck, Jr., Dept. of Physiol., Downstate Med. Ctr., SUNY, Brooklyn, N.Y. 11203.

There are two types of hippocampal theta rhythm (or rhythmic slow activity, RSA) in the rat. One type occurs during immobility and can be abolished by atropine or driven by urethane anesthesia (atropine-sensitive RSA).[1] A second type occurs during walking. The present study uses extra- and intracellular recordings from hippocampal neurons to determine the phase-relations between atropine-sensitive RSA and action potentials or conductance changes. Rats were anesthetized with urethane. Fixed hippocampal macroelectrodes were implanted in dentate and CA1 to record RSA from both regions versus a distant reference. Stimulating electrodes were implanted in afferent and efferent pathways. Hippocampal neurons were identified by electrophysiological characteristics[2] with histological localization.

The phase relations were as follows:

	firing of projection cells	firing of interneurons	max. somatic conductance
CA1	+ (pyramids)	-	- (pyramids)
DENTATE	- (granules)	+	+ (pyramids)

+ & - refer to positive and negative peaks of dentate RSA

The major finding shown above is the occurrence of the maximum firing rate for CA1 interneurons and dentate granule cells on the negative phase of dentate RSA. This is in substantial agreement with results from urethanized rabbits,[3] but is in sharp contrast to our data for RSA in rats during treadmill walking:[4] all hippocampal neurons (pyramidal cells, granule cells and interneurons) in both CA1 and dentate were most likely to fire on the positive phase of dentate RSA. There are clearly radical differences in the synaptic mechanisms generating the two types of RSA. The extracellular data are supported by intracellular recordings. Intracellular impedance analysis[5] in pyramidal cells showed changes in impedance at up to 100 Hz, phase-locked to RSA. Changes in impedance at such high frequencies must be produced by conductance changes on the soma.[5] This coincidence of the maximum somatic conductance of pyramids and the maximum firing rate of local interneurons supports the hypothesis that projection cells are being inhibited by our putative interneurons on the phase at which the interneurons fire most rapidly. 148.6 WET DOG SHAKES CAUSED BY HIPPOCAMPAL ACTIVATION ARE INHIBITED IN RATS WITH KAINIC ACID LESIONS. B.P. Damiano* and J.D. Connor. Dept. Pharmacol., Penn State Univ. Col. of Med., Hershey, PA.

Although wet dog shakes (WDS) occur during morphine withdrawal in rats, they can be caused by a variety of pharmacological and environmental stimuli. WDS have also been noted in association with hippocampal epileptiform activity (MacLean, 1957). The purpose of the present study was to determine: 1) if stimulation of hippocampal neurons through the perforant path (PP), an excitatory pathway into the hippocampus, causes WDS and, 2) if lesions of CA3 pyramidal cells, the main output cells of the hippocampus, prevent these WDS. Awake, unrestrained rats with implanted electrodes were tested for their responsiveness to various paradigms of PP stimulation (n=16). The characteristic evoked granule cell (GC) field potential with its population spike was monitored. Stimulation at 0.1 Hz for 2 min, which evoked large GC spikes, rarely caused WDS. However, stimulation at 1 Hz for 2 min caused 3-16 WDS depending on the size of the evoked GC spike. When WDS occurred, they were not usually related temporally to the GC spike. Twin pulse stimulation (1 Hz, 50-80 msec apart) was particularly effective in potentiating the GC spike and in causing WDS (6-21 in 2 min). Twin pulse stimulation (2 Hz, 50-80 msec apart) was also effective in causing WDS but often induced epileptiform activity. Higher frequency stimulation (10 Hz for 5-20 sec) consistently produced epileptiform activity with afterdischarges. Within 3 min of the stimulation, 8-32 WDS were observed, mostly in a cluster immediately following the train or afterdischarge. Direct stimulation of the GC through the recording electrode (10 Hz for 10-20 sec) produced a similar WDS response (8-21 shakes within 3 min). In another set of experiments, rats received bilateral icv injections of CSF (n=4) or kainic acid (400 ng, n=8). After 12-18 days, WDS in response to the various paradigms of PP and GC stimulation was inhibited by 80-95% in kainic acid lesioned rats vs CSF controls. Conversely, evoked GC spiking, epileptiform activity and afterdischarges were usually greater in kainate treated rats. Light microscopy revealed the characteristic kainate-induced CA3 pyramidal cell loss in the hippocampus. These results demonstrate that low frequency activation of hippocampal GC causes WDS in the absence of epileptiform activity. Granule cell axons innervate ipsilateral CA3 pyramidal cells. Although icv kainic acid lesions other brain areas, severe CA3 pyramidal cell loss coupled with blockade of WDS indicates that hippocampal output from the CA3 pyramidal cells may be involved in the WDS produced by hippocampal activation. (Supported by USPHS DA 02007).

148.7 MODULATION OF BACKGROUND ACTIVITY IN A HIPPOCAMPAL NEURAL NETWORK. J. L. Giacchino and J. M. Horowitz. Dept. of Animal Physiology, University of California, Davis, CA 95616.

Previous studies have described damped oscillatory evoked potentials in hippocampal networks (Biol. Cybernetics 37:115-124, 1980). In addition to associating a model with experimental data, the effect of background activity on hippocampal networks has been considered from a mathematical point of view (Intern. J. Neurosci. 5:113-123, 1973). The intent of this study was to determine if experimental data (PST histograms from pyramidal cells) supported model predictions.

Tungsten microelectrodes were used to record PST histograms from hippocampal cells following fornix, commissural or raphe stimulation. In rats anesthetized with sodium pentobarbital, a single unit was isolated using a WPI window discriminator and PST histograms were constructed using a Tracor-Northern digital signal analyzer. Following fornix stimulation in the rat, PST histograms had multiple peaks, with successive peaks showing smaller amplitude and larger width. A pulse train delivered over the commissure provided a means of augmenting the excitation of hippocampal cells. PST histograms for fornix stimulation with this augmentation were modified in that the time between successive peaks was shortened in 6 out of 8 cases. Cells that could be driven by fornix stimulation could also be categorized according to responses of the neuron to concurrent fornix and raphe stimulation. Class one neurons responded with an increase in latency after the concurrent stimulus and class two neurons exhibited decreased latency and increased cell activity.

These data are consistent with the behavior of a hippocampal network composed of pyramidal cells which excite interneurons that in turn inhibit the pyramidal cells. That is, the second and following peaks in the pyramidal cell PST histograms evoked by fornix stimulation may reflect rebound excitation. The PST histograms can be modified by background activity over commissural and brainstem pathways as predicted by the network simulation.

148.8 SPECTRAL CHARACTERISTICS OF HIPPOCAMPAL EEG IN BEHAVING RATS. L. S. Leung. Dept. Psychology, University of Western Ontario, London, Canada N6A 5C2.

Using electrophysiological criteria, 100 μm diameter wire-electrodes were implanted dorsal and ventral to the pyramidal cell layer of the hippocampal CA1 region of the rat. After recovery, the EEG at the electrodes were recorded during the following behaviors: slow-wave sleep (SWS), awake-immobility (AI), grooming, walking, rapid-eye-movement sleep (REM) and awakening from SWS(AW). EEG was also recorded following i.p. injection of sodium pentobarbital (10-20 mg/kg) and atropine sulfate (25 mg/kg). The EEGs were analyzed by fast Fourier transform by a PDP-11 or -12 computer. The power spectra and the coherence and phase spectra between two electrodes were plotted for 0.5-100 c/sec at a resolution of 1-2.2 c/sec and > 60 degrees of freedom.

At least three major components of the hippocampal EEG were inferred: 1. Irregular slow activity (ISA) - mainly power of 0.5-25 c/sec, with low dorsoventral coherence (coherence between EEG at electrodes dorsal and ventral to the pyramidal cell layer) ISA decreased generally in the behavioral sequence: SWS, AI, grooming, REM or walk or AW. Awakening from SWS caused a great decrease of ISA. 2. Rhythmical slow activity (RSA) or theta - characterized by a sharp power peak at 5-8 c/sec and a second harmonic at 12-18 c/sec. Dorsoventral coherence was high at the theta harmonics with a phase difference of 135°-180°. A small RSA peak at 5-7 c/sec could sometimes be observed during grooming or AI. 3. Fast activity (FA) - of about 20-80 c/sec, low peak power ($\leq$ 1/10 of theta peak power) and low dorsoventral coherence FA was larger during walking or REM than during AI, SWS, or AW. FA was similar to the oscillatory CA1 average evoked potentials (AEPs) elicited by electrical stimulation of the stratum radiatum (Leung, L.S., Brain Res., 198:95) in the following ways: (a) similar frequency range, (b) similar correlation with behavior, (c) similar changes following pentobarbital or atropine injections, and (d) a recurrent-inhibition, differential-equation model of the CA1 region (Leung, L.S., Brain Res., 205: 194) predicts both oscillatory AEP and fast EEG and their behavioral correlation. FA increased in power but decreased in peak frequency after pentobarbital. It decreased in power and frequency following atropine (cf. Leung, L.S. and Vanderwolf, C.H., Brain Res., 198:119).

The quantitative spectral analysis allows finer details of the EEG, e.g. FA, frequency contents of ISA, second harmonic of RSA, to be distinguished and studied in different behaviors.

148.9 SPECTRAL SIGNATURES OF COGNITIVE ACTIVITY: SPATIAL MAPPING OF EEG CHANGES CORRELATED WITH TASK DIFFICULTY AND PUPILLOMETRIC RESPONSE. D. Barth* and J. Beatty, Human Neurophysiology Laboratory, Dept. of Psychology, University of California, Los Angeles, CA. 90024.

The performance of complex cognitive functions such as mental multiplication has been shown to elicit widespread momentary increases in sympathetic and decreases in parasympathetic activity that reflect the processing demands imposed by the task. These changes have been interpreted as peripheral signs of activity in the ascending reticular activating system. The current study was designed to investigate the influence of mental arithmetic on the pattern of activity in the central nervous system using spatial mapping and spectral analysis of the electroencephalogram (EEG).

Twelve right handed people were instructed to multiply 28 "easy" (one-digit by one-digit) and "difficult" (one-digit by two-digit) multiplications in a randomly presented sequence. Concurrent measurements were made of EEG (full International 10-20 System) and pupil diameter. The spectral density in each of the traditional EEG frequency bands was computed from Fourier analysis of samples, separately for each quartile of the range in pupil diameter. Four-way analysis of variance demonstrated that there was a significant frontal suppression of spectral density in the combined frequency bands associated with both the presence and degree of mental workload, as indicated by pupil diameter. This effect primarily consisted of changes in the delta, alpha, and beta bands. Left hemispheric suppression and right hemispheric enhancement of beta frequency spectral density accompanied task performance and increased with mental effort.
