Mental multiplication was best discriminated from baseline activity by reduced spectral density in the delta and beta bands over left frontal (F7) and in the beta band left anterior temporal (T3) areas. Posterior enhancements in the beta (T5) and theta (P3, T6) spectral density were also significant. Lowest and highest pupil quartile ranges were best differentiated by reduced right frontal (F8) alpha and increased left posterior temporal (T6) theta density.

This experiment demonstrates a clear pattern of central nervous system activity associated with the presence and difficulty level of a mental multiplication task. The ANOVA and discriminant analysis indicate the differential involvement of both frontal and left hemispheric areas in the task. Posterior enhancement of EEG density may indicate a task related deactivation of cortical tissue.

148.10 ELECTROPHYSIOLOGICAL CORRELATES OF SELECTIVE ATTENTION TO SPEECH SOUNDS. P. W. Dickstein, J. C. Hansen, C. Berka* and S. A. Hillyard. Dept. of Neurosciences, Univ. of California, San Diego, La Jolla, CALIF 92093.

Selectively attending to tone bursts has been reported to enhance the measured negativity of the N1 peak (latency 90-150 msec poststimulus) of the auditory event related potential (ERP) in man. This finding has been interpreted as an electrophysiological correlate of Broadbent's stimulus set attention, which is presumed to involve a rapid selection between attended and unattended channels of stimuli based on analyses of their simple physical attributes such as pitch or location. Recent studies suggest that the enhancement of the measured N1 amplitude to attended tone bursts results from the elicitation of a long-lasting, endogenous negative wave rather than a gating of the auditory evoked potential.

This study was undertaken to find out whether selectively attending to speech sounds distinguished by relatively complex physical features engenders the same ERP components as does attending to tone bursts that differ in pitch. Twelve subjects listened to three different randomized sequences of stimuli consisting of: (1) the syllables /ba/ and /pa/, (2) the syllables /da/ and /ga/ and (3) 375 Hz and 300 Hz tone bursts. All stimuli were presented binaurally at 50 dB SL, and the subject was instructed to listen selectively to one of the two stimulus classes at a time, pressing a button to infrequent, slightly longer duration stimuli of that type. ERPs elicited by each class of stimulus were recorded from midline, left and right scalp locations, and difference waves were formed comparing the ERP to each stimulus when it was attended versus when it was unattended. The attention effect was quantified as a root-mean square measure of the difference wave over the latency range 150-550 msec.

In all three conditions, the attended stimulus elicited a significantly enlarged negative ERP in relation to the unattended stimulus. This negativity had a bilaterally symmetrical scalp distribution for all stimuli. Thus, the electrophysiological correlates of selective attention were qualitatively similar for selections between syllables that differed either in voice onset time (/pa/, /ba/) or direction of formant transition (/ga/, /da/) and for selections between tones differing in frequency. This suggests that the attentional mechanisms involved in selections between complex, speech-related cues and simple pitch cues share similar characteristics. A further implication is that the concept of stimulus set attention may have to be broadened to include complex as well as simple stimulus attributes.

148.11 ENDOGENOUS AUDITORY EVOKED POTENTIALS IN THE CAT. N.K. Squires* and J.S. Buchwald. Mental Retardation Research Center, Brain Research Institute, Dept. of Physiology, UCLA Medical Center, Los Angeles, CA 90024.

Evoked potentials in the cat were examined under conditions parallel to those which are necessary for obtaining endogenous brain activity in human subjects. Clicks of two intensities were presented as task-irrelevant stimuli, while a 4 KHz, 1 sec tone was the CS in a classical eye-blink conditioning procedure. The three stimuli were presented in random order with an ISI of 1.5 sec. In each block of 500 stimuli one of the click intensities occurred frequently (P = .80), the other rarely (P = .15), and the CS with a probability of .05. Evoked potentials were recorded from a stainless-steel screw implanted in the skull just lateral to the midline on the inter-aural line (vertex) referenced to the bulla. Eyeblinks were recorded with bipolar EMG electrodes inserted into the orbicularis oculi. The evoked response to either the loud or soft click was enhanced when the click was rare compared to when it was frequent. This enhancement to the rare stimulus appeared for four peaks in the waveform, a negative wave at approximately 40 msec, a positive wave at 70 msec, a negative wave at 110 msec, and a positive wave at 300 msec. The enhancement did not appear in a cat presented with the same series of rare and frequent stimuli in the absence of the conditioning procedure. Conditioned eye blinks were confined to the CS, and could not account for the waveform increase to the rare click. When the rare event was the omission of a click from an ongoing constant train of clicks, a long-latency (100-500 msec) positive wave was produced. These long-latency potentials resemble those seen in the scalp-recorded evoked response of human subjects under similar conditions of stimulus rareness and attention to the modality of the stimuli. In the human these have been called "endogenous", event related potentials since they vary more with the psychological context in which a stimulus occurs than with the physical characteristics of the evoking event. Finally, in the cat certain components of the these long-latency responses were differentially altered by the administration of pentobarbital and ketamine.

148.12 AUDITORY BRAINSTEM AND ENDOGENOUS EVOKED POTENTIALS IN AGED CATS. J.B. Harrison and J.S. Buchwald, Brain Research Institute, Mental Retardation Research Center and Department of Physiology, UCLA Medical Center, Los Angeles, CA 90024.

Auditory brainstem responses (ABRs) and endogenous potentials were compared in aged cats (10 to 23 years) and young adult cats of known age. An implanted vertex electrode was referenced to the left bulla. The head was held by bars extending into metal sleeves implanted in an acrylic head mount. Click thresholds were higher in the old cats with a mean difference of 35 dB SPL and little overlap between the two groups. Stimulus intensities were set relative to individual thresholds.

With 0.1ms click stimuli, 15, 30 and 45 dB above threshold, ABRs were generally comparable in the young and aged cats. Endogenous potentials were compared between the young and aged cats with the procedure used by Squires and Buchwald (Neurosci. Abst., 1981). Blocks of 500 stimuli were presented in random order with loud and soft clicks on a schedule of frequent (P = .80) or rare (P = .15). A 4KHz CS (P = .05) was paired with a brief shock train to the orbicularis oculi to establish a classical conditioned eyeblink response. In alternate blocks the loud or soft click was the rare stimulus. In some blocks the rare stimulus was absence of a stimulus. Eye movements and the orbicularis oculi EMG were recorded. At latencies shorter than 40ms no evoked response components were dependent on stimulus probability. In the young cats, a negative wave at approximately 40ms, a positive wave at 100ms, a negativity at 150ms and a positivity at 300ms were enhanced by the rare stimulus. The omitted stimulus elicited a late positivity at 250 to 600ms. In the aged cats, the rare stimulus enhanced a negative wave at approximately 50ms, a positive wave at 200 to 400ms, and a positive wave at 500 to 1000ms. A positivity at 500 to 600ms was produced by the omitted stimulus. Thus, the endogenous potentials of the aged cats were marked by diminution or absence of some waves and increased latency of others. These abnormalities were not accompanied by aberrant ABRs, which suggests that aging changes of the endogenous potentials are independent of the auditory brainstem pathway. (This work was supported by USPHS Grants AG1754 and HD04612).

148.13 ANALYSIS OF SINGLE AUDITORY EVOKED RESPONSES TO LINGUISTIC AND NONLINGUISTIC STIMULI IN AUTISTIC AND CONTROL CHILDREN. R.M. Edwards*, P. Tanguay*, S. Hecht*, R. Olch*, J. Vidal and J. Buchwald (SPON: J. Marsh). Depts. of Neuroscience, Psychiatry, Engineering and Physiology, UCLA, Los Angeles, Calif. 90024.

Children with early infantile autism characteristically are impaired in the understanding and use of language. To study this impairment, differences in the auditory evoked responses (AERs) of these children to linguistic and nonlinguistic stimuli were assessed using a stepwise discriminant analysis (SDA).

The AERs of ten autistic children and ten age and sex matched control children were recorded from six electrode configurations, F7, F8, T3, T4, a point midway between T6 and C4, and a point midway between T5 and C3, all referenced to the ipsilateral mastoid. The stimuli, two words and two musical chords, were presented under two conditions: condition 1, a simple listening task, and condition 2, an auditory discrimination task involving a motor response to a fifth stimulus, another word. Each AER consisted of 50 msec prestimulus baseline EEG and 500 msec post-stimulus EEG.

SDAs were applied to each subject's data separately for both conditions. The single AERs from all six channels were first analyzed simultaneously, then the AERs from the left hemisphere, and lastly those from the right. The results were assessed for within group differences and between group differences.

The results show first that the SDA classified the stimuli at a level above chance for all conditions. Secondly, no consistent pattern of higher classification of one stimulus type compared to the other was found. Thirdly, no differences between the two hemisphere's analyses were found. A difference between the two recording conditions was found in that the electrode sites of the best discriminators were equally distributed between the two hemispheres for condition 1, but were found predominantly on the right hemisphere for condition 2.

The autistic group differed from the control group in having a higher per cent correct classification by the SDA, a larger number of high F level discriminant variables occurring in the early part of the AER, and slower motor response times and more response errors for condition 2. No differences between the groups were found in the discriminability of words and chords, in the electrode site or latencies of best discriminant variables, or the separate hemispheric analyses.

148.14 PSYCHOPHYSIOLOGICAL INDICES OF LEVELS OF PROCESSING. Anne Barry* and Michael T. Harvey.* (SPON: Gail R. Marsh). Department of Psychology, Duke Univ., Durham, NC 27706.

Ten subjects participated in an evoked-potential experiment exploring brain indices of 'depth' of processing (Craik, F.I.M. & Lockhart, R.S., J. Verb. Learn. and Verb. Behav., 11:671, 1972). Common English word-pairs were presented in a match-mismatch decision during which processing occurred at one of three levels of porcessing: SIZE, RHYME, or VERB-NONVERB. Word size varied in every trial, even when the subject's matching task was at a deeper level of processing. Behavioral data supported previous findings about levels of processing: words encoded more deeply were better remembered. Task 'depth' produced systematic significant effects on several components elicited after presentation of the second word, as well as on the CNV recorded during the preparatory interval between task instruction and the first word in the pair. Effects of task-irrelevant word size during rhyme and verb-nonverb decisions appeared in an early positive component (P200) and for components as late as 400 msec. post-stimulus. Results both support and fail to support certain findings of previous studies (e.g. Sanquist, T.F. et al., Psychophysiology: 17, 568, 1980).

148.15 CHANGES IN THE COHERENCE SPECTRA OF THE EEG AND AUDITORY EVOKED POTENTIALS OF THE CEREBRAL CORTEX AND AMYGDALA RELATED TO REPEATED DOSES OF d-AMPHETAMINE. R. J. Morgan, C. C. Turbes and G. T. Schneider*. Dept. of Physiology and Biophysics, Colorado State University, Ft. Collins, Colorado 80523.

The coherence function measures and the coherence spectra estimates how well each frequency component of one signal is phase locked to the corresponding frequency components of another signal. Due to normalization, all information about the relative amplitude of the frequency components is lost. In these experiments we examine the action of repeated doses of d- and l-amphetamine on the coherence spectra of the EEG and auditory evoked potentials (AER) of the sigmoid gyrus and basal nucleus of the amygdala. Data from eight cats are used in these experiments. Recordings are made with a polygraph and an FM tape recorder using hardwire and radio telemetry methods. The EEG and AER potentials were selected and analog to digitally converted. The Fast Fourier Transform (FFT) algorithm processing is done in the frequency domain. The EEG and AER averaged coherence spectra of the sigmoid gyrus and amygdala showed similar constituent frequency components phase locked between the two brain regions. There were coherence peaks at 1 Hz to 5 Hz, 12 Hz to 16 Hz and 43 Hz to 45 Hz. The ranges in percent coherence varied with the behavioral state and the sampling procedure before and after d- and l-amphetamine show a decrease in coherence of all but the 1 Hz to 5 Hz at the first dose of amphetamine. There is an increase in percent coherence in the component frequencies at 43 Hz to 100 Hz. There is a coherence peak at 76 Hz to 80 Hz during the second and third doses of the amphetamines in both the EEG and AER. The amphetamines show changes in the coherence spectra between brain regions that play a role in the processing of sensory information related to behavior. These studies give further indication of the functional interaction of these brain regions during sensory information processing, behavior and the action of certain drugs.

148.16 THEORETICAL AND EXPERIMENTAL SPATIAL CORRELATION AND COHERENCE FUNCTIONS OF EEG DUE TO STOCHASTIC FIELDS OF CORTICAL GENERATORS. R. D. Katznelson. Dept. of Elec. Eng. & Comp. Sci., Univ. of California at San Diego, La Jolla, CA 92093.

The study of cortical activity through the use of EEG measurements often require volume conduction (VC) considerations, (Nunez, P.L. and contrib. by Katznelson, R.D., Electric Fields of the Brain Oxford Univ. Press, 1981). It is the underlying neural activity that one is usually interested in characterizing, given the observed potential data. Since usually only statistical measures of EEG are obtained, the approach taken by many researchers is to study the temporal stochastic properties of EEG. However, very little work was done on the EEG as a stochastic field with spatial parameters in addition to the time parameter. In this study, theoretical spatial correlation functions (SCF) of stochastic EEG fields are derived for potentials measured in cortical depths, pial surface and the scalp. It is shown that obtaining these SCF's consists of two distinct problems: (1) Obtaining the SCF of cortical neural generators and (2) VC effects on broadening the cortical SCF. The method of spatial power spectral decomposition is used for specific examples of VC effects on surface SCF's obtained for planar stratified cortical geometry and for a three concentric sphere model representing the brain, skull and scalp. In the isotropic planar geometry example it is shown that for uncorrelated (independent) neural current dipole layer situated at depth h, the surface potential SCF is proportional to

$$R(r) \sim [1+(r/2h)^2]^{-3/2}$$

where r is the distance between the two measuring points. Similar expressions are derived for other geometrical configurations. It is also shown that the coherence (COH) (as measured by Lopes da Silva and others) is essentially a spatial correlation coefficient and that it is real (phase angle of 0 or 180 deg.) for surface isotropic cortical geometries. Since R(r) above corresponds to a correlation length of about 2h, it is expected that realistic cortical SCF's (which are not infinitesimally sharp as in the uncorrelated source layer), would produce surface SCF's wider than 2h. Hence, lower bounds for correlation lengths and COH values are obtained and the implications to COH spectra in animal brains and cerebral lateralization measures in humans are discussed. Some experimental COH spectra are presented and finally problem (1) above is addressed and a neural model to account for the decrease in observed COH with temporal frequency is presented.

149.1 RATE-DEPENDENT AND SCHEDULE-DEPENDENT EFFECTS OF SEROTONIN ANTAGONISTS ON OPERANT BEHAVIOR. P.C. Mele*and M.A. Caplan. Dept. Psych., Adelphi Univ., Garden City, N.Y. 11530

Drugs which deplete or antagonize serotonin (5HT) may alter operant behavior when administered alone or in combination with amphetamine. However, the behavioral variables which mediate the effects of these drug treatments are not well understood. The present study examined baseline rate of responding and reinforcement contingency as factors which may influence the behavioral effects of the structurally distinct 5HT antagonists methysergide (M) and cinanserin (C).

A multiple fixed-interval 2 min differential-reinforcement-of-low-rate 18 sec schedule of sweetened milk delivery (mult FI DRL) was used to maintain responding in rats. M (1-17 mg/kg) increased the moderate FI rates of responding without altering the positively accelerated pattern of responding and produced only minor alterations in the low DRL rates. C altered FI and DRL responding primarily at the highest dose tested (64 mg/kg); 8-32 mg/kg did not consistently alter behavior. 64 mg/kg of C increased the low DRL rates and shortened interresponse times; FI responding was disrupted such that low rates occurring early in the interval were increased and higher rates occurring later in the interval were decreased. The effects of 64 mg/kg of C were similar to those found with amphetamine (A, 0.25-3 mg/kg) and chlordiazepoxide (2.5-20 mg/kg). Thus, the effects of C on mult FI DRL performance appear to be rate-dependent whereas those of M are schedule-dependent.

The combined administration of A plus M (10 mg/kg) or C (32 mg/kg) generally produced similar effects in both components of the multiple schedule. For FI, response rates were typically reduced relative to those obtained with A alone. For DRL, the drug combinations frequently produced potentiated rate increases at low doses of A; at higher A dose combinations the rate increasing effects seen with A alone were attenuated. It is suggested that the effects of the drug combinations, like the effects of amphetamine alone, are best described as rate-dependent.

The qualitative differences between the effects of M and C may be due to differences in their pharmacological actions (e.g. Clineschmidt and Lotti. Br. J. Pharmac., 50, 311-313,1974). In contrast, the similarity in the effects of the drug combinations suggests that 5HT antagonism was the common mechanism of action which altered the effects of amphetamine.

149.2 MEDIAL-LATERAL DIFFERENCES IN SUBSTANTIA NIGRA MECHANISMS MEDIATING CIRCLING. F. Vaccarino and K. B. J. Franklin* (SPON: T.L. Sourkes). Dept. of Psychol., McGill Univ., Montreal, Quebec

It is well known that when drugs or lesions cause an imbalance in nigrostriatal dopamine (DA) activity rats will circle contralateral to the more active nigrostriatal system. However, more recently it has been shown that the nigrostriatal system may not be functionally homogeneous with respect to circling behavior. It has been reported that contralateral circling can be evoked in rats following systemic apomorphine if lesions were restricted to the medial parts of the substantia nigra(SN). However, when the lesions were restricted to the more lateral components of the SN rats circled ipsilaterally (Thal et al., Brain Research 170:381, 1979).

The present experiments confirm and extend the differences found between medial and lateral SN mechanisms mediating circling behavior. Rats were tested for their circling response to imposed continuous electrical stimulation (100 Hz, .2 msec pulses) of either the medial or lateral SN. The results showed that the direction of circling depended on the medial-lateral position of the electrode in the SN. That is, stimulation of the medial SN produced contralateral circling and stimulation of the lateral SN produced ipsilateral circling. In addition, rats were tested for their circling response to d-amphetamine (2 mg/kg) following lesions restricted to either the medial or lateral SN. It was found that d-amphetamine induced ipsilateral circling following medial SN damage and contralateral circling following lateral SN damage.

A second experiment showed that both ipsilateral and contralateral circling induced by electrical stimulation (.2 sec trains of 100 Hz, .2 msec pulses delivered at the rate of 4 trains per sec) of the lateral and medial SN sites, respectively, depended on the proximity of SN DA cells to the locus of stimulation.

Also, pimozide, a DA antagonist, dose dependently blocked both ipsilateral and contralateral stimulation induced circling elicited from the SN but did not affect circling elicited from the cerebral peduncle.

The results of these experiments suggest that the lateral SN is functionally different and possibly antagonistic to medial SN mechanisms involved in circling behavior. Furthermore, both medial and lateral mechanisms appear to be DA dependent.

149.3 SNOUT CONTACT FIXATION IS AN INVARIANT FEATURE OF STEREOTYPED BEHAVIOR INDUCED BY APOMORPHINE. H. Szechtman[1], K. Ornstein[*2], P. Teitelbaum[3] and I. Golani[*4]. 1. Dept. of Neurosciences, McMaster Univ., Hamilton, Ont., L8N 3Z5. 2. Dept. of Isotope Research, Weizmann Inst. Science, Rehovot, Israel. 3. Dept. of Psychology, Univ. of Illinois, Champaign, Il. 61820. 4. Dept. of Zoology, Tel Aviv., Ramat Aviv, Israel.

The stereotypy of rats injected with apomorphine (APO) is strikingly different in a small walled enclosure and in an open field without walls. After 2.5 to 20 mg/kg of APO, rats (N=28) assume an upright posture in a walled cage and remain elevated, as if attempting to climb up the wall, for as long as 36 to 42 min during a 60 min test. In an open field, however, rats (N=7) show no rearing during the same time period but locomote with the snout close to the horizontal surface, as if sniffing. Inspite of its different appearance, there is an invariance in the stereotypy exhibited in the two environments. Using the Eshkol-Wachmann movement notation to describe and analyze the relationship between the rat's snout and the environment, it became evident that in either environment rats establish close snout contact with a surface within 2-3 min after drug injection. Once contact is established, it is not released until 50 to 90 min later, when the drug seems to wear off. This suggests that on a horizontal surface APO-injected rats do not rear because that would entail breaking snout contact. Indeed, with a hood over the head to provide pressure on the snout, rats did not maintain uninterrupted snout contact and 3 of 6 animals reared in the open field during a 10 min test. Thus, the maintenance of snout contact may be a fundamental behavioral process induced by APO, accounting in part for environmental molding of the drug's behavioral manifestations.

149.4 6-OHDA LESIONS OF THE NAS REDUCE THE FACILITATORY EFFECTS OF D-AMPHETAMINE ON LOCOMOTOR ACTIVITY BUT NOT ON SELF-STIMULATION. A. Robertson and K.B.J. Franklin* (SPON: R. Hirsh). Dept. of Psychol., McGill Univ., Montreal, Quebec.

We examined the effects of 6-hydroxydopamine (6-OHDA) lesions of the dopamine-containing nucleus accumbens (NAS) on the facilitatory actions of D-amphetamine on self-stimulation response rates and on locomotor activity. Forty-two rats received bilateral infusions of 6-OHDA (2 µl of 4 µg/µl) or 0.1% ascorbic acid vehicle into the NAS. Twenty six (14 6-OHDA lesioned and 12 controls) of these rats were also implanted with a bipolar electrode aimed at the lateral hypothalamus and were then trained to self-stimulate through this electrode. Starting three weeks later, they were tested with 0.3, 0.8 and 2.0 mg/kg D-amphetamine sulfate, injected at three day intervals. In the second group of 16 rats (8 6-OHDA lesioned and 8 control), the locomotor stimulant effects of the same three doses of D-amphetamine were measured in a box equipped with photocell beams and a tilt floor. Extent of dopamine denervation of the NAS in both groups, determined by glyoxylic acid histofluorescence, ranged from 22% to 97% of the structure. Correlated to this, there was damage to adjacent structures including the olfactory tubercle and anterior caudate-putamen. In the locomotor group, amphetamine increased activity in a dose-related manner, but more so in controls than in experimentals. In contrast, none of the 14 self-stimulating rats treated with 6-OHDA showed any change in their responsiveness to D-amphetamine compared to controls, regardless of the extent of damage. The results suggest that a functional dissociation can be made between the effects of D-amphetamine on locomotor activity and on self-stimulation. The former but not the latter seems to critically depend upon a substrate involving the mesolimbic dopamine system terminating in the NAS.

149.5 CYCLES OF DEMAND FOR ELECTRICAL BRAIN STIMULATION OF RATS. L.H. Schneider[#], E.E. Coons[#], R.B. Murphy[%], A.V. Reed[*@] and D.Lewart[*$]. [#]Department of Psychology, and [%]Department of Chemistry, New York University, New York, NY 10003, [@]Graduate Faculty, The New School for Social Research, New York, NY 10011, and [$] M.I.T. , Cambridge, MA

The temporal pattern of responses was recorded under precisely controled self-administration of constant current stimuli into the Ventral Tegmental Area of Tsai in male Sprague-Dawley rats. The duration and amplitude of each pulse were fixed at 0.1 msec and for the individual rats at 75, 100, 125, 140, and 200 μA. The separation (10 msec) and the number (50) of pulses per train, trains per trial (20), and trials per session (25) were held constant throughout the experiment. The distribution of interresponse times, measured to the nearest millisecond, was analyzed; periodicities were found under autocorrelation. These were of similar duration (8±1 daily experimental sessions) in all five animals. Observation of behaviors suggests the involvement of opiate as well as monaminergic neurotransmitter pathways. We speculate that these effects arise as a result of the functional modulation of catecholamine receptor density and/or affinity. Preliminary examination of dopamine receptor density as reported by the in vitro binding of the ligand [3H]-spiroperidol to striatal homogenates from stimulated animals is used to assess the functional significance of these changes. (This work was supported in part under NIMH predoctoral fellowship 5F31 MH05787-02)

149.6 SPATIAL LEARNING ABILITY IS RELATED TO AN ENDOGENOUS ASYMMETRY IN THE NIGROSTRIATAL DOPAMINE SYSTEM IN RATS. Dianne M. Camp*, Barbara A. Therrien, and Terry E. Robinson (SPON: E.S. Valenstein). Psychology Department and Neuroscience Laboratory, University of Michigan, Ann Arbor, MI, 48109.

A wide variety of behaviors, including rotational behavior, side preferences and learning a T-maze, have been related to an endogenous asymmetry in the nigrostriatal dopamine (DA) system of rodents. However, the adaptive advantage of this asymmetry is not well understood. It has been suggested that some degree of asymmetry allows an animal to distinguish left from right, and thus may aid in spatial localization (Glick, 1977). To test this hypothesis we have examined the ability of lateralized and non-lateralized rats to perform a spatial task which required learning the position of a concealed goal using only distal cues.

Adult female Holtzman rats were individually placed in a 1.52 m diameter tank filled to a depth of 16 cm with 20°C opaque water. To escape from the water each rat had to swim to a 10.2 cm diameter platform which was concealed under 1 cm of water. A trial consisted of placing an animal in 1 of 4 randomly determined locations and recording a) the time taken to find the goal, b) the path taken to reach the goal and c) the initial direction the rat swam. Every rat received 4 trials/day for 4 days (initial learning). On the 5th day the goal was moved to a new location, and the animals received an additional 4 consecutive days of testing (reversal learning). Each animal was allowed to remain on the platform for 30 sec during which time its behavior was recorded. There were at least 2 min between each trial. During this training it was not known which animals were lateralized and which were not. This was estimated post-hoc by testing every rat for amphetamine (AMPH)-induced rotational behavior (1.25 mg/kg, i.p.). On the basis of their rotational behavior the animals were divided into 2 groups: 1) a lateralized group which made more than 10 net rotations/hr after AMPH, and 2) a non-lateralized group which made 10 or fewer net rotations.

In the initial task all animals learned the position of the goal, and there was no difference between lateralized and non-lateralized rats on any of the measures taken. However, when the error in initial direction was calculated (the angle between a line drawn directly to the goal and the direction the animal initially swam) it was apparent that lateralized rats learned the reversal task significantly faster than non-lateralized rats ($p < .05$). In addition, degree of lateralization was negatively correlated with the error in initial direction ($p < .05$). These results support the idea that some degree of asymmetry in the nigrostriatal DA system facilitates spatial learning.

149.7 MEASUREMENT OF 3-METHOXY-4-HYDROXYPHENYLGLYCOL IN RAT BRAIN USING HPLC WITH ELECTROCHEMICAL DETECTION. Ann L. Acheson and Richard W. Keller, Jr. Dept. Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

3-Methoxy-4-hydroxyphenylglycol (MHPG) is a major deaminated metabolite of norepinephrine (NE) in rat brain, and, as such, can be useful as an index of the rate of NE utilization. We now report a method for measuring MHPG using high pressure liquid chromatography (HPLC) with electrochemical (EC) detection. The chromatographic system consists of a μBondapak C-18 column with a mobile phase containing 14.2 g monochloroacetic acid, 1.0 ml 0.1 M Na_2EDTA, 20 ml methanol and 2.0 ml 0.2 M octyl sulfate per liter, adjusted to pH 3.0. The EC detector is set at an applied potential of +0.92 V vs Ag/AgCl. Tissue is homogenized in 0.1 N $HClO_4$ containing 0.2 mM bisulfite and centrifuged at 39,000 X g for 15 min. Since most of the MHPG in rat brain exists in a sulfate-conjugated form which is not electrochemically active, an aliquot of the supernatant is first acid hydrolyzed at 100° C for 15 min to convert conjugated MHPG to free MHPG. This hydrolysate is then extracted with chloroform. The aqueous layer is applied to a Sephadex G10 column at pH 6.0. MHPG is eluted with 0.01 N $HClO_4$ in a 600 μl fraction and extracted with ethyl acetate at pH 6.0. Ethyl acetate is then evaporated to dryness under N_2, and the sample is reconstituted in 0.1 N $HClO_4$. This preparative phase of the procedure takes about 40 minutes and can be carried out on 4-6 samples simultaneously. Finally, the sample is injected into the chromatographic system. With a flow rate of 1.2 ml/min, MHPG elutes at 6 minutes, and is well separated from the solvent front and from other unidentified peaks. Recovery of MHPG through the entire procedure is 65-80% as determined by the addition of known amounts of MHPG to tissue.

We have used this procedure to measure MHPG in specific regions of rat brain. For example, the MHPG content of hippocampus was observed to be approximately 90 ng/g and of cerebellum, 60 ng/g. These values were decreased to 43% of control 30 minutes after the administration of the MAO inhibitor, pargyline (75 mg/kg, i.p.), illustrating the role of deamination in the formation of MHPG.

This method has several advantages: (1) It is sufficiently sensitive to detect 50 pg of MHPG. (2) It is highly reproducible (12% variation among 5 replicates). (3) NE can be measured in a separate aliquot of the tissue supernatant using the same mobile phase together with a much simplified preparatory step which has been described previously (Acheson et al., Life Sciences 28:1407-1420, 1981).

149.8 IN VIVO VOLTAMMETRY IN RHESUS MONKEY STRIATUM. J. G. Herndon*, W. S. Lindsay*, R. D. Blakely*, J. B. Justice* and D. B. Neill* (SPON: J. Tigges). Division of Neurobiology of the Yerkes Primate Center, and Departments of Chemistry and Psychology, Emory University, Atlanta, GA 30322.

Recently, voltammetric techniques have been employed to measure release of neurochemical substances from the brains of rodents. The use of this technology in the primate offers several theoretical and practical advantages. Theoretically, the richer behavioral repertoire of the primate may permit the acquisition of more information than can be obtained from lower species. On a practical level, the larger brain of the macaque offers the possibility of implanting a larger number of detecting electrodes in a single animal, and may permit significant signal changes to be characterized more discretely with regard to anatomical locus.

In this preliminary study, we implanted carbon-paste electrodes into the caudate and putamen of a chair-restrained, adult (6 kg) female rhesus monkey. Voltammetric measurements were made by a computer-controlled system, in which 0.6 V pulses were applied and current was measured 1 sec later (Lindsay et al., Chem., Biomed., and Environ. Instrumentation 10:311, 1980). When the electrochemical signal had stabilized, the animal was given food or exposed to a visual stimulus (a leather capture glove) which caused obvious behavioral arousal. Both stimuli resulted in significant ($p<0.05$) increases in the magnitude of the voltammetric signal. These results are comparable to those obtained following behavioral arousal and eating in rats.

The present study confirms in the monkey several earlier observations made in rodents, and demonstrates the feasibility of applying voltammetric methods to primates.

149.9 HALOPERIDOL-INDUCED INCREASE IN BRAIN DOPAC IS CORRELATED WITH INCREASED TYROSINE HYDROXYLASE ACTIVITY. Linda Toth Kennedy and Michael J. Zigmond (SPON: B. Dixit). University of Pittsburgh, Pittsburgh, PA 15260.

Activation of tyrosine hydroxylase (TH) is believed to underlie the sustained increase in dopamine (DA) turnover which occurs in DA neurons during increased impulse flow. However, we have observed that the increased DA turnover in frontal cortex produced by restraint stress is not accompanied by increased TH activity in that structure (Kennedy and Zigmond, Neurosci. Abs., 1980). This could be the result of the unique nature of mesocortical DA neurons, the type of stimulus used, or the relatively small increase in DA turnover produced. To distinguish among these alternatives we have examined dihydroxyphenylacetic acid (DOPAC), an index of DA turnover, and TH activity after systemic administration of haloperidol, a DA receptor antagonist known to increase impulse flow in DA neurons. One hr after administration of 1 mg/kg haloperidol to adult, male Sprague-Dawley rats, an increase was observed in both DOPAC content (+285%) and TH activity (+67%) in striatum. In contrast, while DOPAC was also increased in frontal cortex (+30%), there was no significant change in TH activity. The following lines of evidence suggest to us that this apparent dissociation results from the relative insensitivity of mesocortical DA neurons to haloperidol and from the difficulty of detecting small changes in TH activity: First, we compared the haloperidol-induced increase in DOPAC content with the changes in TH activity in individual samples of striatum, frontal cortex, and two other DA-rich areas, olfactory tubercle and hypothalamus. We observed a strong correlation between these two variables ($r=0.78$, $p<.01$) which was independent of brain region. Second, we examined the effect on TH activity in striatum of low doses of haloperidol (10-100 ug/kg) which produced increases in DOPAC comparable to those observed in frontal cortex after higher drug doses. Again, the change in TH activity was correlated with that in DOPAC level, although this was only observable when the enzyme was assayed at pH 7.0, a pH well above its pH optimum, permitting the expression of small increases in TH activation. (The specific activity of the enzyme in frontal cortex is too low to be assayed under these conditions.) Third, a similar correlation was observed when the striatal DOPAC response was attenuated by using shorter post-injection intervals (10-30 min). Thus, our observations support the hypothesis that activation of TH accompanies and may be causally related to increases in DA turnover during increased impulse flow. However, they also indicate that in structures containing relatively little TH, small but significant changes in enzyme activity may not be easily detected. 149.10 A BEHAVIORAL PARADIGM TO ASSESS THE RELATIVE DOPAMINERGIC AND SEROTONERGIC ANTAGONISTIC PROPERTIES OF SELECTED DRUGS. W.J. Heinze*, R.F. Schlemmer, Jr., J.I. Javaid, and J.M. Davis (SPON: L.F. Eastman). Illinois State Psychiatric Institute Chicago, IL 60612 and National College, Lombard, IL 60148

A behavioral paradigm is proposed for assessing the relative dopaminergic (DA) and serotonergic (5-HT) antagonist properties of drugs using rats. The paradigm employs two well studied drug-induced behaviors as tests. Antagonism of stereotyped licking & chewing (LC), induced by the DA agonist, apomorphine (APO), is used to assess DA antagonist properties of drugs. Antagonism of repetitive pawing (RP), induced by the 5-HT agonist, 5-methoxy N,N-dimethyltryptamine (5-MeODMT), is used to assess 5-HT antagonist properties of drugs. Male Sprague-Dawley rats no less than 50 days old were used throughout the study. Observation was conducted by a "blind" observer who rated the presence (behavior observed > 5 sec.) or absence & the duration of each behavior on a checklist of more than 10 behaviors described as components of stereotyped behavior & the 5-HT syndrome. During this time each rat was rated for 30 sec. once every 15 mins. for 1 hr. for the APO expt. and once every 5 mins. for 30 mins. for the 5-MeODMT expt. All drugs were administered i.p. & all doses are expressed as the base. A dose-response study of the behavioral effects of APO and 5-MeODMT revealed a dose-dependent increase in LC from 0.5 to 2.5 mg/kg APO which peaked at 15 mins. and a similar dose-dependent increase in RP from 1 to 5 mg/kg with 5-MeODMT which peaked at 5 mins. Six drugs with varying DA & 5-HT antagonist properties were then tested: haloperidol & trifluoperazine (which reportedly have greater DA than 5-HT antagonist properties), chlorpromazine & methiothepin (antagonists of both DA & 5-HT), & the 5-HT antagonists cyproheptadine & cinanserin. 4-5 doses of antagonist were administered 30 mins. prior to APO or 5-MeODMT & 4 rats were tested per dose. ID50's were determined for each drug for the presence of APO-induced LC and 5-MeODMT-induced RP using probit analysis. Haloperidol was the most potent drug in inhibiting LC, 17x greater than the ID50 for RP. Trifluoperazine was more than 4x more potent in inhibiting LC than RP. Chlorpromazine & methiothepin ID50's were approximately the same for LC and RP for each drug. Cyproheptadine was the most potent antagonist of RP, more than 20x more potent than inhibiting LC. Cinanserin was more than 7x more potent in antagonizing RP than LC. These results suggest that haloperidol and to a lesser extent trifluoperazine are more potent DA than 5-HT antagonists, cyproheptadine & cinanserin are more potent 5-HT than DA antagonists, and that chlorpromazine & methiothepin are approximately equipotent antagonists of DA & 5-HT systems. We suggest that this paradigm will be useful in determining in vivo relative DA & 5-HT antagonist properties of drugs.

149.11 INCREASED NOREPINEPHRINE TURNOVER AND INCREASED FIRING RATE IN RESIDUAL NEURONS AFTER NE-DEPLETING LESIONS. M.J. Zigmond, A.L. Acheson, L.A. Chiodo and E.M. Stricker. Depts. of Biological Sci. and Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Intracerebroventricular administration of the neurotoxin 6-hydroxydopamine (6HDA; 250 µg) has little gross behavioral effect on rats under basal laboratory conditions, despite the loss of 80-90% of norepinephrine (NE)-containing nerve terminals in brain. One possible explanation is that following 6HDA, the noradrenergic cells and their residual terminals are able to provide a near-normal output of transmitter thereby compensating for the lesion. We have examined this hypothesis in two ways. First, NE turnover was assessed by measuring levels of the NE metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), in a terminal-rich area, hippocampus, using HPLC with electrochemical detection (see Acheson and Keller, this volume). Second, the NE cells of the locus coeruleus (LC), which are not damaged by 6HDA, were identified using standard electrophysiological and pharmacological criteria, and their firing rate was measured under chloral hydrate anesthesia (400 mg/kg, i.p.). Thirty-six hr after administration of 6HDA to adult, male Sprague-Dawley rats, hippocampal NE content had decreased to 10% of control. In contrast, MHPG levels were virtually unaffected, resulting in a 10-fold increase in the ratio of MHPG to NE, a possible index of NE turnover in residual terminals. Consistent with this, firing rate in LC cells had increased 4-fold. These effects persisted for 21-28 days post-lesion.

	Firing Rate in LC (Hz)	Hippocampal NE ug/g	%	Hippocampal MHPG ng/g	%	MHPG/NE
SHAM	2.7±0.3	0.49 ±.04	100	91.0 ±2.0	100	1.0
6HDA						
36 hr	13.5±2.0	0.043±.002	10	86.6±14.0	95	9.5
21-28 d	11.6±1.6	0.047±.008	9	70.4 ±4.4	78	8.7

Mean ± S.E.M. of 4-10 animals.

NE released from recurrent collaterals exerts an inhibitory influence on LC firing rate. To determine whether increased firing of LC cells in lesioned animals was accompanied by subsensitivity of cells to NE, we measured the inhibitory effect of iontophoretically applied NE (0.1 M, pH 4.0, 5-40 nA). At both 36 hr and 21-28 days post-lesion, the effect of NE on LC firing was markedly reduced, as evidenced by a 4-fold shift in the dose-response curve. These changes may underlie an adaptive increase in NE release from residual terminals, thus leading to a functional reinnervation of target cells.

150.1 CORRELATION BETWEEN CYTOCHROME OXIDASE ACTIVITY AND NEURONAL ACTIVITY IN THE HIPPOCAMPUS. G. H. Kageyama* and M. Wong-Riley (SPON: R. Harris). Dept. of Anat., U. of Calif. San Fran. CA94143

Studies on normal and physiologically altered neuronal systems have indicated that there is a close relationship between physiological activity, glucose utilization and oxidative metabolism in the brain (Reivich et al.,'75; Wong-Riley,'79). If such a relationship exists in individual neurons, one would expect that cells with a higher level of spontaneous or synaptic activity would have a higher level of oxidative enzymes as well. In the hippocampal formation, several distinct cell types are present with known levels of spontaneous activity (Vinogradova,'75; Schwartzkroin and Mathers,'78). This study was aimed at determining whether there is any regional, cellular and subcellular differences in the level of cytochrome oxidase (C.O.) staining that could be correlated with the levels of neuronal activity there.

Hippocampal sections from bat, mouse, rat, woodrat, gerbil, cat and squirrel monkey were reacted for C.O. histochemistry. Four patterns of enzymatic distribution were discerned in all species. (1) Layers: stratum moleculare/lacunosum of the hippocampus and the outer molecular layer of the dentate were the most reactive layers, while stratum oriens was moderately reactive and stratum radiatum was the least reactive. (2) Regional: CA3 was the most reactive region followed by CA1 and the dentate. (3) Cellular: presumed short-axon and basket interneurons (resembling in shape and distribution GAD-positive cells described by Ribak et al.'78) had the highest C.O. activity in their somata and varicose dendrites. These cells also have the highest spontaneous activity in the hippocampus. CA1 pyramidal cells were more reactive than granule cells but less reactive than CA3 pyramidal cells, again correlated with reported levels of spontaneous activity.(4) Subcellular: the most darkly-reactive mitochondria were found in the somata, dendrites and axon terminals of presumed interneurons. Moderate to highly reactive mitochondria were found in high concentrations in the distal apical dendrites (region of entorhinal input) of granule and pyramidal cells, while much lower concentrations of reactive mitochondria were found in the proximal apical dendrites of the same cells. CA3 pyramidal cells had more reactive mitochondria than CA1 cells, while granule cell bodies, axons and axon terminals generally were nonreactive.

These findings are consistent with our hypothesis that neurons with higher levels of spontaneous and synaptic activity (e.g. CA3 pyramidal cells and presumed GABAergic neurons) also have higher levels of C.O. activity. Moreover, the distribution of C.O. activity can vary on a laminar, regional, cellular and subcellular level, presumably reflecting differential or localized concentrations of synaptic or metabolic activity.

150.2 MAKING MEMORIES OF REWARDS IN THE ENVIRONMENT METABOLIC: RADIAL MAZE LEARNING ALTERS PYRUVATE DEHYDROGENASE IN VIVO PHOSPHORYLATION. S. Caine*, R. Akers*, I. J. Collier*, and A. Routtenberg Cresap Neuroscience Laboratory, Northwestern University, Evanston, Ill. 60201.

Recent evidence from our laboratory indicates that brain phosphorylation studied in vitro is influenced by the behavioral state of the animal (Routtenberg, A., Prog. Neurobiology, 12:85-113, 1979). This is particularly true for band F-2 (MW~41K) which is altered by an aversive experience (Routtenberg, A.and Benson, G., Behav. Neural Biol., 29:168-175, 1980). We have identified band F-2 as the alpha-subunit of pyruvate dehydrogenase (PDH; Morgan, D. G. and Routtenberg, A., Biochem. Biophys. Res. Comm., 95:569-576, NO. 2, 1980). Moreover, PDH activity, which is inversely related to PDH phosphorylation, is elevated following aversive experience.

We now report the effects on PDH phosphorylation of an appetitive task where animals have eight chances to find food in eight arms of a radial maze environment. The three groups of animals compared were a food-deprived control group, a group sacrificed immediately following completion of the task and a group sacrificed 24 hrs after completion of the task. Band F-2 phosphorylation in the dorsal hippocampus was significantly reduced ($p<.05$) in homogenate tissue from animals sacrificed immediately following the task. Band F-2 phosphorylation in a crude synaptosomal preparation (P-2) from the same tissue was also reduced. No differences in band F-2 phosphorylation were observed in neostriatal homogenate tissue.

These results indicate that PDH phosphorylation in specific brain locations can be altered by behavioral manipulations which are known to require the participation of these specific structures. In addition, these results may be taken to suggest that memory formation processes involve regulation of key intermediary metabolic enzymes, perhaps at specific synaptic junctions. This metabolic mechanism is not simply based on increased energy need as both increments and decrements have been observed following learning. Rather, PDH activity may be altered in relation to the type of task and brain location studied. Supported by N.I.M.H. 25281 to A. R.

150.3 HIPPOCAMPAL RECURRENT INHIBITION: DECREASED PYRAMIDAL CELL FIRING WITH INCREASED METABOLISM IN THE PYRAMIDAL CELL LAYER DEMONSTRATED BY THE 2-DEOXYGLUCOSE AUTORADIOGRAPHIC TECHNIQUE. Robert F. Ackermann, David M. Finch, Thomas L. Babb, and Jerome Engel, Jr. Reed Neurological Research Center, and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Postsynaptic inhibition is often invoked to account for subnormal brain metabolism as measured by the Sokoloff 2-deoxyglucose (2DG) method. However, IPSPs are themselves a product of neuronal firing and synaptic processes, both of which require energy to sustain. The present experiments were performed in order to provide more direct information concerning the metabolic demands of neuronal inhibition. Electrical stimulation of the fornix antidromically activates hippocampal pyramidal cells and initiates a profound short-latency, long-lasting recurrent postsynaptic inhibition of pyramidal cell firing. The inhibition is mediated by increased firing of internuncial basket cells. In the present experiments, anesthetized rats were stimulated in the fornix for 60 min under 14C-2DG administration. Multiple unit activity was recorded bilaterally from the CA3 region of the hippocampus throughout the experiment. In 7 of 8 animals the expected recurrent inhibition of CA3 pyramidal cells was accompanied by a distinct increase of hippocampal 2DG uptake; increased uptake was particularly apparent in the pyramidal cell body layer, which is the locus of the dense basket-cell plexus of inhibitory synaptic terminals. Both inhibition and increased 2DG uptake were bilateral, but greater ipsilateral to the stimulating electrode. In 3 of the 7 animals, the hippocampal commissures and the fornix were cut several weeks prior to the 2DG experiments to allow afferent fibers to degenerate; excitatory influences from the septum and contralateral hippocampus were thus removed. Inhibition and increased 2DG uptake in these 3 animals were the same as in intact animals, except that they were restricted to the ipsilateral hippocampus. The single animal in which 2DG uptake did not accompany stimulation had its 'fornix' electrode misplaced caudally to the anterior hippocampus; stimulation in this animal produced only short-duration inhibition and no unusual 2DG uptake. These results indicate that hippocampal postsynaptic inhibition, when it is powerfully evoked as in the fornix stimulation paradigm, requires more metabolic energy than it saves. Although it is possible that regions of hypometabolism observed in other paradigms do in fact represent active inhibition, other mechanisms such as disfacilitation must also be considered.

150.4 PERFORANT PATH AFFERENTS TO THE HIPPOCAMPUS: HIPPOCAMPAL PYRAMIDAL CELL FIRING AND REGIONAL METABOLISM DEMONSTRATED BY THE 2-DEOXYGLUCOSE AUTORADIOGRAPHIC TECHNIQUE. David M. Finch, Robert F. Ackermann, Thomas L. Babb, and Jerome Engel, Jr. Reed Neurological Research Center, and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Experiments were performed to determine the distribution of glucose utilization within the hippocampus during repetitive activation of an excitatory input to the hippocampus, the perforant path (PP). PP axons from the entorhinal cortex via the angular bundle excite dendrites of granule and pyramidal cells; the terminal zone appears as a distinct band (the PP band) in 2-deoxyglucose (2DG) autoradiographs. Anesthetized rats were stimulated in the entorhinal cortex or angular bundle for 60 min under 14C-2DG administration. Frequency of stimulation was varied from 2-9/sec in different experiments. Multiple unit activity was recorded bilaterally from the CA3 region of the hippocampus. Three of the animals had received prior sections of the fornix and hippocampal commissures so that experimental effects could be restricted to the ipsilateral side. In two control animals in which electrodes were implanted but not stimulated, no asymmetries in the PP band 2DG uptake were seen. Entorhinal stimulation evoked a brief burst of action potentials followed by recurrent inhibition lasting from 33 msec to more than 150 msec. The results were frequency-dependent. At higher frequencies (7-9/sec) the 2DG autoradiographs showed, in 4 out of 6 cases, evidence of both PP excitation and intrinsic inhibition. Increased 2DG uptake in the PP band reflected the excitatory input, and increased uptake in the pyramidal cell body layer reflected the recurrent inhibition (see Ackermann et al., 1981, this volume). One case with mild epileptiform activity showed similar but greater 2DG uptake. By contrast, low frequency stimulation (2-4/sec) decreased 2DG uptake in ipsilateral hippocampus in 4 out of 4 animals; this decrease was most evident in the PP band. The reduced 2DG uptake in the ipsilateral hippocampus could be due to: 1) reduced net PP excitation of hippocampal pyramids (disfacilitation) secondary to recurrent inhibition in the entorhinal cortex and 2) entrainment by low frequency stimulation of hippocampal pyramidal cells and inhibitory interneurons to lower than baseline net firing rates.

150.5 METABOLIC CHANGES AND IRREVERSIBLE LOSS OF SYNAPTIC TRANSMISSION DUE TO SEVERE HYPOXIA IN THE RAT HIPPOCAMPAL SLICE. Ira S. Kass and Peter Lipton. Dept. of Physiology, Sch. Med., Univ. of Wisconsin, Madison, WI 53706.

Hippocampal slices from adult (110-150 day old) and young (30-40 day old) rats were subjected to severe hypoxia for 10 minutes and allowed to recover for one hour. The perforant path was stimulated once every 15 seconds and the evoked population spike was recorded from the dentate granule cell layer.

The population spike from adult slices recovers to only 10% of control values one hour after the 10 minutes of hypoxia. ATP declines from (all metabolites expressed as nM/mg protein) 13.9 to 3.6 during the hypoxia and then recovers to 9.7 one hour later. Thus while ATP recovered, it did not reach its prehypoxic level.

Previous studies by Whittingham and Lipton (Neurosci Abst. 6, 1980) showed that adding 25 mM creatine to the medium bathing guinea pig hippocampal slices protects against ATP loss during acute hypoxia. We preincubated hippocampal slices from adult rats in buffer containing 25 mM Cr for 2 hours. When these slices were exposed to 10 minutes of hypoxia and allowed to recover for one hour the population spike recovered to 80% of its control value. ATP dropped from 14.6 to 7.9 during the hypoxic period and recovered to 11.9 one hour later. Thus the preincubation with Cr protected the fall in ATP during hypoxia and allowed greater recovery of the ATP. Using the creatine kinase equilibrium reaction to determine intracellular pH we found that the pH fell to the same level during hypoxia in the Cr treated and the normal slices. These results indicate that it is the level to which ATP falls during hypoxia and/or the level it attains during recovery that determines the extent of irreversible electrophysiological damage in the hippocampal slice.

Hippocampal slices from young rats showed a much better electrophysiolgocal recovery from hypoxia than did the slices from adult rats. However, both ATP and pH fell to the same level during hypoxia. ATP levels following recovery from hypoxia reached a higher level in the slices from young rats than in those from the adults (13.2 vs. 9.7).

Thus, adult hippocampal slices show irreversible loss of function after 10 minutes of severe hypoxia; they can be protected against this loss by a treatment that maintains ATP levels. This suggests that the fall in ATP is at least partially responsible for the irreversible damage. However, young rats show as great a decrease in ATP and pH as the adult animals yet they show much better electrophysiological recovery. This indicates that young animals are protected from irreversible damage in spite of the fall in high energy metabolites. (Supp. by NINCDS)

150.6 CHANGES IN THE ENERGY PROFILE AND ELECTRICAL RESPONSE OF HIPPOCAMPAL SLICES DURING DECAPITATION ISCHEMIA AND RECOVERY IN VITRO. T.S. Whittingham, W.D. Lust, H. Arai*, A.B. Wheaton* and J.V. Passonneau. Lab. of Neurochem. NINCDS, NIH, Bethesda, MD 20205

The neurophysiological characteristics of the hippocampal (H) slice have been extensively studied. However, the biochemical status of the slice under similar conditions is less well defined. In this study, the levels of the adenylates and P-creatine (P-cr) were measured in guinea pig H slices during either 7 or 15 min of decapitation induced ischemia and during a 30 min recovery superfusion in Krebs-Ringer Bicarbonate medium containing glucose and oxgyen. In another series, the slices were exposed to a second 7 min period of ischemia in vitro and then allowed to recover. The trans-synaptic evoked activity was monitored from the perforant path-dentate granule cell region of one slice to assess function. The P-cr levels were essentially depleted by 2 min of ischemia, while the fall in ATP was biphasic; the half-times were 1.7 and 7.6 min for the fast and slow phases, respectively. The AMP concentrations increased to a peak at 7 min of ischemia and then decreased thereafter. A similar response occurred during the second period of ischemia. Total AXP (ATP + ADP + AMP) decreased during the ischemic period to 40% of the 2 min value (30 nmole/mg prot). The AXP levels were maintained during the second ischemic insult. During the recovery period, the metabolites reached a similar steady-state concentration in all ischemic groups. P-cr and ATP increased to about 20 and 9 nmole/mg prot., respectively and AMP decreased to 2 nmole/mg prot. within 30 min of reperfusion. The recovery values for AXP in all groups was approximately 14 nmole/mg prot. Following the changes in AXP during the initial decapitation-induced ischemic insult, the levels remained unchanged during recovery and any subsequent ischemic periods. The depressed energy charge (ATP + 0.5 ADP/AXP) during ischemia was partially restored within 30 min of recovery. The evoked EPSP returned within 2 to 9 min of recovery in the 7 min ischemic group, while the response was delayed or absent in the 15 min ischemic group. Thus, the original ischemia induced by decapitation irreversibly alters the metabolic profile of the in vitro hippocampus, even during recovery. Subseqent ischemic insults in vitro produced a transient change in the metabolites which were reversible to the new steady-state. In spite of the uniformity of the biochemical responses, there were significant differences between the return of the electrical response in the 7 and 15 min ischemic groups.

150.7 METABOLIC ALTERATIONS ASSOCIATED WITH ISCHEMIA AND RECOVERY IN THE HIPPOCAMPAL SLICE. W.D. Lust, T.S. Whittingham, H. Arai*, A.B. Wheaton* and J.V. Passonneau. NINCDS, NIH, Bethesda, MD 20205

The hippocampal slice has been used extensively as a model for the investigation of a variety of neural functions. However, there is little or no information about the metabolic status of the hippocampus in vitro. Therefore, the concentrations of glucose, lactate, creatine, GABA and cyclic AMP were measured in slices both during and for 35 min following an ischemic insult. Since all hippocampal slices are subjected to varying periods of decapitation-induced ischemia, the effect of ischemia on hippocampal metabolism was examined in three different groups. The first two groups represent those slices deprived of oxygen and glucose for either 7 or 15 min following decapitation. At the appropriate times, the slices were perfused with oxygenated Krebs-Ringer Bicarbonate containing 4 mM glucose (pH 7.45, 37°) for 35 min. The third group included slices that were exposed to an additional "second ischemia" in vitro by perfusing the slices with a medium devoid of glucose and equilibrated with 95%N_2-5%CO_2. The intracellular pH was calculated from the creatine kinase equilibrium. The glucose levels decreased to a minimum within 2 min of decapitation and within 5 min following the onset of the second ischemia. The lactate concentrations increased rapidly to a peak (125 nmole/mg prot) at 7 min in the decapitation groups and decreased to 40 nmole/mg prot during 30 min of recovery. In contrast, the lactate levels remained unchanged in the slices undergoing a second ischemia. In all three groups, the intracellular pH decreased to about 6.5 during the first five minutes of ischemia. Upon the restoration of oxygen and glucose, the intracellular pH rapidly increased to 7.2 and then gradually increased to 7.5 at 15 min of recovery. The creatine concentration increased to a maximum (90 nmoles/mg prot) at 2 min following decapitation and then gradually decreased (half-time = 30 min) during the ensuing 25 min of ischemia and recovery. The initial rise in creatine reflects the rapid loss of P-creatine during this period, whereas the creatine decrease represents a net loss from the tissue. The GABA levels were essentially unchanged during ischemia, but increased approximately 50% during the first 15 min of recovery and then remained constant. While the concentrations of cyclic AMP did not vary substantially from 2 to 15 min of ischemia, there were large increases of up to 1000 pmole/mg prot during the early stages of recovery. Further, the magnitude of the response increased with longer periods of ischemia. While the changes in the metabolites reported here suggest that the metabolic profile of the hippocampal slice is quite distinct from the hippocampus in vivo, these marked changes are compatible with neural function.

151.1 DENDRITIC AND AXONAL MORPHOLOGY IN THE DORSAL LATERAL GENICULATE NUCLEUS OF MACAQUE MONKEYS. J.A. Robson. Dept. of Anatomy, Upstate Med. Center, Syracuse, NY 13210.

In the dorsal lateral geniculate nucleus of primates distinct functional cell types are segregated into the parvocellular laminae (3-6) and magnocellular laminae (1-2). In the present study these different laminar regions are examined for their dendritic and axonal morphology. Dendrites were revealed by Golgi impregnation and retino-geniculate axons were filled with horseradish peroxidase. The results of the Golgi studies are similar to those of Wilson and Hendrickson (1981) and indicate that the main distinctions between neurons in the magnocellular and parvocellular laminae are the size of their somata and the distribution of their dendrites. That is, neurons contributing dendrites to more than one lamina are mostly in the magnocellular laminae. There is tremendous variation in dendritic patterns throughout the nucleus and, with one exception (see below), separate classes cannot be defined. Dendrites frequently enter the interlaminar zones and in some cases are confined predominately to these zones. The one clearly distinct cell type that is particularly striking in our material is found in all laminae. These neurons have small to medium sized somata, few primary dendrites (usually 2-4), and correspond to the type B cell of Wilson and Hendrickson. The striking feature of these cells is the complexity of their dendritic endings which usually give rise to many short branches and appendages. In most respects these dendrites resemble axons in their branching patterns and terminal morphology. Retino-geniculate axons in macaque monkeys are also similar in the magnocellular and parvocellular laminae. Large diameter axons (>4μm) are primarily in the magnocellular laminae but they are quite rare. Most retino-geniculate axons are of medium diameter (1.5-2.5μm) and give rise to numerous branches. Compared with our findings in the cat (Mason and Robson, 1979) retino-geniculate axons in macaque monkeys give rise to more fine diameter, beaded branches and more terminals in the interlaminar zones. Retinal innervation of the interlaminar zones is particularly common adjacent to magnocellular laminae in the 1-2 and 2-3 zones. However, terminals can also be found in the zones between parvocellular laminae. Compared with the cat terminal swellings on macaque retino-geniculate axons show less variation in size and shape. Very few have the large crenulated appearance indicative of glomerular synaptic relationships in cats. Correspondingly, electron microscopic studies of HRP-filled axons indicate that complex glomerular synaptic arrangements are relatively rare in macaque monkeys. (Supported by the Research Foundation of SUNY and USPHS Grants EY03490, NS14283).

151.2 TWO TYPES OF PRESYNAPTIC DENDRITES IN THE DORSAL LATERAL GENICULATE NUCLEUS (LGNd) OF MONKEYS. Tauba Pasik, Pedro Pasik and József Hámori. Dept. Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029, and 1st Dept. Anat., Semmelweis Univ. Med. Sch., 1450 Budapest, Hungary.

The LGNd of four normal monkeys (M. mulatta) and of two other such animals with total ablation of the visual cortices (4-6 days survival) were examined in serial thin sections with the electron microscope. As in previous demonstrations, the neuropil contains at least two types of dendritic profiles and four types of axonal endings. The dendrites belonging to projective or principal neurons (P-cells) are exclusively postsynaptic to various vesicle-containing profiles, and exhibit large, dark mitochondria; smooth endoplasmic cisterns which appear in cross-sections as vesicles exceeding 100 nm in diameter; and non-synaptic attachment plaques with retinal terminals and other P-cell dendrites. The dendrites of interneurons (I-cells) show small dense mitochondria, and also small pleomorphic or ovoid synaptic vesicles. These profiles, designated as presynaptic dendrites, have both postsynaptic and presynaptic sites. The latter synapse is of the symmetric type. The axon terminals of retinal and cortical origin contain spheroid vesicles, whereas those from I-cell axons and other endings of extrinsic nature are pleomorphic or flat respectively.

In the present study we have observed a new component of the LGNd neuropil. It has all the above mentioned cytological characteristics of P-cell dendrites but, in addition, it contains large spheroid synaptic vesicles. This profile can be seen in a postsynaptic position to any of the four types of axon terminals, but it is presynaptic only to I-cell presynaptic dendrites. The latter synaptic contact is always of the asymmetric type and, occasionally, a reciprocal synapse is formed between the two profiles. The novel elements are seen more frequently in the specimens with cortical ablations although their number is still very much lower than that of the other classic components of the neuropil. Measurements made on 80,000X electron micrographs of at least 300 spheroid vesicles contained in retinal terminals, cortical endings and the new profile hereby described, resulted in mean diameters of 38.6 nm, 33.3 nm and 44.3 nm respectively. The differences between the means are statistically significant.

Although the profile with large dense mitochondria and large spheroid vesicles may represent a dendrite of a different I-cell type, or a recurrent axon collateral of a P-cell, it appears more probable that it is a presynaptic dendrite of a P-cell. The infrequent but consistent occurrence of these elements suggests that at least some P-cells have the potential to develop presynaptic sites on their dendrites, a property which contributes to the synaptic complexity of the LGNd.

151.3 IDENTIFICATION OF RETINAL SYNAPSE TYPES IN THE CAT DORSAL LATERAL GENICULATE NUCLEUS USING QUANTITATIVE ELECTRON MICROSCOPY. R. Ranney Mize, Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.

Three physiological classes of retinal input have been identified in the dorsal lateral geniculate nucleus (dLGN). We have studied the retinal synapses of the cat dLGN quantitatively to determine whether different types can be distinguished morphologically. Retinal synapses were identified by their characteristic pale mitochondria and were systematically sampled at 4 rostral-caudal planes through the dLGN. The laminar position of each terminal was measured using a computerized e.m. plotter. The cross-sectional area, perimeter, number of presynaptic dendrite contacts, and total synapse contact density were measured using a computer-based digitizer.

Retinal glomerular synapses were easily identified as central terminals with scalloped contours. They were virtually surrounded by dendritic and axonal elements, some of which contained flattened vesicles. The glomerular synapses were medium-sized (mean= 3.35 um^2) and had high contact densities (mean= 0.24 per um surface area) and a high percentage of presynaptic dendrite contacts (35%). They were numerous within the rostral dLGN, accounting for 46% of all pale mitochondria terminals. They were found in fewer numbers more caudally, comprising only 23% in the most caudal dLGN. They were found throughout laminae A and A_1, but were almost never encountered within the C laminae.

The remaining population of pale mitochondria terminals fell into two peak size distributions. The first group had a peak cross-sectional area of 0.80 um^2. These terminals had a low contact density. They were most densely distributed within the C laminae. Their size range resembled that of small retinal terminals located in the upper superficial gray layer of the cat superior colliculus.

A second group had a peak cross-sectional area of 3.8 um^2. They also had a low contact density. They were commonly found within both laminae A and A_1, but were seen infrequently within the C laminae. Many had a bulbous shape, similar to large retinal terminals in the deep superficial gray layer of the cat colliculus.

Although there is substantial overlap in size, our analysis suggests there are at least three separate populations of retinal synapse in the cat dLGN. One class is easily distinguished by its glomerular organization, elaborate synaptic relationships, and laminar location. The other two types have simpler synaptic arrangements and differ dramatically in size and laminar position (Supported by NIH Grant EY-02973-02).

151.4 FINE STRUCTURE AND SYNAPTIC ORGANIZATION OF CAT PERIGENICULATE NUCLEUS. Linda S. Ide. Dept. of Pharmacol. and Physiol. Sci., The University of Chicago, Chicago, IL 60637.

The perigeniculate nucleus (PGN) is a layer of scattered cells apposed to the dorsal surface of the dorsal lateral geniculate nucleus (dLGN). Based mainly on electrophysiological data, it has been suggested (e.g., Dubin & Cleland, 1977) that these cells mediate a recurrent inhibition of dLGN relay cells. Most PGN cells are multipolar or fusiform cells with perikaryal diameters of 15-35μm. They have postsynaptic spines on both proximal and distal dendritic segments, and on their perikarya (in contrast to cells of dLGN, which lack somatic spines).

The majority of synaptic terminals in PGN fit into five major classes: 1) RSD terminals. These are small profiles, densely packed with uniform round vesicles, that make asymmetric synaptic contacts, mainly onto small and medium-diameter dendritic profiles. These terminals resemble terminals in other thalamic nuclei identified as having a cortical origin. 2) RLD terminals. These are frequently large (up to 2.5 x 6μm), contain large round vesicles, clusters of dark mitochondria, a few profiles of smooth ER, and occasionally, bundles of neurofilaments. Individual terminals make multiple asymmetric synaptic contacts onto somatic or dendritic spines, and in some cases also onto adjoining portions of the perikaryal or dendritic surface. A floccular dense material is found in expanded extracellular spaces next to many of these terminals. 3) FD1 terminals. These contain small ovoid and flat vesicles and make symmetric synaptic contacts onto dendrites, dendritic spines, somatic spines, and rarely, the perikaryal surface. They resemble the F1 profiles in dLGN. 4) FD2 terminals. These are pale profiles which contain small numbers of predominantly ovoid vesicles, and in which ribosomes occur occasionally. They are postsynaptic to other terminals, most commonly to RLDs, and presynaptic (at symmetric contacts) to dendrites and spines. They resemble the F2 profiles (P boutons) in dLGN. 5) FP terminals. These contain large polymorphic vesicles, pale mitochondria and scattered glycogen granules. They make symmetric synaptic contacts onto dendritic shafts and spines, and perikaryal surfaces and spines. In addition to these major classes of terminals, a few profiles resembling retinal terminals in dLGN (RLP terminals) occur in PGN.

Small numbers of PGN-like RLD and FP profiles occur in dLGN (cf. Famiglietti & Peters, 1972). Further, we have found a few cells in dLGN that have spines on their perikarya and receive synaptic contacts from such terminals. These rare dLGN cells bear a striking resemblance to cells in PGN.

151.5 BRAINSTEM PROJECTIONS TO THE LATERAL GENICULATE NUCLEUS IN THE CAT. H. C. Hughes, Dept. of Psychology, Dartmouth College, Hanover, N.H. 03755.

Ascending connections of structures within the brainstem to the lateral geniculate nucleus (LGN) have been considered by many to be the anatomical substrate for a variety of non-visual influences on visual processing (for example, corollary discharge prior to saccades and the effects of attention). In order to reveal these projections in their totality, 3 cats were prepared with injections of horse-radish peroxidase into the laminated portion of the LGN. The injections (0.05-0.1μL) were delivered hydrolically via a glass micropipette which also served as a recording electrode. Placement of the injection sites was guided by electrophysiological criteria. Following a 24 hour post-injection survival period, alternate sections through the thalamus and brainstem were processed with O-Dianisidine using standard procedures.

Comparable results were obtained in all 3 cases. Labeled cells were observed in 1) the nucleus of the optic tract, 2) lamina II1, II2 and to a lesser extent II3 of the superior colliculus, 3) the parabigeminal nucleus, 4) the mesencephalic reticular nucleus and 5) nucleus locus coeruleus and subcoeruleus. The projections from the mesencephalic reticular nucleus, n. locus coeruleus, n. subcoeruleus, and the parabigeminal nucleus were all of bilateral origin, although the ipsilateral projections were dominant.

Scattered labeling was also observed in the periaquaductal grey, nucleus raphe magnus, and in the vicinity of the interpeduncular nucleus and the substania nigre.

The results emphasize the diversity of brainstem-geniculate projections and indicate that these projections convey both visual and non-visual information.

151.6 LATERAL GENICULATE CELL POPULATIONS ARE DIFFERENTLY AFFECTED BY MONOCULAR DEPRIVATION (MD) IN THE CAT. M.L. Schmidt. Dept.of Anat., Sch.of Med., U.of Penn., Phila., Pa 19104

LeVay and Ferster (J.Comp.Neurol.,172(1977)563-584)proposed that X-cells contain cytoplasmic laminated bodies (CLB) and that small and large geniculate neurons lacking CLBs are interneurons and Y-cells respectively.

In the present study neurons in the LGN A-laminae of normal and MD cats were measured from paraffin sections stained with a modified Kluver-Barrera procedure.The results show that medium sized neurons containing CLBs, most of which might be X-cells, hypertrophy in non-deprived laminae but show little or no decrease in size in deprived laminae. Large neurons lacking CLBs, which might be Y-cells, are decreased in size in deprived laminae. These cells also hypertrophy in non-deprived laminae with the exception of the largest ones. The smallest cell population was the same size in normal and deprived cats. The number of small to medium sized nerve cells that do not contain CLBs exceeds previous estimates of interneurons and thus it is concluded that at least some of these cells are relay cells.

151.7 OBSERVATIONS ON ANTEROGRADE TRANSNEURONAL DEGENERATION IN THE CHICK ECTOMAMILLARY NUCLEUS. J. D. Peduzzi and W. J. Crossland, Department of Anatomy, Wayne State University, School of Medicine, Detroit, Michigan 48201

While making a detailed qualitative and quantitative study of anterograde transneuronal degeneration in the chick ectomamillary nucleus (EMN) following eye removal at hatching, two questions arose: Is the observed neuronal cell death (20-40%) real or do some neurons atrophy to a point where they are misidentified as glia? Second, in regard to the observed neuron atrophy (20% decrease in mean soma cross-sectional area), do all types of neurons atrophy to the same extent?

To answer these questions, 0.6 μl (3mg/10μl) of horseradish peroxidase (HRP) was injected into two of the terminal fields of the EMN (vestibulocerebellum and inferior olive) in three month old chickens enucleated at hatching. In one animal in which over 1/3 of the cells were retrogradely filled with HRP, every labeled EMN neuron in every 15th section was drawn using a camera lucida then counterstained with cresyl violet. Each cell which had been drawn was relocated in the section. Every retrogradely labeled cell was examined to determine whether it was a glial cell or a neuron. Only neurons were retrogradely labeled suggesting that either glia-like neurons are not present or they no longer project to these targets. In some neurons, the dendrites were sufficiently backfilled to determine the type of neuron labeled. Previous Golgi studies have revealed four types of neurons in the EMN. Type I neurons (large, >250 μm^2, multipolar) underwent the greatest shrinkage (47%), while type II neurons (fusiform soma, >150 μm^2, frequently branching dendrites) decreased by 12.3% and type III (fusiform soma, 150-250 μm^2, rarely branching dendrites) by 31.7%. No type IV neurons (small round soma, <150 μm^2, issuing intrinsic axon collaterals) neurons were labeled. Unlabeled Nissl stained neurons below the size ranges for types I, II and III were assumed to be type IV. These neurons were reduced in mean cross-sectional area by 33.1%. Furthermore, if a distribution of soma areas from the unaffected EMN is plotted so that the atrophy of each neuron type is considered, and compared with the affected EMN, there is no massive cell loss from any one category.

We conclude from this data: 1) it is doubtful that atrophic neurons are misidentified as glia, 2) the type IV neurons may not project outside the EMN, 3) all four types of EMN neurons undergo transneuronal atrophy and transneuronal cell loss.

151.8 RELATION OF THE RETINA AND OPTIC TECTUM TO THE LATERAL GENICULATE COMPLEX IN GARTER SNAKES (THAMNOPHIS SIRTALIS). S. du Lac* and D. M. Dacey* (SPON: S. P. Grossman). Dept. Anatomy, Univ. of Chicago, Chicago, IL. 60637.

Both the retina and optic tectum project to several nuclear groups in the dorsal thalamus of snakes, but the precise relationship of tectal and retinal terminal fields within the geniculate complex is unknown. This study used orthograde and retrograde tracing techniques to determine the relation of retina and tectum to cytoarchitecturally defined fields in the thalamus of Thamnophis.

The geniculate comprises a neuropile, a dorsal segment and a ventral segment. The neuropile lies medial to the optic tract and contains scattered cell bodies. The dorsal segment contains densely packed cells and is continuous rostrally with nucleus ovalis. At intermediate levels, it includes a pars dorsomedialis, pars dorsalis and pars ventralis, but only the pars ventralis continues to its caudal pole. The ventral segment is situated ventromedial to the dorsal segment and contains neurons whose dendrites extend ventrolaterally into the retinorecipient neuropile.

Retinal input, as determined autoradiographically, extends contralaterally over the entire neuropile and partes dorsalis and dorsomedialis of the dorsal segment, and ipsilaterally over the dorsal tip of the ovalis cell plate and pars dorsomedialis. Injections of horseradish peroxidase into tectum reveal that it projects to the dorsal and ventral segments of the geniculate complex via two pathways. One pathway travels ipsilaterally via the marginal optic tract and issues a topographically organized projection to the dorsal and ventral segments. The second travels via the tectothalamic tract to terminate bilaterally in the ventral segment and in a cell poor zone medial to the dorsal segment. It consists of diffusely organized, fine caliber terminal collaterals that are not topographically organized. The crossed projection to the dorsal segment is via the habenular commissure; that to the ventral segment is via the ventral supraoptic decussation.

Thus, retinal and tectal projections to the geniculate present a complex pattern in which there is some spatial segregation of retinal and tectal input, but the dendritic fields of geniculate cells are positioned so that these systems might converge on different parts of the same geniculate cells.

151.9 NUCLEUS ROTUNDUS IN A SNAKE (THAMNOPHIS SIRTALIS). D.M. Dacey* (SPON: W.T. Rainey). Dept. Anatomy, Univ. of Chicago, Chicago, IL.

One major feature of visual pathway organization in reptiles and birds is an ascending tectal projection to the large dorsal thalamic structure, nucleus rotundus (Ro). Previous work has shown that Ro is characterized by, 1) a massive, bilateral input from the tectothalamic tract that is not retinotopically organized, 2) a lack of retinal input, due to the closed nature of its dendritic structure and 3) an ascending projection to a subdivision of the pallial dorsal ventricular ridge (DVR). Surprisingly, this major visual structure has not heretofore been identifiable in snakes. Since the tectum projects heavily to all geniculate subdivisions in snakes it has been suggested that Ro may be incorporated in the massive geniculate complex. However, a well developed nucleus rotundus in Thamnophis is clearly identified with orthograde and retrograde horseradish peroxidase tracing techniques in the present study.

HRP injections into DVR retrogradely fill a large population of cells positioned caudomedial to the geniculate complex and ventrolateral to the thalamic lentiform nucleus. The nucleus is encapsulated by a cell poor zone and can be clearly identified in Nissl material. Solid filled cells vary in size but share a characteristic morphology: they are multipolar with long, sparsely branched dendrites that reach the borders of Ro but do not extend beyond it. Dendrites of cells at the periphery of Ro are directed inward to form a "closed" nucleus. All dendrites are spine free but do bear occasional short protrusions and longer lobulated appendages.

HRP injections into the optic tectum solid filled tectorotundal axons. They join the tectothalamic tract at the lateral and ventral margin of the tectal roof, coursing rostrally to pretectal levels, where they turn medially beneath the caudal pole of the geniculate. Here they form a large, spherical mass of terminal collaterals, filling the nuclear boundaries of Ro. A lighter, crossed input reaches this region via the ventral supraoptic decussation. Solid filled tectal axons do not form restricted terminal arbors in Ro but issue fine diameter, beaded collaterals that distribute diffusely throughout the nucleus.

Using the same techniques a strikingly similar pattern of Ro intrinsic organization has been described in the pond turtle (Rainey,'80, Neurosci. Abst. 6:748). Thus, both connections and intrinsic morphology establish the identity in Thamnophis of Ro as part of an ascending tectal pathway, distinct from the retinogeniculate system. (Supported by PHS grant NS-12518).

151.10 MOTION SENSITIVITY IN TURTLE ANTERIOR DORSAL VENTRICULAR RIDGE. K. R. Dünser*, J.H. Maxwell and A. M. Granda, Institute for Neuroscience, University of Delaware, Newark, DE 19711.

Dorsal ventricular ridge (DVR) is a subcortical structure in the reptilian forebrain receiving visual input from thalamus. We studied the anterior portion (ADVR) in Pseudemys for general functional properties using extracellular, single unit recording techniques. Cells were stimulated and receptive fields were mapped with moving light stimuli projected onto a hemispheric screen centered on the turtle's left eye.

Whereas all cells revealed motion sensitivity,none were found showing clear directional selectivity. Vector analyses of data from cells stimulated by light bars moved in eight directions consistently gave even circular distributions of response strength. Vectors did not exceed 0.24 and were usually less than 0.1 (Max.: 1.0; Min.: 0.0). While there was a general lack of directional selectivity, the majority of cells processed vertical movement differently from any other directional axis when scanned with stimuli distributed across the visible spectrum.

Spectral response plots to equal quantal input revealed mirror-imaged curves for up versus down directions of movement. All other directions tested were undifferentiated in this manner: Opposite directions of movement produced essentially parallel spectral response curves.

A simple scheme might explain this phenomenon: Information from down-selective and up-selective retinal cells is processed into two channels with similar spectral sensitivities. An ADVR cell receives its inputs from one channel (e.g., down-selective information) via excitatory synapses and from the opposite channel (in this example, up-selective information) via inhibitory synapses. Such a mechanism would account for the mirror-imaging seen here for vertical movement. The data suggest that these cells receive non-vertical information via inputs within the same mode; input concerning opposite directions of movement (e.g., left versus right) arrives via synapses that are either only excitatory or only inhibitory.

151.11 THE PRETECTAL COMPLEX OF THE SQUIRREL MONKEY: A REINVESTIGATION OF THE CYTOARCHITECTURE AND RETINAL CONNECTIONS. Hutchins, Bob and Joseph T. Weber, Dept. of Anatomy, Tulane Univ. Med. Sch., New Orleans, La. 70112.

The cytoarchitecture of the pretectal complex of the squirrel monkey was examined in Nissl and fiber stained sections in the coronal, horizontal and sagittal plane. The pretectum of this primate is best seen in horizontal sections and our results are derived primarily from tissue cut in this plane. Five different pretectal subdivisions can be identified on the basis of their nuclear morphology. The general orientation and cytoarchitecture of the pretectal nuclei are similar to that described for non-primate mammals (See Scalia, J.C.N. 145:223-258, 1972). Thus, the nomenclature used to designate the pretectal nuclei in other species can now be applied to the squirrel monkey. According to this standard terminology, the pretectal complex of Saimiri consists of the nucleus of the optic tract, the pretectal olivary nucleus and the medial, anterior and posterior pretectal nuclei.

In Nissl and fiber stained sections, the pretectal olivary nucleus appears laminated. That is, in all planes of section three distinct cellular zones and two cell poor zones are apparent. This particular morphology of the olivary nucleus has never been described for the squirrel monkey.

The pattern of retinal innervation to the pretectum was determined by placing an intraocular injection of ^{3}H-proline into one eye and processing the tissue according to standard autoradiographic techniques. The pattern of transported label is more dense over the contralateral nuclei as compared with the ipsilateral side. In particular, dense transported label overlies the pretectal olivary nucleus and the nucleus of the optic tract with sparse label over the posterior pretectal nucleus, bilaterally. Additionally, sparse label overlies the contralateral medial pretectal nucleus. The pattern of transported label over both the contra- and ipsilateral pretectal olivary nucleus appears laminated in the sagittal and horizontal sections. Moreover, contralateral to the injected eye the silver grains are located primarily over cell poor zones with some sparse label over cellular zones. Ipsilateral to the injected eye the transported label is located primarily over cellular zones with some sparse label over cell poor zones. Such a distribution of label would suggest a segregation of ocular input within the pretectal olivary nucleus.

Supported by Grants BRSG 531105 and EY03731.

151.12 PROJECTIONS OF MEDIAL TERMINAL NUCLEUS OF ACCESSORY OPTIC SYSTEM TO PRETECTUM IN PIGMENTED RAT. Roland A. Giolli, Robert H.I. Blanks and Sang Pham*, Depts. of Anatomy and Surgery, Coll. of Med., Univ. of Calif., Irvine, CA 92717.

Both the medial terminal nucleus (MTN) of the accessory optic system (AOS) and the nucleus of the optic tract (NOT) have been implicated as important structures in the vestibulo-ocular and optokinetic pathways, yet except for a demonstrated NOT-MTN projection, the synaptic interconnections between pretectal nuclei and AOS are poorly understood. In order to examine this problem, small amounts of H^{3}-leucine were injected unilaterally into the MTN of pigmented rats and the tissue processed autoradiographically for light microscopic studies. It was found that the MTN projects by separate pathways upon two pretectal nuclei in a highly specific fashion. One bundle courses with the superior fasciculus of the AOS to terminate densely throughout the ipsilateral dorsal terminal nucleus (DTN) of the AOS. A second, larger bundle runs dorsolaterally through the ipsilateral midbrain tegmentum to terminate as a dense patch within the lateral portion of the NOT and sparse, smaller patches located within the dorsomedial part of this nucleus. The MTN could be shown to project neither to other subdivisions of the pretectal complex nor to the superior colliculus. Control injections into adjacent structures, e.g., substantia nigra (2 cases), subcuneiform nucleus (2 cases) or mammillary nuclei (2 cases), failed to provide evidence for nigral, reticular or hypothalamic afferents to DTN or NOT.

The MTN-NOT projection was also confirmed by using the method of retrograde transport of horseradish peroxidase (HRP). Following HRP injections into the pretectum in 3 rats, a substantial number (clearly 40-50%) of the neurons in the ventral division of the MTN were HRP-filled, whereas only a few of the neurons of the dorsal division were labeled. The present demonstration of a strong, strictly ipsilateral MTN-NOT projection suggests that the MTN must play a significant role in modifying the receptive field properties of NOT neurons.

151.13 AN ANATOMICAL SUBSTRATE FOR THE PUPILLARY LIGHT REFLEX IN THE PIGEON (COLUMBA LIVIA). Paul D.R. Gamlin, Jonathan T. Erichsen, David H. Cohen and Harvey J. Karten. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, N.Y. 11794.

The Edinger-Westphal nucleus (EW) is the preganglionic source of the parasympathetic pathway controlling pupil diameter. In this study we investigated the visual pathway to EW in the pigeon.

Transneuronal autoradiographic studies of the retinal projections in the pigeon (Streit, Stella & Cuenod, Neurosci., 5:763, 1980) indicate that EW receives a major input from the ipsilateral retina, presumably via a contralateral retinorecipient area.

Horseradish peroxidase (HRP, Boehringer-Mannheim, 50%) was injected into EW. Only one contralateral retinorecipient area exhibited labeled cells: the nucleus Area Pretectalis (AP), a dorsomedial pretectal nucleus located anterolateral to the posterior commissure. These cells are scattered throughout the nucleus and do not appear to be of a single morphological type.

The role of AP in the pupillary light reflex was assessed following its unilateral destruction. Such lesions were found to abolish the pupillary light reflex and resulted in a permanent dilation of the pupil in the contralateral eye.

In order to characterize the distribution and morphology of the retinal ganglion cells projecting to AP, HRP was injected into this nucleus. Preliminary studies indicate a differential distribution of retinal ganglion cells with an apparent absence in the fovea and Red Field. At least half the labeled cells have a soma diameter of 15-25μm and are classified as "giant" ganglion cells. They are at least 500μm apart, and their total adjusted number is estimated to be 500-1000 cells.

Hodological and anatomical considerations strongly suggest that AP may be comparable to the mammalian olivary pretectal nucleus, and thus the avian visual pathway to EW is organized similarly to that reported in mammals (Steiger & Buttner-Ennever, Brain Res., 160:1, 1979). Furthermore, many of the retinal ganglion cells contributing to this pathway in birds are large, presumably with broad dendritic fields. These cells are therefore well suited to detect the changes in whole field illumination which elicit the pupillary light reflex.

151.14 BILATERAL TECTAL AND PRETECTAL PROJECTIONS TO THE CENTRAL LATERAL NUCLEUS IN THE CAT. J. Graham and N. Berman. Depts. of Anatomy and Biochemistry/Physiology, Medical College of Pennsylvania, Philadelphia, PA 19129.

In order to study the origins of the projections to the central lateral nucleus (CL) from the superior colliculus (SC) and the pretectum (PT), unilateral injections of horseradish peroxidase (0.15-0.20 μl of a saturated solution in 2% dimethyl sulfoxide) were made in the CL in three adult cats. Neurons, containing retrogradely transported horseradish peroxidase, were visualized using various methods: cobalt-diaminobenzidine, Hanker-Yates and tetramethyl benzidine. In the SC, the majority of retrogradely labeled neurons were found in the ipsilateral stratum griseum intermediale, where neurons of all sizes of somata were labeled. In addition, a few labeled neurons were located in the contralateral stratum griseum intermediale and bilaterally in the stratum griseum profundum.

In the PT, labeled neurons were scattered throughout all subdivisions, bilaterally. As in the SC, the majority of labeled neurons were ipsilateral to the injection site. The densest concentrations of labeled neurons were in the medial pretectal nucleus, the nucleus of the posterior commissure and the anterior pretectal nucleus, in both the pars compacta and the pars reticulata. There was no evidence of a topographic organization of the projections from the SC or the PT to the CL.

In summary, the CL receives bilateral projections from both the SC and the PT. The majority of these tectal and pretectal relay neurons are not in the retinal recipient regions, but rather, at least in the SC, in the regions that are associated with eye movements (Stein, B.E., S.J. Goldberg and H.P. Clamann, Brain Res., 118:469-474, 1976). This correlates with the report of Schlag and Schlag-Rey (J. Neurophysiol., 40:156-173, 1977) that CL plays a role in visually initiated eye movements. (Supported by EY 02088).

151.15 CELLS OF ORIGIN OF TECTOFUGAL PATHWAYS; A HORSERADISH PEROXIDASE ANALYSIS. M.F.Huerta and J.K. Harting*, Department of Anatomy, University of Wisconsin, Madison, Wisconsin 53706

We have used the horseradish peroxidase method to analyze the specific cells of origin of various ascending and descending pathways of the cat's superior colliculus. Our preliminary studies have focused upon the connections of the superior colliculus with the following regions: the inferior olivary complex, the pontine reticular formation, the sensory trigeminal complex, the zona incerta, the ventral lateral geniculate nucleus, the dorsal lateral geniculate nucleus, the lateral posterior nucleus and the parafascicular-central lateral complex.

Our most interesting finding is that following HRP injections into many of these areas, retrogradely labeled collicular neurons occur in groups or clumps. Such neuronal groupings are apparent in most of our experiments and occur in the superficial, intermediate, and deep subdivisions of the superior colliculus.

The significance of this clumping of tectofugal neurons may be related to patchy patterns of afferents within the superior colliculus. Thus, in experiments where HRP-WGA was injected into the region of the pons adjacent to and including the nucleus oralis of the spinal trigeminal nucleus, aggregates of collicular (i.e., tectofugal) neurons were intimately associated with puffs of anterogradely labeled trigeminocollicular axons. This suggests a modular arrangement of the afferent and efferent connections between the sensory trigeminal complex and the superior colliculus.

In addition to our finding of neuronal clumping of efferent collicular neurons, our data reveal that cells within the intermediate grey project to extremely wide areas of the neuraxis. At present, we are attempting to correlate the size, the precise laminar position, the topography, and the clumping patterns of collicular neurons with particular axonal distributions.

Supported by Grant EY01277.

151.16 CONNECTIONS OF THE SUPERFICIAL LAMINAE OF THE GROUND SQUIRREL SUPERIOR COLLICULUS. N. Lugo-García and E. Kicliter. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, P.R. 00936.

The superior colliculus of the ground squirrel (Spermophilus tridecemlineatus) is interconnected with several di- and mesencephalic nuclei known to be involved in vision. Among these are the dorsal and ventral lateral geniculate nuclei and the parabigeminal nucleus. It is not known 1)whether these interconnections are restricted to specific tectal laminae nor 2)is it known whether visual field topology is maintained in these connections. In order to study the first question horseradish peroxidase (HRP) was injected into either deep (three animals) or superficial (three animals) tectal laminae. After survival periods of 48 or 72 hrs. the animals were killed and the locations of HRP were determined histochemically. Only the superficial laminae were found to be interconnected with the visual system nuclei and these connections appeared to be reciprocal. The issue of topology was investigated in the three subjects with superficial HRP injections plus three additional squirrels in which the enzyme was injected into both deep and superficial layers. Visual field topology was found to be maintained by connections between the superior colliculus and the dorsal lateral geniculate and parabigeminal nuclei. Topology between the superior colliculus and lateralis posterior was not so obvious, if present at all. These findings demonstrate that the ground squirrel superior colliculus is interconnected in a very specific fashion with other visual system nuclei. (Supported by PHS grant NS-07464).

151.17 RETINAL PROJECTIONS TO THE HUMAN SUPERIOR COLLICULUS: A PRELIMINARY REPORT. Lois E. Smith*, Alfredo A. Sadun, Walle J.H. Nauta, and Gerald E. Schneider (SPON: S. Wray). Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA 02114. and Department of Psychology, Massachusetts Institute of Technology, Cambridge, MA 02139.

The superior colliculus (SC) has been shown to be a major primary visual structure in many animals and to play an important role in orienting eye movements. In man, however, a retinal projection has not been described until recently (Smith et al., ARVO 1981).

Previous visual neuroanatomical studies in man were largely limited to gross dissections, since the silver staining of degenerating fibers was technically unsatisfactory in human brain tissue. On the basis of classical techniques, early investigations indicated that in man most retinal ganglion cell fibers project to the lateral geniculate nucleus. A smaller primary projection to the human pretectum has also been proposed to explain the pupillary reflex. These descriptions of the retinal projections in man never included the SC.

We obtained brain specimens from human cases in which prior ocular damage had been documented. Employing a new technique for staining and histologically following degenerating axons (Sadun et al., Soc. Neurosci. 1981), we were able to trace retinofugal fibers.

The retinal projections to the lateral geniculate nucleus and pretectum in man were confirmed. More important, we were able to establish, in man, a retinotectal pathway and to map the pattern of its fiber distribution. Fibers were seen, apparently terminating, in a superficial band just below the surface of the SC. In this stratum, there was a suggestion of alternating clusters and gaps of degeneration. A second layer of larger degenerating axons and terminals was seen in the SC deeper than expected from animal studies. It is not surprising that the SC, shown to be an important visual nucleus in animals, also receives a direct input from the retina in man. However, details of this projection and the histoarchitecture of the superior colliculus have some unusual features requiring further analysis.

151.18 THE LATERAL SPIRIFORM NUCLEUS OF BIRDS HAS AN ENKEPHALINERGIC PROJECTION TO LAYERS 8-13 OF THE AVIAN TECTUM. Anton Reiner, Harvey J. Karten and Nicholas C. Brecha. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, N.Y. 11794.

Using immunohistochemical techniques with antisera directed against either leucine-enkephalin or methionine-enkephalin (generously supplied by K.-J. Chang), four distinct bands of fibers showing enkephalin-like immunoreactivity were seen in the pigeon tectum: a) a thin band of thick fibers and tightly clustered bulbous swellings in layer 3, b) a broader band of fibers with less tightly clustered bulbous swellings in layer 5, c) a broad band of numerous obliquely- and radially-oriented fibers that spanned layers 8-13, and d) a band of sinuous fibers in layer 15. In addition, numerous enkephalinergic cell bodies with radially-ascending processes were seen in layers 8-10.

Since the neurons of the avian lateral spiriform nucleus (SpL) of the pretectum are known to contain enkephalin (Davis et al., Neurosci. Abs., '80) and project to the tectum (Brecha et al., Neurosci. Abs., '76), unilateral electrolytic lesions were made of SpL. In birds with unilateral lesions of SpL, layers 8-13 of the ipsilateral tectum were nearly devoid of enkephalinergic fibers, but no alterations were seen in layers 3,5 and 15. Since no other neurons in the vicinity of SpL are enkephalinergic and project to the tectum, the loss of enkephalin-immunoreactive fibers in the ipsilateral tectal layers 8-13 seems attributable to the destruction of SpL. Although the source of the enkephalinergic fibers in tectal layers 3,5 and 15 is unclear, part of the enkephalin pattern in layers 3 and 5 may derive from the ascending processes of the enkephalinergic neurons of layers 8-10.

The present results thus indicate that SpL has an enkephalinergic projection to layers 8-13 of the ipsilateral tectum. Since SpL receives its major input from the ipsilateral basal ganglia (Karten and Dubbeldam, JCN, '73) and projects to the tectal layers 8-13, the layers of origin of the major tectal efferent projections, the enkephalinergic fibers in layers 8-13 may have some influence upon the motor output functions of the avian tectum. This research was supported by NS 12078 and EY 02164 to H.J.K. and NS 16857 to A.R.

151.19 LAMINAR ORGANIZATION OF PEPTIDE-LIKE IMMUNOREACTIVITY IN THE ANURAN OPTIC TECTUM. Rodrigo O. Kuljis and Harvey J. Karten, Dept. Neurobiology and Behavior, S.U.N.Y. at Stony Brook, New York 11790.

Pedro Ramón described (1890-1946) an orderly laminar pattern of fifteen fibrous and cellular layers within the frog's optic tectum. Most subsequent authors have agreed on the presence of eight deeper strata (layers 1-8) in this animal's optic tectum. Considerable controversy remains, however, regarding Ramón's description of the stratification in the superficial region of this structure (layers 9-15, stratum fibrosum et griseum superficiale), the major zone of retinal termination.

Peptide-like [leucine-enkephalin (LENK), substance P (SP), cholecystokinin octapeptide (CCK8), bombesin (BOM)] and 5-hydroxytryptamine (5HT)- and tyrosine hydroxylase (TOH)-like immunoreactivity were assessed in the optic tectum of 27 specimens of Rana Pipiens by means of peroxidase-antiperoxidase and indirect fluorescent double-labeling methods.

Both 5HT- and TOH-like immunoreactivity disclosed a diffuse plexus of processes throughout the entire tectum. LENK, SP, CCK8 and BOM antisera, however, revealed a specific laminar pattern of distribution characteristic for each of these substances. Within layers 11 to 13 of Ramón, in an internal to external sequence, four independent and non-overlapping bands display SP-, LENK-, BOM- and SP-like reactivity. A CCK8 band partially overlaps the LENK and BOM bands. These specific bands have rather sharp boundaries, unlike Ramón's superficial layers, and seem to be formed in part by the level-specific horizontal expansions of the superficially directed processes of cells located in layers 2,4 and 6 that contain these substances. Since no retinal ganglion cells have been found to contain any of these peptides (Brecha and Karten, unpublished observations), none of these processes seem to be of retinal origin.

The present study shows that exquisite lamination exists in the superficial layers of the optic tectum of the frog. A feature that can be made evident through the use of cytochemical techniques while escaping the capabilities of all other available anatomical methods.

151.20 DOES THE FROG VISUAL SYSTEM HAVE FREQUENCY CHANNEL ANALYZERS? By Evangelia Tzanakou, Dept. of Electrical Engineering, RUTGERS UNIV. P.O. BOX 909, Piscataway, N.J. 08854

In the mammalian visual system there is evidence about about the existence of frequency channel analyzers.

I tested the same hypothesis in the frog visual system. Last year we presented a new method of analyzing the intensity profiles of visual receptive fields, with a two-dimenstional Fourier transform. There, the power spectrum was calculated and the peak frequencies were used to reconstruct intensity patterns with an inverse Fourier transform.

In this paper I am going to present data recorded from retinal fibers in the frog's visual tectum. In these experiments, the receptive field was mapped and its intensity profile was analyzed with the method described above. The peak frequency pairs from the two-dimensional power spectrum were used to reconstruct patterns which in turn were used as stimuli.

The response of the neuron was recorded for each of the frequency components and their combinations.

Most of the cells recorded show maximal response to the reconstruction of the pattern corresponding to the fundamental frequency components.

The results of this study and their implications will be discussed.

152.1 DEVELOPMENT OF THE FROG CUTANEOUS PECTORIS NERVE AND MUSCLE. D. Card Linden & M. Letinsky UCLA School of Med., Dept. of Physiol., Ahmanson Lab. of Neurobiology, and Jerry Lewis Neuro-Muscular Research Center, Los Angeles, CA. 90024.

The development of the bull frog (Rana catesbeiana) cutaneous pectoris nerve and muscle has been assessed in young tadpoles through adult-aged frogs. We have determined the numbers of motor, sensory and autonomic axons, and the maturity and degree of myelination of these axons at various stages of development using light and electron microscopic techniques. Muscle fiber development was also correlated with the nerves' maturity.

In tadpoles as young as stage XVIII (metamorphosis occurs at stage XXV) the adult number of myelinated motor and sensory axons was present in the cutaneous pectoris nerve, although many axons appeared to be relatively immature and in the process of developing myelin sheaths. The total number of myelinated axons increased only slightly from stage XVIII (24 ± 5) to adult (33 ± 6). In contrast to the myelinated axon development, the number of unmyelinated axons dropped dramatically from 143 ± 38 (stage XVIII) to 80 ± 40 (17 days post metamorphosis and adult). In young animals unmyelinated, catecholamine containing axons are diffusely distributed throughout the muscle. At later stages and in adult animals, the catecholamine containing axons are primarily associated with blood vessels.

The cutaneous pectoris muscle at stage XVIII is quite immature; the number of muscle fibers is less than half that found in the adult (stage XVIII, 280 ± 56; adult, 778 ± 67). Electron microscopic analysis revealed that at stage XVIII about 40% of the muscle cells are undifferentiated and devoid of myofilaments, 8% are undifferentiated, but contain a few myofilaments, and about 53% are myotubes packed with myofilaments. Thus, at early stages of development, the muscle is composed of cells in a variety of stages of differentiation. In addition, the maturity of the muscle fibers on the muscle's lateral border is obviously greater than that of the muscle fibers on the medial border. This regional difference in maturation is also reflected in the neuromuscular contacts, as reported by Morrison-Graham (Soc. for Neurosci. Abstracts 6: 567, 1980), and Letinsky and Morrison-Graham (J. Neurocytol. 9: 321, 1980).

Even at the relatively young developmental stage XVIII, the adult complement of myelinated axons is present, although only half the adult number of muscle fibers is present. Since the nerve appears much more mature than the muscle, this may mean that, as reported by others, the nerve does indeed have an important inductive influence in muscle development.

152.2 DEVELOPMENT OF THE SEGMENTAL PATTERN OF SKIN SENSORY INNERVATION IN THE CHICK HINDLIMB. S.A. Scott, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11974.

In adult vertebrates sensory innervation of skin is organized segmentally; axons from each dorsal root ganglion (DRG) innervate skin in a characteristic location, termed a dermatome. Honig (Neurosci. Abst. '79) has shown that from their earliest outgrowth skin afferents from the three most rostral hindlimb DRGs project through the limb via precise pathways. I have confirmed and extended her observations by studying the development of the dermatomes of all eight hindlimb DRGs to determine the precision with which skin sensory innervation per se is established.

The "mature" pattern of dermatomes was mapped in St37-38 embryos, after the peak of cell death, by recording from each dorsal root while stimulating the skin electrically or with a fine bristle. These maps showed that lumbosacral DRGs 1-3 innervate the anterior thigh and knee, DRGs 4-6 the distal shank and foot, and DRGs 7-8 the posterior thigh and shank. The location and amount of overlap of dermatomes mapped in embryos as young as St29, when skin innervation is clearly functional, were essentially similar to the mature pattern. To study younger embryos in which physiological mapping is difficult or impossible each DRG was labeled with horseradish peroxidase in embryos from St26, before cell death, to St32. Reconstructions of axonal pathways within the limb showed that axons from each DRG grow to their dermatomes via characteristic sets of nerves. Axons were rarely found in "aberrant" pathways, even at early stages before they reached the skin. Whole mounts of skin from limbs with a labeled DRG showed that axons first reach the skin at about St27, invading the skin at one or more characteristic spots. The dermatomes then enlarge, adding fine axonal branches. Dermatomes seen morphologically were about the same size, shape and location as those mapped physiologically at each stage.

Together these findings rule out several possible mechanisms by which dermatomes might develop. Axons do not simply grow to the nearest available skin, nor are axons "towed" to their final location by skin movements; moreover dermatomes are not shaped by cell death and elimination of random or excessive axonal projections in the limb or the skin. Rather it appears that skin afferents from each DRG grow directly to their target skin along a defined set of pathways and establish their dermatome precisely at its characteristic location. (Supported by NIH grant NS16067).

152.3 RECIPROCAL CONNECTIONS BETWEEN INDIVIDUAL THALAMIC NUCLEI AND NEOCORTICAL FIELDS IN PERINATAL MICE. J.E. Crandall and V.S. Caviness, Jr. E.K. Shriver Center for Mental Retardation, Inc., Waltham, MA 02154

Thalamocortical axons are known from analyses of orthograde degeneration and Golgi impregnations to reach the subplate of developing neocortex of mice and rats, future layers V and VI, during the third week of gestation. The axons ascend to terminate upon their principal cellular targets, stellate cells of layer IV and pyramidal cells of layer III, only later during the first postnatal week. The present study is an analysis of connections between individual thalamic nuclei and neocortical fields in mice ages embryonic day 17 to postnatal day 1. This interval comes after thalamocortical axons arrive in the subplate but before they invade the suprajacent layers. Horseradish peroxidase (HRP), impregnated in polyacrylamide gels or recrystallized as micropellets, was applied via trochar to limited sectors of various frontal, parietal and occipital neocortical fields. Descending projections were demonstrated by this method only if the injected HRP extended into the subplate and not if it penetrated no deeper than the marginal zone and cortical plate. Within the thalamus, orthogradely labeled fibers were found to be distributed congruently with retrogradely labeled neuronal somata. The reciprocal connections between individual neocortical fields and thalamic nuclei demonstrated in this fashion in developing mice correspond well with those of the adult: parietal fields 3 and 1, 40 & 40a with VB, Po & Pom, respectively; occipital fields 17 & 18b with LGN & L; and frontal fields 4 & 6 with VL (Caviness and Frost, J. Comp. Neurol., 194:335,1980). These observations indicate that reciprocal connections become definitively established between individual neocortical fields and thalamic nuclei at a time in development when thalamocortical axons are confined to the subplate and before they are distributed to their principal target cell classes in layers IV and III.

Supported in part by NIH grant 1-Rol-NS12005-02.

152.4 INNERVATION PATTERN OF CHICK WINGS WITH A PROXIMAL-DISTAL DUPLICATION: ELECTROPHYSIOLOGICAL STUDY. C. Muniak* and M. Neset (SPON: ,C. Edwards). Neurobiology Research Center, SUNY Albany, Albany, N.Y. 12222.

Motor nerves are known to form specific connections with the limb muscles during development. In the present study, electrophysiological methods were used to examine the motor innervation pattern of the normal and surgically altered chick wing. Particular attention was paid to which spinal segments innervate the flexor carpi ulnaris (f.c.u.). Donor grafts were added to 4 day old embryos such that the distal part of the operated wing was duplicated along the proximo-distal axis. This was done at day 4, before the limb was innervated. Therefore, the choices of muscles to be innervated by the motor nerves growing into the limb was greater than normal. In normal embryos (day 12 or older), the largest electrical response from the f.c.u. was recorded when spinal root 16 was stimulated. A response approximately one-third as large was obtained when root 15 was stimulated. Stimulation of root 14 gave no response. In the experimental embryos where the host f.c.u.'s were well developed, stimulation of the spinal roots elicited a robust response in the host but only a small or no response in the donor f.c.u. However, in cases where the host f.c.u. was small or absent, the donor f.c.u. responded to spinal root stimulation. When the donor f.c.u. was innervated, it was innervated the same way as the control, that is, predominantly by spinal segment 16. Supported by grants from the Muscular Dystrophy Association and the NIH (NS07681).

152.5 INNERVATION OF CHICK WINGS WITH A PROXIMO-DISTAL DUPLICATION; A MORPHOLOGICAL STUDY. M. Neset and C. Edwards. Neurobiology Research Center, SUNY Albany, Albany, N.Y. 12222

To learn more about the origin of nerve-muscle specificity we have studied the innervation of the flexor carpi ulnaris muscle (f.c.u.) in 12 day embryonic chick wings having limb segments serially duplicated along the proximo-distal axis. Duplications were produced microsurgically by grafting whole day 4 (st. 19/20) wing buds to the stumps of partially truncated host wing buds (st. 23). Innervation is absent at this stage. The embryos were sacrificed at day 12, at which time the adult nerve pattern has been laid down and the main period of cell death is over. The innervation of the grafted limbs was studied in whole mounts and in sections.

The innervation of the f.c.u.-muscle of the graft was found to vary with the extent of development of the f.c.u.-muscle of the host. In limbs in which the host f.c.u.-muscle was lacking, the f.c.u.-muscle of the graft was well innervated. In limbs in which the f.c.u.-muscle of the host was present, the innervation of the muscle of the graft was sparse or absent. The density of innervation, as measured by cross-sectional area of the nerve, seemed to be a function of the relative mass of the host and donor muscle.

The f.c.u.-muscle in operated wings was injected with HRP at 12 days to localize, in the cord, the motor neurons innervating the muscle. The number of labelled cells and the localization in the cord varied with the type of graft. Labelled cells were always present in spinal segment 16, which contributes the main innervation of the normal chick wing, and in segment 15 in some animals. These data are supported by electrophysiological recording. The simplest model to explain the results is to assume that a certain number of nerve fibers are destined to connect with the f.c.u.-muscle.

Supported by the Muscular Dystrophy Association.

152.6 THE CONSTANT NUMBER OF GRANULE CELLS PER UNIT SURFACE AREA OF THE FASCIAE DENTATAE OF THREE DIFFERENT SPECIES. Mark J. West. Institute of Anatomy B, University of Aarhus, 8000 Aarhus C, Denmark.

A comparison of the number of granule cells per unit surface area (isomorphic plane) of the fasciae dentatae of three species (European hedgehog, Insectivora, erinaceus europaeus; Wistar albino rat; DBA-2J mouse) that vary significantly in absolute size and evolutionary development reveals no significant differences in the number of neurons per unit surface area of this archicortical structure in these three species. The number of granule cells was determined from estimates of neuron density in the stratum granulosum (stereological) and from estimates of the volume of the stratum granulosum. The volume and surface area of the stratum granulosum of four to five adults of each species were computed from the volume and area at each level of a series of sections passing through the entire hippocampal region (West and Andersen, Brain Res. Rev. 2: 317-348, 1980). With coefficients of variation of about 15% for species, the number of granule cells per mm^2 of the isomorphic plane was found to be:

mouse	1.25×10^5 cells/mm^2
rat	1.04×10^5 cells/mm^2
hedgehog	1.14×10^5 cells/mm^2.

The similarity between these three area densities and those estimated from the data from different neocortical areas of a number of species, including mouse, rat, monkey and man (Bok, S.T., Histonomy of the Cerebral Cortex, Elsevier, 1959; Rockel, A.J. et al., Brain 103: 221-244, 1980) indicates that the number of neurons per unit surface area of cortex is the same in the neocortex and allocortex of a wide range of mammalian species and that differences in the volumetric density of neurons in the different cortical areas of these animals is proportional to differences in the thickness of the cortex. This common feature of cortical organization facilitates inter- and intra-species comparisons of cortical structure and function.

152.7 RETZIUS-CAJAL CELLS: AN ULTRASTRUCTURAL STUDY IN THE DEVELOPING VISUAL CORTEX OF THE RAT. S.M. Edmunds* and J.G. Parnavelas (SPON: D.C. German). Dept. of Cell Biology, The Univ. of Texas Health Science Center, Dallas, TX 75235.

Retzius-Cajal cells are a unique feature of developing cortical layer I in a variety of mammalian species. Autoradiographic studies have demonstrated that they are the first cells of the cerebral cortex to be generated, and their maturation is extremely precocious. Although these cells have received much attention for nearly a century, their life history remains enigmatic. In this ultrastructural study we sought to investigate the ontogenesis of Retzius-Cajal cells in the visual cortex of a closely spaced time series of rats between 17 days of gestation and adulthood.

Sprague-Dawley albino rats of both sexes were perfused with mixtures of aldehydes, and tissue from the visual cortex was processed for electron microscopy. Serial sections cut in both coronal and tangential orientations were used to identify and study these cells at various stages of development. At 17 days of gestation, Retzius-Cajal cells begin to acquire the characteristic appearance and cytoplasmic organelles by which they are identified in the perinatal period. At birth they are recognized in layer I by their large size, long processes, dark cytoplasmic ground substance and abundance of tightly packed organelles. One feature which is most typical of these cells is the presence in the cytoplasm of numerous wide cisterns of rough endoplasmic reticulum filled with electron-opaque material. Synapses are rarely seen on the perikarya and processes during the first week of postnatal life but become more frequent later in development. A pattern of modifications becomes noticeable in the morphology of these cells during the first postnatal week with the appearance of growth cones and new processes of varying sizes. Furthermore, their cytoplasm slowly acquires a lighter appearance, organelles become more organized, and the size of the cell body and characteristically long processes diminish. The frequency of Retzius-Cajal cells decreases with age and at postnatal day 18 only very few can be recognized with certainty. Careful examination of a large series of sections at the subsequent days revealed that the morphological characteristics of Retzius-Cajal cells eventually resemble and become virtually indistinguishable from classical cortical non-pyramidal neurons.

Supported by USPHS Grant EY02964 and by the Alfred P. Sloan Foundation.

152.8 DISPLACED PHOTORECEPTOR CELLS IN THE DEVELOPING RAT RETINA. A.W. Spira, M. Patten*, and R. Hannah*, Lions Sight Centre, Dept. Anat., Faculty of Medicine, Univ. of Calgary, Calgary, Alberta, Canada T2N 1N4.

Differentiation of the neural retina involves a migration and segration of neuroblasts into three layers of perikarya separated by two synaptic zones. Although neuroblast cells normally differentiate only after they reach their definitive layer, maturation may proceed before migration has ceased (e.g. ganglion cells). Several authors have noted that during early postnatal stages in the rat and mouse retina there exists a group of cells located in the inner nuclear layer (INL) whose nuclei resemble photoreceptor (PR) cells in the outer nuclear layer (ONL) (Sanyal and Bal, Z. Anat. Entwickl-Gesch. 142: 219, 1973; Raedler and Sievers, The development of the visual system in the albino rat, Springer-Verlag, 1975; Blanks and Bok, J. Comp. Neur. 174: 317, 1977). These cells have been considered to be either differentiating bipolar cells destined to remain in the INL, or PR cells on the wrong side of the outer synaptic layer (OSL) which subsequently migrate back to the ONL. Our light and electron microscopic study of Sprague Dawley (albino) and Long Evans Hooded (pigmented) rats has supported the view that these cells are the precursors of photoreceptor cells. Their nuclei resembled closely those of the photoreceptor cells in the ONL even as the latter changed their chromatin pattern during differentiation. They were located in the OSL and outer region of the INL during the first two postnatal weeks and scattered through the middle and outer regions of the INL during the third p.n. week. Their numbers decreased with increasing postnatal age. PR-like cells were evident as late as the third postnatal month. The maximum decrease in their number occurred coincident with the peak period of cell death in the INL. Ultrastructural cytoplasmic features attested to their PR cell identity. These included myoid (Golgi complex) and ellipsoid (mitochondrial) regions. Long cilia associated with a basal apparatus extended from the perikarya in a scleral direction. Outer segments were occasionally seen filled with closely packed membranous lamellae. Some cells contained a synaptic ribbon. Some of these displaced cells likely comprised a part of the degenerating population of cells in the INL, containing some characteristics of degenerating neurones. Those cells remaining in the INL in later stages were often found adjacent to capillaries, some extending processes to the basal lamina of endothelial cells. These observations confirm that not only are these cells displaced PR cells but also that they possess a substantial capacity to differentiate in vivo at a considerable distance from the retinal pigmented epithelium.

(Supported by MRC of Canada)

152.9 THE REPRESENTATION OF AGE IN THE GOLDFISH OPTIC NERVE. Anne C. Rusoff. Oklahoma State University, Stillwater, OK 74078.

Retinal ganglion cell axons in the goldfish optic nerve are organized near the retina according to two patterns: 1) Axons from dorsal retinal ganglion cells are separated from axons from ventral retinal ganglion cells. Near the retina the x-section of the optic nerve is shaped like a trapezoid. The axons from dorsal cells fill a central band perpendicular to the two parallel sides of the trapezoid. Axons from ventral retinal cells fill the two flanking bands. 2) Axons from annuli of retinal ganglion cells, that is, axons of the same age, are clustered together.

The obvious question is how do these two patterns fit together in the nerve? The cluster of axons from the newest ganglion cells is easily identifiable in 1 um thick x-sections of the nerve because its axons are not yet myelinated. In x-sections of the nerve this cluster of axons is found at the narrow end of the trapezoid where the bands of axons from dorsal and ventral retinal cells come together. This position of the newest axons suggests that age may be plotted in a line across the nerve with the newest axons at one end (the narrow end of the trapezoid) and the oldest axons (from central retinal cells) at the other end (the base of the trapezoid). I have tested this suggestion by tracing axons at different positions in the x-section of the nerve back to their cell bodies in the retina. To accomplish this, the optic nerve was hemisected mid-orbitally, and the cut axons were coated with horseradish peroxidase (HRP). Fish survived 1-2 days; then the fish were killed and the retinas and optic nerves removed. Retinas were prepared as whole mounts and the optic nerves were cut into serial 40 um sections. The tissue was reacted with o-dianisidine and H_2O_2 to reveal the cells and axons filled with HRP. Alternate sections of the optic nerve were embedded in epon and sectioned at 1 um. These sections were used to determine the relationship between the axons filled with HRP-reaction product and the non-myelinated (newest) axons. The retinal whole mounts were traced with a drawing tube and the areas containing cells filled with HRP-reaction product were noted on the tracings. In all cases the pattern of HRP-reaction product in the retina and in the optic nerve was compatible with the suggestion that axons are arranged by age across the diameter of the nerve with the oldest axons (from most central cells) at one side and the newest axons being continually added at the opposite edge of the nerve. Thus one may think of the newest axons as a slab which adds onto one edge of the nerve with new axons from each retinal region in register with slightly older axons from the same retinal region. (Supported by PHS Grant # EY03666.)

152.10 MONOCLONAL ANTIBODIES TO RAT CEREBELLAR ANTIGENS. Richard Hawkes* and Evelyn Niday (SPON: A. Matus). Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

We are studying the neurogenesis of the rat cerebellum using a panel of monoclonal antibodies developed for this purpose. Starting with a rat cerebellum synaptosomal plasma membrane fraction as antigen, several hundred hybridoma cell lines were derived which secrete antibodies against cerebellar antigens. We routinely characterise the antigens in three ways. Firstly, using immunohistochemistry at both light and electron microscope levels, the cellular distribution of the antigen is determined. Secondly, we identify the specific polypeptide antigens by gel electrophoresis and immunoblotting. Thirdly, we use a solid phase dot immunobinding assay to establish the antibody titer and class and to study the tissue and species distribution of the antigen. This poster describes the results of one experiment, which yielded 176 hybridoma lines secreting anti-cerebellar antibodies of more than 20 different specificities.

152.11 HISTOGENESIS OF THE NEURONS OF THE EXTRA-PYRAMIDAL SYSTEM OF THE RAT BRAIN. R.G. Marchand and L.J. Poirier. Lab. de Neurobiologie, Hôpital de l'Enfant-Jésus, Québec, Canada, G1J 1Z4.

This study provides basic data on the time of origin as well as on the spatio-temporal setting patterns of the neurons of the neostriatum, the globus pallidus, the basal nucleus complex, the entopeduncular nucleus, the subthalamic nucleus, the small parvocellular group of neurons embedded in the fibers of the cerebral peduncle immediately rostral to the substantia nigra, and the substantia nigra. Twelve gestating rats of 10, 11, 12... 21 days and 3 pups, aged 1, 2, 3 days respectively were injected with ^{3}H-thymidine. The brain of 40 and 125 day old pups were studied. The nucleus of every neuron which contained 25 silver grains or more (heavily labeled) was considered to represent a neuron that entered its final mitotic cycle shortly after the injection of ^{3}H-thymidine during gestation. The small parvocellular group of neurons embedded in the cerebral peduncle display heavily labeled nuclei on day 11 and 12. The neurons of the entopeduncular nucleus and globus pallidus are generated from days 11 to 14 and days 11 to 15, respectively. In the pallidum the first neurons to form on day 11 settle caudally and while on day 15 neurogenesis has ceased in this area, it is still intense in the rostral extremity of the pallidum. The neurogenesis of the small to medium sized neurons of the neostriatum extends from day 12 to at least postnatal day 3. Neurogenesis of the neostriatum follows a moderate caudo-rostral gradient. The heavily labeled neurons are located at the caudal extremity of the neostriatum on day 12 and in the rostromedial areas on postnatal days. Three modes of development have been observed in the neostriatum of the rat. In the caudal neostriatum (putamen), at the level of the entopeduncular nucleus, the neurons display an inside-out spatio-temporal gradient in which earlier generated neurons are located along the globus pallidus and later formed neurons along the external capsule. More rostrally the neurons of the neostriatum do not exhibit any clear spatio-temporal gradients in their distribution. However, the first neurons generated for this area on days 13 and 14 settle according to two patterns. Many neurons settle rather densely along the external capsule occupying more rostral sites on day 14. Other neurons settling in the body of the neostriatum are grouped in clusters more or less uniformly distributed on these days. In this area, neurogenesis reaches its peak on days 15 and 16. Large chromophilic neurons of the neostriatum appear exclusively in the earlier period, that is on days 12-14. Similarly, the large neurons of the substantia innominata-basal nucleus complex which are mixed with the neurons of the globus pallidus in the rat also appear on days 12 to 14. The neurons of the subthalamic nucleus and of the substantia nigra are generated on days 13-15 and days 12-15, respectively.

152.12 TRANSPLANTATION OF FETAL RETINA, SUPERIOR COLLICULUS AND LATERAL GENICULATE NUCLEUS TO HOST VISUAL CORTEX. A LIGHT AND ELECTRON MICROSCOPIC ANALYSIS. M. A. Matthews. Dept. Anat., LSU Med. Ctr. New Orleans, LA. 70119.

It is now well established that a variety of CNS tissues, including cerebellum, brainstem, hippocampus and visual neuronal elements can be transplanted to the brain of a host animal. Such transplants have been shown to survive and to establish reciprocal connections with the host. The purpose of our experiments were: 1) to examine neuronal and synaptic development within the transplant; 2) to determine if axonal sprouts from the transplant grow into appropriate targets. Following injection with ^{3}H Thymidine on gestation days 12-15 to label transplant neurons, pregnant female albino rats were laparotomized on gestation days 15-17 and samples of fetal retina, superior colliculus and dorsolateral thalamus containing the lateral geniculate nucleus were removed from the fetuses and transplanted to the visual cortex of neonatal host rats of the same strain.

Analysis of retinal transplants reveals a partial retention of histotypic organization with the appearance of ganglion, bipolar and sensory cells which become arranged in rosettes. Apicolateral junctions are readily identified near the center of a rosette to form a rudimentary limiting membrane. Formation of photoreceptor elements and synapses of the plexiform layers is stunted. Examination of the periphery of the transplant demonstrated concentrations of axons corresponding to the optic fiber layer of the normal retina. Transplants of retina together with superior colliculus were analyzed with silver methods for axons and this procedure reveals numerous fibers arising from the retinal ganglion cells, coursing into the adjacent transplant of superior colliculus and ramifying among these cells. Very few axons arose from the portion of transplanted retina in contact with the cortex. Transplants of thalamic tissue containing the lateral geniculate nucleus exhibit normal neuronal and synaptic development with the notable exception of the encapsulated glomerular complex of the retino-fugal terminal. Such transplants also display projections which enter the host visual cortex and the numbers of such axons appear to increase substantially if axon transport inhibitors are injected into the contralateral eye at the time of transplantation.

These preliminary studies show that some degree of specificity exists in transplanted mammalian CNS and should lead to an important model for further study of plasticity in host-transplant reciprocal projections.

152.13 HYDROCEPHALUS PRODUCED BY PRENATAL IRRADIATION. C. J. D'Amato and S. P. Hicks. Department of Pathology, University of Michigan Medical Center, Ann Arbor, MI 48109.

Hydrocephalus with greatly enlarged ventricles has been produced in rats by early prenatal irradiation, and some animals have grown to maturity, but the morphogenesis of the condition has not been worked out. Rats pregnant 11 days, fetal stage of about 16 to 24 somite pairs, were exposed to 200 R (250 kvcp x-rays, 60 R/min) and fetuses were removed surgically at intervals afterward for serial histologic sections to study the development of the hydrocephalus in stepwise fashion. Enlargement of the head owing to dilation of the lateral and third ventricles became evident between 18 and 20 days. It corresponded to a gradual narrowing of the lumen of the aqueduct to closure, owing to disorderly overgrowth of the rostral tectum (superior colliculus) and pretectal region. The ependyma of the stenosed aqueduct remained intact. The posterior and superior colliculus commissures, and usually the subcommissural organ, did not form. The pituitary was displaced into the nasal mucosa through the sphenoid bone. Most animals had eye defects. Abnormality of the tectal-pretectal region was first seen about the 15th day when the commissures failed to develop. By 18 days the affected midbrain and pretectal region were dorsoventrally thickened, and the dorsal convexity of the midbrain was flattened. Some animals deviated from this developmental constellation showing severely malformed faces and others showed a dorsal midbrain encephalocoele or malformed forebrain. The initial injury was a destruction of many primitive neural and mesenchymal cells, chiefly G1 and G2, as we have described in detail. By 48 hours regulative regeneration by residual primitive cells had substantially restituted the damage except in the regions noted. Other litters exposed to 150 R on the 11th day showed no hydrocephalus.

This radiation induced development of hydrocephalus resembled that caused by a recessive mutation in which early overgrowth of the commissural fibers and cells in the tectal-pretectal region led to obstruction of the aqueduct around the 19th day (D'Amato, Hicks 1981). The latter period seems to be critical for the development of the proper caliber of the aqueduct. (USPHS NS 10531)

152.14 THE CENTRAL CANAL AREA OF THE IMMATURE RAT: NORMAL DEVELOPMENT AND RADIATION SENSITIVITY. S. A. Gilmore, J. E. Leiting* and T. J. Sims, Depts. of Anatomy and Pathology, Univ. Arkansas Med. Sciences, Little Rock, AR 72205.

The central canal area of the spinal cord in the immature rat differs in appearance from that in the adult. During the early postnatal period, particularly the first two weeks, the cellular arrangement at the dorsal and ventral aspects of the walls of the central canal is markedly different from that present in the mature state. Dorsally, cells extend upward into the median septum giving this portion of the central canal the appearance of having an apex. Ventrally, a cluster of cells extends from the central canal; these cells are closely packed in contrast to neighboring neurons and neuroglia. Cursory observations in previous studies suggest that these cells at the ventral aspect may be extremely sensitive to ionizing radiation. The present study was undertaken to evaluate the effects of x-rays on the central canal area, particularly its ventral aspect, and to characterize the cells ultrastructurally.

A 5-mm length of lumbosacral spinal cord was x-irradiated (4000R) in Charles River CD rats. Groups of rats were perfuse-fixed from 2 hours to 2 days post-irradiation (P-I). The vertebral columns containing the irradiated and the adjacent non-irradiated regions of spinal cord were removed, and interrupted serial sections were prepared for light microscopic observation. Spinal cords from normal 3-day-old rats were prepared for ultrastructural studies.

As early as 2 hours P-I, an occasional cell in the ventral cluster is pyknotic, and by 6 hours pyknosis is a prominent feature of this area. Within 12 hours, karyorrhexis is occurring, and at this time most of the cells remaining in this cluster are either pyknotic or karyorrhectic. Some cells apparently have disappeared because there are clear areas lacking any cells. By 20 to 24 hours, this ventral aspect of the central canal is essentially acellular, containing only an occasional pyknotic cell. A similar situation persists at 2 days P-I. During this 2-day interval, some pyknotic cells occur in the lateral walls and at the dorsum of the canal, but they are much less frequent than at the ventral aspect.

These data indicate that the population of cells at the ventral aspect of the central canal is extremely sensitive to ionizing radiation. Ultrastructural studies are in progress to identify these cells, and other studies are planned to evaluate whether or not this population is reconstituted following irradiation.

152.15 NEURONAL MORPHOLOGY IN ECTOPIC CORTEX FOLLOWING GESTATIONAL X-IRRADIATION. J.A. Donoso and S. Norton.* Ralph L. Smith Research Center and Pharmacology Department, University of Kansas Medical Center, Kansas City, Ks. 66103.

When dividing cells of the ventricular ependymal layer are exposed to antimitotic agents breakage of the layer occurs. Double breaks in the layer result in rosettes containing dividing matrix cells. Neuroblasts forming in these rosettes from subsequent divisions do not migrate normally to form the cerebral cortical layers, but form cortical ectopias below the corpus callosum. About one third of the total cortical mass developed ectopically. The present study was conducted to describe the ectopic cortex with respect to neuronal cell type, orientation of neurons and synaptic arrangement on the neurons using light and electron microscopy. Rats were irradiated with 125 R on gestational day 15 and examined at 4 weeks and 4 months postnatally. No specific layers were identified in the ectopic cortex. With maturation, the rosettes which are clearly demonstrated at birth tend to fuse. At 4 weeks of age many ectopic pyramidal cells have few spines and short branches with many varicosities, resembling immature pyramidal cells. At 4 months, many of the immature looking cells have disappeared. The total number of spines in the apical dendrite of ectopic cortex pyramidal cells does not change with age and is significantly less than those present in the corresponding irradiated cortex located above the corpus callosum. Electron microscopic examination of ectopic and irradiated cortex as well as control cortex shows axodendritic and axosomatic synapses. The synapses in control cortex and irradiated cortex above or below (ectopic) the corpus callosum are morphologically indistinguishable. Therefore, the pyramidal cells in the ectopic cortex have synaptic contacts which present the structural basis necessary to participate in neuronal interaction with other brain areas. This research was supported by a NIH Grant NS 16694-01 and U.S.P.H.S. Grant HD-02528.

152.16 EMBRYOGENESIS OF THE CORTICAL PLATE: A COMPARATIVE STUDY IN THE THREE REPTILIAN ORDERS. A.M. GOFFINET(SPON: M. David-Remacle). Unité de Neurologie du Développement, Université de Louvain, Bruxelles, Belgium.

Radial presentation is a general characteristic of the neurons of the mammalian cortical plate. In order to know wether this property is general and necessary for the formation of the cerebral cortex, the embryogenesis of the CP has been studied in reptiles, the vertebrates which have the most primitive cerebral cortex.

The observations were made on embryological series of a turtle (E. orbicularis), a squamate (L. viridis) and a crocodile (C. niloticus), and confirmed by the examination of at least another species in each order.

In all species observed, the CP develops according to the same sequence : it appears in the dorsal part of the hemispheres and extends medially and laterally; during the last third of incubation the three architectonic areas of the cortex are recognized, namely the general pallium, brachetted between the medial (hippocampal) and the lateral (pyriform) cortices.

However, there is a constant difference in the cytology of the CP, between turtles and crocodiles on one end, and squamates on the other end. In the latter the CP cells, from their earliest stage of differentiation, manifest the property of radial presentation: the neurons are arranged radially, closely packed into a well defined plate. At later stages, the CP remains compact, the molecular zone (MZ) increases considerably, presumably reflecting the development of the apical dendrites; both the MZ and the white matter are clearly delimited. In turtles and crocodiles, the organization of the early bipolar CP cells within the CP is less regular than in squamates; the cells are more obliquely oriented and the plate appears as a loose network. At later stages, the neurons increase in size and the apical dendrites develop predominantly towards the pial surface; the spatial definition of the cortex, the MZ and the white matter improves but remains imperfect.

This study shows that the property of radial presentation of CP cells is present in squamates but lacking in turtles and crocodiles, and provides support to the theory that the evolution of the cortex can be dissected into discrete steps. The biological basis for this phenomenon is unknown but it might reflect species differences in the interaction between neurons and radial glial guides during embryogenesis.

153.1 NEUROPHYSIOLOGICAL STUDIES ON REINNERVATED MECHANORECEPTORS IN THE GLABROUS SKIN IN MAN. R.MACKEL* AND A.STRUPPLER* (SPON: B. Peterson)Department of Neurology, Technical University of Munich, Munich, FRG

Percutaneous microneurographic recordings from single regenerated afferent fibers were performed in 12 patients following complete traumatic transsection of the median (5 patients) or ulnar (7 patients) nerves. The cut ends of the nerves were bridged with a piece of the sural nerve and 39 mechanoreceptors were studied by recording their discharge characteristics proximal to the site of injury, following peripheral mechanical skin stimulation. The time elapsed between injury and nerve repair ranged between 2 and 24 months between nerve repair and examination 1 to 10 years. The age of the patients ranged between 16 and 59 years.

The discharge characteristics of identified mechanoreceptors were found to be comparable to those observed in normal human glabrous skin. They could be classified as Rapidly Adapting (RA,n=10) and Slowly Adapting (SA I,n=9 and SA II,n=18). Two receptors were classified as joint receptors. High threshold mechanical stimulation of the skin was usually required to activate the receptors, although some receptors responded to very low stimulation. Most reinnervated receptors were located in deeper tissues and more proximally in the extremity. Almost all mechano-receptors had only one circumscribed receptive field, which was usually located in the representative projection zones of the ulnar or median nerves. Receptive field location, whether distal or proximal in the extremity, and receptive field distribution, either singly or multiply represented, could be attributed to factors such as the time elapsed between the injury and the nerve repair, the age of the patients and the location of the injury i.e. distal at the wrist or more proximal towards the elbow.

It is concluded that these factors are responsible for the distribution and location of receptive fields, but not for the shaping of the functional discharge characteristics of the reinnervated mechanoreceptors.

153.2 ^{3}H 2 DEOXYGLUCOSE UPTAKE IN THE HYPOGLOSSAL NUCLEUS AFTER NERVE TRANSECTION. Philip Singer and Sharon Mehler*. Neurology Histochemistry Laboratory, Veterans Administration Medical Center, Kansas City, MO 64128

We have demonstrated (Singer, P. and Mehler, S., Neuroscience Absts. 5:683, 1979 and Exp. Neurol. 69:611-626, 1980) and others have confirmed (Kreutzberg, G. and Emmert, H., Exp. Neurol. 70: 712-716, 1980) that there is a marked increase in glucose utilization in the hypoglossal nucleus beginning 24 hours after hypoglossal nerve transection. These results were obtained with the ^{14}C 2 deoxyglucose technique. This technique is not capable of cellular resolution because of the problem of diffusion of the glucose when the sections are applied to slides. Therefore, the question of cellular location of the glucose uptake remains unresolved. We used the ^{3}H 2 deoxyglucose technique as described by Sharp (Sharp, F.R., Brain Res. 110:127-139, 1976) and modified by Steward (Steward, O. and Smith, L., Exp. Neurol. 65:513-527, 1980) to attempt to obtain cellular resolution.

150 gm male Sprague-Dawley rats underwent left hypoglossal nerve transection under nembutal (50 mg/kg IP) anesthesia. They were sacrificed at 1, 3, 7 or 14 days after axotomy. At the time of sacrifice 67 μCi/100 gm ^{3}H 2 deoxyglucose was injected IV via the tail vein while they were awake. Forty-five minutes later they were again anesethized with pentobarbital and the brainstem was removed and frozen in Freon cooled to -70°C. Slides were cleaned and coated with Kodak NTB emulsion and stored with drierite in light proof boxes at 5°C until use. Twenty micron sections were cut in a cryostat at -18°C under a safelight and applied to the precoated slides. These were exposed at room temperature for three weeks and then processed in D-19 developer and fixer and lightly stained with cresyl violet.

Some sections showed obvious evidence of diffusion of the isotope with smearing of surrounding high grain density into the 4th ventricle, central canal and tears in sections. Other sections, however, showed good localization of increased grain densities not impinging on to these structures and were selected for further analysis. In these sections there was a higher grain density in the nucleus on the side of nerve transection compared to the control side but there was a uniform distribution of grains over the neuropil and cell bodies with no definite localization in either cell bodies or neuropil. This suggests that increased glucose use is not only confined to the cell body but includes the neuropil as well. Thus, in addition to cell synthetic activity increased glial glucose use or dendritic electrical activity are possible pathways. However, because of the possibility of diffusion firm conclusions must await substantiation with other techniques.

153.3 EFFECTS OF VARIOUS POTENTIAL DIFFERENCES ON TRIGEMINAL GANGLIA NERVE REGENERATION IN VITRO. Betty F. Sisken and Philippe Sechaud.* Wenner-Gren Research Lab, and Department of Anatomy, University of Kentucky, Lexington, KY, 40536. Low levels of direct current have been used to augment bone healing, increase DNA synthesis in chondrocytes and to stimulate limb regeneration in non-regenerating vertebrate forms. We have also reported that the administration of nA levels of direct current (10nA total) by tantalum electrodes act to increase neurite outgrowth in sensory and sympathetic ganglia of the chick embryo; this outgrowth is oriented to the cathode. Additionally, after 3 days of constant exposure to the current, neuronal survival is increased in both explant and dissociated cultures. We have used this system to stimulate neurite outgrowth and maintain the neuronal population in studies to ascertain the interactions of trigeminal ganglia co-cultured with developing cornea.

In order to determine the electrochemical contributions to this system we have completed voltage/current experiments and found that 10nA, the current routinely used, corresponds to an electrode potential of -400mV/SCE. Therefore, we decided to look at the effects of imposing different levels of electric current by maintaining fixed electrode potentials on the neurite outgrowth and cellular morphology of cultured trigeminal ganglia. Potentials of 200,400,600 and 800mV were imposed on our culture dishes containing either platinum or tantalum electrodes by employing an agar bridge to a saturated calomel reference electrode connected to a potentiostat.

The results obtained in these experiments depended on the metal used for the electrodes and the current imposed. When platinum was used, the greatest neurite outgrowth was obtained between 200-400mV (20-40nA). No effects were obtained at 600mV (100nA), and tissue destruction occurred at 800mV. When tantalum electrodes were used, no effects were seen at 200mV (2nA), stimulation of neurite outgrowth occurred at 400-600mV (10-20nA) and no effects were seen at 800mV (40nA).

These experiments illustrate that a direct relationship exists between current and voltage levels in term of their biological effects. They also serve to define specific "windows" within which electric current/voltage reflect maximum stimulation.

153.4 RELATIONSHIP BETWEEN AXONAL ELONGATION AND DEGENERATION AND SLOW FLOW. P. Cancalon. Dept. of Biological Science, Florida State University, Tallahassee, FL 32306.

Previous studies of the olfactory nerve have indicated that axonal injury causes total degeneration of the mature neurones followed by their replacement by new neuronal cells arising from undifferentiated mucosal cells. A constant turnover of the olfactory neurones has also been demonstrated in the intact olfactory nerve.

The olfactory nerve of the garfish was crushed 1.5 cm from the mucosa. Degeneration and regeneration were followed by measuring the proximo-distal decrease or increase in nerve weight in successive 3 mm segments. Regeneration was also followed by measuring the accumulation in the growing nerve endings, of labeled proteins transported by fast intra-axonal transport. As shown previously three distinct population of regenerating fibers were characterized. Each of the first two phases represent 3 to 5% of the original axonal population and at 21°C the leading fibers in each group progress at 5.8 ± 0.3 mm/d and 2.1 ± 0.1 mm/d. The third population contains 50 to 70% of the original axonal population and grows at a velocity of 0.8 ± 0.2 mm/d. At 31°C significantly higher regenerating velocities were measured: 10.3 ± 0.7 mm/d for the first phase fibers and 6.3 ± 0.4 for the third phase axons.

Rates of axonal transport were measured at different temperatures in these various phases of regenerating axons. The rate of fast transport is temperature dependent but is unaffected by regeneration. Slow flow velocity is also temperature dependent but is greatly affected by regeneration. Similar rates of slow flow were measured in the three populations of regenerating fibers. In the first phase fibers the base front of the slow peak moves at 5.2 ± 0.6 mm/d at 21°C and 9.8 ± 0.8 mm/d at 31°C. Slow flow appears to be the factor limiting the growth of the most rapidly regenerating fibers. Since these first phase fibers represent the axons already growing in the nerve before the crush the fastest rate of regeneration may represent the actual rate of nerve elongation during neuronal turnover occurring in intact nerves. Other limiting factors are preventing the fibers in the other phases to grow at the maximum speed (A lack of conditioning effect has been postulated).

After nerve crush, degeneration progresses along the nerve at 5.7 ± 0.3 mm/d at 21°C and 11.4 ± 0.5 mm/d at 31°C, values again similar to the rate of slow flow. It can be hypothesized that the extensive degeneration of the nerve is triggered by the lack of molecules provided by slow flow. From these results, it appears that slow flow plays a major role in the mechanisms of nerve degeneration and regeneration. (NIH 17198).

153.5 ELECTROPHYSIOLOGICAL, MORPHOLOGICAL AND BIOCHEMICAL CORRELATES OF NEUROMUSCULAR JUNCTION REFORMATION IN RAT PERIPHERAL NERVE REGENERATION. A. Gorio, G. Carmignoto, *M. Finesso, *L. Di Giamberardino,°* J. Y. Couraud°* and M. G. Nunzi *Fidia Research Laboratories, Department of Cytopharmacology, Abano Terme, Italy and °Centre d'Etudes Nucleaires, Commissariat a l'Energie Atomique de Saclay, Departement de Biologie, 91190 Gif-sur-Yvette, France.

Rat EDL muscles are denervated by crushing the sciatic nerve at the last gluteal branch. Reinnervation of the muscle starts 2 weeks after. Unmyelinated axons penetrate the muscle and make the synaptic contact at the old post-synaptic site. At this stage the ultrastructure of the nerve endings is not well differentiated yet, they are small, contain very few vesicles and seem to be changing from growth cone to synaptic terminals. The neuromuscular transmission is however recovered rapidly and in less than 24 hours the end-plate potential is capable of inducing muscle contraction. On the other hand, m.e.p.p.'s are rare at this stage and recover their frequency and distribution only two months after denervation. Electrophysiologically and histochemically we have shown that polyneuronal innervation begins immediately and reaches its maximum 7-10 days after reinnervation. The end-plate is invaded by flat nerve endings which gradually grow in size and differentiate in synaptic terminals. The correlation between the repression of the redundant innervation and the ultrastructural features of the terminals will be discussed. The flow-rates of the AChE forms drops after nerve crush and it recovers quite rapidly, beginning from the 2nd week post-crush.

The recovery is complete by 30 days post-crush for A_{12} and $G_1 + G_2$ while G_4 shows a slower rise. The concentration of the AChE forms in the denervated EDL also shows a decline and recovery pattern after nerve crush. The form G_4 reaches its lowest concentration 2 weeks post-crush and recovers afterward, yet without reaching the control value, at least until 60 days post-crush.The form A_{12} exhibit an extremely low concentration at 7 days, it starts rising at 15 days and is maximal at 30 days, with a kinetic almost superimposable to that of the flow-rate of A_{12} in the nerve. The recovery rate of A_{12} form in the muscle is similar to the recovery of the muscle membrane resting potential suggesting that mechanical activity may be responsible for both of them. Our results are suggesting that the complete restoration of synaptic transmission may be related to the recovery of axonal components very slowly transported.

153.6 Axon Regeneration Is Initiated But Not Maintained In The Absence of a Cell Body Response. Richard C. Carlsen, Jane E. Kiff, Karen Ryugo. Departments of Human Physiology and Zoology, University of California, Davis, CA 95616.

Frog spinal neurons, in animals maintained at environmental temperatures above 20°C, show all of the classic features of the cell body response following peripheral axotomy. In contrast, axotomized spinal neurons in frogs held at an ambient temperture of 15°C show no apparent cell body response to injury. The 15°C neurons retain their normal morphology, continue to synthesize and transport normal levels of acetylcholinesterase activity, and sustain their normal reflex connections. However, despite the apparent absence of a cell body response, the proximal nerve stump begins to regenerate. The dissociation of cell body changes and peripheral axon regeneration may offer some insight into the mechanisms responsible for both phenomena. The initiation of the cell body response, for example, does not appear to be due to the elimination of a normal peripherally-derived axonal constituent. Injured axons at 15°C were still able to acquire and transport horseradish peroxidase from the point of transection to the cell body. This suggests that normal retrogradely-transported material should also be drained from the injured 15°C axons over time, yet a cell body response does not appear. Similarly, the initiation of axonal sprouting and regeneration may not depend on alterations in the cell body. The 15°C proximal nerve stump begins to regenerate after a post-axotomy latent period of approximately 4.5 days. Regeneration of the most rapidly growing axons proceeds at a rate of 0.6 mm/day for at least the first 21 days. Subsequently, regeneration slows and may cease. Reinnervation of skeletal muscles 3cm distal to the point of injury (using either transection or crush) has not been observed after recovery intervals as long as 92 days. We propose that changes in the local environment surrounding the injured axon, e.g. increased vascular or axonal permeability to exogenous protein, may serve as a trigger for the initiation of axonal growth. Subsequently, the local influences are supplanted by intraaxonal contributions from the cell body which maintain continued axonal regeneration. In the absence of cell body support regeneration slows and may stop. (Supported by NIH NS 15065).

153.7 NERVE REGENERATION AND MUSCLE REINNERVATION. P.K. Law and T.E. Bertorini*. Dept. Neurol., Univ. of Tennessee, Memphis, TN 38163.

Reinnervation of denervated muscles depends on nerve regeneration and the presence of denervation changes in the muscle. This study tests if nerve regeneration is triggered by the muscle changes. We tested if earlier development of denervation changes in the muscle would lead to earlier reinnervation, and possibly, better recovery of muscle function. The sciatic nerve of 1-month-old C57BL/6 mice was cut *in situ* in both legs just distal to the bifurcation with the femoral nerve. The right soleus nerve was then cut where it entered the soleus. Whereas reinnervation of right and left solei required regeneration of similar lengths of nerves, the right soleus should develop denervation changes sooner because its shorter nerve stump provided less trophic support. Conversely, because the left soleus was trophically maintained longer by a longer nerve stump, its fibers should become less atrophic and generate greater tensions, provided that both solei were reinnervated simultaneously. The earliest detected reinnervation occurred at 3-4 weeks after surgery when supramaxial nerve stimulations of any soleus elicited twitch tensions of variable amplitudes. Both solei of the mouse responded to nerve stimulation indicating that the right soleus was not reinnervated earlier than the left. Due to incomplete reinnervation and inconsistence of immature motor unit responses, the tensions at this stage were not quantified. At 5-6 weeks and at 14 weeks after surgery, the left solei generated greater twitch (Po) and tetanus (Pt) tensions than the right. Although Pt increased from 5-6 weeks to 14 weeks, Po remained unchanged. Mean contraction time (CT) and half-relaxation time (½RT) were longer for the right solei than the left at 5-6 weeks. These time differences disappeared at 14 weeks. Fiber atrophy was more pronounced in the right than the left.

	5-6 Weeks		14 Weeks	
	Right	Left	Right	Left
Po(g)	1.80±0.55	2.66±0.99	1.79±0.31	2.73±0.68
Pt(g)	4.20±1.23	9.90±1.37	9.13±3.98	15.13±4.61
CT(msec)	24.20±4.70	13.70±2.21	10.00±1.31	9.75±2.05*
1/2RT(msec)	41.90±11.84	15.90±3.51	12.44±3.88	12.33±6.91*

In vivo measurements at 37°c; $\bar{x} \pm$ SD shown; all differences significant at P<0.005 by paired-t tests except *, not significant; 10 mice at 5-6 weeks, 8 mice at 14 weeks.

We conclude that the nerve regenerates primarily in response to injury. Unlike axonal sprouting, such regeneration is not initiated by denervation changes in the muscle. In addition, the muscle function recovered following denervation is dependent on the neurotrophic support prior to reinnervation. (Supported by MDA and NSF PCM 7921008 awarded to P.K.L.)

153.8 INDUCTION OF CHEMOSENSITIVITY IN A MUSCLE NERVE AFTER GRAFTING THE CAROTID BODY INTO THE MUSCLE. L. Monti-Bloch*, L.J. Stensaas and C. Eyzaguirre. Dept. Physiol., Univ. Utah Col. Med., Salt Lake City, UT 84108.

An important problem in neurobiology is to determine whether or not the periphery can influence the specificity of sensory fibers. To study this, the carotid body of six cats was unilaterally removed under anesthesia, grafted into the pelvic end of the tenuissimus muscle and the pelvic branch of its nerve sutured to the graft. A small piece of fat tissue served as a control implant in two other animals. Five months later the cats were again anesthetized and the graft implantation site exposed by opening the skin and making a paraffin-filled pool. The knee branch of the tenuissimus nerve was cut as was the main trunk of the nerve near the sciatic. Its distal end was then placed on electrodes to record afferent discharges. The cats were allowed to spontaneously breathe room air through a tracheal cannula. The grafted carotid bodies were stimulated by delivering special gas mixtures through the cannula or by drugs topically applied to the surface of the graft. In five animals the grafted carotid body survived and was reinnervated by tenuissimus nerve fibers. It did not survive in one animal where only a neuroma was observed. In the five successfully implanted cats, inhalation of 100% N_2 or 5% CO_2 in O_2 and applications of NaCN (1-10 µg) increased the discharge frequency of 9 units while 2 were unaffected or depressed. ACh (25-200 µg) increased the activity of 6 units, depressed 2 and was without effect in 3. Nicotine (0.5-10 µg) increased the afferent activity of all (11) fibers. Bethanechol (50-100 µg) and dopamine (40-200 µg) had variable effects. These drugs alternately increased or depressed the discharge of several fibers. All afferent fibers connected to the grafts responded with an increased discharge to mechanical tapping and muscle stretch. The conduction velocity of the active fibers was 12.5-20 m/sec at 31-35° pool temperature. The normal tenuissimus muscle and preparations containing transplanted fat tissue or the neuroma responded to tapping and to applications of ACh or nicotine as a consequence of muscular and, presumably, intrafusal contractions. These preparations did not respond to N_2, CO_2, NaCN or dopamine. Electron microscopy of grafts with a chemosensitivie response revealed numerous glomus (type I) cells--some of them innervated--and sustentacular (type II) cells. It is concluded that carotid body cells can induce chemosensitivity in muscle nerve fibers which also have mechanosensory properties. Supported by grants NS 05666, NS 07938 and GM 24487.

153.9 THE EFFECT OF TESTOSTERONE ON THE REGENERATION OF THE HYPOGLOSSAL NERVE IN MALE RATS. W.H.A. Yu. Dept. of Anatomy, Mount Sinai Sch.of Med. New York, N.Y. 10029.

Administration of testosterone proprionate (TP) to female rats after hypoglossectomy accelerated axonal outgrowth (Yu & Srinivasan, Exp.Neurol. 71:431,1981). The present study was designed to determine whether or not TP promotes nerve regeneration in male rats and to trace the regenerating fibers as they travel to their targets. In 6 weeks old rats the hypoglossal nerve was transected unilaterally in the neck region proximal to its bifurcations. The cut ends of the nerve were opposed without suturing. After surgery, the rats were divided into two groups and treated as follows: 5mg TP in 0.1 ml sesame oil, 3 times per week; or oil vehicle alone. Seven rats from each group were killed 1,2,3, and 4 weeks post-operatively (PO). 24h prior to killing, 50 ul of a 10% horseradish peroxidase (HRP) solution was injected into the midline of the tongue. The presence of HRP-labeled neurons in the hypoglossal nucleus ipsilateral to the side of axotomy indicates that the regenerating fibers reached the tongue. No HRP-labeled neurons were seen in the side of lesion 1 week PO. However, labeled neurons were present at 2 weeks PO; their number was significantly higher in the TP group. By 3 and 4 weeks PO, there was no difference in the degree of regeneration between the two groups. Four weeks PO, another 7 rats each from both groups were subjected to bilateral resection of the medial branch of the hypoglossal nerve prior to the HRP injection. This procedure blocked HRP transport in the medial division but allowed the neurons whose axons reached the tongue via the lateral division to be labeled by HRP. A comparison of the patterns of labeled neurons in the hypoglossal nuclei between ipsilateral and contralateral to the side of the first lesion indicated that regenerating fibers entered the two divisions at random. These findings suggest that TP promotes nerve regeneration also in the male rat; however, the accelerated regeneration does not facilitate the reestablishment of the specificity of innervation. The somatotopic organizations were altered after regeneration similarly in both groups. Supported by a grant from the Organon Pharmaceuticals.

153.11 IN VIVO MODEL FOR NERVE REGENERATION: PRESENCE OF NEURONOTROPHIC FACTORS. Frank L. Longo*, Göran Lundborg*, Marston Manthorpe, Stephen D. Skaper and Silvio Varon. Dept. Biol., Sch. Med., Univ. Calif. San Diego, La Jolla, CA 92093

Lundborg and coworkers have developed an in vivo model, where pre-formed cylindrical chambers are implanted into adult rats in such a way that proximal and distal stumps of a resected nerve are inserted into the opposite ends of the chamber, allowing up to a 1 cm gap between them. Within 1-3 months, a fully organized nerve structure develops across the gap culminating in some motor and sensory function (Lundborg & Hansson, Brain Res. 178, 153, 1979; J. Hand Surg. 5, 35, 1980). A silicone tube can replace the previously used "mesothelial" chamber, with similar results. Within this silicone chamber, however, the regenerating nerve structure is surrounded by fluid, which can be collected and tested in vitro for neuronotrophic activities. We have examined fluid collected from chambers implanted in the rat which has received both proximal and distal stumps (P-D), only one stump (P-O or O-D, respectively, with the empty end ligated), or neither (both ends open). Miniturized test cultures included sensory neurons from newborn mice, and sensory, sympathetic and spinal cord neurons from embryonic chick (Varon et al, Dev. Brain Res. 1, 73, 1981; Longo et al, Trans. Am. Soc. Neurochem. 12, 188, 1981). All in vivo-derived fluids displayed neuronotrophic activity for all the neurons tested, and exhibited much higher titers than observed from in vitro cell conditioned media. Activity was present at least as early as 6 days after chamber implantation. The results indicate that such neuronotrophic factors i) are not solely produced in vitro, and ii) can occur in the immediate environment of a regenerating nerve in vivo. Their direct relevance to the regeneration process is currently being examined.

153.12 EFFECT OF PARTIAL TARGET AREA ROTATION ON THE REGENERATION OF SPECIFIC CRAYFISH NEUROMUSCULAR CONNECTIONS. James F. Clement*, William P. Hunt and Samuel J. Velez. (SPON: M. Marin-Padilla). Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

The six axons that innervate the superficial flexor muscles of the crayfish can regenerate their connections with a high degree of specificity (Ely & Velez, Soc. Neurosci. Abstr., Vol. 5, p. 677, 1979). In previous work we have reported that if the target area of the nerve is changed, some of the neurons are capable of forming normal maps while others do not form normal patterns (Hunt & Velez, Soc. Neurosci. Abstr., Vol. 5, p. 679, 1979). When transplanted to the contralateral muscle, axons 2 and 3 form normal connections but axons 1 and 4 are unable to do so. In control animals, and in contralateral transplants, the nerve approaches the muscle field from a medial-to-lateral direction; the first fibers receiving connections are always on the medial edge of the muscle. We are presently studying the changes in the connectivity maps that might occur as a result of changes in muscle fiber spatial arrangements. The superficial flexor nerve was transplanted to its contralateral muscle and was secured in place at the medial-lateral junction, approximately at the mid-point of the muscle field. The medial-lateral junction separates the field of innervation for most of the axons in this system. The nerve was allowed to regenerate for 10 weeks, the time period for complete regeneration, and the animals were analyzed by recording junction potentials from all the muscle fibers and closely matching them with the spikes of identified axons. Preliminary results indicate that the regenerated maps of all axons studied are not affected by the new entry point of the nerve into the muscle field. The connectivity patterns were similar for axons 1, 2, 3 and 4 when the nerve grew into the contralateral muscle following the normal medial-to-lateral growth path and when the nerve grew following a central-to-edges growth path. This suggest to us that this nerve is capable of following a spatial gradient on the surface of the muscle.

153.13 EFFECT OF INTERSEGMENTAL TRANSPLANTS ON THE REGENERATION OF SPECIFIC CRAYFISH NEUROMUSCULAR CONNECTIONS. Ji-Chuu Hwang*, William P. Hunt and Samuel J. Velez. Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

The superficial flexor muscle of the third abdominal segment of the crayfish Procambarus clarkii is innervated by six axons which distribute their innervation in a very specific pattern over the muscle surface (Velez & Wyman, J. Neurophysiol. 41: 75-96). Axon 3 innervates all the medial fibers and most of the laterals; the probability of lateral muscle fibers receiving connections from this axon decreases as the lateral edge of the muscle is approached. Axon 4 innervates all the lateral fibers and some of the medials; the probability of medial muscle fibers receiving connections from this axon increases as the lateral fibers are approached. The connections to the superficial flexor muscles of the second abdominal segment were examined and a specific connectivity map was also found. The maps of homologous axons 3 and 4 on the second segment were the reverse of the maps of axons 3 and 4 on the third segment. We investigated the effect of changing the target area of the third segment nerve on the connectivity patterns of axons 3 and 4. The third segment nerve was transplanted into the second segment of the animal, and analysis was performed at regular intervals after the operation. Analysis consisted on recording junction potentials from the muscle fibers and matching them with the spikes recorded from the spontaneous activity of the nerve in isolated abdomens. Preliminary results indicate that during the initial stages of regeneration, axon 3 growing into the second segment forms the pattern of connections that correspond to the third segment. However, axon 4 growing into the second segment forms the pattern of connections that correspond to the second segment. Thus, the connectivity maps of the two axons are the same. This suggest to us that the growth pattern of axon 3 is not being affected by changes in the target, whereas the growth pattern of axon 4 is more sensitive to alterations in its environment.

153.14 THE DISTRIBUTION OF REGENERATED FIBER TRACTS IN THE GOLDFISH SPINAL CORD STUDIED BY USE OF HORSERADISH PEROXIDASE (HRP). P. F. Moebs* and S. M. Bunt. Dept. of Anatomy, Med. Univ. of S.C., Charleston, S.C. 29425.

Because of renewed interest in the possibility of obtaining regeneration in the mammalian spinal cord, we have examined the ability of regenerating fiber tracts to maintain or regain their normal pathways following a spinal cord transection. This study also investigates whether preservation of normal fiber pathways is essential for formation of appropriate connections in the regenerated goldfish spinal cord.

Spinal cords were transected in 70 goldfish. Verification of complete transection in randomly chosen fish was obtained using the Holmes' silver technique to demonstrate nerve fibers. Three months later, regeneration was observed both by histological examination and by return of sensation and voluntary movement in caudal segments.

Descending and ascending tracts were identified in normal goldfish by transecting the spinal cord and examining sections for degeneration at both light and electron microscopic levels. Comparison of the above with sections of the regenerated spinal cord revealed that although a great disruption of the normal fiber tracts was seen at the transection site, the morphology of spinal cord segments more distal to this site appeared normal with little evidence of displaced fiber tracts.

HRP labeling of the regenerated spinal cord either rostral or caudal to the original transection demonstrated regenerated ascending fibers terminating in the first few segments rostral to the transection site, while regenerated descending fibers could be labeled up to 1 cm caudal to the site.

To investigate the fine ordering of regenerated fiber tracts, partial HRP applications were made either rostral or caudal to the transection site in the regenerated cord and the distribution of the labeled fibers examined in 2 μm plastic sections. Although displaced fiber bundles were observed in some sections of regenerated spinal cord, the sections more distal to the transection site appeared grossly normal.

We conclude, therefore, that maintenance or restitution of normal fiber ordering at the site of the spinal cord injury may not be necessary for return of fibers to their normal pathways. (Supported by NIH grant EY03414)

154.1 SPROUTING OF CATECHOLAMINERGIC AXON TERMINALS IN THE PARTIALLY DEAFFERENTED INTERPEDUNCULAR NUCLEUS. Z. Gottesfeld. Department of Neurobiology and Anatomy, The University of Texas Medical School, Houston, Texas 77030

The interpeduncular nucleus (IPN), a mesencephalic tegmental structure, receives a massive fiber input, especially from the habenular complex (Hb), via the fasciculus retroflexus (FR). Some of these fibers have been characterized as cholinergic, while others have been shown to contain substance P. However, the noradrenergic and dopaminergic innervation of the IPN project to this nucleus via pathways other than the FR. Thus, by removing the FR projections from the IPN, the catecholaminergic innervation will remain intact in this nucleus. The question addressed by this work is whether or not these spared axon terminals will grow new sprouts in the partially deafferented IPN. Sprouting was assessed both chemically and by fluorescent histochemistry.

Radiofrequency lesions were produced in the Hb of male Sprague Dawley rats (200g). Sham-treated control animals underwent similar surgical procedures except lesioning current was not passed. After survival periods of 1 day, 3 days, 6 weeks or 6 months, the rats were killed by decapitation. Brain sections (300 μm thick) were cut in a cryostat at -8°C and the accuracy of the lesions were verified histologically in 60 μm thick sections. Two tissue pellets (750 μm id) were removed from the IPN, then homogenized in 100 μl of 0.1 N perchloric acid and aliquots were taken for catecholamine assays[1] and for protein determination[2]. No significant changes were found in norepinephrine (NE) or dopamine (DA) levels following 1 or 3 days survival after Hb lesions. However, both NE and DA increased significantly ($P<0.001$) after surviving lesions for 6 weeks or 6 months. The subsequent use of fluorescent histochemistry[3] demonstrated increased proliferation of catecholaminergic axon terminals following the long-term survival periods.

Thus, the combined use of chemical assays and morphological visualization provide evidence that NE and DA have the capacity to sprout concurrently in the partially deafferented IPN.

154.2 THE EFFECT OF ACUTE AND CHRONIC DENERVATION ON THE RAT SPINAL CORD. H. Markus*, D. Krushelnycky*, B. Pomeranz. Dept. of Zoology, University of Toronto, Toronto, ONT., CANADA M5S 1A1.

Previous reports indicate that following peripheral nerve or dorsal root lesion, dorsal horn cells respond to electrical or mechanical stimulation of areas of skin outside their normal receptive fields. In this study the left sciatic nerve was lesioned and ligated in mid-thigh. 23 days later the right sciatic was acutely lesioned and extracellular unit recordings were made from those areas of the cord which normally receive input from the saphenous and sciatic nerves.

In the acutely denervated side we found the area of the cord which responded to mechanical stimulation of the leg as well as to electrical stimulation of the saphenous nerve. Caudal to this area there was a 2nd zone which responded to electrical stimulation of the saphenous nerve but not to mechanical stimulation of the leg in regions normally served by the sciatic afferents. Caudal to this there was a 3rd zone which responded to mechanical stimulation of the leg and tail in regions above the site of the sciatic lesion but not to electrical stimulation of the saphenous.

In the chronically denervated side there was a rostral zone which responded to electrical stimulation of the saphenous nerve as well as mechanical stimulation of the leg. Caudal to this zone was a 2nd zone which responded to mechanical stimulation of the leg and tail but not to electrical stimulation of the saphenous. The border of the electrically and mechanically responsive zone was more caudal on the chronically denervated than on the acutely denervated side of the cord suggesting that chronic denervation caused the saphenous inputs to spread caudally several mm into the sciatic zone of the cord. In the acutely denervated side these inputs may exist but are weak and therefore only activated electrically. In the chronically denervated side the inputs are strengthened and therefore respond to mechanical stimulation.

154.3 ACUTE DEXAMETHASONE TREATMENT ALTERS AXON SPROUTING IN THE DENTATE GYRUS OF THE HIPPOCAMPAL FORMATION. Stephen W. Scheff and Steven T. DeKosky. Depts. Anatomy & Neurology, Univ. of Kentucky, Lexington, Kentucky, 40536.

The dentate gyrus of the hippocampal formation has been utilized extensively to study reactive synaptogenesis (axon sprouting) in the mammalian CNS. Previous experiments have shown that animals treated continuously with hydrocortisone or corticosterone, two naturally occuring glucocorticoids, manifest reduced axon sprouting in the dentate gyrus. The present study was designed to test whether or not a synthetic glucocorticoid, dexamethasone could be effective in altering the same growth response. Dexamethasone is the glucocorticoid frequently administered to neurosurgical patients post-operatively or following traumatic brain injury.

Adult male Sprague-Dawley rats, 75-90 days of age, received a unilateral electrolytic lesion of te entorhinal cortex. This lesion partially denervates the dentate gyrus ipsilaterally. At the same time of surgery the animals received glucocorticoid treatment which continued for eight consecutive post-operative days. Treatment consisted of a single daily injection of dexamethasone (0.2mg/kg) subcutaneously, a dosage similar to that administered to human patients. Control animals were injected with the vehicle alone. Following the eight days of treatment all animals were allowed an additional seven days of convalescence.

The brains were examined for changes in hippocampal circuitry as a result of axon sprouting elicited by partial denervation of the dentate gyrus. The cholinergic projections were monitored with AChE histochemistry and revealed little qualitative difference between steroid treated animals and controls. Changes in the commissural-associational fibers, as monitored by the Holmes' fiber stain, revealed a statistically significant difference between the two groups. Control animals showed a normal sprouting response in agreement with previous results. Dexamethasone treated rats showed a significant decrease in the sprouting response as compared to controls. Finally, sections from each brain were stained with Cajal's gold sublimate for astrocytes. Dexamethasone treated animals showed hypertrophy of astrocytes throughout the hippocampal formation.

Dexamethasone, a synthetic glucocorticoid has thus been shown to depress the sprouting reaction in the dentate gyrus. The mechanism underlying this effect may relate either to its specific effects in the hippocampal system, which contains numerous glucocorticoid receptors, or as a result of a generalized effect on CNS inflammatory and/or immune response.

154.4 NEONATAL SEPTAL LESIONS RESULT IN SYMPATHOHIPPOCAMPAL INNERVATION. K.A.Crutcher.Department of Anatomy, University of Utah College of Medicine, Salt Lake City, Utah 84132.

Sympathetic axons,arising in the superior cervical ganglion, appear in the rat hippocampal formation and neocortex following cholinergic denervation of these brain regions. Such sympathetic sprouting appears to occur specifically in response to loss of central cholinergic fibers in the adult since denervation of other cortical afferent fibers does not elicit this response. The purpose of the present study was to determine whether the transmitter identity, i.e., the "cholinergicity", of the lost fibers, is related to subsequent sympathetic sprouting. This was accomplished by destroying the septum before evidence of cholinergic innervation to the hippocampal formation develops e.g., high-affinity choline uptake, acetylcholine synthesis, choline acetyltransferase activity, and acetylcholinesterase activity. The septal region was aspirated on postnatal day 2 or 3. At 2 months of age the animals were killed and sections through the hippocampal formation were examined with acetylcholinesterase (AChE) and fluorescence histochemistry for the presence of cholinergic and sympathetic fibers, respectively.

In all cases in which the medial septum had been destroyed there was a tremendous loss of hippocampal AChE staining compared to control littermates. Adjacent sections stained for noradrenergic fluorescence revealed the presence of sympathetic axons within the hippocampal formation with a distribution and extent indistinguishable from that obtained following adult septal lesions. In those cases in which the cingulum had also been interrupted sympathetic fibers were present within the cingulate cortex posterior to the level of the lesion. Sympathetic fibers were not present within the hippocampal formation or cingulate cortex ipsilateral to a superior cervical ganglionectomy. These results indicate that the "cholinergicity" of the lost septohippocampal pathway is not related to sympathohippocampal sprouting. However, it is not possible to rule out a potential role for non-cholinergic or pre-cholinergic axons in eliciting sympathetic sprouting since recent retrograde tracing studies with the fluorescent marker bisbenzimide demonstrate the presence of numerous septohippocampal axons as early as the day of birth.

Based upon the specificity of this neuronal rearrangement and the early age at which it can be elicited, it is hypothesized that the same tropic factor accounts for the normal development of the septohippocampal innervation and sympathetic sprouting following septal lesions. The normal lack of sympathohippocampal fibers may be accounted for by their later arrival compared to septal fibers. SUPPORTED BY NS 17131-01.

154.5 SYMPATHETIC INNERVATION OF PINEAL AND HABENULA INCREASES AFTER SEPTAL LESIONS: COVARIATION WITH SYMPATHOHIPPOCAMPAL SPROUTING. F.H. Gage and M.D. Chafetz (SPON:J. Flynn). Chemistry of Behavior Program, Psychology Department, Texas Christian University, Fort Worth, TX 76129.

Sympathetic nerve endings innervate the pineal body (Axelrod, 1974) and habenula (Bjorklund, Owman, & West, 1972). During the course of a quantitative study of sympathohippocampal sprouting, measurements of the sympathetic innervation of pineal and habenula were obtained. If a cell body response to distal axotomy occurred during the growth of sympathohippocampal fibers, central sites of normal sympathetic innervation might be affected.

The measurement procedure used was developed by Chafetz and Gage (1981). Two specific and independent indices of the field of fluorescence are obtained with this procedure: fiber intensity (normalized for fading) and areal density. The animals were killed for preparation of fluorescence histochemistry (de la Torre and Surgeon, 1976) between 1 and 39 days after septal lesions. Statistically significant positive correlations were found for areal density in pineal, fiber intensity in habenula, and areal density in hippocampus. These correlations indexed an increase in the innervation of these areas over time. The results were discussed as relating to a retrograde response of the cell body to distal axotomy. The implications for functional changes as a result of septal lesions were also discussed.

154.6 REPEATED ADMINISTRATION OF HIGH DOSES OF ETHANOL MAY INHIBIT LESION-INDUCED AXONAL SPROUTING IN THE RAT HIPPOCAMPUS. M.D. Lind*, J.R. West, R.M. Demuth*[1], E.S. Parker*[2], R.L. Alkana[3], and A.C. Black, Jr. Dept. Anatomy, Univ. Iowa Coll. Med., Iowa City, IA, [1]Dept. Psychol., Univ. N. Illinois, De Kalb, IL, [2]Lab. Clin. Studies, N.I.A.A.A., Bethesda, MD, and [3]School of Pharmacy, USC, Los Angeles, CA.

Axonal sprouting by several different inputs produces alterations in the characteristic width of the laminated afferent zones of the molecular layer of rat dentate gyrus following unilateral electrolytic lesions of the entorhinal cortex (EC). Adult Sprague-Dawley rats were given 6 gm/kg-day ethanol by gastric intubation (n=5) or 11.6 ± 0.5 gm/kg-day ethanol in a liquid diet[1] (n=8) for 2 weeks. They were then given a unilateral electrolytic EC lesion under ether anesthesia and continued on the ethanol regimen for an additional 9 days after lesion. Rats were sacrificed and their brains processed for acetylcholinesterase (AChE) histochemistry according to a modification of the method of Geneser-Jensen and Blackstad[2]. Results were compared to normal controls (n=5), and controls which had received unilateral EC lesions without ethanol (n=5). Intensified AChE staining in the outer molecular layer is the result of a proliferation of AChE-containing terminals (presumably septal in origin) and is normally observed as soon as 4-5 days post-lesion. Although all ethanol-treated rats exhibited increased AChE staining in the outer molecular layer, the increase was less obvious in the liquid diet group. Moreover, the commissural/associational (C/A) zone usually exhibits increased width and diminished AChE staining between 5 and 12 days after lesion[3]. This change in staining is believed to denote the sprouting of C/A fibers into a more distal region of the molecular layer. The width of the pale staining C/A zone was significantly increased in all lesioned rats except those receiving the higher dose of ethanol by liquid diet. Interpretation: Sprouting occurs in the C/A zone following EC lesion, but such sprouting is reduced in animals receiving large daily doses of ethanol. Thus high concentrations of ethanol may have deleterious effects on axonal sprouting occurring in response to brain injury. [1]Ethanol was added to a liquid diet (Bio-Serv 711-PR) so that it represented 35% of the total calories available to the rats as the sole source of food and water. [2]Z. Zellforsch. 114:460-481, 1971. [3]Nadler et al., J. Comp. Neurol. 171:561-588, 1977. (Supported by grant AA-03884 to J.R.W. from the N.I.A.A.A., and by grants from the National Council on Alcoholism to JR.W. and A.C.B.).

154.7 AXONAL SPROUTING AT THE NEUROMUSCULAR JUNCTION OF ADULT AND AGED RATS. G. E. Fagg*, S. W. Scheff and C. W. Cotman (SPON: V. Vijayan). Dept. of Psychobiology, University of California, Irvine, CA 92717.

Partial denervation of a skeletal muscle in the adult animal is followed within a few days by a characteristic repair response, involving the growth of fine processes (sprouts) from the remaining intramuscular nerves. These sprouts, derived either from the end-plate region (terminal sprouting--TS) or from nodes of Ranvier (collateral sprouts--CS), eventually reinnervate the denervated muscle fibers. In the present study, we have compared the response to unilateral partial denervation (L4 transection) of the soleus muscle in adult (3 month-old) and aged (27 month-old) Sprague-Dawley rats. Two weeks postoperatively, muscles were stained using the zinc iodide/osmium tetroxide procedure, and sprouting was assessed by measuring the percentage of end-plates with TS (%TS), the percentage of pre-terminal axons with CS (%CS), the end-plate length and the length of TS. In adult control animals, end-plates were small (43 ± 1 um), %TS and %CS were low (6 ± 2 and 7 ± 2, respectively) and TS were short (23 ± 2 um). Partial denervation significantly (P 0.01) increased these parameters by 1.2-fold (end-plate length), 3.8-fold (%TS), 2.6-fold (%CS) and 1.7-fold (TS length); there were no differences between contralateral and control muscles. In aged controls, end-plates were much larger (65 ± 4 um) and more complex, frequently comprising 2-3 components arising from the terminal axon and 1 or 2 collateral sprouts; %TS and %CS were high (19 ± 2 and 55 ± 10, respectively) and TS were relatively long (51 ± 7 um). In this age group, partial denervation significantly increased only end-plate length and %TS (1.3- and 1.7-fold, respectively); again, there were no differences between contralateral and control muscles. Hence, relative to controls, aged rats exhibit a more limited capacity than adults to respond to nerve injury with compensatory axonal growth. Since aged animals show evidence of considerable sprouting prior to partial denervation, one explanation may be that there is a maximum limit to the amount of axonal growth for each motor neuron determined by the synthetic capacity of the cell. Alternatively, the diminished response in aged animals may be due to a longer latency or higher threshold for repair than in adults. Supported by NIA grant AG00538.

154.8 THE FATE OF DISUSE-INDUCED TERMINAL SPROUTS AT THE RAT NEUROMUSCULAR JUNCTION. Greg L. Harris* (SPON: A.R. Light). Dept. Physiol., Sch. Med., U. of N.C., Chapel Hill, N.C. 27514

The relationship between motor nerve terminal sprouting and junctional transmitter release was studied in disused rat extensor digitorum longus (EDL) muscles following an 8-9 day conduction block of the sciatic nerve with tetrodotoxin (TTX). Mean quantum content (m) and the frequency of miniature endplate potentials (m.e.p.p.s) were estimated from intracellular recordings of disused and control (contralateral EDL) muscle fibers in excised muscle-nerve preparations superfused by an oxygenated low Ca^{2+}-high Mg^{2+} saline solution. Following the electrophysiological experiments, the muscles were stained to allow visualization of the motor nerve terminals and junctional acetylcholinesterase. Endplate size was estimated by tracing the course of the nerve terminal arborization along the surface of single dissected muscle fibers.

As was the case for rat soleus muscles (Snider and Harris, Nature 281:69, 1979.), the synaptic efficacy of EDL muscles was significantly enhanced by disuse. The mean m and m.e.p.p. frequency (f) of disused junctions were ~3.5 and ~2 times the control values, respectively. Seventy percent of the disused and 5% of the control junctions were judged to possess terminal sprouts. The measured nerve terminal lengths (Ln) of disused junctions were, on the average, 1.7 times the control lengths.

The Ca^{2+} dependence of evoked release and the effects of K^{+}-induced depolarization on f were compared at junctions of disused and control muscles to determine if the increased synaptic efficacy of disused junctions may be due, in part, to alterations in the properties of the transmitter release process. There were no significant differences in the response of disused and control junctions to these tests.

Junctional morphology and synaptic efficacy were also studied 4 and 10 weeks following the resumption of muscle activity in animals permitted to recover from an 8-9 day TTX block. At 4 weeks, the incidence of sprouting at disused endplates had returned to control levels. The mean Ln of disused junctions, however, was 1.5 times the mean control length. The quantum content and f at disused junctions were ~1.7 and ~2 times the respective control values. At 10 weeks, there were no significant differences in Ln, m or f at disused and control junctions. The similarity of morphological and electrophysiological parameters at 10 weeks appeared to be due to increases in control rather than decreases in disused values.

The data support the hypothesis that terminal sprouts are able to form functional connections with disused muscle fibers.

(supported by USPHS grant NS 10319)

154.9 GROWTH OF SYMPATHOHIPPOCAMPAL FIBERS MEASURED QUANTITATIVELY USING A NEW MICROFLUOROMETRIC METHOD. M.D. Chafetz and F.H. Gage (SPON: M. Emmett-Oglesby). Chemistry of Behavior Program, Psychology Department, Texas Christian University, Fort Worth, TX 76129.

Sympathetic nerve endings innervate the hippocampal formation as a result of damage to septohippocampal fibers (Loy & Moore, 1977; Stenevi & Bjorklund, 1978). These sympathetic endings are not observed as a result of damage to entorhinal afferents or to specific monoamine projections, nor are they seen in undamaged animals. In order to study the functional significance of this sympathetic growth, a quantitative index of fiber density is needed. This index should be specific for the fluorophore, sensitive to the experimental manipulations, and easily obtained for practical use. No such index is currently available.

A method was developed using a microspectrofluorometer to sample fields of fluorescence at specific wavelengths. Multivariate analyses were used to analyze the variables obtained with several different criteria. Two independent components (n=309) were identified: fiber intensity and areal density. The indices of density were identified as the best discriminators between animals with septal lesions and sham controls. Indices of intensity, normalized for fading, exhibited a statistically significant correlation with time (days) between days 1 and 39 after septal lesions. These measures were insensitive to several of the criteria employed. This finding indicated that different investigators who might use slightly different criteria would obtain a consistent measurement of the two underlying variables.

154.10 INCREASES IN INCORPORATION OF PROTEIN PRECURSORS DURING REINNERVATION OF RAT DENTATE GYRUS ARE PARALLELED BY INCREASES IN THE INCIDENCE OF POLYRIBOSOMES ASSOCIATED WITH DENDRITIC SPINES. Oswald Steward and Barry Fass. Dept. of Neurosurgery, University of Virginia School of Medicine, Charlottesville, VA 22908.

When the dentate gyrus (DG) is denervated by destroying afferents from the ipsilateral entorhinal cortex (EC), the denervated dendrites are reinnervated by several surviving afferent systems. Recent quantitative autoradiographic studies designed to assess protein synthesis revealed an increased incorporation of protein precursors in the denervated neuropil during the reinnervation, especially 6-12 days postlesion (Fass & Steward, Anat.Rec., 199; 80A, 1981). The present study evaluates some aspects of the distribution of polyribosomes in granule cell dendrites during the period of reinnervation and increased incorporation.

Adult rats received unilateral EC lesions and were prepared for electron microscopy 2,4,6,8,10,12,14, and approximately 180 days postlesion. The incidence and location of polyribosomes in denervated dendrites (ipsilateral to the lesion) was compared with that on the contralateral (control) side and in the DG of intact rats.

In the control DG, granule cell dendrites contain polyribosomes which often are associated with dendritic spines, lying under the intersection of the spine neck and main dendritic shaft. No polyribosomal rosettes were observed in spine heads in control material. Quantitative analyses of identified neck/shaft intersections in mid proximo-distal locations along the dendrite (within EC terminal field) revealed that 10% of the intersections has associated polyribosomes. In denervated dendrites, the incidence of polyribosomes under neck/shaft intersections increased during the period of reinnervation. The increase first became apparent 6 days postlesion, peaked at about 8 days, and declined thereafter. The average incidence of polyribosomes increased almost 4-fold at 8 days postlesion, with 38% of the intersections having polyribosomes. In contrast to the control, polyribosomes were also found in spine heads in the denervated DG of 6- and 8-day cases, immediately subjacent to the postsynaptic membrane specialization.

The altered distribution of polyribosomes closely parallels the increased incorporation of protein precursors observed during the period of reinnervation. Both changes become apparent at about 6 days postlesion, peak at 8 days, and decline thereafter. Although our studies were performed on separate groups of rats, the parallels suggest that the polyribosomes might be responsible for the increased incorporation. We propose that these changes reflect the synthesis of postsynaptic protein(s) associated with the reinnervation process. Supported by NIH Grant 5 RO1 Ns12333-06 and RCDA 5 K04 NS00325 to O.S.

154.11 ATTENUATION OF LOCOMOTOR HYPERACTIVITY AFTER BILATERAL PRIMING- AND SECONDARY-LESIONS OF ENTORHINAL CORTEX. Barry Fass and Oswald Steward. Dept. of Neurosurgery, University of Virginia School of Medicine, Charlottesville, VA 22908.

Although bilateral lesions of the entorhinal cortex (EC) partially denervate the dentate gyrus, surviving afferent systems proliferate and reinnervate the vacated synaptic sites on dentate granule cell dendrites (Lynch et al., Brain Res., 110:57, 1976; ibid, 42: 311, 1972). The extent and/or rate of proliferation apparently can be increased by damaging the EC progressively;i.e. by making a priming lesion of the medial EC, followed several days later by a secondary lesion of the remaining EC (Scheff et al., Brain Res., 150: 45, 1978). The present study assesses some of the behavioral consequences of progressive EC lesions. Simultaneous bilateral lesions of the EC result in an increase of open-field locomotor activity which peaks 4-5 days postlesion and subsequently "attenuates" (returns toward control levels)(Steward et al., Brain Res. Bull., 2: 41, 1977). The parallel between attenuation of hyperactivity and sprouting implies that the two might be related. If the behavioral changes are related to sprouting, then progressive bilateral lesions of the EC might facilitate this attenuation.

Adult male albino rats were tested in an open field for 4 consecutive days prior to receiving bilateral lesions of the medial EC or control surgery. Half of the operated rats received secondary bilateral lesions of the remaining EC 11 days later. They underwent testing for 6 consecutive days beginning on day 13. The remaining operated rats were tested similarly without receiving secondary lesions. Another group of rats received simultaneous bilateral lesions and was tested similarly.

Progressive bilateral lesions resulted in virtually complete destruction of the medial and lateral EC, whereas medial lesions were selective. Despite intergroup differences in lesion size, the two operated groups exhibited comparable levels of locomotor activity between 13 and 18 days postlesion. Intact control rats showed lower and fairly stable levels of activity. By contrast, rats with simultaneous bilateral lesions displayed greater activity during the 13-18 day postlesion interval than did rats with progressive lesions of equivalent size. The present findings indicate that bilateral priming- and secondary-lesions of the EC produce increases in locomotor activity similar to those produced by bilateral lesions restricted to the medial EC, but that the increases are less than those after simultaneous bilateral lesions. These findings are consistent with the proposal that progressive lesions produce less severe behavioral changes by enhancing the extent and /or rate of sprouting.

154.12 EVIDENCE THAT THE ASSOCIATIONAL AFFERENTS TO THE DENTATE GYRUS ARE CAPABLE OF RESPONDING BOTH TO THE ELIMINATION OF THE COMMISSURAL FIBERS AND THE LATER REMOVAL OF THE ENTORHINAL AFFERENTS. G.M. Peterson, D.D.M. O'Leary, and W.M. Cowan. The Salk Institute, La Jolla, CA 92037.

It has been known for some time that lesions of the entorhinal cortex or interruption of the perforant path through which the afferents from the entorhinal cortex reach the outer two-thirds of the molecular layer of the dentate gyrus, result in a prompt sprouting reaction in several of the other extrinsic afferents to the dentate gyrus. We have re-analyzed the response of the so-called hippocampo-dentate or ipsilateral associational afferents to lesions of the entorhinal cortex in young adult rats with the autoradiographic and Timm's methods, and have examined the capacity of this system to respond to an entorhinal lesion in animals in which they can be assumed to have previously expanded their distribution in response to the early postnatal elimination of the commissural afferents (O'Leary et al., Anat. Embryol., 1979, 156: 283-289; McWilliams and Lynch, J. Comp. Neur., 1979, 187: 191-198).

After injections of ^{3}H-proline into the caudal hilar region of the dentate gyrus in normal young adult rats, the associational afferents can be shown, in appropriate autoradiographs, to occupy a zone corresponding to the inner 25-28% of the molecular layer at more septal levels. Eight weeks after an entorhinal lesion comparable autoradiographs indicate that the zone occupied by the associational afferents has expanded to occupy approximately 40% of the molecular layer, but since the molecular layer as a whole is appreciably shrunken, the actual expansion of the associational afferents amounts to about 16-20%; this is comparable to the degree of expansion of the commissural afferents that occurs after similar lesions.

In a series of 16 week-old animals in which the commissural fibers were eliminated by the ablation of the contralateral hippocampus on the day of birth, and the fibers of the perforant path sectioned at 8 weeks of age, the associational fibers were again found to occupy about 40-45% of the molecular layer. Since the degree of shrinkage of the molecular layer was comparable to that in the previous experiments, the actual expansion of the associational afferents was at least as great as that following entorhinal lesions alone. This implies that the associational afferents are able to expand their distribution on at least two separate occasions, first to occupy all or most of the synaptic sites made available by the elimination of the commissural fibers and later, to occupy some proportion of the space vacated by the removal of the entorhinal afferents.

154.13 INDUCED DENDRITIC SPROUTING AND SOMA EXCITABILITY ARE DETERMINED BY THE SITE OF AXON TRANSECTION. E. Roederer* and M.J. Cohen. Biol. Dept., Yale Univ., New Haven, CT 06511.

When the axon of an identified central interneuron of adult crickets (Acheta domesticus) is transected, the remaining arborization, axon stump and cell body undergo characteristic injury responses. We find that when the axon in the central connective is cut 200 μm or closer to the ganglion containing the dendritic arborization and cell body of the medial giant interneuron (MGI), the cell body becomes excitable by 24 hours and supernumerary neurites emerge from the arborization in the neuropil by 2 days.

The MGI has a well-defined, characteristic morphology and its cell body normally does not support action potentials. Previously, we had demonstrated for axon transection at distances greater than 200 μm the following response of the MGI: (i) Sprouts emerge from the proximal axon stump by 2 days. (ii) Dendritic morphology and afferent synaptic inputs are not obviously modified at any time following transection. (iii) By 40 days post-transection neuritic sprouts emerge directly from the soma which is normally rounded and smooth. (iv) The electrophysiological properties of the MGI cell body do not appear substantially altered.

However, if the axon is transected at a distance of 200 μm or closer to the ganglion, a different response is observed in the MGI: (i) As early as 18 hours after such close transections, the cell body can now generate overshooting action potentials. By 2 to 3 days, however, this induced excitability is lost. (ii) Substantial "die-back" of the proximal axon stump is observed, often retracting well into the neuropil of the ganglion. (iii) By 2 days post-axotomy, supernumerary sprouts emerge from the dendritic arborization, often bearing growth-cone-like swellings at their terminals. They continue to grow throughout the post-axotomy period and often take paths not normally followed by the MGI, such as peripheral nerve trunks and contralateral, central connectives. (iv) The dendritic arborization of the MGI remains excitable to synaptic input from the cercal sensory afferents at all times.

The contralateral, intact MGI served as the control and its morphology and electrophysiological properties remained unchanged.

The sprouting from the dendritic arborization induced by axotomy displayed two features: (i) Rather than emerging from random points along the arborization, supernumerary neurites preferentially arose from certain branch points, axon collaterals and some dendritic tips. (ii) The amount of dendritic sprouting induced in the MGI was roughly inversely proportional to the length of the proximal axon stump.

We conclude that the induction of dendritic sprouting and soma excitability by axotomy, depends on the distance of the axonal lesion from the soma. (Supported by N.I.H. Spinal Trauma Center Grant 2P50 NS10174-07.)

154.14 HIPPOCAMPAL CHOLINERGIC RECEPTOR LEVELS REMAIN CONSTANT IN RESPONSE TO ENTORHINAL LESIONS. D.A. Matthews and P.M. Salvaterra. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

Alterations in the distribution and number of cholinergic terminals have been found in the molecular layer of the dentate gyrus following entorhinal lesions. The activity of the acetylcholine synthetic enzyme, cholineacetyltransferase (ChAT) and degradative enzyme, acetylcholinesterase (AChE) also increase. In an attempt to assess functional capabilities of this proliferated afferent system we have used micro-ligand binding assays to measure levels of cholinergic receptors. [^{125}I]α-bungarotoxin ([^{125}I]αBTX) and [^{3}H]quinuclidinylbenzilate ([^{3}H]QNB) were used to measure putative nicotinic and muscarinic receptors. Standard microassays were also used to measure ChAT, AChE and protein on the same samples. Homogenates were made by pooling hand dissected molecular layers of the dentate gyrus from individual adult male rats 165 days after unilateral lesion of the entorhinal cortex or from unoperated control animals. In agreement with other reports, both AChE and ChAT levels were significantly elevated in samples from the lesioned side compared to the contralateral control samples. However, only AChE levels were significantly higher (about two-fold) than those found in samples from unoperated animals. ChAT levels were generally only half that found in unoperated controls. No change was seen in the binding of either ligand in lesioned samples compared to either the contralateral or unoperated control samples. [^{125}I]αBTX and [^{3}H]QNB binding levels in the molecular layer were also about the same as we have previously reported for whole hippocampal samples. The short term effects of afferent removal and possible transient nature of alterations in the septal-hippocampal cholinergic system will also be examined by assays of samples obtained from animals which are allowed to survive 30 days after entorhinal lesion. Supported by NS 12116.

155.1 Varieties of Supraspinal Motor Control Established by Different Degrees of Spinal Cord Injury in Man . M.R. Dimitrijevic, J. Faganel*, W.B. McKay*, A.M. Sherwood Clinical Neurophysiology, The Institute for Rehabilitation and Research, Houston, Texas, 77030.

At least four distinct patterns of abnormal suprasegmental motor control can be recognized in spinal cord injury patients: 1) control of isolated, organized joint movement via a pool of motor neurones surrounded by proximal and distal pools exhibiting no motor control, 2), the presence of gross flexor and or extensor pattern movements via suprasegmental initiation; 3), the presence of restricted sub-clinical activation of single motor units; and 4), supraspinal modification of ongoing segmental reflex activity within paralyzed muscles. We have documented these types of motor control through the systematic study of segmental reflex response behaviors and their dependence on supraspinal mechanisms. Utilizing 12 pairs of surface EMG electrodes, with five pairs on the muscles of each leg, plus 1 each on the abdomen and lower back, we have examined more than 200 spinal cord injury patients by invoking a standardized series of maneuvers involving volitional attempts to activate their (paralyzed) muscles, passive movement of their legs, elicitation of reflexes such as tendon jerks, vibratory reflexes and clonus, and reinforcement maneuvers carried out in the non-paralyzed muscles of the upper trunk and extremities. The resulting EMG activity, recorded with a Mingograph 800 Hz bandwidth ink jet recorder, has been carefully analyzed to determine the patterns of EMG activity that can be categorized as described above. Illustrations of each pattern will be presented. The significance of these findings for neurocontrol of motor activity in man will be discussed with special regard for the function of the residual integrated descending motor control pathways.

155.2 NEUROMUSCULAR PATTERNING OF A SEQUENTIAL MOVEMENT. M. C. CARTER* and D. C. SHAPIRO* (SPON: G. P. Moore). Dept. of Kinesiology UCLA, Los Angeles, CA 90024.

Previous evidence suggests that movement sequences are composed of invariant and variant timing characteristics. In various tasks, Terzuolo and Viviani (1980), Shapiro (1976;1979) and Shapiro, Zernicke, Gregor and Diestel (1981) have demonstrated that relative timing, the maintenance of the temporal relationship among a movement sequence regardless of actual movement time was maintained while the overall speed of the movement sequence varied. The present study examined whether relative timing is also reflected in the neuromuscular patterning underlying sequential movements.

Four subjects practiced a rapid movement sequence consisting of pronation and supination of the forearm to specified targets (90^{o}, 65^{o}, 35^{o}, & 60^{o}). In addition, subjects were to arrive at each target location in specific movement times (200, 100, 130 & 160 msec). Thus, the total time of the spatial-temporal pattern was 600 msec. Electromyographic (EMG) activity was recorded from the biceps brachii and pronator teres muscles by surface electrodes. After several days of practice, subjects were asked to ignore timing while increasing the movement velocity and maintaining target accuracy.

The results demonstrated that subjects significantly reduced movement time ($p < .01$) while maintaining target accuracy at each movement segment. However, relative timing was maintained across the two velocity conditions. The maintenance of the relative timing was also reflected in the neuromuscular patterning of the response since the proportion of time that each muscle was active remained constant across conditions. In addition, the proportion of time to reach peak velocity for each segment of the movement sequence was similar in both conditions. In general, the biceps and pronator-teres muscles were reciprocally activated with little or no cocontraction during the production of the response.

In summary, the invariance of relative timing is a characteristic of both the overt movement pattern and the neuromuscular pattern underlying the movement sequence. Velocity appears to be a variant property that can be imposed on the movement sequence to vary total movement time.

155.3 SHORT LATENCY REACTION TIMES TO LOADING OF LIMB AND RESPIRATORY SYSTEMS: WITHIN AND ACROSS SYSTEM COMPARISONS. L. H. Meyerink* and R. Lansing. Dept. of Psychol. Univ. of Arizona, Tucson, AZ 85721.

Many investigators, attempting to identify late reflex (M2) responses to loading from computer averaged EMGs have assumed that learned reaction times (RT) must have latencies greater than 70 to 80 msec. Evarts and Granit (Prog. Brain Res, 1976) however reported "intended" biceps responses as early as 65 msec after loading, and we have found the minimal RTs for abdominal muscle responses to respiratory loads in the 45 to 60 msec range (Lansing & Meyerink, J. Physiol., in press).

The purpose of this research was 1) to compare minimal RT latencies of responses to limb and respiratory system loading, 2) to obtain a clear separation of learned RT and reflex components by loading respiratory and limb movements separately and requiring a response in the unloaded system, 3) to determine the dependence of EMG component latencies on the method of measurement. EMGs were recorded over abdominal and biceps muscles in 4 unpracticed college students. Latencies were measured for each of 160 trials per subject, and from computer averages of the rectified EMG for the same trials. Subjects maintained a pre-load isometric contraction of both abdominal and biceps muscles, holding a constant expiratory pressure and handle position. A sudden load (added pressure at the mouth or handle torque) was delivered 2 to 3 sec after a warning signal and the subject was told to respond as quickly as possible. In several series of trials a response with the loaded muscles was required, in others subjects were instructed to respond with the unloaded muscles.

Early stretch reflexes (15-30 msec) appeared only in biceps muscles, with handle torque loads. Clear separation of early stretch reflex and RT components was achieved by the experimental conditions, but for two subjects the RT response merged with the reflex activity. Learned RT latencies did not differ significantly according to the system loaded or to the muscles responding. The average RT, calculated from individually measured trials was 97 msec (subject means ranged from 78-128). RT latencies measured from the computer average of the same trials was 63 msec (subject range 52-108). Two subjects had very brief RTs regardless of the movement loaded or the muscles responding. Computer latencies were 52 and 67 msec; averages for all individual trials were 72 and 78 msec; over 20% of the trials were in the 40 to 68 msec range.

The results emphasize 1) the dangers of identifying intermediate latency reflexes (M2) on the basis of latency alone and 2) the importance of type of latency measure used to establish minimal RTs.

155.4 H REFLEX CHANGES PRECEDING A VISUALLY ELICITED MOVEMENT, Ann M. Baylor and Bruce R. Etnyre*. Neuromuscular Lab., Dept. PHE, Univ. of Texas, Austin, TX 78712.

Amplitude changes in the 50% H reflex were used as an index of motor pool excitability changes. These changes were a function of a randomized warning period preceding a visually elicited movement. The movement task was a rapid plantar flexion of the preferred foot following both an auditory warning signal and a visual stimulus to respond. Fourteen human males completed 15 practice trials followed by 75 test trials. Response speed was measured by the latency of initial onset of EMG in the soleus muscle. On each trial the H reflex stimulus was either omitted entirely (none, no H reflex) or Presented at one of three intervals with reference to the visual stimulus: 0 (simultaneous with light stimulus), 100 or 200 msec following visual stimulus. Trials were also taken before and after movement (pre and post movement).

Excitability as measured by the H reflex technique showed the highest values in the post movement trials condition (66%) followed by the movement conditions of 200 (57%), 0 (52%) and 100 (51%) and finally the premovement control (47%). The excitability changes as a function of the 2, 3, or 4 sec randomly presented warning interval showed a tendency to maximize at the median or 3 sec interval; however these differences were not statistically different.

Latency of onset of EMG varied greatly as a function of the H reflex presentation. The none (277 msec) and 200 msec (281 msec) responses were very similar to each other but different from the 100 (245 msec) and 0 (185 msec) responses. It seems that on many trials the shock stimulus to elicit the H reflex replaced the visual stimulus to respond and resulted in a much faster EMG response.

The latency of onset of EMG in the muscle was poorly predicted by the motor pool excitability index (H reflex). The onset of EMG was slower following a 2 sec warning than following the 3 or 4 sec warning -- a pattern which was not reflected in the amplitude of H reflex data. When percent maximum H amplitude values were correlated to latency of EMG response at each of the stimulus intervals, the correlations were all of low order and insignificant, indicating that this measure of motor pool excitability is not a good predictor of latency of EMG initiation. Separate mechanisms appear to be responsible for the H reflex amplitude changes preceding EMG in the muscle and the latency of EMG onset in this type of movement.

155.5 THE RELATION OF FORCE AND EMG TO THE PERCEPTION OF EFFORT. L.A. Jones and I.W. Hunter. Psychology Dept., and Biomedical Engineering Unit, McGill Univ., Montreal, Quebec, Canada H3A 1B1.

The concept of a sense of effort is typically related to a memory of the magnitude of a motor command sent to a muscle. It has been proposed by McCloskey (1978) and others that this sensation is employed in the estimation of weight and of the force achieved by muscular contraction. However, several authors have suggested that knowledge of the motor command itself is not sufficient for judgements of force and that afferent signals are important in the estimation of the force achieved (Roland and Ladegaard-Pedersen, 1977).

In this series of experiments a cross-limb matching paradigm was employed to investigate how human subjects matched the effort of an isometric muscular contraction. The matching ratio between the reference and indicator limbs was obtained for a range of forces (from 15% to 85% of maximum voluntary contraction) under fatigued and non-fatigued conditions. EMG recordings were taken from the biceps and triceps brachii muscles of each arm and the concomitant forces exerted were measured. Under non-fatigued conditions a linear relation was found between the force exerted and the matched force. The EMGs of the reference and indicator arms were similarly related. However, the frequently observed non-linear relation between the force produced and numerical estimates of magnitude was also found. The EMG was non-linearly related to magnitude estimates, but the force-EMG relation was linear. This linear relation was manipulated by fatiguing the muscles of the reference limb at different rates during constant force contractions. Both the reference arm EMGs and the matching ratio increased non-linearly with time. With larger reference forces the rate of these changes increased systematically. From these results we have developed a model relating force, EMG and duration of contraction from which the matching ratio can be predicted.

These results lend support to the notion that force matching and perhaps the sense of effort arise from motor commands to the muscles rather than from afferent signals.

155.6 EFFECTS OF AFFERENT INPUTS ON DYNAMIC AND STATIC PERFORMANCE ERRORS IN HUMANS. J. N. Sanes & E. V. Evarts, Lab. Neurophysiol. NIMH, Bethesda, Md. 20205.

Many investigations of the role of afferent input occurring during movement have dealt with the effects of relatively large disturbances delivered during relatively large movements. However, there is evidence that both cutaneous and muscle receptors have high sensitivity for small signals. Thus, the effects of afferent signals in controlling movement may be seen most clearly if the afferent signals are generated by small perturbations delivered during precisely controlled small movements.

Normal subjects performed forearm pronation-supination movements in a visual tracking task by moving a handle coupled to a torque motor. Handle rotations of 30°, 10° or 3° were performed in separate blocks of 250 trials. At the beginning of each trial the target was displaced from the center and subjects moved the handle to realign their cursor with the target. After 1.2-2 s of realignment the target jumped back to the center and subjects moved the handle as quickly and as accurately as possible to realign the cursor. For 1/2 of the trials the visual display was blanked and on 1/6 of the trials the limb was perturbed for 100 ms; both events occurred when the handle moved beyond the hold zone. Effects of 3 perturbations were studied --(1) a stop, (2) ramp stimuli opposing movement and (3) ramp stimuli assisting movement. The ramps moved the handle forward/backward 1/3 of the total movement size in 100 ms. Error of the handle position relative to movement size was measured when handle velocity first reached zero (dynamic error) and 500 ms later (static error).

In the absence of visual feedback, relative dynamic and static error increased as movement amplitude decreased. Perturbations stopping or opposing handle movement increased percentage error and the increases were greater for smaller movements. Perturbations that assisted handle movement did not alter dynamic error but static error was changed in a manner similar to that seen following other disturbances. The final handle position for large movements tended to be overdamped whereas the handle position for small movements was typically underdamped. The underdamping of small movements was exacerbated by perturbations.

These findings demonstrate that peripheral disturbances modify movement accuracy, with small movements being more affected than large displacements. The mechanism responsible for the effects may be recruitment of a significantly greater proportion of motor units following perturbations delivered during small movements. The source of excitation may be both segmental and supraspinal since neural elements in both regions are sensitive to small afferent signals.

155.7 EMG RESPONSES TO FORCE PERTURBATIONS PRECEDING ACCURATE ARM MOVEMENTS IN HUMANS. Susan H. Brown and J. D. Cooke, Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada.

Recent investigations in this laboratory have shown that the triphasic EMG pattern associated with rapid limb movements is also characteristic of slower, more accurate movements. It has also been shown, for fast movements, that the late phase of the initial agonist EMG burst can be modulated by force perturbations applied prior to movement onset with no change occurring during the early part. The present experiments were designed to determine the effects of perturbations applied prior to the onset of slower, accurate movements.

Experiments were performed on normal human subjects performing a visual step-tracking task involving flexion-extension movements about the elbow. Emphasis was placed on accuracy in reaching the target rather than on speed. In randomly selected trials, brief (50 msec) torque pulses were applied following the change in target position but before movement onset. Perturbations either opposed or assisted flexion (flexion load and flexion unload).

The initial agonist burst of unperturbed flexion movements often showed two components: an initial component lasting 75±12 msec duration immediately followed by a second component 74±12 msec in duration. As seen previously for fast movements, unloading prior to onset of these slower, accurate movements resulted in a reduction in the magnitude of the late component. In some cases this component was completely lacking. Conversely, loading forces increased the magnitude of this late component. In general, the magnitude of the late component was proportional to the magnitude of the force perturbation. The early component of the initial agonist burst showed a marked increase in magnitude during both loading and unloading of these accurate movements. This was in contrast to the lack of modulation of this early component during fast movements.

The results suggest that the initial agonist burst of the triphasic EMG pattern is, in fact, comprised of two separate components and that the degree to which the early component can be modulated is dependent upon movement strategy.

155.8 MODIFICATION OF MOTOR OUTPUT TO COMPENSATE FOR UNEXPECTED LOAD CONDITIONS DURING BALLISTIC MOVEMENTS. R.G. Lee, G.E. Lucier and D.G. White*. Neuroscience Research Group, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1

Twenty normal human subjects were trained to perform rapid wrist flexions to move a cursor to a specified position on an oscilloscope screen. These movements were performed repeatedly against a constant small load generated by a torque motor. When the subjects had "learned" the program to produce the required movement against the predicted load, the torque was increased prior to movement on a small percentage of randomly selected trials. Since the task was initiated with the manipulandum resting against a mechanical stop, the subjects had no cue that load conditions had changed until after the movement commenced. Wrist position, torque, and EMG activity from agonist and antagonist muscles were averaged and patterns associated with movement against each of the load conditions were compared.

When the load was greater than predicted the velocity of the movement was slightly decreased and there was a compensatory increase in the EMG output from the agonist muscle. This occurred approximately 20-25 msec. after the onset of movement or 30-40 msec. following the earliest change in the torque recordings associated with the two load conditions. At the same time there was a decrease in the EMG burst from the antagonist muscle. The magnitude of the compensatory increase in agonist EMG activity was linearly related to the amount of difference between the predicted and the actual load.

The latency of this compensatory change in EMG output is compatible with a monosynaptic reflex and suggests that it is mediated by spinal rather than long loop mechanisms. Since the increase in EMG output occurred at a time when the muscle was being shortened, it cannot be considered a stretch reflex in the true sense. However increased discharge from spindle afferents could occur as a result of a mismatch between gamma motoneuron output and the expected velocity of the movement. These observations suggest that mechanisms exist at the spinal level to allow rapid modification of motor programs when unexpected load conditions are encountered during ballistic movements.

155.9 POSTURAL ADJUSTMENTS ASSOCIATED WITH PRECISE ARM MOVEMENTS IN FREELY STANDING SUBJECTS. L. M. Nashner and P. J. Cordo. Neurol. Sci. Inst., Portland, OR 97209.

When a freely standing subject pulls upon an external object, the forces acting between the subject and the object upset the distribution of support forces which maintain equilibrium. We and a number of other investigators reported earlier that postural adjustments helping to maintain equilibrium anticipate the force perturbations caused by reaction time arm pulls. Furthermore, we reported that the linkages between voluntary and associated postural activities are "set" dependent and are mediated by rapid acting, low level motor circuits.

If a freely standing subject is asked to produce a precise force waveform while standing freely, arm and associated postural activity must both be precisely modulated. If the associated postural adjustments are imprecise, shifts in the orientation of the subject will disturb the accuracy of the arm pull. We have compared the tracking accuracy of subjects following step and ramp waveforms while standing with postural support and while standing freely in order to determine the role played by posture in the execution of precise, focal movements.

Subjects were given a compensatory visual display (force error deflected a horizontal line upward or downward on an oscilloscope screen) and asked to keep the force trace aligned with a fixed target. At random times, the error trace was deflected (step or 1 sec. ramp), and the subject was required to pull on the handle to restore it to the target position.

Despite the increased organizational complexity required to follow a precise force waveform while freely standing, subjects could perform this task as quickly and as accurately during free standing as during supported trials. While postural muscles were quiescent during supported trials, they were activated in anticipation of the arm movement. Furthermore, the torque waveform produced by postural muscles against the support surface was coincident with or slightly advanced in time and precisely mirrored the force trajectory produced by the arm.

We argue that set dependent coordination of intentional motor and associated postural activities enable the subject to execute pulls with equal precision while performing under different configurations of postural support. Linkages between postural and focal muscles combine motions of the various body parts into a fixed functional unit. By establishing the appropriate temporal and metrical relationships between focal and postural activities in advance of movement, waveform tracking can be accurately executed under freestanding conditions.

155.10 Are Motor Units Fully Activated During Strong Effort?
A.Y. Belanger and A.J. McComas
Department of Neurosciences, McMaster University Medical Centre, Hamilton, Ontario, L8S 4J9

It is still not known whether motor units are fully activated during maximal voluntary contractions. One approach to the problem would be to compare the force of a maximal voluntary contraction with that developed during tetanic stimulation of the same muscle. Although simple in concept, the method is fraught with technical difficulties and is uncomfortable for the subject. We have therefore preferred the following technique (Merton, P.A., J. Physiol., Lond., 123:553, 1954): during a strong effort a single maximal electrical stimulus is delivered to the appropriate motor nerve. In theory a twitch should be superimposed on the force recording only if some motor units have either not been recruited or are discharging at less than their tetanic fusion frequencies. The validity of this method has been established in various ways and tests have been conducted on the ankle plantarflexor and dorsiflexor muscles of 28 healthy men and women aged 19-45 years. Measurement of muscle contraction was made with a specially designed leg-holding device (Marsh et al, J. Applied Physiol., 1981, in press). Plantarflexor muscles (PF) were excited through the tibial nerve at the popliteal fossa whereas tibialis anterior (TA) was stimulated indirectly over its muscle belly. It was found that full activation of TA could be achieved quite easily in all subjects (27/28); in contrast, PF activation was not quite maximal in 14 subjects despite the greatest effort having been made. A possible explanation for the incomplete activation of PF muscles would be that the PF motoneurones, although receiving strong inputs from homonymous muscle spindles, have less powerful synaptic connections from volitional motor pathways.

155.11 NEUROMUSCULAR CONTROL OF MAXIMUM HEIGHT JUMPING IN HUMANS WITH ALL JOINTS VOLUNTARILY CONSTRAINED FROM MOTION EXCEPT THE ANKLE. F.E. Zajac[1,2], W.S. Levine[3], M.R. Zomlefer[1], M. Belzer*[3]. Rehab. Eng. Res. and Dev. Ctr. (153), VA Medical Ctr., Palo Alto, CA 94304[1], Mech. Eng. Dept., Stanford Univ., Stanford, CA 94305[2], Elect. Eng. Dept., Univ. of Maryland, College Park, MD 20742[3].

This constrained jump was chosen for study in order to develop a theoretical basis for understanding muscle coordination patterns needed to jump maximally, given that the jump may start from one of many initial postures. This jump can be modeled by a 2-segment inverted pendulum controlled by neural activation of lower leg musculature, whereas models of unconstrained jumps are more complex. Optimal control theory predicts that the jump must be partitioned into three epochs regardless of the details of the muscle model. In the first epoch, with the feet flat on the ground any one of many ankle torque trajectories can be used to statically position the center of body mass over the toes and any one of innumerable muscular activation patterns would suffice. In the second epoch, leg muscles must develop a unique, but less than maximal, ankle extensor torque to propel the upper body to an optimal position and velocity. Again, there exist many activation patterns that could be used.

During the third and final epoch of propulsion the heels must be off the ground, ankle flexor muscles must be de-activated and ankle extensor muscles must be fully activated until lift-off. Ground force, body trajectory (using a Selspot system) and medial gastrocnemius and tibialis anterior intramuscular activity were recorded. We found that for the third epoch of propulsion to be consonant with physiological observed forces, trajectories, and calculated ankle torques, both the force-length and lag properties of muscle must be accurately specified. However, these muscle properties severely degrade performance and there is no way by which the nervous system can provide compensation, even with a priori knowledge of these actuator properties, since theory predicts and experiment suggests that ankle extensor muscles are already subjected to maximum activation. For the prior two propulsion epochs, compensation for these muscle properties is possible, and apparently occurs, via either anticipatory or feedback-controlled neural commands.

155.12 ABSENCE OF NEUROMUSCULAR BLOCK IN FATIGUE OF MAXIMUM VOLUNTARY ISOMETRIC CONTRACTIONS. B. Bigland-Ritchie, C.G. Kukulka and J.J. Woods*. John B. Pierce Foundation and Quinnipiac College, New Haven, CT. 06519.

Merton (1954) found no change in the size of muscle surface mass action potentials (M waves) evoked by single maximal shocks to the motor nerve during fatigue of sustained maximum isometric voluntary contractions (MVC) of the adductor pollicis muscle. From this he concluded that loss of force is not due to progressive neuromuscular block. This observation has been confirmed, also on adductor pollicis, by Bigland-Ritchie, Jones and Woods (1979) and by Bigland-Ritchie and Lippold (1979); but it is at variance with that of Stephens and Taylor (1972). Using similar techniques on the first dorsal interosseous (FDI) muscle they found a decline in the M wave and considered that neuromuscular block was a major factor in this type of fatigue. We have repeated these experiments on both the adductor pollicis and FDI muscles using intramuscular as well as surface recording. When supramaximal stimulation was assured and the whole potential area measured, all changed in a similar manner and no decline in response was seen. A slight slowing of conduction velocity increased the potential duration without loss of amplitude, increasing the total area by some 30% during 60s MVC. This may account for the apparent decline observed by Stephens and Taylor who measured the area only over a fixed time interval. Cross contamination by potentials from other muscles also innervated by the ulnar nerve but not involved in the voluntary fatiguing contraction is an unlikely source of error. With surface recording some cross contamination between either FDI and/or adductor pollicis and the adjacent opponens pollicis was seen when the ulnar and medial nerves were stimulated alternately, but not when the recording was intramuscular. Any cross contamination between FDI and adductor pollicis would not, in any case, influence our results since co-contractions fatigued both muscles simultaneously. For both muscles we confirm a progressive reduction in surface EMG during this type of fatigue but cannot attribute this to neuromuscular block. It must, therefore result from a reduced motor drive from the central nervous system. The effects on force production will be discussed.

155.13 MOTOR AFTER-EFFECTS OF SHORT-TERM VOLUNTARY MOVEMENT. D.G.D. Watt. Aviation Med. Res. Unit, McGill University, Montreal, Canada, H3G 1Y6.

Following prolonged exposure to moving environments (boats, aircraft), many persons experience sensations of self-motion which may come and go for up to several days. Craske has demonstrated recently that involuntary decaying oscillations of the arm follow a mere 80 sec of alternating isometric flexion and extension of that limb. The present experiments were designed to test the functional significance of motor after-effects during normal locomotor activity.

It is known that subjects asked to hop rhythmically up and down on both feet without external cues will do so at a particular and reproducible preferred frequency, typically about 2.2 times per sec. In these experiments, 4 subjects were asked to hop steadily for 1 minute in synchrony with a periodic auditory cue adjusted to 10% below or above their previously measured preferred hopping frequencies. The effect of this forced hopping on their preferred frequencies was then tested repeatedly for up to 8 minutes.

The preferred hopping frequency of each subject was lowered significantly following forced hopping at a lower rate (from an average 2.20Hz to an average 2.06Hz, $P<.001$), and increased significantly following forced hopping at a faster rate (from an average 2.20Hz to an average 2.25Hz, $P<.001$). In both cases, the effect diminished systematically, but was still present 8 minutes after forcing. The effect of forced hopping at a slower than normal rate was always greater than the effect of forced hopping at a faster than normal rate, but this may simply reflect the fact that all subjects were exposed to slower and than faster hopping, and the former may have influenced the latter.

These findings suggest that certain kinds of voluntary movement are not only the result of what an individual wants to do, but also depend on what he has just done. This is compatible with theories that postulate an internal model for motor control that generates motor commands as required, but which is continuously updated on the basis of recent experience. According to the present results, these changes occur with a time constant of minutes. This "fine-tuning" of motor programs could explain the effectiveness of a short warm-up period just before an atheletic or musical performance.

155.14 ALPHA-GAMMA BALANCE DURING HUMAN VOLUNTARY ACTIVITY. B. T. Shahani and R. R. Young Clinical Neurophysiology Laboratory, Massachusetts General Hospital, Boston, Ma 02114.

Although it has been reported that there may be a rise in fusimotor activity preceding alpha activity in some instances in experimental animals, there is no evidence that spindle sensitization precedes voluntary extrafusal muscle contractions in man. In order to determine whether or not there is appropriate balance between skeletomotor and fusimotor systems during graded voluntary activity, unloading reflexes were recorded from biceps brachii muscles of 5 healthy volunteers. Subjects, seated in a comfortable chair and resting the arm on the table, were asked to pull, at different times, against 1, 2, 3 and 4 Kg weights attached by an electromagnet which could be electronically de-energized. EMG activity from biceps and triceps muscles, a marker signalling release of the magnet and angle of displacement at the elbow joint were displayed on the oscilloscope and permanent records (4 superimposed traces) were made with Polaroid film. Duration of the silent period (SP) produced by unloading was relatively constant for each individual and ranged in different subjects from 31 ± 3.5 msec to 65 ± 5 msec. when a 1 Kg weight was released. Although all showed a tendency for SP duration to increase ($p < .01$ only in one) when heavier weights were released, these changes were not statistically significant. In one subject (who had great difficulty holding to heavier weights) release of 4 Kg weight produced SPs of shorter duration (71% of SP produced by 1 Kg release). Since this SP is presumed to be due to withdrawal of Ia input and the motor activity following the SP due to renewal of spindle afferent discharge, it is suggested that during moderate voluntary contraction there is appropriate alpha-gamma balance whereas during maximal voluntary effort the increase in fusimotor activity may be out of proportion to the alpha activity resulting in shortening of the SP and early resumption of motor activity. Our preliminary data also suggest that Ia facilitation is more important for maintaining alpha motoneurones at their firing level during moderate voluntary contractions rather than during minimal and maximal effort.

155.15 MECHANISMS OF TRAJECTORY FORMATION IN INTACT AND DEAFFERENTED MONKEYS. E. Bizzi, N. Accornero*, W. D. Chapple and N. Hogan*. Dept. of Psychology, M.I.T., Cambridge, MA 02139.

The formation of forearm trajectories was studied in monkeys performing a simple visuo-motor task. Recently, it has been proposed that the transition from a given position to another may occur whenever the central nervous system generates a signal shifting the equilibrium point between opposing muscle groups by selecting a new set of length-tension curves. In these experiments we have studied the time-course of this transition. The monkeys were seated in a primate chair with the right arm strapped to a splint which allowed rotation of the forearm about the elbow in the horizontal plane. Ten target lights were placed along a perimeter centered on the axis of rotation of the elbow. To obtain a reward the monkey had to point to an electrically defined target (10°). During the experimental sessions an opaque cover was placed over the arm to prevent the animal from seeing the moving arm. We performed a bilateral section of the dorsal roots from C1 to T3. After deafferentation, the forearm visuo-motor responses which had been learned in the preoperative state could be evoked by presenting the targets.

In deafferented animals the position of the arm was displaced and maintained in a new location by the action of a torque motor. After completion of a displacement, a target light was turned on at the location corresponding to the new arm position. After the appearance of the agonist EMGs in the muscles, the arm was released. We observed that the arm moved first towards the position from which it had initially been displaced, then changed direction and returned to the position specified by the target light. While the to-and-fro movement took place, the agonist muscle developed an EMG comparable to that observed during undisturbed movements. This cannot be explained if the muscles are regarded as pure force generators, but is readily explained if the length dependence of muscle force is taken into account.

In additional experiments in both intact and deafferented animals the limb was clamped and released at various times after the onset of EMG activity. We measured the acceleration of the limb immediately after the release and the isometric force during the holding. Both acceleration and isometric tension showed a gradual increase with time.

Taken together, these findings suggest the existence of a gradually changing control signal during movement of the forearm from one position to the next and are not consistent with the view postulating a step-like shift to a final equilibrium point. 155.16 TRAJECTORIES OF BALLISTIC MOVEMENTS CAN BE ALTERED BY MODIFYING ANTAGONIST MUSCLE ACTIVITY. D. S. Hoffman and P. L. Strick. V. A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-Upstate, Syracuse, NY 13210.

Ballistic movements are initiated by a burst of agonist muscle activity which precedes movement and are decelerated by a burst of antagonist muscle activity which occurs at or just after movement onset. Prior studies have demonstrated that the amplitudes of both bursts of muscle activity are directly related to movement velocity. These interrelations have suggested that the antagonist burst might be generated by the same central mechanisms which generate the agonist burst and/or by reflex mechanisms related to peripheral feedback. The present experiments were designed to test whether the magnitude of the antagonist burst could be uncoupled from the magnitudes of both the agonist burst and the initial parameters of movement.

Human subjects were asked to perform a visual reaction time task in which ballistic wrist movements (20 degrees of ulnar deviation) were made to a visual target. After a series of 20 degree movements, a "trick" trial was presented to the subject. The visual target for these trials unexpectedly required only a 10 degree movement. Muscle activity was recorded from extensor carpi radialis longus (ECR) and extensor carpi ulnaris (ECU) while subjects repeatedly performed this task.

As expected, the magnitudes of both the agonist burst in ECU and the antagonist burst in ECR were directly related to movement velocity for the 20 degree trials. Agonist bursts and initial movement parameters on some "trick" trials and some 20 degree moves were identical. In contrast, the antagonist burst on the same "trick" trials was larger (in some cases nearly doubled) and earlier (as much as 10 msec.) than that observed with 20 degree moves of comparable initial velocity. The changes in the antagonist burst during the "trick" trials resulted in a greater and earlier movement deceleration than was observed during the 20 degree moves. Thus, for "trick" trials there was a clear dissociation between the magnitude and timing of the antagonist burst and the magnitude of both the agonist burst and the initial movement parameters.

These observations indicate that the antagonist burst is not determined solely by kinesthetic feedback and may be modulated independent of changes in agonist muscle activity. Furthermore, the trajectory of a ballistic movement can be modified shortly after movement onset by altering the magnitude and timing of the "brake" applied by antagonist muscle activity. 155.17 RAPID VOLUNTARY ARM MOVEMENTS IN MAN: ELECTROMYOGRAPHY AND PERFORMANCE. P. J. Cordo and L. M. Nashner, Neurol. Sci. Inst., Portland, OR 97209.

Electromyographic (EMG) signals associated with rapid (reaction time) arm flexions in man, monkeys and cats have been previously described by a number of other investigators. The relationships between these muscle activation patterns and peformance are still somewhat controversial. We have studied a variety of visually triggered rapid arm movements, some of which required force tracking and others which were not metrically constrained, to determine the relationships between activity of involved muscles and performance.

Adult subjects stood against a chest-height support and pulled and pushed on an isometric handle by flexing or extending the elbow joint. Multiunit, filtered EMG was recorded from the biceps and triceps brachii muscles during the following visually-triggered tasks: 1) rapid flexion with no end-point specification, 2) rapid flexion followed by rapid extension also without metrical specificity, and 3) step and ramp tracking using a visual compensatory display.

Rapid flexions and extensions with unspecified metrics (the first two paradigms) were executed with approximately synchronous coactivation of biceps and triceps. Single, 100-150 msec phasic bursts of EMG in both muscles were associated with movement in each direction. EMG associated with the two tracking tasks was also highly stereotyped. In these tracking paradigms, biceps activation (EMG) was more sustained in character with phasic bursts occurring only with overshoots. Furthermore, changes in the level of triceps activity were minimal during the movement. In all movement paradigms, modulation of the level of activation in both muscles often appeared to be synchronized, as if both muscles were driven with the same control signal. The accuracy of tracking (performance) was also clearly correlated with the associated patterns of muscle activation. We conclude that, with consideration of the mechanical properties of the involved musculature, movement performance may be predicted from patterns of muscle activation or, conversely, the functional role of segments of EMG activity in the performance of accurate movements may be evaluated. Furthermore, the synchronous patterns of activity in the agonist and antagonist musculature suggest that the movement commands to the muscle pair have common organizational properties.

155.18 ELECTROMYOGRAPHIC ANALYSIS OF THE FINAL POSITION HYPOTHESIS. J. Matheson*, A. Berardelli* and M. Hallett. Lab. of Clinical Neurophysiology, Brigham & Women's Hospital, Boston, MA 02115.

Ghez has proposed that rapid limb movements can be analyzed into successive pulse and step phases, the pulse specifying the dynamic features of the movement and the step specifying final position. Recent investigations by Bizzi and colleagues have suggested that final position of a limb is specified by a relationship in the activity of the antagonist muscles acting about a joint. The following experiments were undertaken to see if the complex EMG activity in biceps and triceps following the initial "triphasic pattern" of a ballistic elbow movement could be explained on the assumption that this activity is specifying the final position of the limb.

EMG activity was recorded with surface electrodes from biceps and triceps, rectified and integrated in 100-500 ms windows. The arm was held in a light splint with the shoulder at 90° and the forearm fully supinated. Elbow position was measured using a potentiometer in the splint. The arm was held at several specified angles and EMG at each angle was recorded during different levels of activity. These different levels were achieved by voluntarily altering the amount of co-contraction. For each angle there was a clear relationship between the amount of biceps and triceps activity and this relationship changed for each angle.

Subjects then made short and long, ballistic elbow flexion and extension movements using as final positions the same angles as used during the holding task. Slow movements were also studied. EMG activity after the limb arrived at the final position was analyzed and compared to the EMG obtained during the holding task. The relationship was sometimes the same in the two circumstances, but often it was different. It appears that features in addition to final-position control play a role in setting the level of EMG activity in the seconds immediately following a dynamic movement.

155.19 MUSCLE MOLECULAR MECHANISMS: IMPLICATIONS FOR MOTOR PROGRAMS. P.Dev. Rehab. Eng. R&D Ctr., V.A. Medical Ctr., Palo Alto, CA.

Crossbridge models of muscle have been shown to possess emergent properties of force generation, viscosity and series elasticity (Huxley, 1957). We show that these models provide insight into muscle and load dynamics during the translation of different motor programs into movement.

A simplified, two-state, crossbridge model of muscle was selected. The intensity of neural input determines the fraction of attachment sites available. To simulate a movement, a limb was modelled as a mass with two opposing muscles, agonist and antagonist.

We postulate two kinds of motor programs -- timing programs and equilibrium setting programs. In a timing program, the temporal pattern of neural input to the muscle is shown to be significant in starting and stopping a movement. To highlight this effect, we hypothesize that isometric muscle tension has no dependence on length. In the equilibrium setting program, we assume that muscle tension does depend on length, i.e. the fraction of available sites depends on muscle length, and that the input intensities to the two muscles specify the equilibrium position. Timing Programs . Three elements of neural input patterns were investigated : 1) a pulse of increased input to the agonist muscle, 2) a pulse of decreased input to the antagonist, 3) a braking pulse of increased input to the antagonist. Increased input to the agonist alters the balance of agonist and antagonist crossbridges and accelerates the movement. Cessation of this increased input is sufficient to halt the movement eventually as the crossbridge balance is restored. The amplitude of the movement depends on the duration of the agonist pulse and on the final input intensities to the two muscles. While a braking pulse is not necessary to halt the movement, it is extremely effective in halting a fast movement or the movement of a large mass. Equilibrium Setting Programs. The input patterns were a maintained increase in agonist input and a maintained decrease in antagonist input. This pattern is effective in initiating movement. The specified equilibrium position is approached asymptotically, and the movement duration is considerably longer than occurs for timing programs.

Therefore, both kinds of programs can generate complete movements. For muscles in which tension depends on length, equilibrium setting is necessary to specify a position to be maintained. However, the addition of timing programs supplies control over the speed with which the equilibrium position is approached.

Huxley, A.F., Prog. Biophys. Biophys. Chem., 7:257, 1957.

155.20 KINEMATICS OF POINTING AND GRASPING MOVEMENTS. F. Lacquaniti* and J. F. Soechting. Lab. Neurophysiol., Univ. Minnesota Med. Sch., Minneapolis, MN 55455.

Arm movements involving forward projection of the hand toward a target were studied in two experimental conditions. In the first task, the subjects performed a pointing movement so as to touch one of four targets presented on a TV screen with their index finger. The movement involved two degrees of freedom (forward flexion at the shoulder and extension at the elbow). The second task was to reach for and grasp a handle at different orientations: the subjects started with the hand supinated and had to pronate it (or vice versa) during the movement in order to grasp the handle. Elbow and wrist angular positions were measured goniometrically and shoulder angular position was estimated indirectly. For each target location the relation between elbow and shoulder instantaneous angular position proved to be consistent and was independent of movement speed. Furthermore, this relation was not appreciably affected by the presence or absence of wrist rotation. During the deceleratory phase of the movement the ratio of elbow angular velocity to shoulder angular velocity was constant and independent of target position. These results indicate that the motions at the elbow joint and the shoulder joint are coupled and one can conclude that such a link comes about because of the inertial coupling between the motion at the two joints and the modality of its central control. On the contrary, no invariant relationship exists between wrist rotation and elbow or shoulder movements. The rotation of the wrist (in both pronatory and supinatory directions) appeared to be a multiphasic movement highly variable in timing and duration. However, it can not be said that wrist rotation is unrelated to the elbow movement; on the basis of our data (including the pattern of EMG activity of some of the muscles involved in wrist rotation) it appears that wrist rotation is constrained by the presence of simultaneous elbow movements, the constraint deriving from the bifunctional nature of most of the muscles involved.

156.1 ACTIVITY OF VESTIBULAR NUCLEI NEURONS AFTER FLOCCULECTOMY DURING VISUAL-VESTIBULAR STIMULATION IN THE MONKEY. Walter Waespe* and Bernard Cohen, Dept. of Neurology, Mount Sinai School of Med., New York, N.Y. 10029.

Recordings of neuronal activity in the vestibular nuclei and in the flocculus suggest complementary processing of vestibular and visual (optokinetic) information (Waespe & Henn, Exp. Brain Res., 1981, in press). Each structure is tuned to specific stimulus ranges. These results suggest that modulation of vestibular nuclei neurons during visual-vest. interactions would not be dramatically affected by flocculectomy. This postulate was tested in two monkeys in whom the flocculus was removed on both sides, and recordings were done in the vestibular nuclei. Stimuli consisted of rotation in darkness (vestibular stimulation), rotation of the visual surround around the stationary monkey (optokinetic stimulation), rotation in a lighted stationary surround (combined stimulation) and rotation of the monkey and the visual surround together in the same direction (conflict stimulation). Twenty horizontal type I neurons, i.e. neurons that were activated during ipsilateral rotation and inhibited during contralateral rotation, were recorded. Sensitivity of the type I neurons to vestibular stimulation was low. No horizontal type II neurons or omnipause type I cells with a high vestibular sensitivity were found. These omnipause neurons are typical for the medial vestibular nucleus and most likely project to the flocculus. Firing rates of the type I neurons were modulated during optokinetic stimulation in the usual way. They increased their activity during contralateral drum rotation up to velocities of 60^{o}/sec. The time to the build up of steady state frequencies was very long, up to 40-60 sec, paralleling the development of OKN slow phase velocity after flocculectomy. During OKAN, neuronal activity decayed in parallel with slow phase velocity. During conflict stimulation the decay time constant of neuronal activity and of nystagmus was shortened to less than 8-10 sec. The results indicate that flocculectomy does not dramatically alter activity of type I cells in the vestibular nuclei. These cells seem capable of processing visual information in the absence of floccular projections. Steady state values during optokinetic stimulation were similar in flocculectomized as in normal animals, but a longer time was needed to reach these values. The fact that no type II horizontal and no omnipause type I neurons with high sensitivity were found is an interesting but preliminary finding. It can be explained by assuming that the vestibular neurons which project to the flocculus retrogradely degenerate after lesions of this area.

Supported by Fogarty Fellowship FO5 TW02768 (W.W.) and NINDS Grant NS 00294.

156.2 LACK OF TOPOGRAPHIC SEPARATION OF SEMICIRCULAR CANAL AND OTHER VESTIBULAR AFFERENTS IN THE PIGEON'S VESTIBULO-CEREBELLUM. I.E. Schwarz* and D.W.F. Schwarz, Lab. of Otoneurology, Dept. of Otolaryngology & Physiology, Univ. of Toronto, Toronto, Ontario.

We have previously shown that directional information about rotational planes of head movements is encoded in firing-patterns of cerebellar neurons more precisely than in vestibular afferents coming from semicircular canals. It was, therefore, interesting to know if rotational planes are topographically represented in the pigeon's vestibulo-cerebellum. Since all mossy fiber afferents originating in one semicircular canal represent the same head rotation plane, we investigated if there is a topographical segregation of mossy fibers originating in different organelles of the labyrinth. A number of tracers were used to achieve the necessary transneural labeling, but only tritiated leucine yielded sufficiently strong clean mossy fiber labeling patterns. 50 uC of ^{3}H leucine in 0.5 ul were injected into one crista of either the lateral, anterior or posterior canal or into the macula-utricui. After one day survival the pigeons were fixed by transfusion and frontal serial sections were processed for radioautography. Labeled mossy fiber rosettes were semiautomatically plotted on section charts in order to permit precise topographic mapping. Controls consisted of injections of the same dosage, a few hundred um away from the crista in either the perilymphatic space or the endolymph. No labeled rosettes were found under these conditions, indicating that label injected into one crista could not have been effectively spread to other cristae. Injections into each crista resulted in similar spatial distributions of labeled rosettes. Only a minority of all rosettes was labeled in all cases, however, the rosettes were distributed throughout the ipsilateral side of the total vestibulo-cerebellum with no spatial concentrations for individual canal afferents. Utricular injections resulted in virtually identical distributions and injections into the cochlea yielded fewer labeled rosettes which appear randomly distributed throughout the ipsilateral vestibulocerebellum. These can be attributed to labeled lagenar afferents. It must be concluded that mossy fibers signaling specific movement directions and planes are not concentrated in specific regions of the vestibulocerebellum. It is unknown if cerebellar neurons carrying sharp plane information are orderly arrayed, however, it can be assumed that each of the highly plane and directionally specific neurons requires information from many if not all vestibular afferent categories.

156.3 HORSERADISH PEROXIDASE AND GOLGI INVESTIGATIONS OF NUCLEUS Y IN THE MOUSE. C.D. Smith*, A.F. Scoville, M.H. Frederickson, and C.J. Frederickson (Spon: G. Moushegian). Dept. of Psychology, Univ. of Texas at Dallas, Richarson, Tx. 75080.

Brodal and Pomeiano (J. Anat., 1957, 91:438) were first to separately identify (as area Y) the aggregate of vestibular neurons which lie just dorsal to the restiform body, and it was Gacek (Acta Oto-laryngol., 1969, Supp. 254:1) who showed that the primary afferents from the saccular statolith organ project extensively to that vestibular region. As a prelude to study of the effects of altered statolith sensory input upon the structure of second-order neurons of the Y nucleus, we have examined the Y nucleus in normal, adult mice using HRP and Golgi methods.

HRP was used to label the primary vestibular afferents from the saccular macula. To label the afferents, we made stab wounds in the saccular neuroepithelium, perfused the vestibule with HRP solution, and then (after 24 hr survival) reacted the brain-stem tissue with TMB. In the resulting material, the labeled fibers showed the typical, vivid, Golgi-like anterograde staining, and could be readily followed to the Y nucleus. The Y nucleus was distinctly demarcated by the dense plexus of fine, afferent fibers and preterminal fibers which ramified extensively within the region. In coronal sections, the Y nucleus appeared as a small triangle (about 250 μm across) lying on top of the restiform body with the lateral vertex adjacent to the glial cap of cochlear nucleus and the medial vertices oriented along a vertical line just at the lateral margin of the lateral vestibular nucleus.

In the Golgi material, Y neurons proved to be rather homogeneous. The cells were generally small (12 - 20 μm), typically either bipolar, with a fusiform soma, or tripolar, with a more spherical soma. The few, slim primary dendrites branched sparsely, most often into only two daughter branches. Dendrites were generally short (100 - 200 μm) and rarely extended beyond the boundaries of the Y nucleus; dendrites approaching the borders of the Y area were frequently observed to curl away from the border, back into the nucleus. Exceptions to the latter rule were dendrites which descended ventrally and laterally (amidst the ascending primary afferent fibers) along the medial margin of the restiform body.

Fine, hairlike appendages, classical "lollipop" spines, and synaptic crests were all in evidence on the dendrites of Y neurons, although, except at the extreme distal tips, the appendages were not particularly numerous. Both spines and filamentous hairs were identified on the somas of Y nucleus neurons. (Supported by NSF)

156.4 VESTIBULAR CENTERS IN THORNBACK RAY: EVOKED POTENTIAL AND UNIT RECORDING. Wolfgang Plassmann*. (SPON: H.H. Zakon). Neurobiol. Unit, Scripps Instit. Oceanog. and Dept. Neurosci., U.C.S.D., La Jolla, CA 92093.

Little is known about central processing of vestibular input in the elasmobranchs. This study locates vestibular nuclei and pathways at different brain levels and undertakes to distinguish among vestibular modalities represented in these areas in Platyrhinoidis triseriata.

Electrical stimulation of nerve VIII or of individual vestibular nuclei in the medulla and recording of evoked potentials leads to the following findings: (a) the anterior (AN), magnocellular (MN), and descending nuclei (DN) are connected with their opposite medullary counterparts via commissural fibers; (b) a certain vestibular area of the torus semicircularis (TS) receives its main input from AN and MN via the lateral lemniscus; (c) the oculomotor nucleus (OMN) gets vestibular information from AN and MN via the medial longitudinal fasciculus; (d) vestibular input reaches a contralateral diencephalic area as well as the upper and lower leaves of the corpus cerebelli.

Delivery of pulse trains with varying stimulation frequencies reveals at least three response types. The first type is mainly found immediately dorsal to MN, in the dorso-medio-caudal part of AN, and in TS; it responds to stimulation frequencies up to 5/s. The second type occurs predominantly in DN and MN, in TS, and in the cerebellum, while responding to frequencies up to 50/s. The third type responds up to 100/s and preferably occurs in AN and OMN.

Unit recording during presentation of various natural stimuli allows one to establish areas of preference for different vestibular modalities. Pitch and yaw produce phasic responses of neurons located mainly in AN, in a medial portion of DN, and in OMN. Static changes in head position generate a phasic-tonic response in neurons throughout DN. Neurons highly sensitive to vibration stimuli occur predominantly in a region dorsal MN which continues into a caudo-medial portion of AN. They can also be found in some areas of DN and TS.

The findings suggest that TS and OMN receive vestibular input via AN and MN. The information passed on to them, however, appears to be partly different. DN is apparently not involved at this level.

Aided by grants to T.H. Bullock from NIH and NSF and to W. Plassmann from DFG.

156.5 A MODEL OF THE VESTIBULO-COLLIC REFLEX. R. J. Peterka* (SPON: D. L. Tomko). Div. Physiological Acoustics, Dept. Otolaryngology, Univ. Pittsburgh Sch. Med., Eye and Ear Hospital, Pittsburgh, PA 15213.

The vestibulo-collic reflex (VCR) tends to stabilize the head in space during whole body movements. The VCR places the semicircular canals (SSCs) in a negative feedback loop in which compensatory head rotations null the stimulus to the canals. To understand the VCR's dynamic properties, it is necessary to determine the consequences of this feedback arrangement. The purpose of this paper is to present control system models of the VCR which can contribute to this understanding and provide specific predictions (hypotheses) which are testable by appropriately designed animal experiments.

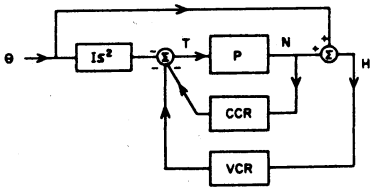
The simplest VCR model predicts that the gain of the VCR will decline at low frequencies since the SSCs cannot accurately encode head velocities below $1/(2\pi\tau_c)$ Hz, where τ_c is the SSC long time constant. However, the VCR corner frequency, above which compensatory head movements are most accurate, is not determined solely by τ_c, but by the sum of τ_c and the open loop gain, K, of the reflex. Above the corner frequency, the model predicts that the gain approaches a value of $K/(K + \tau_c)$ and will therefore always be less than unity. Larger values of K and/or τ_c will increase the VCR bandwidth, and increasing the $K{:}\tau_c$ ratio will enhance VCR gain. The value of these parameters might differ in different species of animals to match their VCR characteristics to specific behavioral needs, neck muscle properties, or various head sizes.

This model can also include an optokinetic system (OKS) component with the same functional form as described by D.A. Robinson (in Control of Gaze by Brain Stem Neurons, Baker and Berthoz eds., Elsevier, 1977) for the vestibulo-ocular reflex (VOR). The OKS provides the VCR with low frequency head rotation information which is combined with higher frequency information from the SSCs to give the overall VCR a response to DC during rotations in the light. The overall VCR has constant gain across all frequencies if the time constant associated with the OKS is equal to the SSC time constant. This choice of an OKS time constant is also consistent with Robinson's VOR model. Since this makes the OKS for the VOR and VCR functionally and parametrically identical, it can be hypothesized that a single OKS can provide the required low frequency head rotation information to both the VOR and VCR.

156.6 A MODEL OF THE NECK MOTOR SYSTEM IN THE ALERT CAT. J. Goldberg* G. Bilotto, B.W. Peterson (Spon: J. Winson). The Rockefeller University, New York. N.Y. 10021

To determine the roles of the vestibulocollic reflex (VCR) and the cervicocollic reflex (CCR) in controlling head position, we have observed head rotation (head free) or head torque (head restrained) about an axis through C_{1-2} during forced horizontal rotation of the body where body angle (θ) was equal to a sum of ten sinusoids ranging from 0.2 to 4.0 Hz. The model below shows how inertial (Is^2) and reflex (VCR, CCR) forces can be expected to sum to produce a torque (T) which acts on the neck motor plant (P) to induce rotations of the head relative to the body (N) and to space (H). Observations in anesthetized cats indicated that P could be modeled as a linear second order system (Eqn. 1, where I is head inertia, B - muscle viscosity, K - muscle spring constant, and s - the Laplace operator). Assuming similar dynamics and linear summation of torques (predicted from our earlier EMG studies), the alert cat's neck motor system will have the transfer function given in Eqn. 2.

In blindfolded, alert cats rotation of the free head was 180° out of phase with θ and gain, $|N/\theta|$ was 0.5-0.7. Our model predicted this behavior from the torque measurements obtained with the head fixed. Increasing I with weights showed that $Is^2 \ll$ VCR below 3 Hz. Torque and EMG measurements indicated that $CCR \cong VCR > BS + K$. Thus the observed head rotation appears to be dominated by antagonistic interaction of VCR and CCR so that: $N/\theta \cong \frac{-VCR}{VCR + CCR}$. (Supported by EY02249, EY00100, NS02619.)



$$(1)\quad P = \frac{1}{Is^2 + Bs + K}$$

$$(2)\quad \frac{N}{\theta} = \frac{-Is^2 - VCR}{Is^2 + Bs + K + CCR + VCR}$$

156.7 EFFECT OF REVERSIBLE LESIONS AND ELECTRICAL STIMULATION OF THE OLIVOCEREBELLAR SYSTEM ON GAIN OF THE VESTIBULO-OCULAR REFLEX (VOR). J. L. Demer* and D. A. Robinson. The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Lesions of the inferior olive (IO) or flocculus abolish plasticity of VOR gain. Modifiable synapses mediating this motor learning might be in cerebellar cortex, or might be elsewhere and the learned component simply carried through the climbing fiber (CF)-Purkinje cell (PC) system. The former theory predicts that momentary CF block would not alter VOR gain, regardless of its adapted value; the latter predicts that gain would immediately revert to some fixed value. Electrical stimulation of the CF's during head rotation might produce a lasting change in VOR gain if modifiable synapses are in the cerebellum, but only a transient change if not. These predictions were tested in 12 cats adapted to low (0.3) and high (1.2-1.5) gains by chronic wearing of optical devices. The field potential created by stimulating the inf. cerebellar peduncle (ICP) was used to locate the IO. An electrode and cannula were placed in the midline at the CF decussation (CFD). 5-10 µL of lidocaine were infused into the CFD of alert cats during VOR gain measurement in darkness. Abolition of CF activity was demonstrated by loss of ICP field potential on CFD stimulation. Regardless of initial state of gain adaptation, there was an immediate increase in VOR gain at 1.2 and 0.05 Hz to some value specific to each cat. Mean gain of 9 cats at 0.05 Hz was 1.50 ± 0.37 (mean ± SD, range 1.02-2.20). Mean gain of 5 cats at 1.2 Hz was 1.23 ± 0.58 (range 0.71-2.18). These gains were obtained in darkness; VOR gain in light was 3-20% lower. Procaine, lidocaine, and tetrodotoxin produced gain increases; glucose and saline did not. As the anesthetic wore off, gain declined to prelesion values as the ICP field potential reappeared. The 26 effective infusion sites were in the rostral half of the CFD; infusions into 20 surrounding sites caused no VOR gain changes.

Bilateral ICP stimulation in darkness (20-100 Hz, 20-100 µA) produced a 15-60% VOR gain decrease in 6 cats, no change in 4, and a 15-75% increase in one cat. Changes, observed at 1.2 and 0.05 Hz, came and went within 5-20 sec of the onset and cessation of stimulation. The effect of ICP stimulation was the same regardless of the initial state of gain adaptation, and was also observed during CFD anesthesia. ICP stimulation produced smaller gain changes in light than darkness. CFD stimulation in darkness produced 10-25% gain decreases in 8 cats. Stimulation never produced lasting changes in VOR gain. These results suggest that learning does not reside in the cerebellum. More must be known, however, about CF action on PC's before this interpretation can be confirmed.

156.8 VESTIBULO-OCULAR REFLEX RESPONSE DYNAMICS DURING PARABOLIC FLIGHT MANEUVERS IN THE SQUIRREL MONKEY. Lionel O. Greene, Jr.* and Nancy G. Daunton. NASA, Ames Res. Ctr., Moffett Field, Ca. 94035

It is implied from manned space flight that the change in certain sensory cues, including gravitational biases from the otolith end organs, may contribute to the onset of disorientation, motion illusions and sickness. Vestibulo-ocular reflex (VOR) nystagmus, an index of vestibular function, has been shown modifiable by otolith stimulation.

An instrumented, restrained squirrel monkey was accelerated about the Earth vertical axis during Learjet meneuvers producing 1, 1/3, 1/6 and zero gravity (G). Horizontal optokinetic (OKN) and vestibular (VOR) nystagmus were evoked by 90°/sec² acceleration to 70°/sec constant angular velocity, and decelerations 70°/sec² to 0°/sec. Baseline (1 G) data were obtained on the ground and in flight. OKN. Optokinetically driven eye movements were not affected by varying G level. VOR. The rate of nystagmus response decay was similar across G levels per acceleration, but the rate and duration of post-rotary nystagmus decay differed significantly at 1 vs. zero G. At 1/6 G, per acceleration VOR gain and latency increased significantly from 1 G, while the per vs. post acceleration average beat frequency (ABF) was significantly from the remaining G forces. There was no difference in the per vs. post accelerations at zero G. These data are presented in figure and table below.

	GAIN per	GAIN post	LATENCY per	LATENCY post	DURATION per	DURATION post	ABF per	ABF post
1 G	.55	.51	0.4	0.3	7.3	5.5	2.6	3.4
1/3 G	.50	.45	0.5	1.5	6.0	3.2	1.5	1.4
1/6 G	.55	.37	1.2	0.7	6.5	1.4	1.2	4.0
Zero G	.47	.43	0.5	0.8	5.2	4.5	1.8	1.4

Orbiting Astronauts have reported motion illusions and episodes of sickness that may be explained by the change in VOR response topography as reported. Adaptation of the vestibular apparatus is speculated the reason for similar experiences being reported upon return to Earth. Long-term habituation to environments of G levels differing from Earth may require an equivalent rehabituation period before normal behavioral activity may ensue.

156.9 RESPONSE OF THE RABBIT VESTIBULO-OCULAR REFLEX TO DIFFERENT MAGNITUDES OF ACCELERATION. R.W. Baloh* and J. Kimm. Animal Vestibular Lab., U.C.L.A. Sch. of Med., Los Angeles, Calif.90024

The vestibulo-ocular reflex of 5 normal adult Dutch pigmented rabbits was tested over a wide velocity range (15-120 deg./s) using step (140 deg./s^2) and sinusoidal (0.0125-0.4 Hz) accelerations. Eye movements were recorded with an implanted induction coil and were analyzed with digital computer techniques. The time constants of decay in slow phase eye velocity after a step change in platform velocity (defined by decay to 37% of initial velocity) were compared with the time constants predicted from the phase lead of slow phase eye velocity during sinusoidal oscillations. There was good agreement between observed and predicted time constants at any given peak velocity but both measurements were markedly velocity dependent. For example, the mean time constants for step changes in platform velocity of 30 and 120 deg./s were 5.8 ±1.5s and 15.8s ±5.2s respectively and the corner frequencies for sinusoidal oscillation at the same peak velocities were 0.038 Hz and 0.009 respectively. These latter values correspond to time constants of 4.2s for a peak velocity of 30 deg./s and 17.5s for a peak velocity of 120 deg./s. By contrast, gain measurements were minimally dependent on velocity (e.g. the average gain values for the 30 and 120 deg./s steps were 0.82 ±0.16 and 0.87 ±0.15 respectively.

The observed increasing time constants and decreasing corner frequencies with increasing platform velocities could be explained on the basis of recruitment of afferent neurons with progressively longer time constants as stimulus magnitude increases. Recent studies documenting a broad range of behavior of primary afferent vestibular neurons in the ray, frog, and cat are consistent with such speculation.

156.10 EFFECTS OF CEREBELLAR STIMULATION AND ABLATION ON THE GOLDFISH VESTIBULO-OCULAR REFLEX (VOR). J.J. Michnovicz* and M.V.L. Bennett, Div. of Cellular Neurobiology, Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

The goldfish cerebellum is essential for adaptive gain changes in the VOR (Schairer and Bennett, Soc. Neurosci. Abstr. 3:485, 1977). Cerebellar units were recorded while training fish to lower VOR gain by rotating the fish inside a brightly lit striped drum rotating in phase (Michnovicz et al., Soc. Neurosci. Abstr. 6:693,1980). Only units showing an immediate change in firing rate when the training stimulus was presented were followed for longer periods. These units(n=31) had a resting discharge of 10-30 impulses/sec (ips), and were modulated less than ±5 ips when rotated in the dark(1/8 Hz, ±20 deg.). The training stimulus immediately increased modulation as much as ±20 ips. 19 units responded maximally to contralateral table velocity, and 12 to ipsilateral. 5 units were held 30-90 minutes, while VOR gain dropped up to 70%. Depth of modulation increased in the dark, as well as during the training. Increases in depth of modulation were correlated with the change in gain.

Cerebellectomy in alert fish is performed in about one minute by aspiration, with no apparent damage to the underlying brain. Three types of fish were operated on: A)untrained(n=5); B)trained to gain of 0(n=5); C)trained to gain of 2(n=3). The average gain for all fish was initially 0.82±0.12. Training lasted 5 hrs in B and C, with resulting gains of 0.13±0.10 and 1.82±0.17. The immediate post-aspiration gains of A, B and C were 1.29±0.13, 1.18 ±0.08 and 1.21±0.18. This hypermetric gain was no longer altered by subsequent training for periods up to 2 hrs.

The cerebellum was stimulated through 3 M NaCl-filled microelectrodes (DC resistance 0.5-1 MΩ) with pulse trains (33/sec, 20 msec duration) of 1-10 μamps. Most vigorous nystagmus was evoked when the electrode was at the depth where most vestibular-sensitive units are recorded, which is in a well-defined layer of Purkinje cells. Sensitivity 0.5 mm deeper was greatly reduced, indicating that there was negligible current spread to the underlying brainstem.

Cathodal current in the dark evoked nystagmus with ipsilateral slow movements. The velocity of the slow phases was approximately linearly related to current strength, and was reversed by anodal current. Strong nystagmus elicited in the dark was suppressed when the fish was surrounded by a brightly lit stationary striped drum. Ipsilateral optokinetic nystagmus produced by moving the drum was increased by electrical stimulation.

These results demonstrate a powerful cerebellar influence on teleost eye movements, which could be mediated by monosynaptic inhibition of neurons in the ipsilateral vestibular nucleus.

156.11 A QUANTITATIVE EVALUATION OF VESTIBULAR COMPENSATION IN FISH. J. F. Ott. Dept. of Biology, Univ. So. Cal., Los Angeles, CA 90007.

Vestibular compensation is the term applied to gradual restoration of normal function after loss of gravistatic input from the inner ear. The functional loss and subsequent recovery have been studied in many species. An especially useful group is the fishes which have no tactile cues or head-neck-trunk interactions. I have studied goldfish after unilateral removal of the utricle, their major gravistatic organ, to find reliable behavioral correlates of the plastic changes involved in vestibular compensation. Although other species of fish have been studied, changes in post-operative lateral tilt were measured strictly by observation (Schoen, L., Z. fur vergl. Physiol. 32: 121, 1950; von Holst, E., Z. fur vergl. Physiol. 32: 60, 1950). I reevaluated this behavior using an automated photographic method in an effort to decrease observer bias. Goldfish were used because their anatomy is well described and they are hardy animals on which it is easy to do further physiological and behavioral experiments.

I have found that vestibular compensation in goldfish takes place in two distinct phases. The acute phase begins immediately after recovery from anesthesia and normally lasts 15-30 minutes. It is characterized by several features. The muscles of the operated side (ipsilateral) are contracted so the body is flexed. Swimming is sporadic and uncontrolled, with fin movements rolling the animal to the ipsilateral side. There is no nystagmus as seen in vestibular compensation in other vertebrates; instead, both eyes roll strongly toward the operated side. The acute phase ends abruptly when the eyes "unlock" from their ipsilateral position. Seconds later, the muscles of the ipsilateral side relax and swimming is normal. In this acute phase, there is very little variation in the duration or intensity.

The chronic phase extends for many days beyond the end of the acute phase. It is characterized by a lateral tilt to the operated side, with an amplitude that decreases to approach zero asymptotically over a period of 5-20 days. In this phase there is a very large variation in both duration and intensity. Some animals appear to compensate immediately, with no residual tilt at all, while others take up to three weeks to return to control values. A single fish may have consecutive daily means that differ by more than 20°, and standard deviations as great as 25°. Pooled data, however, have standard errors of the mean in the range of 1-7°. These results are in contrast to the previous work on fish in which such detailed quantification is not offered. (This work was supported by a Grants-in-Aid for Research from Sigma Xi.)

156.12 OPTOKINETIC AND VESTIBULOOCULAR REFLEXES IN RABBITS WITH BILATERAL PLUGS OF THE HORIZONTAL OR ANTERIOR SEMICIRCULAR CANALS N. H. Barmack and R. G. Erickson*. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland, Oregon 97210.

Bilateral labyrinthectomies not only abolish vestibulooocular reflexes, but also reduce the gain of the horizontal optokinetic reflex (HOKR) in rabbits. One possible explanation for this reduction in gain of the HOKR is that the spontaneous activity of secondary vestibular neurons is reduced by the loss of spontaneous primary afferent input. The consequent reduction in secondary vestibular neuron activity would restrict the range of discharge frequencies over which this activity could be modulated by other sensory inputs; specifically vision. The present experiment was undertaken with the purpose of testing whether an equivalent reduction in the gain of vestibulooocular reflexes (eye velocity/head velocity) produced by bilateral plugs of the horizontal or anterior semicircular canals would reduce the gain of the HOKR (eye velocity/stimulus velocity).

Fifteen rabbits were subjected to either bilateral plugs of the horizontal (HSC) or anterior semicircular canals (ASC). The horizontal optokinetic reflex (HOKR), horizontal vestibulooocular reflex (HVOR), and vertical vestibulooocular reflex (VVOR) were tested before and after the plugging operation, and at various times following removal of the plugs. Plugs were constructed from silver wire formed into a spindle under heat. After a small opening was made in the bony portion of the semicircular canals at least 1 mm from the ampullae in anesthetized rabbits, plugs were inserted into the semicircular canals where they compressed the membranous labyrinth. The plugs were left in place for 24-48 hr, after which the rabbits were re-anesthetized and the plugs removed. Bilateral plugs of the HSC or ASC caused no significant decrease in the gain of the monocularly-evoked HOKR tested with a stimulus field of 72 x 72 deg at velocity of 00.4-50.0 deg/sec. Bilateral plugs of the HSC abolished the HVOR over the frequency range of 0.02-0.80 Hz. The gain of the VVOR in rabbits with bilateral HSC plugs was not reduced. Conversely, bilateral plugs of the ASC caused a reduction in the gains of both the VVOR and HVOR. Upon removal of the plugs of the HSC or ASC, the gains of the HVOR and VVOR returned to within 75% of normal within 10 days. We conclude that bilateral plugs of the HSC and ASC cause a reduction in the gain of the appropriate vestibulooocular reflex by restricting the flow of endolymph rather than by directly damaging the ampullae. Unlike labyrinthectomies, bilateral plugs of the semicircular canals do not reduce the gain of the HOKR. (Supported by NIH grant EY00848 and the Oregon Lions Sight and Hearing Foundation.)

156.13 ETIOLOGY OF SPACE MOTION SICKNESS: ROLE OF OTOLITH- SEMICIRCULAR CANAL INTERACTIONS. J.R. Lackner and Ashton Graybiel* Psychology Department, Brandeis University, Waltham, MA 02254.

Astronauts often experience symptoms of motion sickness (MS) during their first days in orbital flight, especially when making head movements (Graybiel, 1980, Aviat. Space Environ. Med. 51, 814-822). These symptoms may be related in part to alteration of the vestibulo-ocular reflex (VOR) in free fall: relative to earth-gravity values, VOR gain diminishes in the free fall phases of parabolic flight and increases in the high force (≥1.8g) phases (Lackner and Graybiel, 1981, Aviat. Space Environ. Med.52, 154-158).

To test this hypothesis, 20 subjects (Ss) were exposed on the ground and in parabolic flight to provocative vestibular stimulation until a MS endpoint of nausea was reached. Ss were accelerated at $15^{o}/s^{2}$ to a clockwise angular velocity of $300^{o}/s$, maintained at this velocity for 30s, and decelerated to rest within 1.5s. For the first 20 stops, each S was blindfolded, for the next 20 his eyes were open and he viewed passively the vertically-striped cylindrical experimental enclosure, for the final 20 stops, his eyes were open and the direction of rotation was reversed. The number of stops tolerated before the MS endpoint was reached served as an index of susceptibility. Each S was first tested in the laboratory and then in parabolic flight maneuvers in a Boeing KC-135 aircraft. In one flight test, Ss were accelerated to constant velocity in free fall and decelerated to rest in the high force (≥1.8g) phase of flight. In another test, accleration was in the high force phase and deceleration in free fall. Test order was balanced across Ss.

MS susceptibility was significantly greater ($p<.001$) both in free fall and in the high force phases of parabolic flight than in 1g test conditions. Ss developed symptoms more rapidly and the symptoms also persisted longer. Susceptibility did not differ, however, for the free fall and high force test conditions ($p>.05$).

These findings demonstrate that departures in either direction from earth-gravity force levels increase MS susceptibility. This suggests that the otolith organs, which are influenced by gravitoinertial force level,affect canalicular responsiveness. This interpretation accords with changes in the VOR in supra- and infra-g test conditions and the report by Igarashi et al., 1977 (Arch. Oto-Rhino-Laryng. 217, 183-188) that pendular rotation nystagmus decreases after ablation of the otolith organs.

156.14 TORSIONAL EYE MOVEMENTS IN MAN DURING LINEAR ACCELERATIONS UPON EMERGING FROM WEIGHTLESSNESS. A. P. Arrott*and L. R. Young.
Man-Vehicle Laboratory, M.I.T., Cambridge, MA 02139.

Experiments were conducted to investigate the relation between gravitoinertial force (GIF is gravity minus linear acceleration) and the resulting torsional eye movements (ocular torsion, OT) in man. The OT of human subjects was measured using a binocular photographic technique. OT is known to occur in response to lateral head tilt and in response to lateral acceleration with the head upright. Both of these stimuli consist of a rotation of the GIF vector relative to the head. The question arises whether the rotation of the vector or merely the change in its lateral component is the adequate stimulus for OT.

A linear acceleration cart was used to accelerate subjects sinusoidally at a frequency of 0.4 Hz at amplitudes between 0.2g and 0.8g. Over this range the resulting OT was sinusoidal, with sensitivity of about 3 deg/g in the upright position and about 1 deg/g in the supine position (deg/g: deg. of OT per g of head lateral GIF). Head tilt at this frequency results in OT of about 3 deg/g.

The conditions of parabolic flight were used to achieve lateral acceleration with no pre-existing GIF and consequently no rotation of the GIF vector. OT was measured during the transition from the free fall phase (0g) to the pull-up phase (about 2g) of the flight trajectory. Subjects were positioned in the aircraft such that this change in GIF occurred laterally with respect to the head (lying on the side). OT was observed in the same direction as if the subject had been tilted to this position from the upright. The sensitivity of OT was about 4 deg/g. Actual tilting in gravity using a similar time course would produce OT of about 6 deg/g.

The results of these experiments support the notion that a change in the lateral component of GIF rather than a rotation of the gravitoinertial vector, is the adequate stimulus for ocular torsion.

This research was supported in part by NASA grants NAS9-15343 and NSG-2032. A.P.A. was supported in part by the MIT Sloan Basic Research Fund and NIH Training Grant 5-T32-GM07301-05.

156.15 VESTIBULAR RESPONSE DECLINE, SKEWNESS, & INPUT-DEPENDENT GAIN & THRESHOLD ARE EXPLAINED BY A SINGLE MECHANISM. Bernard N. Segal and John S. Outerbridge*. Dept. Physiol., Biomed. Eng. Unit, Dept. Otolaryngol., McGill Univ., Montréal, Québec, H3G 1Y6.

It was previously shown that during prolonged 0.3 Hz sinusoidal rotation most bullfrog semicircular canal primary neurons exhibit input-dependent gain and threshold, as well as response decline. This could be accounted for by assuming that significant hair cell non-linearities precede adaptation and high frequency lead phenomena associated with the hair cell-primary neuron synapse (Neurosci. Abst. 5:692). Neural response skewness has now been characterized by the skewness coefficient (g_1) in order to further test these assumptions. It was found that (1) most (73%) cells tended to exhibit positively skewed responses (had longer right-hand tails), (2) skewness was significantly correlated with stimulus amplitude, and with 'high-frequency phase discrepancy', attributable to a high-frequency lead element and (3) skewness was uncorrelated with either viscoelastic (semicircular canal) or adaptation time constants, estimated from responses to lower-frequency stimuli.

Simulation studies have shown that a single mechanism - approximate differentation of the output of a thresholding and saturating non-linearity - can account for these observations, as well as response decline and input-dependent gain and threshold. If a saturating rectifier is followed by approximate differentiation due to an adaptation element, response decline occurs during prolonged high-frequency sinusoidal stimulation and input-dependent gain and threshold characterizes the late non-declining response; at low-frequencies, the positive peaks of the response are positively skewed. If a saturating rectifier is followed by approximate differentiation due to a lead-lag element, response decline occurs during higher-frequency stimulation; at mid-frequencies, the peaks of the phase leading response exhibit positive skewness which increases with stimulus amplitude. If both adaptation and lead-lag elements follow a saturating rectifier, as was assumed for the bullfrog semicircular canal primary afferent pathway, the positive peaks of the response are positively skewed, skewness increases with stimulus magnitude, and skewness increases with the phase lead introduced by the lead-lag element. The lack of correlation, in the neural data, between skewness and adaptation, or viscoelastic,time constants was expected because adaptation had negligible effects at 0.3 Hz, and because canal mechanics were assumed to precede the dominant (hair cell) non-linearity of this pathway. Thus the proposed mechanism accounts for a wide variety of phenomena which otherwise appear unrelated.

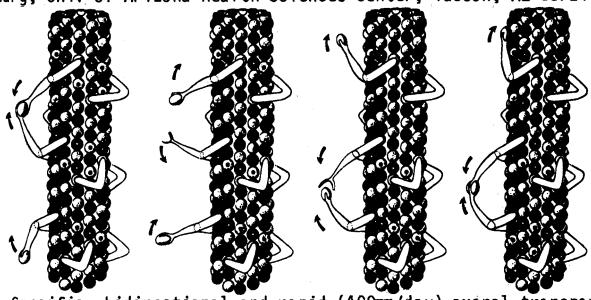
156.16 VESTIBULAR INVOLVEMENT IN SPATIAL ORIENTATION. S.L. Miller*, M. Potegal and L. Abraham (SPON: A.M. Gentile). Teachers College, Columbia Univ., New York, NY 10027; N.Y. State Psychiatric Inst., New York, NY 10032 and Dept. of Physical & Health Ed., Univ. of Texas, Austin, TX 78712.

The importance of vestibular contributions to spatial orientation has long been debated. Studies have yielded conflicting results; while some investigators found long distance bird navigation unimpaired by vestibular dysfunction, others continued to report indirect evidence for vestibular involvement in shorter distance tasks (Barlow, J. Theoretical Biol., 6, 1964). Beritov demonstrated that labyrinthine damage impaired performance of a vestibular/spatial orientation task requiring animals to return to a target point from which they had been passively transported (Beritov, Neural Mechanisms of Higher Vertebrate Behavior, 1965). We have developed a similar "passive transport and return" task (PTR) for rats. In PTR, water deprived rats are passively transported through right angle trajectories of varying distances in an opaque vehicle from one of eight identical spouts bordering a visually homogenous room. To obtain water upon release, the rat must return to the target spout from which he was transported on that trial. We have demonstrated that blinded rats can perform PTR, and that vestibular nuclei, but not cerebellar cortex lesions severely impair PTR performance in blinded rats (Miller et al., E.P.A., 1979), not effecting their performance in a control, olfactory/spatial task.

We report here an extension of these findings. Seven visually intact rats received vestibular nuclei lesions; six rats, dorsal column nuclei (DCN) lesions; and eight rats, sham operations. In PTR acquistion, vestibularly lesioned rats were significantly impaired compared to sham operated rats; DCN lesioned rats' performance was intermediate. In a control task, eight vestibular nuclei, nine DCN and eight sham rats were required to choose a scented string from one of seven visually identical strings and follow it to its end for a water reward. There were no significant differences among groups on this olfactory/spatial task which was at least as difficult (judging by the sham rats' performance) as the vestibular/spatial task. The efficacy of vestibular lesions in producing vestibular dysfunction is indicated by air righting responses for rats in both tasks, which revealed that the vestibular group was significantly different from sham and DCN groups in angle of head inclination at landing. These findings support the hypothesis that vestibular information is necessary for successful performance of specific spatial tasks.

157.1 "COMPUTER-LIKE" MICROTUBULE MODEL OF AXONAL TRANSPORT. S.R. Hameroff, R.C. Watt*, J.C. Oakley*,Dept Anesthesiology,Div Neurol Surg, Univ of Arizona Health Sciences Center, Tucson, AZ 58724



Specific, bidirectional and rapid (400mm/day) axonal transport depends on microtubules (MT) and associated ATPase proteins. Mechanisms of spatial arrangement and temporal control of attached contractile proteins remains unknown in axonal transport and similar MT functions. Atema (J Theor Biol 38:181, 1973) proposed that sensory cilia MT transferred information by propagated conformational changes among MT subunits (alternating α and β tubulin). Tubulin conformational states may be coupled to transferable Ca^{2+} binding (via calmodulin), energy state, electron occupancy, or electron excitation in aromatic hydrophobic regions (Frolich H: Proc Natl Acad Sci 72:4211, 1975). The cylindrical grid-like MT structure, connecting proteins, and intracellular trabecular networks (Porter KR, Tucker JB: Sci Am 244:56, 1981) could provide programmable switching matrices for information transfer resulting in temporal and spatial control of axonal transport. Media of information transfer among the 4 nm, 55,000 dalton subunits could include conformational states coupled to any of the previously mentioned modes. Tubulin switching programming regulating directional transfer could ensue from genetically-controlled primary protein structure, or post translational effects including binding of proteins, ions, or other substances. Pulsed reading, switching, and transduction could be driven by nerve membrane depolarization or calcium ion fluxes. Key intraprotein hydrophobic environments could thus integrate and transduce several input modes to determine conformational state and mechanical activities. Aspects of this model are analogous to information and computer technologies including programmable Boolean switching matrices, transistor circuits, bubble memory, charge transfer devices, and/or surface acoustic wave resonators.

157.2 COBALT INDUCED DISRUPTION OF THE GOLGI APPARATUS BLOCKS ASSEMBLY OF FORMING FACE ELEMENT. James D. Lindsey and Mark H. Ellisman, Department of Neurosciences, University of California, San Diego, School of Medicine, La Jolla, CA 92093.

Low levels of cobalt have been shown to selectively block the initiation of fast axonal transport. Ultrastructurally, such cobalt treatment produces a specific depletion of the Golgi apparatus (GA). Concomitantly, there is a dramatic accumulation of smooth membranous cisternae which do not stain for thiamine pyrophosphatase (TPP). To examine the interaction of cobalt with the GA cis (forming) element, bullfrog spinal ganglia were incubated for 12 hrs. in a modified Ringer's solution both with and without 0.18 mM cobalt and then subjected to an osmium impregnation protocol. Thin and thick sections were studied by conventional as well as high voltage electron microscopy.

This impregnation technique results in deposition of osmium in the cis element of the GA. Also stained were a few isolated small rounded profiles. In thick section, the cis element is seen to be large, regularly perforated, sheet-like cisterns. Anastomotic with these cisterns were two distinct types of "accessory tubules". The first, 50-80 nm in width, was smooth surfaced and often ran in pairs or small bundles. The second, 20-30 nm in width, was characterized by regularly spaced swellings and usually coursed as isolated individuals through the cytoplasm. These tubules probably correspond to the small isolated profiles seen in thin section.

Examination of the cobalt treated ganglia revealed that many of the accumulated smooth membranous cisternae were stained. In thick section, the osmiphillic elements appeared as small, flat, perforated cisterns and as clustered vesicles varying from 50-120 nm in diameter. The accessory tubule systems appeared largely intact except that they now ended blindly or in small end bulbs.

These findings suggest two major conclusions. First, the "accessory tubule system" is seperate from and probably antecedent to the cis element. Second, low levels of cobalt specifically block GA cis element assembly which consequentially results in falure of the trans element's maturation.

157.3 EFFECTS OF ANTIMITOTIC DRUGS ON AXOPLASMIC TRANSPORT IN TISSUE CULTURED NERVE CELLS. H. HORIE*, T. TAKENAKA* and K. INOMATA* (SPON : M. Sato) Dept. of Physiology, Sch. of Med., Yokohama City University, Minamiku, Yokohama, Japan 232

The role of microtubules in the axoplasmic transport was studied by using the antimitotic drugs in tissue cultured nerve cells. Dorsal root ganglion cells dissected from 6-day-old chick embryos were cultured in Eagle's minimal essential medium supplemented with 10% horse serum and 5% chick embryo extract. A cultured dish was made of a silicon plate fixed a cover glass on the bottom. After 3 days, the transported particles in the neurites (dia : 1.5-2.5μm) near the growth cones were observed with Nomarski differential interference contrast microscopy and cultured medium was perfused with the solution containing the antimitotic drugs. The movements of the particles were recorded with a video tape recorder.

Colchicine at $1x10^{-6}$M caused the decrease of the number of the transported particles in the neurites. At 30 min after the application of colchicine the number of the transported particles decreased to about 50%. Two types of the particle movement were observed. Small particles (<0.5μm) were transported smoothly and those velocities were 1.0-1.8μm/sec, which values were almost same as those in control. On the other hand the movements of the large size particles were to-and-fro. At 60 min the transported particles could not be observed. Morphologically the neurites did not retract and the position of the neurites did not change. But some resions in the neurites swelled and the particles transported into those resions stopped. The same effects on the axoplasmic transport were observed in vinblastine at $1x10^{-6}$M. The concentration required to supress the axoplasmic transport of 50% at 60 min after the drug application was approximately $1x10^{-7}$M, which value coincides with the binding constant of colchicine to chick embryo brain tubulin, $5x10^{-7}$M. Cytochalasin D at $2x10^{-5}$M had no effect on the number of transported particles and their velocities at 60 min after application. These results suggest that colchicine or vinblastin disrupted the microtubules in the neurites and as a result of it the movements of the transported particles were supressed. So microtubules play an important role in axoplasmic transport in tissue cultured nerve cells.

157.4 TUBULIN ADP-RIBOSYLATION IS CATALYZED BY CHOLERA TOXIN. Dan J. Hawkins* and Edward T. Browning (SPON: Roger C. Duvoisin). CMDNJ-Rutgers Medical School, Dept. of Pharmacology, Piscataway, NJ 08854.

The covalent modification of proteins by an ADP-ribosyl moiety derived from NAD^+ is catalyzed by cholera toxin. Cholera toxin catalyzes the ADP-ribosylation of several proteins including the regulatory component (G/F) of hormone-sensitive adenylate cyclase. The ramifications of cholera toxin-catalyzed ADP-ribosylations are still poorly understood.

Rat C6 glioma cell membranes and cytosol were prepared by the method of Jett et al. (JBC 252: 2134). Membranes and/or cytosol were incubated with ^{32}P-NAD^+ and cholera toxin and the proteins resolved on the basis of isoelectric point and mol. wt. using 2-dimensional gel electrophoresis. Gels were stained with Coomassie blue, destained, and the dried gels subjected to autoradiography. Cholera toxin catalyzed the ^{32}P-ADP-ribosylation of putative subunits of the membrane G/F protein. Cholera toxin also catalyzed the ADP-ribosylation of several cytosolic proteins. One of these cholera toxin-dependent ^{32}P-ADP-ribosylations in cytosol was located by autoradiography as an acid satellite relative to stained tubulin. This ^{32}P-ADP-ribosylation was preferentially associated with beta tubulin. Tubulin modified by ADP-ribosylation would undergo an acid shift in 2-D gels due to the charge of the ADP-ribosyl moiety. No toxin catalyzed acidic shift was discernible for the stained tubulin. The data suggested that a small amount of tubulin may have undergone a cholera toxin-catalyzed ADP-ribosylation. The presence of GTP promoted the cholera toxin-catalyzed ^{32}P-ADP-ribosylation of the ^{32}P-ADP-ribosylated protein associated with tubulin and the ^{32}P-ADP-ribosylated membrane G/F peptide subunits.

Bovine brain tubulin was prepared by three cycles of warm/cold polymerization/depolymerization according to Shelanski et al. (PNAS 70: 765). Bovine brain tubulin incubated with ^{32}P-NAD^+, GTP, and cholera toxin was observed in 2-D gels to possess a ^{32}P-ADP-ribosylated acidic satellite in autoradiograms relative to stained tubulin just as was found with rat C6 glioma cell tubulin. Peptide mapping of bovine brain tubulin and the associated ^{32}P-ADP-ribosylated protein was performed using the method of Cleveland et al. (JBC 252: 1102). Correspondence was observed between the autoradiographic images of the peptide map and the stained peptide fragments. This served to confirm that cholera toxin catalyzes the ADP-ribosylation of tubulin. ADP-ribosylation of even a small fraction of tubulin might effect alterations in certain microtubule-associated processes (e.g., treadmilling). (Supported by NIH grant NS 08436 and CMDNJ Foundation grant 29-81.)

157.5 SODIUM REQUIREMENT FOR FAST AXONAL TRANSPORT IN THE FROG DORSAL ROOT GANGLION-SPINAL NERVE PREPARATION. P.-A. Lavoie. Département de pharmacologie, Université de Montréal, Montréal, Canada.

A previous study had showed that the substitution of sucrose for the NaCl of the incubation medium decreased the quantity of [^{3}H]leucine-labeled proteins carried by the fast axonal transport system (Lavoie, Can. J. Physiol. Pharmacol. 59: 31-36, 1981); the effect was demonstrable when either the dorsal root ganglion or the desheathed spinal nerve was exposed to the modified medium. Since sucrose is not only a Na^+ substitution but also a Cl^- substitution, it was appropriate to study the influence of a selective substitution of Na^+ ions: to that effect, the 114 mM NaCl of the normal incubation medium was replaced by 114 mM LiCl in the modified medium used for the present experiments.

Frog dorsal root ganglia were exposed to [^{3}H]leucine for 1 h *in vitro*, and the ganglia and spinal nerves were incubated for a further 16-17 h at 18°C in medium free of added radioactivity; the ganglion was isolated from most of the nerve trunk by a silicone grease barrier during this incubation. For experiments on the dorsal root ganglion, control ganglia and spinal nerves and experimental nerves were in normal medium whereas experimental ganglia were in modified medium; with this set-up, a 60% reduction in the quantity of fast-transported [^{3}H]proteins was observed. For the set of experiments on spinal nerves, all spinal nerves were desheathed along 4-5 mm of their length (approx. midway between the ganglion and the junction of the spinal nerve to the sciatic nerve) prior to labeling of ganglia with [^{3}H]leucine. The desheathed nerves of the control preparations were incubated in normal medium as were the control and experimental ganglia, but the desheathed nerves of the experimental preparations were incubated in modified medium. Axonal transport through the desheathed region of nerve was quantitated by the level of trichloroacetic acid-insoluble radioactivity present at a ligature distal to the desheathed area of the nerve, and it amounted to approx. 50% of control in nerves exposed to the LiCl medium.

Thus the presence of Na^+ ions in the extracellular fluid seems required if normal fast axonal transport is to be maintained in this biological preparation from frog. It has been speculated that sodium deficiency may inhibit transport in the cat hypogastric nerve by increasing intracellular Ca^{2+} (Esquerro et al., Brit. J. Pharmacol. 70: 375-381, 1980), but this is probably not the mechanism of inhibition in the frog preparation since Li^+ is a form of Na^+ substitution which does not modify Ca^{2+} fluxes across the plasma membrane in neurons of the frog spinal nerve (Stout & Diecke, Can. J. Physiol. Pharmacol. 58: 1366-1372,1980).

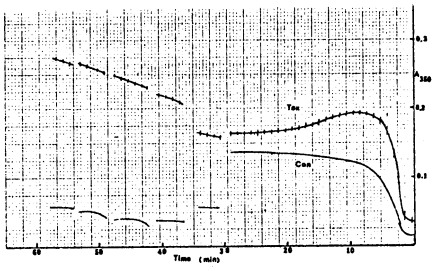
157.6 EFFECTS OF L. QUINQUESTRIATUS SCORPION VENOM ON THE IN VITRO POLYMERIZAITON OF TUBULIN. Lelland C. Tolbert and George B. Brown. Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

We have studied the effects of crude and fractionated scorpion venom from Leiurus quinquestriatus on the polymerization of cycle-purified tubulin from bovine brain. Tubulin at a concentration of 1-2 mg/ml was incubated under the assembly conditions of Weingarten et al (Biochem. 13:5529, 1974) with or without addition of scorpion venom and polymerization was followed by the increase in light scattering at 350 nm. Crude scorpion venom (separated from insoluble mucopolysacccharides), at final concentrations of 10-15 µg protein/ml, had dramatic effects on both the rate of increase in light scattering and the lability of tubules to Ca^{++}-induced depolymerization. Incubations containing scorpion venom actually gave an increase in light scattering in response to addition of Ca^{++}. These effects are indicated in the figure below. Each break in the curves corresponds to the addition of CaCl such that the net concentration of calcium is increased by 0.75 mM. Similar effects were obtained from one and only fraction resulting from ion exchange chromatography of crude scorpion venom on SP-Sephadex. These effects are distinguished from those of other agents affecting the polymerization of tubulin, e.g., nerve growth factor, taxol and natural and synthetic polycations.

The active fraction is also the most lethal fraction (determined by bioassay in mice) resulting from the chromatography and contains the component which binds to voltage sensitive sodium channels and enhances the binding of batrachotoxin to its sodium channel site. This fraction contains less than 10% of the protein in the crude venom. Thus, the effective concentraiton for the effects on tubulin is $\leq$ 1 µg protein/ml.



157.7 REDISTRIBUTION OF FAST AXONAL TRANSPORT OF PROTEINS IN β,β'-IMINODIPROPIONITRILE (IDPN) INTOXICATION. AN ULTRASTRUCTURAL AUTORADIOGRAPHIC STUDY. S. Ch. Papasozomenos* L. Autilio-Gambetti*, P. Gambetti. Division of Neuropathology, CWRU, Cleveland, Ohio 44106.

IDPN intoxication selectively impairs the transport of neurofilament proteins, while the rate of the fast anterograde and retrograde transports are not affected (Griffin et al., Science, 202:633, 1978). We have recently shown that IDPN intoxication produces a rearrangement of axonal organelles, with displacement of neurofilaments towards the periphery and of microtubules, smooth endoplasmic reticulum (SER) and mitochondria towards the center of the axon (Papasozomenos et al., J. Neuropathol. Exp. Neurol., 39:380, 1980). Quantitative electron microscopic autoradiography (EMAR) was undertaken to determine the distribution of proteins migrating with the fast component of axonal transport in IDPN-treated and control rats. A mixture of ^{3}H-proline and ^{3}H-lysine was injected into the spinal cord, and six hours after, the sciatic nerve was dissected out and sectioned into 2 mm pieces. Radioactivity was determined by liquid scintillation counting in alternate segments and the region of the nerve containing the front of the transported proteins was processed for EMAR. The results show that proteins migrating with the fast component of axonal transport are displaced towards the center of the axon, as compared to the control. This redistribution parallels that of microtubules and SER previously found by us in this experimental model.
(Supported by NIH Grants NS-14509 and AG_00795).

157.8 COMPARISON OF RAPIDLY TRANSPORTED PROTEINS IN FROG AND RAT SENSORY NEURONES. G.W. Perry* and David L. Wilson. Dept. of Physiol. and Biophys., Univ. of Miami, Sch. of Med., Miami, Fl 33101.

Some studies have suggested that the electrophoretic profiles of rapidly transported proteins might be similar in the axons of different species (Barker et al 1975; Bisby, 1977), but Neale et al (1980) report very little correspondence in the profiles of these proteins from the sensory neurones of rat and frog. We have resolved this issue by studying rapidly transport proteins on two dimensional polyacrylamide gels. Dorsal root ganglion (DRG) neurones from rat and frog were labeled in vitro with ^{35}S-methionine, and the newly synthesized, rapidly transported proteins were collected at ligatures on the sciatic nerves approximately 30 mm from DRG as described in Stone & Wilson (1979).

The rat preparation was incubated for 10 hrs at 30°C and the frog preparation for 24 hrs at 18°C. A co-migration analysis (triplets of gels compared: one gel from frog, one gel from rat, one gel from frog + rat) revealed three classes of proteins. (1) Some proteins spots, including A2, A17-18, $B3_{a-g}$, $B14_{a-i}$, and C1 co-migrated on the gels, suggesting that these abundantly transported proteins have been well conserved during evolution (gel spot notation as in Stone & Wilson, 1979; Perry & Wilson, 1981). (2) Other protein spots had similar, but not identical positions on the gels. The gels separate proteins according to isoelectric point in one dimension and molecular weight in the second dimension. Thus slight differences in position reflect differences in size and charge which could result from (minor) evolutionary modifications of proteins with similar functions. (3) A number of the rat and frog proteins appeared to be species specific. However, these could have resulted from very radical abundance changes (protein abundance or methionine-residue abundance) or very radical position changes on the gels. The species apparantly unique to frog include $A1_{a-i}$, $A4_{a-d}$, A10, C2-6, C8-11, and C18.

The gel staining patterns of unlabeled proteins in the sciatic nerves of rat and frog show some similarities: for example, actin, serum albumin, and the α and β subunits of tubulin are in identical positions on the gels. Each pattern also has major spots that are unique.

It appears then, that there are not only a number of highly (evolutionarily) conserved proteins in rapid transport and in the sciatic nerve, but also a number of species-specific proteins.

157.9 HIGH AND LOW AFFINITY MUSCARINIC CHOLINERGIC RECEPTORS UNDERGO AXONAL TRANSPORT. M.A. Zarbin*, J.K. Wamsley and M.J. Kuhar. Dept. of Neuroscience, Johns Hopkins Univ., Sch. of Med., Balto., MD 21205.

Axonal flow of opiate and muscarinic receptors has recently been found in the rat vagus and dog splenic nerve, respectively (Young et al., Science 210:76, 1980; Laduron, Nature 286:287, 1980). Here, we report that muscarinic receptors are also undergoing transport in the rat vagus nerve. Transported muscarinic binding sites were assayed as described previously (Wamsley et al., Brain Res., in press).

Muscarinic binding sites accumulate in a time dependent manner both proximal and distal to ligatures placed around the vagus nerve trunk. The rate of accumulation appears to be constant during the first 24 hrs. of ligation. The accumulation proximal to the ligature is greater than the accumulation distally. The calculated average rate of receptor transport is roughly 15 mm/day for receptor accumulation proximal to the ligature and roughly 10 mm/day for receptor accumulation distal to the ligature. These values are an underestimate of the true rate of receptor transport because only a small fraction of the axonal receptors seems to be moving.

The transported muscarinic binding sites have pharmacologic characteristics appropriate for a muscarinic receptor.

Muscarinic receptor transport is inhibited by the injection of low doses of colchicine into the vagal nerve trunk. Double ligature experiments reveal a build up of binding sites proximal to both ligatues and distal to the ligature furthest from the nodose ganglion. These data are consistent with the notion that peripherally transported receptors move by fast transport while centrally tranported receptors move by retrograde transport.

Preliminary experiments indicate that the bulk of peripherally transported binding sites are high affinity muscarinic receptors, while most of the receptors accumulating distal to the ligature are low affinity muscarinic receptors. Similar results have been obtained for tranported muscarinic receptors in the rat sciatic nerve (Wamsley, et al., ibid.).

The presence and transport of cholecystokinin and insulin receptors has also been detected in the rat vagus nerve. Neither the presence nor the transport of glycine, H-1 histamine, beta-adrenergic, and benzodiazepine receptors has been detected in the rat vagus. In the rat sciatic nerve, however, the presence and transport of beta-receptors and H-1 histamine receptors has been detected. Thus, receptor transport may be a property of most neurotransmitter receptors.

157.10 AXONAL TRANSPORT OF GANGLIOSIDES IN MAMMALIAN PERIPHERAL NERVE. U.R. Tipnis*, J.H. Hofteig, H.W. Palay*, K.S. Leon*, and A.J. Yates. Department of Pathology, Ohio State University College of Medicine, Columbus, Ohio 43210

The following studies were performed to determine the time course of incorporation of radioactivity from (^{3}H)-glucosamine injected into dorsal root ganglia (DRG) into gangliosides of 3 segments of this nerve unit: DRG, lumbosacral trunk (LST) and sciatic nerve (SN). Normal adult female New Zealand white rabbits were anaesthetized with nitrous oxide and halothane. Both L-7 DRG were aseptically exposed and injected with 50µci (^{3}H)-glucosamine (S.A=39.6Ci/mmole). Animals were allowed to survive 1, 2, 7, 15, and 21 days at which times they were killed and DRG, LST, and SN removed and frozen. Specimens were homogenized and extracted in chloroform-methanol (C-M) 2:1 and C-M-water 1:2:5%. Gangliosides were purified by a Folch partition, treatment of upper phase with alkaline phosphatase and phosphodiesterase, alkaline methanolysis, dialysis and silicic acid column chromatography. Radioactivity was determined on aliquots of initial homogenate, acid soluble fraction, and purified gangliosides. Expressed as a percent of the total radioactivity present in the homogenate of all 3 segments (DRG + LST + SN) radioactivity in the DRG decreased from 95% at day 1 to 80% at day 21. Radioactivity in homogenates of LST and SN increased from 3 to 14% and 1 to 5% respectively, and acid soluble radioactivity progressively decreased over the same time in all 3 segments. Radioactivity in the gangliosides of DRG at day 21 was only 46% that of day 1, but radioactivity in LST and SN increased 5-and 6-fold respectively (Table 1). Colchicine injected into DRG prior to (^{3}H)-glucosamine completely blocked the transport of all lipids into LST and SN. These results are compatible with the synthesis of gangliosides in DRG and their subsequent transport into LST and SN. However, the possibility of local synthesis of gangliosides within LST and SN cannot be ruled out.

TABLE 1. RADIOACTIVITY (DPM) IN GANGLIOSIDES

Anatomic Segment	Days Following Injection 1	2	7	15	21
D.R. Ganglion	26,800	18,500	14,200	13,200	12,600
Lumbosacral Trunk	1,070	1,700	1,300	3,600	5,400
Sciatic Nerve	590	1,140	1,600	1,800	3,500

157.11 ^{3}H-PUTRESCINE IS INCORPORATED INTO PROTEINS AFTER INJECTION INTO THE GIANT NEURON R2: RAPID AXONAL TRANSPORT OF THE LABELED PROTEIN. Richard Ambron and Leon Kremzner*, Depts. Anatomy, Neurology, and Rehab. Med., P&S, Columbia Univ., N.Y., N.Y. 10032.

A relationship between cell surface macromolecules and the intracellular cytoskeleton has been suggested by a number of studies but the nature of the interaction remains unknown. Transglutaminase, an enzyme that cross-links proteins, is a good candidate as an effector of such surface-cytoskeletal interactions and recently was shown to participate in carrier-mediated endocytosis (Davies et al., Nature, 1980). The function of this enzyme appears to be regulated by polyamines, which act as substrates, and are incorporated into protein (Folk et al., J. Biol. Chem., 1980). We have found transglutaminase activity in R2, the giant cholinergic neuron of Aplysia (Kremzner and Ambron, in prep.) and have shown that ^{3}H-putrescine (^{3}H-Put) injected directly into R2, becomes covalently linked to protein. This was accomplished by isolating and characterizing γ-glutamylputrescine (Kremzner and Ambron, These Proceedings). Among the soluble proteins labeled by putrescine are several (m.w. 56Kd, 48Kd, and 42Kd) that are precipitated by vinblastine: the 56 Kd protein migrates on gradient gels with tubulin isolated from rat brain. Several high m.w. membrane proteins also become labeled. We have not established whether the putrescine is covalently linked to each of these specific proteins, however.

^{3}H-Put injected into R2 is rapidly metabolized to spermidine, spermine, GABA, and and monoacetylputrescine, as determined by HPLC. Analysis of Aplysia nervous tissue detected the polyamines in approximately the same proportion as found for the labeled compounds in R2, indicating that injected putrescine is metabolized like the endogenous compound. The soluble polyamines diffuse along R2's axon where additional metabolism can occur: assays of extruded axoplasm indicate the presence of S-adenosylmethionine decarboxylase activity. In contrast, examination of radioactivity in sequential segments of R2's axon shows that ^{3}H-polyamine(s) associated with protein is rapidly transported along the axon toward R2's synapses. (Supported by Grants from NIH, Muscular Dystrophy Assoc. and by a Career Development Award to R.A.)

157.12 AXONAL TRANSPORT OF POLYAMINES IN INTACT AND REGENERATING MOTOR AXONS OF THE RAT SCIATIC NERVE. T.D. Lindquist*, N.A. Ingoglia and J.A. Sturman, Depts. of Physiol. and Neurosci., CMDNJ-New Jersey Med. Sch., Newark, NJ 07103 and Dept. of Pathol. Neurobiol., Inst. for Basic Research in Mental Retardation, Staten Island, NY 10314

The axonal transport of polyamines has been demonstrated in regenerating optic axons of goldfish (Ingoglia et al., 1977, Brain Res., 130:433-445) but has been reported not to occur in motor axons of the sciatic nerve of rats (Harik et al., 1979, Exper. Neurol., 63:311-321). The present experiments are similar in design to those of Harik et al. but in contrast to their findings, we report evidence that following injection of ^{3}H-putrescine into the spinal cord, radioactive polyamines are transported axonally along both intact and regenerating motor axons of the rat sciatic nerve.

The left sciatic nerve was crushed 75 mm from the spinal cord in 3 rats, and 10 ds later 66 µCi of ^{3}H-putrescine was injected bilaterally into the lumbar region of the spinal cord. At the same time, ligatures were applied to the right nerve 60 and 75 mm from the cord and to the left (regenerating) nerve 60 mm from the cord. Rats were sacrificed 3 ds later; both sciatic nerves were cut into 5 mm segments and assayed for radioactivity by tissue digestion and liquid scintillation counting. A small but significant peak of radioactivity was found at the distal ligature of the normal nerve and at the site of the crush in regenerating nerves. Since the proximal ligature prevents radioactivity from arriving by axonal transport, we conclude that this represents uptake of radioactive material from the blood at the ligation. In intact nerves, approx. 2xs the radioactivity at the distal ligature accumulated in the nerve segment central to the proximal ligature, indicating axonal transport. In regenerating nerves the amount of radioactivity accumulating central to the proximal ligature was 4.5xs the peak at the more distal crush, and 2.5xs the amount transported in normal nerves. The nature of the transported radioactivity was determined in separate experiments. The majority of the radioactivity was present as spermidine and as a more acidic compound. Further analysis of this compound suggests that it is likely to be a metabolite of spermidine, perhaps an acetylated derivative.

These experiments indicate that polyamines are axonally transported in motor axons of the rat sciatic nerve, that the amount transported is increased several fold in regenerating nerves, and that the polyamines are likely to be metabolized following transport into the nerve.

(Supported by grant EI 02887 from NIH.)

157.13 CHANGES IN FAST AXOPLASMIC TRANSPORT DURING HYPERTHERMIA, J.-H. Kim* and J.L. Johnson, Division of Biochemistry, Physiology, and Pharmacology, The University of South Dakota School of Medicine, Vermillion, South Dakota, 57069.

While the effects of hypothermia on mammalian fast axoplasmic transport have been well documented, there is a singular lack of detailed studies concerning any actions that hyperthermic conditions may have on this process. The purpose of this study was to discern the effects of hyperthermia on fast axoplasmic transport via analysis of the advancing crest of axonal labelled material. This has permitted the detection of any component blocking effects separately from any transport rate effects. ^{3}H-phenylalanine was injected into the L5 sensory ganglia of large Sprague-Dawley rats anesthetized with sodium pentobarbital and 1.5 hrs of in vivo transport was allowed at 37°C for all experiments. In vitro incubation for 1.5 hrs at temperatures ranging from 30-45°C resulted in an exponential increase in fast transport rate from 30-44°C. 1.5 hrs at 45°C, however, completely and irreversibly blocked all transport. Incubation at 45°C for times ranging from 10-60 min enabled estimation of the transport rate at 45°C prior to block (696 mm/day). The Q_{10} for the transport process was 1.9 between the entire range of 30-45°C, and activation energies averaged 11,300 cal/mole. Marked changes during hyperthermia were also occurring in the advancing crest behind the leading edge used to calculate the above rates of transport. The more severe the hyperthermia, the more was the advancing crest amplitude depressed. Simultaneously, there was an increasing amount of stationary material (blocked) left behind this advancing wave. In addition, the slope of the leading edge ahead of the crest peak declined sharply during hyperthermia. Unlike previous data (J. Neurobiol., 7, 1976, 339) there was no decline in the fast axoplasmic transport rate associated with hyperthermic block, with the transport rate increasing continually right up to the point of complete and irreversible block. From 37-45°C there was a progressive block of transport in nerve fibers resulting in a declining edge. These blocked fibers did not contribute, then, to the obtained fast transport rate estimates. Transport rate estimates alone would not detect this fiber loss, which could be occurring even in relatively mild hyperthermic conditions if long enough in duration. Further studies are needed to assess the irreversibility of the transport blocking effects at temperature below 45°C. Supported by USD General Research Support Funds to J.L. Johnson.

158.1 COMPARISON OF TWO TECHNIQUES FOR SEQUENTIAL LIGHT (LM) AND ELECTRON MICROSCOPIC (EM) ANALYSIS OF NEURAL ELEMENTS LABELED WITH HORSERADISH PEROXIDASE (HRP). G.M. Mawe*, M.S. Beattie, and J.C. Bresnahan (SPON: J.S. King). Dept. of Anat. and Div. of Neurosurg., Ohio State Univ. Sch. Med., Columbus, OH 43210.

We have examined two modifications of the HRP technique which have been reported to be more sensitive than the standard diaminobenzidine (DAB) procedure and which yield electron-dense reaction products. The goal has been to develop reliable methods for the sequential LM and EM analysis of retrogradely and transganglionically transported HRP from peripheral nerves.

The sciatic nerves of 6 rats were transected and HRP was applied via a polyethylene tubing cuff. Survival times were 2 or 3 days. Sections of the spinal cord and dorsal root ganglia (DRG) were cut on a vibratome and alternate sections were processed for the visualization of HRP by the glucose oxidase method for enhancement of DAB reaction product (Itoh et. al. Brain Res., 175: 341, 1979) and the benzidine dihydrochloride (BDHC) technique described by Mesulam (J. Histochem. Cytochem., 24:1273,1976). Sections were either mounted on glass slides and counterstained with neutral red or flat embedded in Maraglas between two sheets of clear plastic for sequential LM and EM observations.

Labeling in cells in the DRG and in motoneurons as well as in axons in the dorsal horn was granular in appearance after processing with the GOD protocol. Label was visible mainly in the primary dendrites and somata of motoneurons. In adjacent sections processed using BDHC the label was more diffuse, with occassional dense granules, and typically showed many more dendritic branches, often giving a "Golgi-like" appearance to the cells reminiscent of intracellular labelling, or of the tetramethyl benzidine (TMB) technique. Additionally, many more axons were visible in the DRG.

To date we have only examined labeled motoneurons with the electron microscope. Cells identified as labeled were trimmed from the plastic sections and thin-sectioned for EM. Cells processed by the GOD technique contained numerous lysosome-like inclusions which stained positively for HRP. The BDHC technique, however, produced labeling which was not only confined to lysosomes, but was also dispersed in restricted regions. In these regions the label was aggregated on the surfaces of cytoplasmic organelles. This dispersal of reaction product may account for the increased axonal and dendritic labelling afforded by this technique at the LM level. Additionally, the dispersed label provides for easier identification of HRP-positive elements at the EM level. (Supported by Grants NS-]4457 and -10165.)

158.2 ANTERO- AND RETROGRADE TRANSPORT OF WHEATGERM AGGLUTIN FOLLOWING EXTRA- AND INTRACELLULAR INJECTION IN THE CAT VESTIBULO-OCULOMOTOR SYSTEM. R. Baker, H. Baker, J. Blanchard*, M. Shaw* and D. Soriano*. Dept. Physiol. & Biophys., New York Univ. Med. Ctr. and Dept. Neurol., Cornell Med. Ctr., New York, NY 10016.

Representative of a class of proteins with selective binding affinity for carbohydrate moities, wheatgerm agglutin (WGA) shows considerable promise as a sensitive marker for study of neuronal connectivity, especially due to its transynaptic transport (Coulter, et al, Neurosci. Abst. 6: 389, 1980). In order to test anterograde, transneuronal labeling following intracellular injection of WGA, we employed as a model pathway the extensive synaptic contact between second order vestibular neurons and extraocular motoneurons. To confirm the antero- and retrograde labeling reported above, WGA (0.2-2.0%) was injected intraocularly and into slips of extraocular muscles. Using an immunocytohistochemical technique with anti-WGA antibody provided by E-Y Laboratories (1:5000 dilution) both brown (DAB) and black (TMB) reaction products were localized in appropriate layers of the superior colliculus and motoneuronal subdivisions of the oculomotor complex with particularly striking sensitivity. For intracellular injection, WGA and HRP (the latter for comparison) were dissolved in 0.5M KCl (2.0-4.0%) and electrophoretically injected utilizing 1/2 duty cycle stimulation and a range of 60-200 nA minutes of positive current. Both WGA and HRP were recognized as diffuse brown reaction products (DAB) when injected either in identified second order vestibular neurons 3 mm from their termination sites in the oculomotor nucleus or in motoneuronal axons or somata. Unfortunately, we must report that WGA appears to bind immediately to the intraaxonal membrane at the injection site and it does not diffuse more than about 1 mm from that point, even up to 72 hrs after injection. In contrast, a similar survival time with HRP results in intense labeling of the entire vestibular neuron extending from the vestibular to oculomotor nucleus (1.5 cm). Injection of WGA directly into motoneuronal somata and dendrites produces only localized reaction product, and within 2-4 hrs it is incorporated into lysosomes. We conclude that WGA is indeed an extremely sensitive marker for both antero- and retrograde study of neuronal connectivity including transneuronal targets; however, it cannot function in this capacity when introduced directly into the cytoplasmic compartment. In fact, this lectin as well as others like it, may be more useful for marking injection sites. Other lectins including various conjugated forms of WGA are also being examined in the above model system. Supported by USPHS grants NS13742, EY02007 and NHLB18974.

158.4 PEROXIDASE ANTI-PEROXIDASE AND OTHER LABELED IMMUNOGLOBULINS ARE SENSITIVE RETROGRADE TRACERS. Joseph N. Riley, Department of Neurology, SUNY Stony Brook, Stony Brook, NY 11794

The horseradish peroxidase (HRP)retrograde tracing method has become a widely used neuroanatomical technique. One of the major problems associated with the method is the extensive diffusion of the enzyme. Diffusion severely limits the HRP method in the analysis of local circuit connections. Recently we reported (Brain Research, 205, 1981) that there is significantly less diffusion from microelectrophoretic deposits of fluorescein isothiocyanate-conjugated HRP compared to unconjugated HRP. Speculating that the increased size of the conjugate may slow diffusion, a number of HRP-immunoglobulin conjugates were tested for retrograde transport. These conjugates were found to be transported more effectively than unconjugated HRP.

A number of conjugates have been tested, including peroxidase anti-peroxidase (PAP) produced in goat (Miles) and rabbit (Miles and Polysciences), HRP-labeled goat anti-rabbit (Miles), and HRP-labeled rabbit anti-rat (Polysciences).

For parametric studies, adult Sprague-Dawley rats were injected in the tongue bilaterally with 10 ul of conjugate at various concentrations or a control solution of HRP (Miles or Sigma, Type VI). Following 18 hrs survival, animals were sacrificed and alternate sections through the hypoglossal nucleus were reacted according to Mesulam's TMB procedure. The number of clearly identifiable labeled neurons was used to compare the effectiveness of conjugates to unconjugated HRP. With the exception of one brand of PAP (Polysciences), all conjugates labeled more cells than unconjugated HRP at equimolar concentrations. The concentration necessary to demonstrate retrograde transport was 10-30 times lower for the conjugates. Goat anti-rabbit and rabbit anti-rat labeled up to 200 cells at concentrations that transport of unconjugated HRP could not be demonstrated. Preincubation of conjugates with Protein A or appropriate control serums had no effect on transport.

In additional experiments, conjugates were deposited microelectrophoretically into various brain regions. Using appropriate parameters, conjugates are effective in tracing local circuitry. For example, using PAP, it has been possible to examine intranuclear connections in the suprachiasmatic nucleus of the hypothalamus.

Conjugates were injected into the eye to determine the degree of anterograde transport. At stock concentration, little or no anterograde transport could be demonstrated. A ten-fold concentration of PAP produced only weak labeling as well as a moderate to severe allergic responses.

158.5 POLYETHYLENE GLYCOL: A SUPERIOR EMBEDDING COMPOUND COMPATIBLE WITH IMMUNOHISTOCHEMISTRY AND INTRACELLULAR STAINING.
Kenneth G. Smithson*, Brian A. MacVicar and Glenn I. Hatton. Neuroscience Program and Psychology Department, Michigan State University, East Lansing, MI, 48824.

A technique is described which permits rapid processing of neural tissue for light microscopic analysis of sections from 1-40 μm thickness. This technique was developed as an alternative to paraffin embedding which has several serious disadvantages, such as causing profound tissue shrinkage, producing relatively great reduction in tissue antigenicity, destroying enzymatic activity and often resulting in tissue distortion due to the high temperatures and/or harsh organic solvents used. We needed a technique that: would allow ∿5 μm sections of flat-embedded tissue slices, was rapid, was compatible with locating intracellularly injected fluorescent dyes and would permit differential immunocytochemical analyses. Polyethylene glycol (PEG) is a water soluble polymer which has been used in the past as an embedding medium with a wide variety of stains and satisfies the above criteria. When compared to paraffin, PEG offers the following advantages: 10-15°C lower embedding temperature, 20% tissue shrinkage in PEG which diminishes to 5% upon rehydration vs. 50% in paraffin, approximately one-half the embedding time, and, because PEG is water soluble, ethanol dehydration is not required. Furthermore, tissue orientation during embedding and sectioning is particularly easy to control because of the working properties of PEG, i.e., brain slices can be routinely flat-embedded and sectioned to form excellent ribbons. Also, PEG can be easily removed by washing the tissue with a variety of aqueous solutions such as buffered saline. However, because PEG is hygroscopic, tissue blocks become soft and difficult to section in high ambient humidity. Finally, we have found PEG to be compatible with intracellular staining with Lucifer Yellow or horseradish peroxidase as well as immunohistochemical demonstration of neuronal peptides. Therefore, we conclude PEG is a whole "new" ball of wax.

This research was supported by NIH grants NS 09140 and NS 16942.

158.6 EXTRACELLULAR IONTOPHORETIC INJECTION OF LUCIFER YELLOW STAINS LOCALIZED ARRAYS OF NEURONS WITHIN ORGANIZED CNS EXPLANTS.
D.R. Friedlander and S.M. Crain. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

Although extracellular injection of the fluorescent dye, lucifer yellow (LY), does not stain neurons when applied in amounts that completely fill cells intracellularly injected (e.g.Stewart, Cell 14:741,'78), LY can penetrate into neurons by submerging a cut nerve in a solution of the dye (S. Sharma, pers. commun.).

We have applied LY by iontophoretic injection, via extracellular glass microelectrodes (10 μm tips) filled with 3% LY, placed in selected regions of fetal mouse neural explants, and observed staining of cell bodies and neurites with epi-fluorescence microscopy. Most of these neurons could not be visualized in our relatively thick organotypic CNS explants, even with Nomarski interference optics. Successful results were obtained with negative currents of the order of 1 μA for 10 sec. This localized dye injection generally produced high-contrast Golgi-like labeling of dozens of nearby neurons, within a few min, distributed in variable arrays over areas of the order of 100 μm diam. Large diameter axons (> 1 μm) stained for distances > 1 mm within about 10 min and did not fade for > 1 hr. Extrusion of dye via a pipette almost touching the explant did not stain neurons, even when nearby tissue was damaged with a saline-filled pipette.

In retinal explants (Smalheiser et al, Br. Res. 204:159,'81) ganglion cell bodies and their processes were labeled, and also the growth cones of unidentified neurons. In explants of spinal cord with attached dorsal root ganglia (DRG), where DRG neurites develop specific connections with dorsal horn neurons (Crain and Peterson, Br.Res. 79:145,'74), LY injection into the DRGs labeled a number of cell bodies and also axons which entered the dorsal cord. Application of the dye into dorsal regions of the cord explants stained local cord neurons and neurites and, more faintly, some distant cells including DRG perikarya. LY injections into ventral cord labeled large neurons with stout dendrites, presumably motoneurons, but did not stain DRG neurons.

These results are consonant with horseradish peroxidase injections of similar cultures (Smalheiser et al, Dev.Br.Res. '81, in press) and are thus indicative of the potential value of this new LY method for more rapidly mapping axonal projections to target tissues within CNS explants. Furthermore, since neurons can be made visible in selected regions of living CNS explants, it is now possible to guide microelectrode placements to particular cells within organized multi-layered neural networks for electrophysiologic analyses under direct visual control.

158.7 SUICIDE TRANSPORT: DESTRUCTION OF NEURONS BY RETROGRADE AXONAL TRANSPORT OF THE TOXIC LECTIN, RICIN.
R.G. Wiley, W.W. Blessing and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Sch. of Med. New York, NY 10021.

Ricin, the toxic lectin from castor beans (Ricinis communis), can be taken up and retrogradely transported by peripheral sympathetic nerves. (Lab Invest. 42; 396, 1980). We sought to determine if this lectin, which kills cells by inactivating ribosomes, can be taken up and retrogradely transported by peripheral somatic sensory and motor nerves; if such transport will kill parent neurons; and if so whether the perikaryal response differs from the chromatolytic reaction. Rats or rabbits were anaesthetized and either ricin or ricin conjugated to horseradish peroxidase (HRP) was applied to the cervical vagus (X) or to the hypoglossal nerve (XII). Toxin was applied either by soaking the proximal end of the cut nerve or injecting (0.25-2.5ug of ricin in 0.5ul of saline) into the intact nerve. In control experiments, the nerves were either transected or injected with saline. After 1-16 days, animals were anaesthetized and perfused with aldehyde fixative. The medulla and nodose ganglia (NG) were sectioned and stained with cresyl violet or, for HRP conjugate, with tetramethylbenzidine (ricin-HRP experiments.) One day after injection of ricin-HRP into the cervical vagus, HRP staining was intense & Nissl staining was reduced in neurons in both the ipsilateral NG and the dorsal motor nucleus of the vagus (DMNX.) By 2 days these neurons had lost their Nissl substance without change in nuclear position or morphology. At 3 days, neurons were beginning to disintegrate and HRP staining became diffuse in DMNX. After 4 days there was extensive neuronal loss and some gliosis was evident in DMNX. At 16 days there was almost complete neuronal loss in both ipsilateral DMNX and NG. Similar changes were observed in the XII nucleus after injection of ricin into the XIIth nerve. These cellular events initiated by ricin contrasted to the classic chromatolytic responses observed in NG and DMNX after cervical vagotomy which only resulted in a modest loss of neurons.
We conclude: (a) sensory and motor axons will transport ricin to the perikaryon; (b) such transport results in rapid death of these neurons; (c) the toxic response differs from the retrograde reaction elicited by nerve transection.
We have called this transfer of toxic agents to the nerve cell body "suicide transport". It may prove a powerful tool for correlated anatomical, neurochemical and physiological experiments.

158.8 TRACING NEURONAL CONNECTIONS BY ELECTRON MICROSCOPY USING HORSERADISH PEROXIDASE: A COMPARISON OF EIGHT METHODS.
K.A. Carson[1] and M-M Mesulam. Bullard and Denny-Brown Laboratories, Neurology Unit, and Behavioral Neurology Section, Dept. of Neurology, Beth Israel Hospital and Harvard Medical School, and the Charles A. Dana Research Institute, 330 Brookline Ave., Boston MA 02215. [1]Electron Microscopy Laboratory, Dept. of Biological Sciences, Old Dominion University, Norfolk, VA 23508.

Electron microscopy is being used frequently in studies of neuronal connectivity to visualize the synapic relationships of neurons labeled with tracers such as horseradish peroxidase (HRP). Recently the most commonly used HRP histochemical methods were compared (Mesulam and Rosene,1979, J. Histochem. Cytochem., 27: 763). This quantitative light microscopic comparison showed that methods using tetramethyl benzidine (TMB) and benzidine dihydrochloride (BDHC) were among the most sensitive. Our experiments were undertaken to evaluate and improve the TMB and BDHC ultracytochemical methods for HRP and then compare them to several other commonly used methods for the electron microscopic demonstration of HRP activity. A spinal cord-peripheral nerve system was chosen so that HRP which entered the spinal cord by retrograde or transganglionic axonal transport could be visualized in the same section. Horseradish peroxidase-wheat germ agglutinin conjugate was injected in the gastrocnemius muscle complex in mice. After 48 hours the mice were anesthetized and perfused through the heart with fixative. The lumbar spinal cord was cut coronally on a vibratome at 75 microns into 8 series of about 20 sections each. HRP activity was demonstrated by the following methods: TMB, BDHC, o-tolidine, paraphenylenediamine-pyrocatechol, diaminobenzidine (DAB)-Streit and Reubi, DAB-Malmgren and Olsson, DAB-glucose oxidase and DAB-LaVail and LaVail.

The results showed that TMB and BDHC could be readily used for the ultracytochemical demonstration of HRP activity. In the case of TMB, the temperature and pH of osmication were crucial variables in obtaining an electron dense and insoluble reaction product. A pH of 6.0 and temperature of 45°C gave the best results in this system. The TMB, BDHC and o-tolidine procedures demonstrated the largest distribution of HRP activity in the dorsal and ventral horns. The TMB reaction product was electron dense and had a unique, angular, crystalloid appearance that aided identification of labeled neurons. This useful feature combined with the apparent sensitivity of the TMB ultracytochemical method indicated its potential value in demonstrating processes of labeled neurons containing low amounts of HRP, such as distal dendrites and synaptic boutons. This investigation was supported by NIH Grants 14625, NS 090211, NSF Grant BNS 7823610 and an NIH Post-doctoral Fellowship NS 06550 to K.A.C.

158.9 PHYSIOLOGICALLY ENHANCED HRP LABELING OF SALIVARY NEURONS IN RATS

J.S.Eisenman and E.C.Azmitia.Depts. of Physiology/Biophysics and Anatomy, Mt. Sinai Med. Sch., CUNY, N.Y., N.Y. 10029.

Neurons in the superior salivary nucleus of rats were labeled with HRP by injecting 2μl of a 50% HRP solution (Sigma,type VI) into the lingual nerve.14 1/2 to 24 hrs after injection,the rats were sacrificed by perfusion with physiological saline followed by 2.5% glutaraldehyde.50μm sections were cut and reacted using Mesulam's TMB method (J.Histochem.Cytochem.26;106,1978).Marked cells form a diagonal band in the ipsilateral brainstem,just caudal to the exiting root of the facial nerve and extending about 950μm in a rostrocaudal direction (Hiura,Br.Res.137;145, 1977). A ventral and dorsal cluster of cells are evident at the largest expanse of the nucleus.The neurons are multipolar,with the cell body measuring 30x20μm across.The TMB reaction product is seen as fine granules distributed throughout the cytoplasm and proximal dendrites,leaving the large,centrally placed nucleus (10μm in diameter) unlabeled.Increasing the transport time from 14 1/2 to 24 hrs,led to marking of an exponentially increasing number of cells,from 2 labeled cells at 14 1/2 hrs to 272 cells at 24 hrs.The regression of cells marked on transport time could be fitted with the equation $N=0.001\exp(0.51T)$,$r=0.995$.

In five pairs of rats,the effect of stimulating activity of salivary neurons on HRP labeling was studied.In one rat of each pair,salivation was stimulated by swabbing its mouth with 1% acetic acid for one hr,immediately following HRP injection into the lingual nerve.At each transport time,more HRP labeled cells were counted in stimulated than in unstimulated salivary nuclei. The largest ratio of stimulated:unstimulated cells,13.5:1,was seen following 18 hrs transport time.In stimulated animals,the relationship between number of cells marked and transport time followed a normal cumulative frequency distribution (ogive) curve,with a mean at 18.2 hrs,S.D.=1.6 hrs.Using several dissected specimens,axonal length from injection site to cell body was estimated to be 23-25 mm.Taking visible cell marking as an endpoint,the range of retrograde transport rates was 23-38mm/day.

In these studies,labeling occurred by diffusion of HRP into injured axons,followed by retrograde transport.It seems likely, therefore,that enhanced labeling of stimulated cells was not due to increased pinocytic activity, but may reflect either increased intravesicular packaging and/or increased retrograde transport rate in the stimulated cells.

159.1 THE DISTRIBUTION OF CHOLINERGIC COMPONENTS IN LIMULUS. R. Sukumar*, M. Ivy* and J.G. Townsel. Department of Physiology and Biophysics, University of Illinois Medical Center, Chicago, IL 60612.

The distribution of several biochemical parameters generally accepted as being associated with cholinergic transmission was studied in Limulus muscle and nerve tissue. These studies included a determination of tissue levels of acetylcholine (ACh), choline (Ch), acetylcholinesterase (AChE:E.C.3.1.1.7) and choline acetyltransferase (ChAC, E.C.2.3.1.6). Choline uptake was also studied in these tissues. A high affinity component of the measured uptake was assessed by the determination of tissue/medium distribution ratios (T/M).

In general, ACh and Ch were distributed among all the tissues assayed. The ACh values ranged from a high of 3.00± 0.49 nmole/mg protein in abdominal ganglia to a low of 0.54± 0.04 nmole/mg protein in cardiac muscle. Similarly, AChE was detectable in all tissues assayed. However, the range of activity was an order of magnitude greater with brain roots having the highest level of activity at 2.81±0.73 μmoles of ACh hydrolysed/liter/mg protein/min and skeletal muscle having the lowest level of activity at approximately 1.8% of brain root activity. ChAC was not so widespread in distribution. ChAC activity was not detected in any of the muscle tissues assayed nor was it detected in the cardiac ganglion. The highest level of ChAC activity was measured in the corpora pedunculata (43.15±0.07 nmoles of ACh synthesized/mg protein/min). No direct correlation was found between the level of ChAC activity and the amount of measurable ACh in a tissue. Similar levels of ACh (c.a.2.4 nmoles/mg protein) were found in circumoesophageal ring (CR) and the dorsal roots of the abdominal ganglia (DR-AG); however, the CR had a ten fold greater level of ChAC activity than that measured in the DR-AG (33.2±1.6 nmoles of ACh/mg protein/min vs 3.4±0.9 nmoles of ACh/mg protein/min).

TM ratios indicative of high affinity uptake were selectively distributed ranging from 13.22 to 4.62. In three of the four tissues where ratios in this range were found we also observed an elevated potassium triggered, Ca^{2+}-requiring, specific release of [H^3]-ACh. The significance of these results will be discussed.

(Supported by NIH Grant HL 24140)

159.2 EVIDENCE FOR TWO FUNCTIONALLY DISTINCT POOLS OF BOUND (VESICULAR) ACH IN RAT BRAIN SYNAPTOSOMES. M. E. O'Leary* and J. B. Suszkiw, Dept. of Physiol., Univ. of Cincinnati Med. Ctr., Cincinnati, OH 45267.

Compartmentation of ACh was studied in resting and in K+-depolarized rat brain synaptosomes. In standard Krebs-Ringer solution, [^{3}H]ACh synthesized from [^{3}H]Ch in resting synaptosomes was distributed 40% in bound and 60% in free form. In the presence of 20 μM HC-3, sequential 3-minute exposures of synaptosomes to 50mM K+ resulted in the release of decrementing amounts of [^{3}H]ACh until maximal cumulative release reached 40% of the total initial [^{3}H]ACh in synaptosomes. Bound [^{3}H]ACh decreased in proportion to [^{3}H] ACh released. Resting synaptosomes first labelled with [^{14}C]ACh and then sequentially depolarized by 3-minute exposures to high K+, each followed by a 10-minute recovery period in normal saline containing 1μM [^{3}H]Ch, released [^{14}C]ACh decrementally but the release of the newly forming [^{3}H]ACh continued unabated or increased with each depolarization. The [^{3}H]ACh/[^{14}C]ACh ratio in the perfusate nearly doubled for each successive depolarization and did not correspond to [^{3}H]ACh/[^{14}C]ACh in synaptosomes, vesicles or cytoplasm. These results suggest that:

1) K+ depolarization results in Ca^{++}-dependent-enhanced release of bound vesicular but not of cytoplasmic ACh.

2) After displacement of total reserve ACh, the emptied vesicles cannot be readily replenished from the cytoplasm.

3) A fraction of vesicles can be replenished readily with newly synthesized ACh before this ACh equilibrates with the cytoplasmic pool. This implies tight coupling between choline transport, synthesis of ACh and reloading of the active pool. Functioning of this system appears to be essential for the unabated, evoked release of ACh.

Supported by NIH Grant No. NS15674 and NS 17442.

159.3 HETEROGENEITY OF CENTRAL NERVOUS SYSTEM α-BUNGAROTOXIN BINDING SITES. Ronald J. Lukas. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Ligand binding characteristics of putative mammalian central nervous system nicotinic-type acetylcholine receptor sites have been reinvestigated. Purffied α-bungarotoxin has been radioiodinated and resolved into unlabeled, monoiodinated (I-Bgt) and diiodinated species according to established procedures (Biochem. 17, 3208, 1978). Using fresh preparations of I-Bgt, subcellular membrane fractions rich in synaptic junctional complexes and plasma membranes from brains of male Sprague-Dawley rats; and a modification of published binding assay protocols (Biochem. 18, 2384, 1979), toxin binding saturation profiles have been obtained to ~300nM with non-specific binding levels limited to ~25% of total binding. This increased sensitivity permits resolution of two classes of I-Bgt binding sites in 1:1 stoichiometry, characterized by pre-equilibrium K_d values of ~2nM and ~100nM.

Cholinergic ligand binding competition profiles yield the following rank order of potencies at the high-affinity (at 10nM) I-Bgt site: Nicotine (1uM) > acetylcholine = bromoacetylcholine > carbamylcholine = d-tubocurarine (10uM) > alcuronium > tetraethyl-ammonium > lobeline (100uM) > gallamine = decamethonium = pancuronium > atropine > muscarine (1mM) > mecamylamine = hexamethonium (~10mM).

Delineation of the pharmacological profile for the low affinity I-Bgt site may provide insight into correlates of central nicotinic receptor function.

159.4 PURIFICATION AND IMMUNOCHEMICAL PROPERTIES OF CHICKEN BRAIN CHOLINE ACETYLTRANSFERASE. J. H. Peng*, K. Ma*, P. L. McGeer and E. G. McGeer. Kinsmen Laboratory of Neurological Research, University of British Columbia, Vancouver, B. C., Canada, V6T 1W5.

Chicken brain choline acetyltransferase (CAT) was purified to homogeneity using ammonium sulfate fractionation, followed by chromatography on DEAE-Sephadex (A-25), hydroxyapatite, Sephadex G-150, immunoabsorption and Sephadex-CoA columns. A purification of 3500-fold was achieved and the final preparation had a specific activity of 2.32 μmol ACh formed per min per mg protein. The purified chicken CAT migrated as a single band on polyacrylamide gel electrophoresis in the presence and absence of sodium dodecyl sulfate. The native enzyme, with a molecular weight of 67,000 daltons, consists of two subunits of identical molecular weight. Chicken CAT has a sharp pH optimum of 7.4. It is activated by sodium chloride and potassium chloride but inhibited by cupric ion and N-ethylmaleimide.

An antiserum was obtained from immunized rabbit after three subcutaneous injections of 100 μg each of the pure chicken CAT preparations at various sites near scapular and neck regions. The antibodies appeared to be monospecific for CAT, since they gave only a single precipitin line against pure or crude enzyme preparations from chicken and human brain, and crude enzyme from rat, rabbit, guinea pig and bovine brains in double immunodiffusion and immunoelectrophoresis plates. The antiserum or immunoglobulins also inhibited CAT activities from chicken and mammalian brains in immunoprecipitation studies. As with the inhibition of human enzyme by anti-human CAT, inhibition of chicken CAT was seen after 30 min of pre-incubation with anti-chicken CAT serum or immunoglobulins and the extent of inhibition increased with time of incubation up to 3 h at 37°C and 20 h at 4°C. The maximum levels of inhibition measured was 85% in the reaction mixtures and 96% in the supernatants after centrifugation when compared with similarly incubated samples using pre-immune serum. This and previous studies clearly demonstrated that high titer anti-chicken CAT antibodies do cross-react with CAT from several mammalian species, and vice versa.

159.5 EXCITATORY EFFECT OF ACETYLCHOLINE ON DIFFERENT TYPES OF ANTIDROMICALLY IDENTIFIED CEREBRAL CORTICAL NEURONS. P. Dutar*, Y. Lamour and A. Jobert*. Unité de Recherches de Neurophysiologie Pharmacologique de l'INSERM, U. 161, 2 rue d'Alésia 75014 Paris, France.

Acetylcholine (ACh) has been shown to excite a large percentage of pyramidal tract neurons in the cerebral cortex. The aim of this experiment was to compare in rat somatic sensory cortex (SI) the sensitivity to ACh of pyramidal tract neurons (PTNs), cortico-thalamic neurons (CTNs) and commissural neurons (CNs), identified by antidromic activation. Stimulating electrodes were respectively located in the pyramidal tract, the ipsilateral ventro-basal nucleus of the thalamus and the corpus callosum (in the opposite hemisphere). Rats were anaesthetized with urethane (1.5 g/kg, i.p.). ACh (0.5 M, pH 4) was iontophoretically applied from one channel of a seven barrel electrode. Single unit activity was recorded using a second pipette rigidly fixed to the side of the multibarrelled electrode. Each microelectrode penetration was reconstructed on a camera lucida drawing of 100 µm frozen sections stained with cresyl violet using a dye deposit made at the last recording site. The location of each stimulating electrode was also verified on the sections. A given penetration was taken into account only if at least one excitatory response to ACh was recorded. ACh responses were tested with currents of up to 120 nA for up to 1 minute. Criteria for antidromic activation were : fixed latency, ability to follow high stimulation rates (above 200 Hz) and collision with orthodromic action potentials.

ACh excited 59 % of the PTNs, 52.6 % of the CTNs and only 4.3 % of the CNs. The percentage of unidentified cortical neurons excited by ACh was 27.5 % of the total population (n = 461). PTNs were located in layer Vb and the CTNs in layers V and VI, whereas CNs were scattered in the cortical layers, in agreement with previous anatomical observations. These results suggest that ACh-sensitivity is specific for certain neuronal types. Most of the other unidentified neurons excited by ACh were located in layer Vb and upper part of layer VI, where cortical neurons projecting on subcortical structures are to be found. There might therefore be a relationship between the cells of origin of cortico-subcortical systems and ACh sensitivity. ACh might increase the excitability of cortical output neurons involved in the control of sensori-motor activities.

Supported by DGRST (DN/80.7.0236).

159.6 AN INHIBITORY ACTION OF ACETYLCHOLINE ON THE DENDRITIC EPSPs IN THE AMMON'S HORN. Y. Ben-Ari, E. Cherubini and C. Rovira, Laboratoire de Physiologie Nerveuse, CNRS, 91190 Gif-sur-Yvette, France.

When microiontophoretically applied on pyramidal cells of the ammon's horn, Acetylcholine (Ach) has a double action : a postsynaptic depression of K conductance and a suppression of inhibitory control apparently mediated by a presynaptic action on GABAergic terminals (Ben-Ari, Krnjevic, Reinhardt and Ropert, Neurosci. In Press). We now report an additionnal effect, namely an inhibitory, primarily muscarinic, action on the fields EPSPs recorded in the dendritic layer. Our experiments were done on intact, urethane anaesthetized rats, using multibarreled micropipettes to record field responses evoked in CA1 of the dorsal hippocampus by stimulation of the ventral hippocampal commissure. On several occasions an assembly of glued micropipettes enabled to simultaneously record (and eject various drugs) in the somatic and dendritic layers. At low frequencies of stimulation (usually 1/s a large positive wave, which reflects the powerful IPSPs generated by recurrent collaterals of pyramidal axons (Andersen et al. J. Neurophysiol. 27, 592, 1964) and a negative population spike are recorded in the pyramidal layer and a negative field (with a small positive spike) in the dendritic layer. Application of Ach on the soma produces a reduction of the positivity and the appearance of multiple (2-3) population spikes (see, Reiffenstein, Krnjevic and Ropert Neurosci. abst, 1980). At the dendritic layer, Ach produced a 10-25 % reduction of the field EPSP. This action has typically a slow onset (often more than 20 sec) and recovery. It is also produced by muscarine, and antagonized by atropine or scopolamine and not by benzyl-penicilline. The Ach effect - in contrast to the more powerful inhibitory effect of GABA - is quite localized (approximately 200-250 um of the soma). It is not due to diffusion of the substance to the soma, since simultaneously recorded somatic IPSP and population spikes are not altered. These resultats are in keeping with previous observations of Hounsgaard (Exptl. Neurol. 62, 787, 1978) who reported in the slice preparation a presynaptic inhibitory action of Ach on dendritic EPSP. Since eserine also reduces the fields EPSPs and potentiates the effects of Ach it is possible that cholinergic inputs modulate the excitatory inputs to the dendrites. Interestingly, recent observation suggest that following ipsilateral destruction of the septo-hippocampal cholinergic projection (as controlled by means of acetylcholinesterase staining) there is a denervation suppersensitivity of Ach effects in the dendrites (in preparation).

159.7 CHOLINERGIC GENERATION OF DESYNCHRONIZED SLEEP SIGNS:LOCALIZATION TO THE PONTINE RETICULAR FORMATION. H.A. Baghdoyan*, R.W. McCarley, J.A. Hobson. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, 74 Fenwood Road, Boston, MA 02115.

Carbachol injection into the pontine reticular formation (RF) elicits D carb, a state resembling physiological desynchronized sleep (D). The anatomical specificity of this response is being examined by comparing the effects on sleep-wake states of carbachol injections into the pontine (FTG), midbrain (FTC) and medullary (FTL) RF. Our results show: 1) D carb can be induced only from the pontine RF, and 2) synchronized sleep (S) is markedly suppressed following carbachol injection into all brainstem sites.

Cats are implanted stereotaxically with guide tubes. 0.5-1.0 ul of carbachol (8ug/ul) or saline is pumped through a stainless-steel cannula. Every site receives at least one administration of carbachol and saline. Polygraphic recordings and behavioral observations are conducted for 4 hrs post injection.

Injection of carbachol into the pons produced a 4-fold increase in the percent of total recording time spent in D carb as compared with baseline D values (31 vs 8%, N=7). In contrast cholinergic stimulation of the medullary RF totally suppressed D (N=7). The midbrain effect of carbachol on D is a slight reduction (6 vs 8%, N=4). Carbachol dramatically reduced S at all brainstem sites: S was abolished after all 7 pontine, 5 of 7 medullary and 2 of 4 midbrain injections. Following the other medullary and midbrain injections S was reduced. Waking was increased by carbachol from 39% of total time during baseline recordings (N=36) to 61% for pontine, 98% for medullary and 79% for midbrain sites. In 5 of 7 pontine injections a unique pattern of REMs and PGO waves was induced during D carb: a cluster of large amplitude PGO waves alternates with a cluster of small amplitude PGO waves in one LGB while the reverse occurs in the other. The larger amplitude waves occur in conjunction with ipsilateral REMs, while the small amplitude waves are accompanied by REMs in the opposite direction.

At the medullary site carbachol produced a state of hyperarousal characterized by ataxia and increased motor activity. Midbrain injections caused an arousal lasting at least 2 hrs but with an overall decrease in motor activity; hissing, growling and contralateral turning were elicited at this site. Pontine injections also were characterized by little movement during waking; upon entering D carb the cats would assume a sleep posture and the nictitating membranes would partially close. Pending histological confirmation of injection sites we tentatively conclude that cholinergic generation of D is not medullary and not mesencephalic; it is pontine.

159.8 PRODUCTION AND CHARACTERIZATION OF ANTIBODIES TO CHOLINE ACETYLTRANSFERASE OF RAT STRIATA FOR IMMUNOCHEMISTRY AND IMMUNOCYTOCHEMISTRY. D.H. Park, M.E. Ross, H. Baker, D.J. Reis, and T.H. Joh. Laboratory of Neurobiology, Cornell University Medical College, New York, N.Y., 10021.

We sought to develop antibodies to choline acetyltransferase (CAT) suitable for immunochemistry and immunocytochemistry. CAT was purified from striata of 500 rat brains by the following steps: Homogenization in 10 mM K-phosphate buffer pH 7.5, centrifugation at 100,000 g, lyophilization of the supernatant, followed by five sequential column chromatographic procedures-Sepharose 4B, hydroxylapatite (fast flow), hydroxylapatite (high resolution), Sephadex G150 and CM-Sephadex. The purified enzyme was then subjected to polyacrylamide gel electrophoresis and the active protein band was identified by assaying CAT activity of the gel slices. The active protein in the gel slices was then electrophoretically eluted by ISCO model 1750. The eluted protein showed a single stained band on the gel and was enzymatically active. Antibodies to CAT, either monoclonal (Ross, Neurosci Abs. 1981) or raised in rabbits, were highly specific. They exhibited a single immunoprecipitin arc when run on immunoelectrophoretic plates against a crude enzyme preparation or purified CAT, and strong inhibition of CAT activity when incubated with CAT preparations. However attempts to localize CAT by immunohistochemistry using the PAP technique failed. No cells were stained in tissue preparations of CNS or PNS, even those of cholinergic structures including the neuromuscular junction of diaphragm, hypoglossal nucleus and anterior horn cells of spinal cord.

In contrast, these structures were all autoradiographically labelled by a radiolabelled monoclonal antibody (Ross et al, Neurosci. Abstr 1981). The failure of the PAP to localize CAT may indicate that the CAT-CAT Ab complex formation on the surface of tissues after fixation is weak, although some primary antigen-antibody binding does occur, as demonstrated by autoradiographic localization of the radio-labelled monoclonal Abs. Conceivably, the primary binding of CAT-CAT Ab may be broken off by the addition of secondary antibody, i.e. goat antirabbit IgG or goat antimouse IgG, or may reflect stronger binding of secondary antibody to primary antibody. The results suggest that although antibodies to CAT are specific, the PAP method does not always reveal specific binding of antibodies to antigen. In this case, a direct staining procedure, such as autoradiographic localization of radiolabelled Ab is preferable.

159.9 LOW ACTIVITY OF THE PYRUVATE DEHYDROGENASE COMPLEX AS WELL AS OF CHOLINE ACETYLTRANSFERASE IN HUNTINGTON CAUDATE AND PUTAMEN.
S. Sorbi*, E. D. Bird* and J. P. Blass. Burke Rehabilitation Center-Cornell Med. Coll. and McLean Hospital-Harvard University, White Plains, NY 10605 and Belmont, MA 02178.

Previous reports have described a correlation between the activities of choline acetyltransferase (CAT) and of the pyruvate dehydrogenase complex (PDHC) in cat and rat brain. We examined the distribution of these two enzymes and of the mitochondrial marker fumarase in regions of human brain from controls without neurological disease and from patients with Huntington's disease, who have decreased CAT in affected areas. Samples from a brain bank were studied double blind. Homogenates were assayed for CAT (by Fonnum's radiochemical method), for PDHC (by a spectrophotometric coupled enzyme assay using pigeon-liver arylamine acetyltransferase), and for fumarase (by a standard spectrophotometric method). The correlation between CAT and PDHC activity for all 84 samples studied was $r=0.93$ ($P<0.001$). Fumarase activity did not correlate well with either CAT or PDHC. Activity of PDHC, but not fumarase, was decreased in Huntington caudate (to 50% of controls; $P<0.005$) and putamen (to 40% of controls; $P<0.001$). As expected, CAT activity was lower in Huntington caudate and putamen. These observations are consistent with other data indicating a close relationship between cholinergic function and the capacity for pyruvate oxidation in the mammalian CNS. They suggest that decrease of PDHC is a consequence of Huntington's disease in affected areas. This decrease may prove to play some role in the pathophysiology of the disease, particularly in view of the suggestions that PDHC participates in synaptic plasticity.

159.10 3,4-DIAMINOPYRIDINE AMELIORATES THE EFFECTS OF HYPOXIA ON BEHAVIOR AND ACETYLCHOLINE METABOLISM
C.Peterson* , C.Pelmas* and G.E.Gibson
Cornell University Medical College, The Burke Rehabilitation Center, White Plains, New York 10605

Hypoxia (reduced O_2 availability) decreases mental function in man, impairs performance on standardized behavioral tests in animals and inhibits brain acetylcholine (ACh) metabolism. Although the molecular basis of these changes is unknown, they may be explained in part by a decreased release of ACh. Thus, we studied the Ca^{2+}-dependent-K^+-stimulated release of ACh in hypoxia. The release of ACh from brain slices declined from 100±2% to 46±4% or 35±3% when the percent oxygen was lowered from 100% to 2.5% or 0%, respectively. Since 3,4-diaminopyridine (3,4-DAP), a K^+ channel blocker, enhances the influx of Ca^{2+} into nerve terminals, we examined its pharmacological action on the Ca^{2+}-dependent release of ACh during hypoxia. After treatment with 3,4-DAP (10 nM), the release of ACh only declined from 100±2% to 80±3% (2.5% O_2) or 71±2% (0% O_2).

In vivo, anemic hypoxia (injection of $NaNO_2$, 150 mg/kg) inhibited the synthesis of ACh (nmol/100 mg protein/min) in the hippocampus from 7.6±0.7 to 3.4±0.2 (45% of non-hypoxic control), striatum from 80±7 to 14.8±1.4 (18%) and cortex from 12.2±1.0 to 3.9±0.3 (32%). 3,4-DAP (10 nM) partially ameliorated the effects of hypoxia on ACh synthesis in the hippocampus from 3.4±0.2 to 5.5±0.5 (72% of non-hypoxic control) and the striatum from 14.8±1.4 to 20.1±1.7 (25%) but not in the cortex 3.9±0.3 to 3.9±0.3 (0%). 3,4-DAP did not stimulate ACh synthesis in non-hypoxic control mice. Brain lactate concentrations increased with hypoxia (>300%) but did not show regional specificity and were unaltered by 3,4-DAP treatment. Behavior, as measured by tight rope performance, declined with anemic hypoxia from 13.2±0.1 to 1.4±0.5 (11% of control). Treatment of these hypoxic mice with 3,4-DAP (10 nM) improved their scores to 6.9±1.0 (53% of control), while it did not alter non-hypoxic control scores.

In conclusion, 3,4-DAP, an agent which has been reported to increase influx of Ca^{2+} into nerve terminals, ameliorates some of the effects of low O_2. During hypoxia, 3,4-DAP increased the in vitro release of ACh, stimulated the in vivo synthesis of ACh in the hippocampus and striatum and improved performance on a standardized behavioral test.

159.11 EFFECTS OF HYPNOTIC AND CONVULSANT BARBITURATES ON HIGH AFFINITY CHOLINE UPTAKE IN THE HIPPOCAMPUS.
J.A. Richter, J.M. Gormley*, J.R. Holtman, Jr.* and J.R. Simon. Dept. of Pharmacol. & Inst. Psych. Res., Indiana Univ. Sch. Med., Indianapolis, IN 46223.

Pentobarbital (PB) administration has been shown to inhibit high affinity choline uptake (HACU) in the hippocampus (Simon, Atweh and Kuhar, J. Neurochem. 26: 909, 1976). We have initiated a series of experiments to determine the locus and the mechanism of this effect and the relationship of the physiological effects of barbiturates to their effects on choline uptake.

Experiments were done on male Wistar rats, 200-300g and male Swiss mice, 25-30g. Drugs were injected i.p. and the animals killed by decapitation at selected times after injection. Synaptosomes (P_2 fraction) were prepared from the hippocampus and incubated with 0.5 µM ^{3}H-choline at 30°C for 4'. Blanks were incubated in medium without sodium. Rats were injected with 50 mg/kg ^{14}C PB and decapitated at loss of righting reflex (about 3') or 33', 63' or 123' after injection. The hippocampal choline uptake was inhibited only at 33' and 63' and not at the loss of righting reflex. The concentration of PB in the hippocampus was the same at loss of righting reflex as it was at 63' (with a peak at 33'), indicating no correlation between hippocampal PB levels and the inhibition of choline uptake. These data suggested that either the drug does not act in the hippocampus, or if it does, either the drug levels in the whole region do not reflect the levels at the exact site of action or there is a time lag before the drug effect is manifest. To test the possibility of a long time lag, we injected doses of ^{14}C PB from 35-150 mg/kg and decapitated the rats 7' after injection. At this time the standard 50 mg/kg dose caused an inhibition of uptake, so if there is a time lag, it is very short. However, the degree of uptake inhibition was still not well correlated with the levels of PB in the hippocampus.

Tested in mice, which were decapitated at convulsion, the convulsant barbiturate CHEB (5-(2-cyclohexylidine-ethyl)-5-ethyl B.A.) did not cause a change in HACU in the hippocampus. Another convulsant barbiturate (+) MPPB (1-methyl-5-phenyl-5-propyl B.A.) did cause an increase in hippocampal HACU similar to that originally reported for the convulsant petnylenetetrazol. These data coupled with the lack of inhibition of HACU by PB at the point of loss of righting reflex, suggest that the actions of these drugs are not directly correlated with the behavioral state and therefore are probably not caused by convulsion or hypnosis per se. Further studies are underway to determine the site of action of these drugs on hippocampal HACU by testing them in rats with fimbria/fornix lesions and also by local administration of the drugs into selected CNS sites. Grant DA00796.

159.12 EFFECTS OF ACETYLCHOLINESTERASE INHIBITORS ON 2-DEOXY-D-GLUCOSE UPTAKE IN THE RAT BRAIN.
R.P. Friedland*[1] and R.C. Meibach [2]. [1],Department of Neurology, University of California, Davis, VA Hospital, Martinez, California, 94553 and Donner Laboratory, University of California, Berkeley. [2], Department of Pharmacology, Mount Sinai School of Medicine, N.Y.

The ^{14}C-2-deoxy-D-glucose (2-DDG) technique was employed to determine the effects of two acetylcholinesterase inhibitors, physostigmine and neostigmine, on glucose metabolism in the central nervous system of the rat. Animals were injected with either physostigmine (0.1 or 0.4 mg/kg) or neostigmine (0.03 mg/kg), followed by an injection of 50 µCi 2-DDG. After 30 minutes the animals were killed by quillotine, the brains quickly removed, frozen in liquid freon and cut at 32 µm on a Damon/IEC cryostat. Radioautograms prepared from these animals were compared to saline injected control rats. Following either dose of physostigmine the most striking increase in 2-DDG uptake was found in the superficial layer of the superior colliculus (37%). Smaller increases were seen in caudal retrosplenial cortex, substantia nigra pars compacta, and in the motor nucleus of the Trigeminal nerve. Decreased uptake was observed in lateral thalamic nuclei. There were no significant effects in any other cortical region. After neostigmine administration the autoradiograms were indistinguishable from those of control animals. The results of these experiments are consistent with our knowledge of the distribution of both muscarinic and nicotinic cholinergic receptors. However, most cholinergic areas of the brain did not show demonstrable metabolic effects.

159.13 MODIFICATION OF CHOLINERGIC DYNAMICS IN RAT BRAIN BY INTRAVENTRICULAR ADMINISTRATION OF ADENOSINE ANALOGS. T. F. Murray,* D. L. Cheney and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Endogenously generated adenosine has been shown to behave as a neuromodulator that inhibits the firing of most central neurons. The inhibitory effects of adenosine on both spontaneous neuronal activity and on the generation of postsynaptic potentials in central pathways are mediated by an interaction with specific adenosine receptors which can be blocked by theophylline or caffeine. Considerable evidence indicates that adenosine and its analogs affect adenylate cyclase via two types of extracellular receptors, the A_1 which is a high affinity inhibitory receptor and the A_2 which is a lower affinity stimulatory receptor (Daly, J.W. et al. Life Sci., 28:2093, 1981). We have examined the effects of intraventricular (i.vt.) administration of adenosine receptor agonists and antagonists on the turnover rate of acetylcholine (TR_{ACh}) in various areas of the rat brain in an effort to better understand the role of adenosines as a neuromodulator or cotransmitter. TR_{ACh} was determined by gas chromatographic-mass fragmentographic analysis of the incorporation of deuterium into ACh and choline following an infusion of deuterated phosphorylcholine. The i.vt. administration of the adenosine receptor agonist, 2-chloroadenosine (2-ClAdo), in a dose of 83 nmoles did not alter the ACh or choline content of any of the brain areas examined. This dose of 2-ClAdo elicited significant reductions in the TR_{ACh} in both the hippocampus and frontal cortex, but not in the striatum. The extent of this reduction in TR_{ACh} was greatest in the hippocampus with a 67% decrease, while the TR_{ACh} in the frontal cortex was decreased by 36%. This effect of 2-ClAdo was antagonized by the prior i.vt. injection of theophylline (278 nmoles) suggesting that an activation of adenosine receptors is operative in the action of 2-ClAdo. Further support for this notion was obtained from experiments in which we compared the effects of the L and D isomers of phenylisopropyladenosine (PIA) on TR_{ACh}. The i.vt. administration of L-PIA (65 nmoles) elicited a 79% reduction in the TR_{ACh} in the hippocampus, while D-PIA (65 nmoles i.vt.) had no significant effect on hippocampal TR_{ACh}. This finding that L-PIA is more potent than D-PIA suggests that these effects on TR_{ACh} may be mediated by adenosine A_1-receptors which have been shown to display marked stereospecificity for the isomers of PIA rather than A_2-receptors at which L- and D-PIA have similar potencies.

159.14 EFFECTS OF A SINGLE DOSE OF SOMAN ON LEVELS OF ACETYLCHOLINE AND CHOLINE IN RAT BRAIN AREAS: A TIME COURSE STUDY. Tsung-Ming Shih. U.S. Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

The aim of these studies has been to investigate the time course of the levels of acetylcholine (ACh) and choline (Ch) in discrete brain areas of the rat following a single subcutaneous administration of Soman (120 µg/kg; 9/10 LD50), a completely irreversible anticholinesterase, in order to understand the relationship between neurotransmitter elevation and Soman toxicity. Rats were killed by microwave irradiation focused to the head 5, 10, 15, 20, and 40 min, and 1, 2, 3, 4, 8, 12, 16, 20 and 24 hrs after injection of Soman. One additional group of animals was killed in parallel with experimental groups at different times of day to ascertain possible circadian variations. The levels of ACh and Ch were determined in brain stem (B), cerebral cortex (C), hippocampus (H), midbrain (M), cerebellum (R) and striatum (S) by gas chromatography/mass spectrometry (Anal. Biochem. *55*, 438, 1973). A single dose of Soman caused a different degree and duration of increase of ACh and Ch levels in each brain area. Selective data (mean ± SE) for ACh are summarized in the following table:

Area	Time After Injection (Hours)			
	0	1	4	20
B	13.1±0.37(38)	14.7±1.82(10)	12.6±2.05(11)	11.9±0.42(10)
C	13.7±0.36(36)	32.6±4.80(15)	36.1±7.24(14)	20.2±1.46(10)
H	17.1±0.49(42)	27.7±4.66(15)	30.4±4.06(14)	21.4±1.36(10)
M	22.1±0.52(38)	29.1±2.86(15)	28.4±2.27(15)	23.9±1.69(10)
R	3.7±0.31(37)	4.9±0.42(11)	4.4±0.57(12)	2.3±0.46(10)
S	64.9±2.22(43)	82.4±8.27(11)	79.3±6.50(8)	59.1±3.82(10)

Maximal ACh elevation was reached in B, H, and S at 20 min (↑34.4, 68.3, and 33.3%, respectively); in R at 40 min (↑51.9%); in M at 1 hr (↑31.8%); and in C at 2 hrs (↑320.3%) after Soman. Duration of elevation of ACh was approximately 1/2 hr in B; 2 hrs in R; 4 hrs in S; 8 hrs in M; and 16 hrs in C and H. Thus injection of Soman caused the greatest change in ACh content in areas C and H, both in degree and duration. However, in the case of Ch, time for maximal effect was varied with, and duration of its elevation was shorter than that of ACh in each area. These data indicate that the perturbation of ACh and Ch levels caused by Soman was not uniform throughout the brain regions and suggest that the toxicity produced by Soman may be related to changes in neurotransmitter levels in specific brain areas.

159.15 ELEVATION OF PLASMA ACETYLCHOLINE DURING DEVELOPMENT OF THE ECC SYNDROME. A.C. Sconzert, G. Karp* and B. Haber. Marine Biomedical Institute, UTMB, Galveston, Texas 77550.

The ECC syndrome is a complex of stereotyped behavior characterized by general excitation, circling, and choreiform head and neck movements. This syndrome is induced by the daily intraperitoneal administration of 2,2'-iminodipropionitrile (IDPN; 300 mg/kg) to rats for one week. The expression of the symptoms usually follows a course such that choreiform head movements are first evident at about day 3 and rapid circling activity is present at day 6. During the week following the last injection the syndrome gradually stabilizes until the 15th day after the initial IDPN injection when the behavioral abnormalities can be said to be stabilized. Once induced, the ECC syndrome is permanent and irreversible. Thus the ECC rat may represent a useful animal model in which to explore some of the neurochemical parameters associated with movement disorders. We have previously reported data that regional markers of CNS cholinergic function (levels of acetylcholine, activity of choline acetyltransferase and acetylcholinesterase, and the binding of *QNB) are altered in ECC rats. We have also observed that the plasma GABA levels change in parallel with those seen in the CNS. Therefore it was of interest to measure ACH in the plasma, which is present at the level of 31 nmoles/ml. In the present study, female rats were injected with IDPN and blood obtained by cardiac puncture under pentobarbital anaesthesia at select times during the development of the ECC syndrome and analyzed for acetylcholine (ACH) content by the radioenzymatic method of Goldberg and McCaman (1976). Plasma levels of ACH rose to 171% of control values after a single injection of IDPN, 143% after 3 injections, were the same as control on day 6, and were 236% of control on day 14. This temporal pattern of ACH alterations parallels that seen in plasma GABA, and is the reverse of that seen in the CNS levels of ACH. Therefore, we feel that the measurement of plasma ACH may be useful in the assessment of the cholinergic changes in the development of the permanent ECC syndrome by IDPN.

160.1 PRESENCE OF AN ENDOGENOUS FACTOR IN RAT CNS WHICH INHIBITS BINDING OF α-BUNGAROTOXIN 2.2 TO ITS RECEPTOR. M. Quik. Dept. Pharmacol., McGill Univ., 3655 Drummond St., Montreal, Que. H3G 1Y6.

Although the α-bungarotoxin 2.2 (α-BGT) binding site in nervous tissue has the characteristics of a nicotinic cholinergic receptor, the identity of the site remains unclear as the toxin fails to inhibit cholinergic receptor function at neuronal sites. The possibility of an endogenous ligand for the α-BGT binding site was thus investigated. Cerebral cortical membranes and supernatant were prepared by centrifugation of tissue homogenates at 45,000 xg for 10 min. The supernatant fraction obtained was found to significantly inhibit α-BGT binding to the membrane preparation. After a 3 min incubation period, the supernatant inhibited toxin binding by approximately 65%, while the inhibition declined to about 40% after 30 min of incubation, presumably due to the slow reversibility of α-BGT binding. The choice of buffer was found to be an important determinant of the degree of inhibition observed, with 10 mM Tris pH 7.3 providing the most effective condition. This inhibition of toxin binding to cortical membranes by the supernatant was shown not to be due to adsorption of the radiolabelled compound to soluble or residual particulate material in the supernatant fraction. Specificity of the supernatant for the α-BGT site was demonstrated; a supernatant fraction could be prepared which inhibited toxin binding by 50%, but had no effect on ^{3}H-spiroperidol (DA_2 and 5-HT_2), ^{3}H-prazosin (α_1-adrenergic), ^{3}H-5-hydroxytryptamine (5-HT_1) and ^{3}H-quinuclidinylbenzilate (muscarinic cholinergic) binding. Saturation kinetics indicated that the inhibiting substance affected the maximal number of binding sites (B_{max}), while the apparent affinity (K_d) of α-BGT for its receptor was not altered. The inhibition of toxin binding also occurred in several other CNS regions including hippocampus, brainstem, spinal cord and cerebellum, with an 80 to 90% inhibition of binding occurring in the latter two regions. In addition, the 45,000 xg cortical supernatant completely prevented the binding of α-BGT to extrajunctional neuromuscular receptors and inhibited the binding to junctional receptors by 50%. Supernatants prepared from heart, liver and kidney or bovine serum albumin, at a concentration similar to the cortical supernatant fraction, did not alter radiolabelled toxin binding to cortical membranes. A preliminary characterization of the inhibitory substance indicated it was of molecular weight greater than 1000 and unaffected by heat and trypsin treatments. Supported by the MRC of Canada.

160.2 INTERACTION OF RADIOLABELED ACETYLCHOLINE WITH MUSCLE PARTICULATE FRACTION. V.A. Eterović, P.A. Ferchmin, R. Hann and G. Escalona de Motta¶. Dept. of Biochem. School of Medicine, Univ. Central del Caribe; ¶College of Pharmacy and Lab. of Neurobiology, Medical Science Campus, Univ. Puerto Rico. Cayey, P.R. 00633.

The particulate fraction of toad rectus abdominis muscle binds tritiated acetylcholine (^{3}H)ACh) with high affinity. Two sites are detected by displacement with excess decamethonium. (^{3}H)ACh associates with each binding site through a fast process, which is completed in less than 15 sec under our assay conditions, and dissociates with similar celerity. The higher-affinity site is seen at (^{3}H)ACh concentrations of 10^{-9} to 3 x 10^{-9}M; thre are 1-2pmoles of this site per mg of protein. In addition to (^{3}H)ACh and decamethonium, this site interacts with carbamylcholine and nicotine, but not with d-tubocurarine. Preliminary experiments indicate that about half of the higher-affinity sites are inhibited by α-bungarotoxin. (^{3}H)ACh binding to this site is stimulated by succinic anhydride, which has been previously found to potentiate ACh potentials in the same muscle (Escalona de Motta and del Castillo, Nature 270: 178-180, 1977). We believe that the higher-affinity site is the nicotinic receptor.

Binding of (^{3}H)ACh to the lower-affinity site is seen at free (^{3}H)ACh concentration between 3 x 10^{-9}M and 5 x 10^{-7}M. This binding is partially inhibited by excess carbamylcholine, succinic anhydride, and d-tubocurarine. Decamethonium at low concentrations (10^{-8}M) stimulates (^{3}H)ACh binding to the lower-affinity site, while higher concentrations (10^{-4}M) are inhibitory.

This work was partially supported by the NSF Grant RIM 78-16333.

160.3 IN VIVO DEVELOPMENT AND REGULATION OF THE MUSCARINIC ACETYLCHOLINE RECEPTOR FROM EMBRYONIC CHICK HEART. S.W. Halvorsen* and N.M. Nathanson. Department of Pharmacology, School of Medicine, Univ. of Washington, Seattle, WA 98195.

Sustained exposure of 8-day embryos to cholinergic agonists decreases cardiac muscarinic acetylcholine receptor (mAChR) number as much as 87% as measured by the specific binding of the potent muscarinic antagonist [^{3}H]quinuclidinyl benzilate. The decrease in receptor number is both dose and time dependent. Muscarinic receptor number recovers to control levels when further agonist-receptor interaction is blocked by the mAChR antagonist atropine. When receptor number is decreased 50% by in vivo agonist treatment, isolated atria require a 12-fold greater concentration of the cholinergic agonist carbachol than controls to arrest spontaneous beating. Analysis of the binding of carbachol to the mAChR indicates this shift in response can be accounted for by a decrease in the absolute number of receptors and a change in the relative fraction of the high and low affinity forms of the mAChR with no change in their respective affinities for carbachol.

Other investigators have demonstrated that atria isolated from 3-day embryos are much less responsive to the negative chronotropic effect of muscarinic agonists than are atria from 8-day embryos (Pappano, A.J. and Skowronek, C.A., J. Pharmcol. Exp. Ther. 191: 109-118, 1974). We have found that 3 and 4-day embryos require at least a 10 fold greater dose of agonist to achieve equivalent in vivo loss of cardiac mAChR number as observed in 8-day embryos. Analysis of agonist binding to the mAChR in 4-day embryonic atrial membranes indicates the receptor is significantly less responsive to regulation by guanyl nucleotides than in atrial membranes from 8-day embryos. This suggests that 4-day atria which have not developed a full negative chronotropic response to muscarinic agonists either do not have or are not functionally coupled to a guanyl nucleotide binding protein. In addition, the percentage of high affinity agonist binding sites is greatly enhanced in 4-day atria. Comparison of binding and physiological data from 4-day atria with 8-day atria suggests that the high affinity form of the receptor is not uniquely required for the negative chronotropic response to muscarinic agonists and that the low affinity form is the active one.

160.4 N-ETHYLMALEIMIDE (NEM)-INDUCED ALTERATION IN THE INTERACTION OF AGONISTS WITH MUSCARINIC CHOLINERGIC RECEPTORS (MR). T.K. Harden and M.M. Smith*. Dept. of Pharmacology, Univ. of North Carolina School of Medicine, Chapel Hill, NC 27514.

Pretreatment of washed rat heart membranes with 100 μM NEM resulted in a 10-20 fold decrease in the apparent affinity of the agonist oxotremorine (OXO) for MR assessed in competition binding experiments with ^{3}H-quinuclidinyl benzilate (^{3}H-QNB). No effect of NEM-pretreatment on antagonist interaction with MR was observed. The apparent affinity of OXO for MR in NEM-pretreated membranes was similar to the apparent affinity of OXO in the presence of GTP in control membranes. GTP had no effect on the competition binding curve for OXO in NEM-pretreated membranes. NEM-pretreatment of membranes or the addition of GTP to control membranes increased the steepness of competition binding curves for OXO. Calculated Hill coefficients were 0.66±.01, 0.86±.03, 0.89±.05, and 0.92±.04 for control membranes, control membranes + 100 μM GTP, NEM-pretreated membranes, and NEM-pretreated membranes + 100 μM GTP, respectively. Maximal effects on agonist affinity of a 60 μM NEM pretreatment on ice were observed after 25 min of incubation. The $K_{0.5}$ value for the effect of NEM on OXO affinity was 40 μM for a 25 min incubation on ice and 5 μM for a 20 min incubation at 37°. Pretreatment of membranes with NEM at concentrations as high as 1 mM had no effect on agonist interaction at β-adrenergic receptors. The effects of NEM-pretreatment on the interaction of MR with adenylate cyclase (AC) were also studied. Both basal and isoproterenol-stimulated AC activities in heart membranes were inhibited (25 to 45%) in a concentration-dependent manner by OXO. Pretreatment of membranes with NEM under conditions which reduced the apparent binding affinity of OXO and blocked the effects of GTP on agonist binding affinity did not cause an equivalent reduction of the efficacy of OXO for inhibition of AC. The MR system has also been investigated in WI-38 fibroblasts. PGE_1 and isoproterenol stimulate AC activity 4-6 fold in membranes from these cells. OXO inhibits basal, as well as PGE_1- and isoproterenol-stimulated activities by 40%. Pretreatment of WI-38 membranes with NEM decreases the apparent affinity of OXO measured in ^{3}H-QNB competition binding assays and prevents the effect of GTP on agonist affinity. The concentration-effect curve for NEM is similar to that observed with heart membranes. Preliminary experiments with WI-38 membranes suggest that NEM-induced blockade of the inhibitory effects of OXO on AC occur at concentrations of NEM higher than that necessary to produce large effects on apparent OXO binding affinity. Supported by NIH grant 29536.

160.5 FACTORS INFLUENCING THE CONCENTRATION AND CHOLINERGIC REGULATION OF MUSCARINIC RECEPTORS IN NEURON-LIKE HYBRID CELLS. Hemin R. Chin, Neri M. Cohen*, and W.L.Klein. Dept.of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

Sustained cholinergic stimulation of cultured cells causes a loss of muscarinic receptor binding sites measured in cell homogenates(Klein,W.L.,Proc.West.Pharmacol.Soc.23:449,1980). We have investigated this process further using cultured NG108-15 neuron-like hybrid cells and also have assessed the ability of other factors to influence muscarinic receptor levels. Incubation of cells with 10^{-3} M carbachol for 4 hours caused a 45-55% loss of (^{3}H)-QNB and (^{3}H)-N-methylscopolamine binding sites whether assayed in homogenates or in intact cells. This loss occurred in defined physiological buffer as well as in culture medium supplemented with serum. Treatment of homogenates with up to 1% digitonin or 10^{-3} M GppNp did not result in the appearance of any new binding sites. All available evidence is consistent with the hypothesis that the cholinergic-induced decrease in binding is due to a loss of receptor molecules on the cell surface. We have further found that, in addition to cholinomimetic drugs, several other physiological and biochemical factors influence the concentration of muscarinic receptors in NG108-15 cells. Removal of calcium ions from culture medium with EGTA resulted in a 40% decrease in binding sites within 4 hours. Binding was measured in the presence of calcium. Cells maintained with calcium concentrations either higher or lower than 1.8 mM(concentration in DMEM) had fewer binding sites than cells maintained in normal DMEM. Incubation of cells for 4 hours with either 10^{-3} M adenosine or 10^{-3} M GABA resulted in 30% and 45% increases in binding,respectively. Other transmitters and modulators tested showed no effect. This effect was not seen when carbachol was added, and neither adenosine nor GABA inhibited the loss of the sites caused by carbachol. Further exposure of cells to adenosine for 24 hours caused a 35% decrease in maximum binding and this response was not blocked by atropine. These results show that a variety of modulators, in addition to cholinergic activity, may regulate muscarinic receptor concentrations. (Supported by NIH grant 5 R01 NS 15299-02 to WLK.)

160.6 SEPARATION AND CHARACTERIZATION OF NEURONAL NICOTINIC RECEPTORS USING BROMOACETYLCHOLINE. T.H. Large, H. Chin, D.J. Raithel*and W.L. Klein. (Department of Neurobiology and Physiology, Northwestern University, Evanston, Illinois 60201.)

Nicotinic receptors from avian retina and muscle have been investigated using 3H-bromoacetylcholine (BAC) as a covalent ligand for receptor binding sites. In addition, an affinity column, prepared by linking BAC to agarose beads, has been used to separate receptor-rich membranes from crude homogenates.

As in electroplax (Damle, V.N., et al., Biochem. Biophys. Res. Comm. 84: 845, 1978), 3H-BAC labels covalently the reduced receptor from chick skeletal muscle and retina homogenates. Solubilization of labeled proteins followed by precipitation and filtration of the proteins does not abolish specific binding. Likewise, solubilized proteins from labeled membranes applied to DEAE paper can be washed free of unbound 3H-BAC with no loss of labeled receptors. Although 3H-choline uptake in retina is inhibited by acetylcholine (ACh) and nicotine, no 3H-choline labeled molecules adhere to DEAE paper following solubilization. Alkylation of reduced membranes with NEM blocks 80% of covalent 3H-BAC binding. Receptors are protected from reduction and alkylation by nicotinic agonists. The covalent reaction of 3H-BAC with non-receptor proteins is diminished by alkylation of free sulfhydryls with NEM.

To separate receptor-rich membranes, an affinity gel was prepared by linking BAC to 4% agarose beads (Damle, V.N. and Karlin, A., Biochemistry 17: 2039, 1978). The derivatized gel contained 1.6 umoles of choline carboxy methyl group per gram packed gel. Incubation of chick muscle or retina homogenate with the gel beads gave a dose-dependent loss of 125I-Bungarotoxin (125I-BTX) binding. Separation of gel from crude homogenate by slow-speed centrifugation maximally removed from the suspension 95% of the 125I-BTX binding sites. Nearly all of the homogenate protein remained in the supernatant fraction. This procedure should allow for the isolation of nicotinic receptor-rich membranes and may be extended to permit isolation of single cells containing the nicotinic receptor. This will make possible biochemical comparisons of muscle and CNS receptors and associated synaptic elements.

(supported by NIH grant NS15299 to WLK and a grant from American Cancer Society, Illinois Division)

160.7 NEUROMUSCULAR BLOCKING AGENTS COMPETE FOR AND MAY DISCRIMINATE BETWEEN ^{3}H-QNB BINDING SITES IN RAT ATRIUM. Janet Dunlap* and Joan Heller Brown, Division of Pharmacology, Dept. of Medicine, University of California, San Diego, La Jolla, CA 92093

Muscarinic receptors in the cardiac atrium mediate chronotropic and inotropic responses to acetylcholine, inhibit cyclic AMP formation and modulate norepinephrine release. Physiological studies suggest that muscarinic receptors in the atrium differ from classical muscarinic receptors characterized in other peripheral organs. Among the antagonists that appear to preferentially block atrial muscarinic receptors are gallamine and pancuronium, neuromuscular blocking drugs. We have used radioligand binding studies to compare the affinities of classical muscarinic antagonists and neuromuscular blocking agents for QNB binding sites in rat atrium, and to examine the possibility that subtypes of muscarinic receptors may be selectively antagonized by these agents. Radioligand binding studies were carried out using rat atrial membranes, in a Krebs salt solution buffered with 25 mM Na-Hepes pH 7.4 at 35°C. Binding of ^{3}H-QNB was linear with protein, saturable, and stereospecific. Nonspecific binding determined with 1 μM atropine was always less than 10% of total binding. The K_D for QNB determined by Scatchard analysis was approximately 0.06 nM and $B_{max} \sim 700$ fmol/mg protein. Competition experiments were performed using 0.1-0.3 nM ^{3}H-QNB, and 40-100 μg membrane protein. $K_i$app was calculated from IC_{50} values using the Cheng-Prussof equation.

Antagonist	IC_{50}	$K_i$app	N_H
QNB	0.7 nM	0.11 nM	.95
Dexetimide	16.0 nM	3.6 nM	.94
Atropine	30.0 nM	7.3 nM	.99
Ambenonium	2.0 μM	.44 μM	.70
Pancuronium	2.8 μM	.72 μM	.56
Gallamine	10.0 μM	2.7 μM	.58
d-Tubocurarine	140.0 μM	33.2 μM	.75

Gallamine and pancuronium, as well as ambenonium, a cholinesterase inhibitor with neuromuscular blocking properties, were less potent than classical muscarinic antagonists, but had apparent affinities in the micromolar range. Inhibition by 10 μM gallamine appeared competitive (10-fold increase in K_D with no decrease in B_{max} for QNB). Additionally, Hill slopes for the neuromuscular blocking agents differed from unity. The shallow Hill slopes seen most strikingly with pancuronium and gallamine suggest that the atrium may contain multiple QNB binding sites with equal affinities for classical muscarinic antagonists but differing affinities for neuromuscular blocking drugs. (Supported by NIH 24441.)

160.8 PROTEOLYSIS LEADS TO SELECTIVE LOSS OF ANTIGENIC DETERMINANTS ON ACETYLCHOLINE RECEPTOR. W. Gullick*, B. Einarson*, S. Tzartos* and J. Lindstrom. Receptor Biology Laboratory, The Salk Institute for Biological Studies, San Diego, California 92138.

Proteolytic digestion of Torpedo californica acetylcholine receptor in the membrane or in solution causes loss of antigenic determinants for some monoclonal antibodies. However, binding of monoclonal antibodies to the main immunogenic region on α subunits is not affected by treatment with either trypsin or V8 protease. Protease-labile determinants have been detected on α, β and δ subunits of the receptor. The localization of the proteolytic fragments containing these labile determinants and their role in agonist-induced sodium flux is being studied. Monoclonal antibodies to protease-labile determinants provide a sensitive assay for monitoring the integrity of electric organ receptor during storage and of mammalian muscle receptor during purification.

160.9 MUSCARINIC RECEPTOR REGULATORY MECHANISMS IN MEMBRANE-BOUND AND DETERGENT-SOLUBILIZED PREPARATIONS. Gerald O. Carrier and Robert S. Aronstam. Department of Pharmacology, Medical College of Georgia, Augusta, GA 30912.

Muscarinic acetylcholine receptors can exist in several reactive states which are most clearly defined on the basis of their agonist binding properties. Several mechanisms have been identified which induce interconversions betweeen these states, the functional significance of which is not always obvious. Some researchers have suggested that only the low affinity receptors are active insofar as they are effectively coupled in the membrane to structures involved in the elicitation of cellular responses to receptor stimulation.

Alkylation of neural membranes with N-ethylmaleimide (NEM) increases the affinity of agonists for muscarinic receptors in rat brain. After solubilization of cerebral cortex membranes with 1% digitonin/1 mM Na_2EDTA, NEM treatment still produced a selective increase in agonist binding affinity. The IC50 value for carbamylcholine inhibition of 0.1 nM [^{3}H]QNB binding was reduced from 9 to 1 μM after treatment with 1 mM NEM for 15 minutes.

Certain guanine nucleotides decrease high affinity agonist binding to muscarinic receptors in membranes isolated from rat cerebral cortex. After solubilization, however, 100 μM 5'-guanylylimidodiphosphate did not affect the ability of 10 μM carbamylcholine to inhibit 0.1 nM [^{3}H]methylscopolamine binding, as measured using equilibrium dialysis techniques. In parallel experiments, the nucleotide decreased carbamylcholine binding to membrane-bound receptors. It is possible that receptor and nucleotide subunits were separated during solubilization, although a number of alternate explanations for the failure of nucleotides to affect receptor binding after solubilzation have not been ruled out.

Longitudinal muscles were isolated and mounted in tissue baths for the measurement of isometric contractions. Exposure to 0.3 mM NEM for 30 seconds reduced contractions induced by 1 mM Ba^{++} and 60 mM KCl to a significantly lesser extent than contractions induced by 1 μM ACh. The longitudinal muscles were removed from the bath, homogenized and muscarinic binding properties studied. Specific binding of 0.18 nM [^{3}H]QNB was reduced 30±4% in control and 62±8% in NEM-treated tissues by 1 μMcarbamylcholine.

160.10 PURIFICATION AND SUBUNIT COMPOSITION OF THE ACETYLCHOLINE RECEPTOR FROM DENERVATED CHICKEN SKELETAL MUSCLE. James McManaman,* James Blosser, Stanley H. Appel (Spon: R. Grossman) Department of Neurology, Baylor College of Medicine, Houston, Texas 77030.

Although acetylcholine receptors from the electric organ of the ray have been extensively studied, apart from rat skeletal muscle (Froehner S.C., Reiness C.G. and Hall Z.W. (1977) JBC 252 8589-8596), little is known about the structure of skeletal muscle receptors. In order to provide a basis for further investigation of the cellular regulation of acetylcholine receptors in chick skeletal muscle, we have purified acetylcholine receptors from the leg and breast muscle of denervated chickens.

Acetylcholine receptors were purified from skeletal muscle that had been denervated for seven days. The acetylcholine receptor levels of the denervated muscle were elevated 20 fold over non-denervated muscle. Muscle was homogenized in a 50 mM phosphate buffer pH 7.3 and centrifuged at 38,000 xg for 90 minutes. The 38,000 xg pellet was then extracted with a 50 mM phosphate buffer containing 1% Triton X-100. Acetylcholine receptors were purified 18,000 fold, with a 61% recovery from the Triton X-100 extract by affinity chromatography on an acetylcholine affinity column. Pepstatin A, EGTA and PMSF were included in all purification steps to prevent proteolysis. The binding of ^{125}I-α-bungarotoxin was assayed by sucrose gradient sedimentation, and the purification was monitored by SDS-gel electrophoresis.

For comparison, acetylcholine receptors were also purified from the electric organ of Torpedo californica by the same procedure. The purified acetylcholine receptors from chicken skeletal muscle and Torpedo californica had similar specific activities for α-bungarotoxin binding, and cosedimented on sucrose gradients. Iodination and SDS-gel electrophoresis of purified chicken acetylcholine receptors demonstrated the presence of electrophoretic bands comigrating with the α, γ, and δ subunits of purified Torpedo acetylcholine receptors, and the absence of major contaminants. Supported by NSF grant BNS 7914115 and the Muscular Dystrophy Association.

160.11 THREE AGONIST- AND TWO ANTAGONIST-STATES OF MUSCARINE RECEPTORS. J. Luber-Narod* and L.T. Potter* (Spon. J.N. Barrett) Dept. of Pharmacology, University of Miami School of Medicine, P.O. Box 016189, Miami, Florida 33101.

We have studied the binding of (-) ^{3}H-quinuclidinyl benzilate at saturating concentrations (0.32 nM) to muscarine receptors in unselected membranes from the brainstem and forebrain of rats, in the presence and absence of carbachol, Mn^{++} (1 mM), EDTA (1 mM) and/or GppNHp (10 μM). In EDTA QNB binds to and dissociates from a single class of sites in the brainstem with a kinetic Kd ≃ 15 pM; Mn slows both rates 6-fold. In EDTA QNB binds to one class of sites in the forebrain, but dissociates from two classes, with 3/4ths of the receptors showing a kinetic Kd ≃ 7 pM; Mn slows rates 2-fold. Carbachol competes with QNB in a complex fashion as described by Birdsall et al (Proc. Roy. Soc. 207 1, 1980: evidence for 3 states), with much higher affinity in the brainstem than forebrain. GppNHp irreversibly diminishes carbachol potency in the brainstem, but has little effect in the forebrain. Mn accentuates, and EDTA diminishes, carbachol potency in both regions; these effects are reversible. GppNHp and EDTA reduce carbachol competition with QNB almost to a Langmuir isotherm in the brainstem, but the IC50 (30 μM) is still much lower than that seen in the forebrain.

We conclude that most receptors in the brainstem behave differently than most receptors in the forebrain. While one explanation is that there are two different types of receptors, our working hypothesis is that there is a single receptor type (M) in both regions, with different coupling to a guanine nucleotide binding protein (G). We propose three agonist states: "super-high" affinity = carbachol-MG (a ternary complex with altered conformation), "high" affinity may = carbachol-M...G ± GppNHp (a complex with weaker M...G interaction), and "low" affinity = carbachol-M. We suggest two antagonist states: QNB-M and QNB-M...G ± GppNHp, where QNB-M shows slightly higher affinity. In each case Mn promotes the binding of carbachol or QNB to receptors.

(Supported by grants from the National Parkinson Foundation, the American Parkinson Disease Association and the U. S. Public Health Service HL07188.)

160.12 UNCHANGED BINDING PROPERTIES OF MUSCARINE RECEPTORS IN SOLUTION. Lynn Kalinoski* and L.T. Potter* (Spon: J.C. Hackman), Dept. of Pharmacology, University of Miami School of Medicine, P.O. Box 016189, Miami, Florida 33101.

Muscarine receptors in the rat forebrain are intrinsic membrane proteins which are not dissolved in the cold by sonication, alkaline extraction, 2 M NaCl or 0.5 M Na perchlorate. However receptors saturated in membranes with (-) ^{3}H-quinuclidinyl benzilate (QNB) are fully soluble in most detergents. In Lubrol-PX, as in membranes, QNB dissociates from two classes of sites, and 3/4ths of the sites show slightly higher affinity for QNB than the rest. When high-affinity sites for carbachol are protected during the labeling of receptors in membranes, only one class of sites is seen in Lubrol. Unfortunately, QNB does not bind to receptors in Lubrol.

Digitonin (3 mg/mg protein; in EDTA) appears to solubilize only 3/4ths of the total receptors in membranes, and QNB dissociates from only one class of sites in solution. In digitonin QNB does bind to receptors at 37°C, and bound QNB can be quantitatively recovered after precipitation on ice with 5% protamine sulfate and 20% polyethylene glycol, by collection on glass-fiber filters. Non-specific binding is negligible. Binding is proportional to the concentration of receptors, and is saturable. QNB associates and dissociates in solution from a single population of sites: the association rate is 0.7×10^9 M^{-1} min^{-1}; the dissociation rate is 7×10^{-3} min^{-1}; and the calculated kinetic Kd is 10 pM. (-) Scopolamine shows simple competition with 0.1 nM QNB for receptors; the IC50 value is 10 nM, and the calculated Kd for scopolamine is 0.9 nM. The inhibition curve for carbachol vs. QNB is close to a Langmuir isotherm, with an IC50 value of 0.3 mM; the apparent calculated Kd for carbachol is 30 μM. These values for QNB, scopolamine and carbachol, determined in solution, are nearly identical with those we have found in membranes.

We conclude that 3/4ths of the receptors in the rat forebrain (those with lowest agonist- and highest antagonist-affinities) can be dissolved in digitonin without alteration of their binding properties. This fact facilitates purification of these receptors by affinity chromatography.

(Supported by grants from the National Parkinson Foundation and the American Parkinson Disease Association.)

160.13 FUNCTIONAL CHARACTERIZATION OF PURIFIED ACETYLCHOLINE RECEPTORS RECONSTITUTED IN LIPID VESICLES. R. Anholt[†Π*], V. Hudson[†*], D. R. Fredkin[#*], M. Montal[Π#*], and J. Lindstrom[†]. (SPON: A. E. Traynor [†]). Depts. of Biology[Π] and Physics[#], Univ. of California, San Diego, and The Salk Institute[†], San Diego, CA 92138.

Acetylcholine receptors (AChRs) from Torpedo californica, purified under conditions which preserve the integrity of the agonist-regulated cation channels, and reconstituted in lipid vesicles, were functionally characterized. The vesicles displayed a carbamylcholine-induced uptake of $^{22}Na^+$ which was dose dependent with a midpoint at $\sim 1.4 \times 10^{-6}$ M. Dose dependent desensitization of the AChR was assayed by preincubation with different concentrations of carbamylcholine in the absence of radioisotope, followed by $^{22}Na^+$ - influx assay at 10^{-4} M carbamylcholine. The equilibrium desensitization curve had a midpoint at $\sim 3.2 \times 10^{-7}$ M. The integrated flux response measured after 10 s incubation is limited by desensitization and is proportional to the amount of active AChR present. Both curves were characterized by a Hill coefficient of 2.0 ± 0.4. AChR function was non-competitively blocked by cobratoxin and competitively inhibited by curare. Computer techniques are currently being used in order to explain the observed $^{22}Na^+$ - flux data measured under various conditions in terms of models for AChR function, based on known ligand-binding properties of the AChR.

160.14 ANALYSIS OF PERIPHERAL PROTEINS ASSOCIATED WITH NICOTINIC ACETYL CHOLINE RECEPTORS. R. Gysin*, M. Wirth* and S.D. Flanagan (SPON: A.R. Dravid). Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

Membranes from Torpedo californica electroplax, highly enriched in acetylcholine receptors contain ∿43,000 dalton proteins that are not involved in the ion translocation and ligand binding functions of the receptor. We are interested in these proteins because of their potential role in the supramolecular organization of cholinergic synapses. We report here the subcellular distribution and partial molecular characterization of these proteins.

SDS-gel electrophoresis suggested the existence of at least two subunits. Further analysis on two-dimensional gels revealed extensive heterogeneity in the isoelectric focusing dimension. Two protein families, designated ν_1 and ν_2, were of slightly different molecular weight and each consisted of three major and some minor isoelectric variants focusing between pH 7 and pH 8, more alkaline than most of the other membrane proteins. A third protein, ν_3, was more acidic and focused around pH 6 as a single spot.

Tryptic peptide mapping of the spots cut out from two-dimensional gels gave different patterns for the three proteins, indicating no similarity in their primary sequence. The major isoelectric variants of both ν_1 and ν_2, however, gave internally consistent peptide fingerprints, suggesting that posttranslational modifications may be responsible for the observed charge differences. Using the same techniques it was found that ν_2 and ν_3, but not ν_1, are prominent proteins in the cytoplasm and are therefore present in a soluble form, besides being membrane bound.

All the 43,000 molecular weight subunits are considered to be peripheral proteins because they are removed from the membranes during a brief incubation at pH 11. Work from other laboratories with such alkali-treated membranes has suggested that the 43,000 dalton proteins are involved in controlling the arrangement, stability, and mobility of the receptor complex in the membrane. Our results raise questions concerning the relative contribution of the different protein subunits to these parameters, and the relationship between membrane bound and soluble forms of ν_2 and ν_3. (Supported by postdoctoral fellowship and grant-in-aid of the Muscular Dystrophy Association. S.D.F. is a recipient of an Alfred P. Sloan Foundation Research Fellowship).

160.15 EFFECTS OF CATIONS ON CLOZAPINE AND THIORIDAZINE BINDING TO THE MUSCARINIC CHOLINERGIC RECEPTOR. J.M. HAPPY* (SPON: R.G. Babington). Sandoz, Inc. E. Hanover, N.J. 07936

Clozapine (CLZ) and to a lesser degree, thioridazine (THZ) are distinquished from the classical neuroleptics by their lack of extrapyramidal side effects which has been speculated to be a result of their anticholinergic properties. Therefore, the binding characteristics of CLZ and THZ to the muscarinic receptor were studied through competition studies with the specific muscarinic antagonist, ^{3}H-QNB. CLZ and THZ were found to differ in their binding properties to this receptor. In Tris buffer (pH 7.4 at 24°C), CLZ is approximately 3 times as potent as THZ in displacing ^{3}H-QNB from calf caudate membranes. This is consistent with their in vivo potencies in antagonizing oxotremorine-induced tremors in rats. However, in Tris buffer containing 125 mM NaCl, 5 mM KCl, 2mM $CaCl_2$ and 1 mM $MgCl_2$ the THZ inhibition curve becomes steeper and the difference in potencies between CLZ and THZ diminishes. If in addition, increasing concentrations of ethanol are added to the medium, CLZ and THZ become equipotent in 1% ethanol. In 10% ethanol THZ is 2X as potent as CLZ.

In the presence of $2X10^{-7}$M THZ and increasing conc. of NaCl or KCl, ^{3}H-QNB binding is progressively decreased, while under the same conditions in the presence of $1X10^{-7}$M CLZ, ^{3}H-QNB binding is increased. In both of these cases the changes are small, but significant. Increasing $CaCl_2$ or $MgCl_2$ conc. in the presence of THZ or CLZ progressively decreases ^{3}H-QNB binding. However, the decrease is significantly more pronounced for THZ.

The effects of monovalent and divalent cations on other muscarinic antagonists and agonists were examined. In general, monovalent cations caused a small significant increase in ^{3}H-QNB binding in the presence of agonists and antagonists, except for QNB which showed no change. THZ was the only compound examined which showed a decrease. Divalent cations caused a decrease in ^{3}H-QNB binding in the presence of either agonist or antagonist. THZ was the most sensitive to divalent cations.

160.16 MUSCARINIC AND NICOTINIC EFFECTS OF ACETYLCHOLINE IN THE HIPPOCAMPUS OF THE RAT. N. Ropert and K. Krnjević, Anaesthesia Research Dept, McGill University, Montréal, PQ H3G 1Y6, Canada.

Previous experiments have indicated that the modulatory effect of acetylcholine (ACh) in the hippocampus is probably mediated through muscarinic receptors. The present experiments show that, even though the ACh effect is mainly muscarinic, a component of it may be mediated by nicotinic receptors.

Experiments were performed on urethane-anaesthetized rats (2.5 Kg^{-1};I.P.) whose head was maintained in a stereotaxic apparatus. Extracellular recordings were done in the CA1 and CA3 regions of the dorsal hippocampus using the central barrel (filled with K acetate and Pontamine sky blue) of multibarrelled electrodes whose peripheral barrels were used for iontophoretic application of various drugs: ACh; some muscarinic agonists (muscarine, bethanecol, acetyl-β-methylcholine, pilocarpine, oxotremorine, arecoline) and some nicotinic agonists (tetramethylammonium (TMA), butyrylcholine, nicotine and dimethylphenyl-piperazinium). The muscarinic antagonists, atropine and scopolamine, were injected into the femoral vein.

Low frequency stimulation (≤1 Hz) of the hippocampal commissure induces in the pyramidal cells IPSPs which can be recorded as positive extracellular waves in the stratum pyramidale of CA1 or CA3. We have already shown that ACh can induce the appearance of population spikes, probably by removing GABA-mediated inhibition (Ben-Ari, Y. et al., Neuroscience, In Press, 1981; Krnjević, K. et al., J. Physiol., 308:73P, 1980). Very low doses of muscarine and other muscarinic agonists had a similar effect, which was dose dependent, typically slower in onset and offset than that of ACh, and was seen only when muscarine was applied in the stratum pyramidale. It was completely blocked by scopolamine (i.v.). In contrast, the effect of ACh was not completely blocked by atropine or scopolamine. After scopolamine, the relative sensitivity of the hippocampus to ACh and muscarine was reversed: before scopolamine, it was more sensitive to muscarine; after scopolamine, it became relatively more sensitive to ACh. Moreover, all the nicotinic agents tested (except TMA) were also able to induce population spikes; this effect was typically fast and was not suppressed by scopolamine. These data indicate the possibility that ACh may also act through nicotine receptors.

(Supported by the Canadian Medical Research Council).

161.1 *INHIBITION OF ^{3}H-FLUNITRAZEPAM BINDING BY THE NOVEL TRIAZOLOPYRIDAZINE, CL 218,872 IN VARIOUS REGIONS OF THE HUMAN BRAIN.* *Micaela Morelli*, Susan Yamamura*, Pushpa Deskmukh and Henry I. Yamamura. University of Ariz., Health Sci. Ctr. Tucson, AZ 85724.*

The inhibition of ^{3}H-flunitrazepam binding by the novel triazolopyridazine, CL 218,872 was examined in 8 regions from membrane preparations of post mortem human brain. Brain regions examined for binding inhibition were the cerebellum, thalamus, frontal cortex, globus pallidus, substantia nigra, putamen, hippocampus and hypothalamus. The potency for CL 218,872 inhibition of ^{3}H-flunitrazepam binding was greatest in the cerebellum with a Ki value of about 60nM. Intermediate potencies were seen in the thalamus, frontal cortex, globus pallidus and the substantia nigra with Ki values of 85, 110, 120 and 125nM, respectively. CL 218,872 inhibited ^{3}H-flunitrazepam binding with least potency in the putamen, hippocampus and the hypothalamus with Ki values of 180, 230 and 240nM, respectively. The Hill coefficient was near unity for the cerebellum (0.95) and approximately 0.8 for the rest of the brain regions examined except for the putamen where the Hill coefficient obtained was about 0.68. The inhibition curve obtained in the human putamen was analyzed using nonlinear least squares regression analyses to determine whether CL 218,872 was binding to one or two classes of binding sites. A two site regression model resulted in a highly significant improvement in the fit of the data. A high affinity binding site resulted with a Ki value of about 60nM with 60% of the sites being associated with the high affinity site. A low affinity binding site with a Ki value of about 1300nM with 40% of the sites being associated with the low affinity site was observed. Autoradiographic studies were performed to determine the discrete localization of these binding sites in human brain. Radiolabelled CL 218,872 (10nM) was used and incubated according to the method of Young and Kuhar. The initial results of our studies show that ^{3}H-CL 218,872 specifically labels the benzodiazepine receptor and that there is evidence consistent with receptor heterogeneity.

Portions of these studies were supported by USPHS grants and a Research Scientist Development Award to H.I.Y.

161.2 SUPERSENSITIVITY OF BENZODIAZEPINE RECEPTORS FOLLOWING DENERVATION OF SUBSTANTIA NIGRA. G. Biggio, M.G. Corda, A. Concas and G.L. Gessa (SPON: Walter J. Wojcik)
Institute of Pharmacology, School of Biology and School of Medicine - University of Cagliari (Italy).

The intranigral injection of kainic acid (0.5 µg) produced a 50% loss in the number of ^{3}H-diazepam binding sites (Bmax) in the rat substantia nigra, suggesting that benzodiazepine receptors are localized, in part, on intrinsic neurons (kainic acid-sensitive receptors) and in part, on glia cells and/or terminals of neurons with cell body outside the substantia nigra (kainic acid-resistant receptors). The number (Bmax) of the kainic acid resistant benzodiazepine receptors increased by 100% following destruction of striato-nigral connections produced by the intrastriatal injection of kainic acid (1.5 µg). The observed denervation induced "supersensitivity" suggests that kainic acid resistant benzodiazepine receptors are innervated by neurons originating in the striatum and that the endogenous ligand for benzodiazepine receptors, might be the transmitter of specific neurons or the co-transmitter in GABA neurons. The latter possibility is suggested by the fact that the markers (GABA content and GAD activity) of GABAergic innnervation are almost completely lost in the supersensitive substantia nigra.

161.3 MORPHOLOGICAL STUDIES ON NEUROTRANSMITTER RECEPTORS IN THE BRAIN S. Kito, E. Itoga*, N. Mori*, M. Togo*, T. Kishida* and Y. Nakamura*. Third Dept. of Int. Med., Hiroshima Univ. Sch. of Med.,Hiroshima 734, Japan.

We performed light and electron microscopic autoradiography of receptors of acetylcholine (Ach), gamma aminobutyric acid (GABA) and opiates using ^{3}H-quinuclidinyl benzilate (QNB), ^{3}H-muscimol and ^{3}H-met-enkephalin as ligands.

As for autoradiographic demonstration of Ach-muscarinic receptor sites with QNB, the ligand was appled in vivo. In the cases of muscimol and met-enkephalin, the ligands were applied to the tissues which were lightly fixed, sectioned by cryostat and then mounted on slide glasses. The slides were coated with carbon and emulsion (Ilford L-4)-coated by dipping method. Binding affinities were measured biochemically and compared between materials fixed with 0.1% paraformaldehyde for light microscopic autoradiography and unfixed ones, and also between materials fixed with 2 fold diluted Zamboni solution for electron microscopic autoradiography and unfixed ones. As displacers, atropine, GABA and met-enkephalin were used.

Electron microscopically muscimol binding sites in the cerebellar molecular layer and met-enkephalin binding sites in the amygdaloid nucleus were observed.

For electron microscopic autoradiography, selection of developing method was critical to get high resolution of the pictures. We used elon ascorbic acid (EAA) development in which developed silver grains were much smaller than grains of silver bromide of undeveloped emulsion. Furthermore, in EAA development, a growing speed of silver grains during the development process is so slow that we can easily select the development time adequate for our purpose. Thus we obtained silver grains in a pattern highly localized to the cytoplasmic membrane, i.e. the receptor site by means of EAA development.

Autoradiographic observation of neurotransmitter receptors has still problems to be solved. Nevertheless, this technique is very important to observe morphological relationship between transmitters and their receptor sites.

161.4 CHANGES IN [^{3}H]-MUSCIMOL BINDING IN SUBSTANTIA NIGRA, ENTOPEDUNCULAR NUCLEUS, AND THALAMUS AFTER STRIATAL LESIONS AS DEMONSTRATED BY QUANTITATIVE RECEPTOR AUTORADIOGRAPHY. Helen S. Pan, Anne B. Young, John B. Penney*, Jr. Department of Neurology, University of Michigan, Ann Arbor, Michigan 48109.

We have developed a quantitative autoradiographic technique for measuring the binding of tritiated ligands to neurotransmitter receptors. This technique allows us to measure receptor numbers and affinities for volumes of brain as small as 0.01 cu. mm. We have also quantitated ligand binding kinetics and drug displacements autoradiographically. We have applied the method to the investigation of GABA receptors in rat brain after kainic acid lesions of striatum.

20 µ frozen sections of brain are mounted on subbed slides. To measure GABA receptors the slides are washed 3 times in 50 mM tris-citrate buffer (pH 7.0) for 5 min., dipped in buffer plus varying concentrations (5-90 nM) of [^{3}H]muscimol for 30 min. at 0°C, rinsed 3 times in 0° C buffer for 5 seconds and blown dry. Tritium sensitive film (Ultrofilm ^{3}H LKB) is apposed to the slides and standards for 12 days then developed. Optical densities of areas of interest are compared to the standards and radioactive ligand concentration is calculated.

The effects of lesioning rat striatum at the level of the anterior commissure (A-7000) with 1 nM of microelectrophoretically applied kainate on distant GABA receptors were measured 7 days after the lesion. There is local loss of receptors in striatum. Receptors increase in numbers but not affinity in the ipsilateral entopeduncular nucleus (EPN) and substantia nigra pars reticulata (SNR). There is a decrease in number but not affinity in the ipsilateral anteroventrolateral (VL), ventromedial (VM) and parafasicular (PF) thalamic nuclei. These findings suggest that a loss of GABAergic striatal output results in GABA receptor supersensitivity in EPN and SNR. These areas in turn contain GABA neurons which project to VL, VM and PF. It is suggested that with loss of inhibitory input the GABAergic neurons in EPN and SNR may become more active resulting in GABA receptor subsensitivity in VL, VM and PF. The data supports the hypothesis that striatal GABAergic output cells directly influence GABAergic output from EPN and SNR to thalamus.

161.5 OPIATE/ALPHA-2 INTERACTIONS: CO-LOCALIZATION OF BOTH RECEPTORS BY RADIOHISTOCHEMISTRY. J.R. Unnerstall, J.M. Palacios and M.J. Kuhar. Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

A relationship has been shown to exist between central adrenergic and opioid systems in the control of cardiovascular function and pain sensitivity. The antihypertensive effects of clonidine, a potent alpha-2 adrenergic agonist, can be reversed by naloxone in experimental models of hypertension. Clonidine is also a potent analgesic, and can alleviate some adverse effects of opiate withdrawal. In a previous autoradiographic study (Young and Kuhar, PNAS 77:1696, 1980) it was noted that the distribution of alpha-2 receptors paralleled that of opiate receptors in regions involved in cardiovascular regulation and nociception. We have extended these findings in the rat CNS using the in vitro autoradiographic technique for localization of neurotransmitter receptors by labeling adjacent sections with selective alpha-2 or opiate agonists.

For the localization of alpha-2 receptors, sections were incubated for one hour at room temperature in 1 nM ^{3}H-para-aminoclonidine in the presence of 1 mM $MnCl_2$. Sections were preincubated for 30 minutes in 5 mM EDTA and washed for 10 min. in cold buffer plus Mn^{2+}. Opiate receptors were identified by incubating adjacent sections in 4 nM ^{3}H-dihydromorphine as has been previously described (Young and Kuhar, Brain Res. 179:255, 1979; Goodman, Snyder, Kuhar and Young, PNAS 77:6239, 1980).

In the brainstem, high levels of alpha-2 and opiate receptors were identified in areas involved in cardiovascular regulation; i.e. the nucleus commissuralis, nucleus tractus solatarius, dorsal motor nucleus of the vagus. Elevated levels of both receptors were also observed in areas involved in nociception and attention including the substantia gelatinosa of the spinal cord and trigeminal nucleus, raphe magnus, lateral reticularis gigantocellularis and periaqueductal gray. Particularly high levels of both receptors were observed in the locus coeruleus. In the diencephalon, high densities of both receptors were seen in dorsal and ventral regions of the medial thalamus and in several hypothalamic nuclei. Co-localization of these receptors was also observed in specific amygdaloid nuclei (e.g. central, basal, lateral and posterior cortical), the bed nucleus of the stria terminalis and pyriform and cingulate cortex.

These studies suggest that alpha-2 and opiate receptors are localized to the same areas and possibly the same cells, and may provide an anatomical basis for explaining at least some of the interactions between opiates and clonidine.

161.6 A LOW COST MICROCOMPUTER BASED DENSITOMETER SYSTEM FOR QUANTITATIVE AUTORADIOGRAPHY. G. Dauth, K. Frey* and S. Gilman, Department of Neurology, The University of Michigan, Ann Arbor, MI 48109

Quantitative autoradiographic methods developed in the past five years provide powerful tools for the investigation of regional neurochemical processes in mammalian brain, such as cerebral blood flow, glucose utilization, protein synthesis, and neurotransmitter receptor pharmacology. These techniques are based upon contact autoradiography of [^{3}H] or [^{14}C] labeled brain tissue using x-ray film or LKB Ultrofilm and subsequent densitometric analysis of the film images.

The available methods for reading film density are either slow and cumbersome or expensive. We have developed a computer assisted densitometry system which provides rapid readings of film density, conversion to radionuclide concentration, as well as subsequent conversions, e.g. local cerebral glucose utilization rates or receptor concentrations. The system consists of 4 main components: 1) a Beseler 45 MX, unmodified photographic enlarger; 2) a spot densitometer circuit developed in our laboratory using a PIN silicon photodiode; 3) a Z-80 based microcomputer system with analog to digital converter and floppy disks; and 4) computer software written in Fortran IV. The densitometer sensor is placed on the base board of the enlarger. The film is positioned on the negative stage of the enlarger and moved manually to position the desired area of the image over the sensor, and a foot switch is used to signal the computer to initiate a read cycle.

The system has been used in our laboratory for over 1 year for the quantification of local cerebral glucose utilization and quantitative receptor autoradiography. In addition to its relatively low cost and rapid operation there are two other significant advantages to this system: 1) the image is not obscured by the sensor as is the case with most commercial spot densitometers; and 2) this system allows the image to be magnified in order to read small structures with greater accuracy.

161.7 BENZODIAZEPIN RECEPTORS IN GOLDFISH RETINA. Y. Y. T. Su, J.-Y. Wu, and D. M. K. Lam. Cullen Eye Institute and Cell Biology, Baylor College of Medicine, Houston, Texas 77030

It is very well established that GABA receptor, benzodiazepine receptor and chloride ionopore are part of a functional unit. The GABAergic pathways in goldfish retina have been identified by autoradiographic and immunocytochemical methods. Here we like to report our recent studies of benzodiazepine receptors in goldfish retina. Goldfish retinas were homogenized in 0.32 M sucrose solution. The homogenate was centrifiged at 1000 x g for 15 min and the supernatant was further centrifuged at 45000 x g for 45 min. The pellet, P_2, was resuspended in the same solution and spinned again at 45000 x g for 45 min. The rinsed P_2 preparation was stored at -20 C overnight, resuspended in cold water and spinned at 45000 x g for 45 min. The pellet, crude membrane preparation, was suspended in a small volume of 0.05 M Tris-citrate buffer (pH 7.1). The reaction mixture for the receptor binding experiment contained 320 µg of crude membrane preparation and 5 to 50 nM of ^{3}H-flunitrazepam in the presence (nonspecific binding) or absemce (total binding) of 40 µM of clonopine. The reaction mixture was incubated at ice water bath for 30 min. The reaction was terminated by centrifuged at 45000 x g for 15 min. After quickly rinsed twice with cold distil water containing 10 µM of clonopine the pellet was dissolved in tissue dissolver. The activity was measured in liquid scintillation counter. Scatchard analysis of the binding indicates one binding site with an apparent affinity constant , K_d=2.6 nM. This value is in the range of that of mouse or rat brain membrane preparations. The localization of the receptor and it relation with GABAergic neurons will be discussed.

161.8 CYTOPLASMIC PROGESTERONE RECEPTORS IN THE FEMALE RAT BRAIN: IN VIVO EFFECTS OF ESTROGEN AND PROGESTERONE. T. W. Jasper and V. D. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

We have used the tritiated synthetic progestin, ^{3}H-R 5020, to measure cytoplasmic progestin receptors (PR) in the brain and pituitary of ovariectomized (ovx) and ovariectomized-adrenalectomized (ovx-adrex) rats treated in vivo with estrogen (estradiol benzoate; E) or estrogen plus progesterone. Scatchard analysis of ^{3}H-R 5020 binding in the hypothalamus-preoptic area and pituitary revealed high affinity (Kd < 1.0 nM) and limited capacity binding for progestin. Subcutaneous implantation of silastic capsules containing E (10 mm length, 1.6 mm width id, 235 µg E/ml oil) into ovx rats doubled hypothalamic-preoptic area PR within 2 days and maintained elevated PR levels for at least 12 days. In ovx E-primed rats, in vivo administration of progesterone (1.0 mg/0.1 ml oil sc) reduced hypothalamic-preoptic area PR levels within 1 h and maintained the depressed PR levels for at least 6 h. E stimulation of PR levels in the pituitary was similar in ovx and ovx-adrex rats, but the PR levels were greater in the hypothalamus-preoptic area of ovx-adrex versus ovx rats following E stimulation. In both the hypothalamus-preoptic area and pituitary, PR levels were greater after E stimulation than in the unstimulated controls.

The regional specificity of PR stimulation by E, and its depletion following in vivo progesterone (1.0 mg sc, 1 h before decapitation), was examined in ovx rats. Silastic E treatment elevated PR levels in the medial basal hypothalamus, preoptic area-septum, and pituitary, but not in the cerebellum, parietal cortex, of hindbrain of ovx rats. Progesterone administration reduced PR levels in all tissues examined, regardless of the presence or absence of E pretreatment.

161.9 LAMINAR ANALYSIS OF OPIATE RECEPTOR DISTRIBUTION IN RAT CEREBRAL CORTEX. M. E. Lewis*, A. Pert, C. B. Pert and M. Herkenham (SPON: W. E. Bunney, Jr.). Biological Psychiatry Branch and Lab. of Neurophysiology, NIMH, Bethesda, MD 20205

Although rat cerebral cortex contains easily measurable quantities of opiate peptides, immunocytochemical procedures have revealed very few enkephalin-containing fibers in cortex. Since opiate receptors could be markers for "opiatergic" pathways in brain (Proc. Nat. Acad. Sci. USA, 77:5532, 1980), we carried out a laminar analysis (translaminar autoradiographic grain counting) of different cortical areas which had been labeled for "μ"-like or "δ"-like opiate receptors. These receptors were labeled by [^{3}H]naloxone or [^{3}H]D-Ala^2,D-Leu^5-enkephalin ([^{3}H]DALA), respectively, on slide-mounted rat brain sections which were then processed for autoradiography. In addition, we compared the distribution of binding sites in some areas to thalamocortical projections as determined by [^{3}H]amino acid transport.

The laminar distribution of grains differs markedly across areas with the pattern depending upon which radioligand is used as a receptor label. We also observed correlations between the laminar distribution of "μ"-like binding sites and thalamocortical projections to different regions. For example, the distribution of both [^{3}H]naloxone sites in frontal cortex and [^{3}H]amino acids transported from the mediodorsal nucleus shows a sharp decline in density from the most superficial part of layer I to the border of layer II, and a second peak in layer III. [^{3}H]DALA sites, in contrast, show a shallower layer I peak and a broad peak extending from layers III to VI. The medial frontal, cingulate and retrosplenial areas all show layer VI peaks of [^{3}H]naloxone binding; however, the layer III binding peak disappears in posterior retrosplenial cortex. The insular and entorhinal areas are densely labeled in layer VI by [^{3}H]naloxone; piriform cortex is sparsely labeled throughout. Insular and piriform cortex are the only limbic cortical areas to show more overall [^{3}H]DALA than [^{3}H]naloxone binding. Unique to primary sensory cortices is [^{3}H]naloxone labeling in upper layer V. In addition, area 17 can be easily discriminated from surrounding area 18 by a lower density of labeling in layer VI. Because of evidence that apparent multiple opiate receptors may be functionally different conformations of the same receptor (Bowen et al., Proc. Nat. Acad. Sci. USA, in press), we suggest that laminar differences in [^{3}H]naloxone and [^{3}H]DALA binding reflect an in vitro stabilization of different receptor conformations which undergo dynamic interconversions in vivo.

161.10 VARIATIONS IN OPIATE RECEPTOR DISTRIBUTION IN THE MAMMALIAN STRIATUM. S. Moon Edley*, M. Herkenham, C. B. Pert., Lab. of Neurophysiology, and Biological Psychiatry Branch, NIMH, Bethesda, MD 20205.

The opiate receptor binding patterns in rodents, carnivores, and primates have been investigated using tritiated naloxone, dihydromorphine, and enkephalin on fresh-frozen cryostat-cut sections. Incubated sections were emulsion-dipped (Kodak, NTB-2) for microscopic study, or exposed to tritium-sensitive film (LKB) for computer analysis.

The mouse and rat striata under the appropriate allosteric binding conditions, (Bowen, et al., PNAS, in press) exhibit the same general pattern of high-density opiate receptor patches. In the other mammals examined, the general pattern is that of a ventromedial to dorsolateral gradient of decreasing alkaloid receptor binding. Embossed on this specific blanket labeling are other pattern complexities. In the cat, receptor-rich areas overlay the blanket labeling in the rostral caudate, but caudally, it is interrupted more frequently by receptor-sparse zones. In the dog striatum, the impressive feature is the ventromedial-to-dorsolateral shift in receptor density, though receptor-dense zones can be found. In the one squirrel monkey examined, a more homogeneous opiate receptor pattern is evident. However, the rhesus monkey has a strong laterally shifting decreasing density gradient, embellished by dense zones and sparse holes intermingling at the same level. The heavily labeled human striatum, obtained at autopsy, has the greatest intermingling of the above mentioned patterns of the mammals examined.

The specificity and anatomic validity of the pattern of striatal opiate receptors has been demonstrated in the rat by the precise fit of opiate-dense patches to the areas free of thalamic parafascicular terminals (Herkenham and Pert, Nature, in press). Moreover, the tissue preparation and the sensitivity of the receptor labeling method make it suitable for the study of abnormalities as well. Preliminary evidence suggests a lower opiate receptor density in the striatum of a strain of "genetically nervous" pointer dogs (brains from U. of Arkansas Medical Center, Little Rock, AK) as compared to normal pointer kennel mates. The "nervous" dogs are excessively fearful, becoming extremely cateleptic in the presence of humans or when startled, and are unable to demonstrate operant conditioning without the aid of drugs (Murphee et al., Pav. J. of Biol. Sci., '74). Their catalepsy is reversible by dopamine blockers and naloxone (Shideler, unpublished), making them a candidate for the experimental study of affective disorders. The suggestion of interactions in the striatum between opiate and dopamine systems has encouraged us to examine human brains from victims of schizophrenic disorders.

161.11 PRESENCE OF TWO BENZODIAZEPINE RECEPTORS IN THE RAT HIPPOCAMPUS. L. Volicer and T.M. Biagioni*. E.N. Rogers Memorial Veterans Hospital, Bedford, MA 01730.

Although the initial characterization of benzodiazepine receptors indicated the presence of a single class of binding sites, more recent reports suggest that multiple benzodiazepine receptors exist in the brain. This evidence is mostly indirect, based on the differential effects of GABA agonists on benzodiazepine receptors and on differential inhibition of benzodiazepine binding by various benzodiazepine analogs. We recently found that the presence of two benzodiazepine receptors can be demonstrated in the hippocampus directly by a Scatchard analysis of diazepam binding. Male Sprague-Dawley rats were sacrificed by decapitation and the brains dissected on ice. The synaptosomal membranes were prepared by differential centrifugation and kept frozen for at least 24 hrs. On the day of an assay the membranes were treated with 0.05% Triton X100. The membranes were incubated with ^{3}H-diazepam or ^{3}H-flunitrazepam in the presence or absence of 10^{-5}M flurazepam and the incubation was terminated by filtration on Whatman GF/B filters.

In experiments in which five ligand concentrations were used (0.75 to 35 nM) the number of binding sites in the cerebral cortex and cerebellum were similar for both diazepam and flunitrazepam and the affinity was 4 times lower for diazepam than for flunitrazepam. In contrast, in the hippocampus the number of binding sites was higher for diazepam than for flunitrazepam, and the affinity of diazepam was 17 times lower. Analysis of diazepam binding in the hippocampus using 0.75 to 1517 nM concentrations demonstrated the presence of two binding sites (affinities 4.58 ± 0.38 and 1077 ± 128 nM, and the number of binding sites 0.285 ± 0.056 and 6.09 ± 0.81 p moles/mg of protein for high and low affinity sites respectively, means ±S.E.M. of 5 determinations). The high affinity binding site detected in these experiments, corresponds to the flunitrazepam binding (similar number of receptors, 4 times lower affinity). The presence of two diazepam binding sites in the hippocampus explains the different relationship between diazepam and flunitrazepam binding in this brain area and in the other two areas. The pharmacological function and localization of these receptors remains to be investigated. (Supported by the Veterans Administration).

161.12 REGIONAL DISTRIBUTION OF N^6-CYCLOHEXYL[^{3}H]ADENOSINE BINDING IN RAT AND MOUSE BRAIN. M.G. Murphy* and H.A. Robertson, (SPON: J.G. Rutherford). Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

Adenosine has recently been implicated as a modulator of excitability in the central nervous system, and may be important in the regulation of convulsion activity (Dunwiddie, T.V., Epilepsia 21, 541-548 (1980)). In the initial phase of our investigation of the relationship between adenosine and seizure activity, we have examined the regional distribution of adenosine receptors in rat and mouse brain using N^6-cyclohexyl-[^{3}H]adenosine ([^{3}H]CHA). Following dissection, brain regions were pooled from 3-6 animals and were either homogenized in a physiological Tris medium, or crude synaptosomal (P_2) fractions were isolated in 0.32M sucrose prior to suspension in the same medium. All experiments were carried out with fresh membrane preparations. Following incubation with adenosine deaminase (20 units/g wet weight) to remove endogenous adenosine, membranes were washed, and incubated for 1.5 h at 25°C at 5 concentrations (1.25-20nM) of [^{3}H]CHA. Displaceable binding, which accounted for 92-99% of total binding at 1nM [^{3}H]CHA, was determined using 10 μM 2-chloroadenosine. Scatchard analyses were carried out on all preparations.

Specific binding in the P_2 fractions was 2 to 4 fold higher than in homogenates of the corresponding regions. Considerable variation was observed in adenosine-receptor density (B_{max}) in the P_2 of rat brain; density was highest in cerebellum and lowest in amygdala.

Brain Region	Bmax (fmol/mg Protein	K_D (nM)
Cerebellum	940.6	1.90
Hippocampus	714.2	1.66
Cortex	668.4	1.91
Striatum	351.3	2.81
Hypothalamers	225.5	2.55
Amygdala	165.6	2.37

In contrast, density of binding sites in mouse brain was higher in cerebral cortex (B_{max} 447.6) than in cerebellum (B_{max} 310.8). Preliminary studies have been carried out to determine the effects of pentylenetetrazol-induced seizures on adenosine binding in different regions of rat brain. Results indicate that following convulsion, there is a selective decrease in the number of [^{3}H]CHA binding site in the hippocampus. (Supported by the Medical Research Council of Canada).

161.13 CHARACTERIZATION AND REGIONAL DISTRIBUTION OF ACIDIC AMINO ACID BINDING SITES IN RAT BRAIN. D.T. Monaghan, A.C. Foster, G.E. Fagg, E.E. Mena, and C.W. Cotman (SPON: T.J. Cicero). Dept. of Psychobiology, Univ. of Calif. Irvine, Irvine, Calif. 92717.

Ligand binding studies have demonstrated L-[3H]-glutamate binding sites in rat brain synaptic membranes. Previous work from this laboratory has demonstrated the presence of a Ca++ dependent L-Glu binding site which has a similar pharmacology to that of the lateral entorhinal perforant path-granule cell evoked response as determined by use of the phosphonic acid derivatives 2-amino-3-phosphonopropionic acid (APP), 2-amino-4-phosphonobutyric acid (APB), and 2-amino-5-phosphonovalerate (APV). These compounds were a generous gift of Dr. J.C. Watkins. Both the binding of L-Glu in the presence of Ca++ and the synaptic response of the perforant path are inhibited by APB, and less so by APV and APP.

To further clarify the role of this Ca++ dependent, APB sensitive L-Glu receptor, binding of L-[3H]-Glu (50nM) to rat synaptic plasma membranes was measured using a microfuge assay, and inhibition constants were determined: APP 1000uM; APV 39uM; L-APB 5uM; and D-APB 75uM, which are similar to the apparent Ki's determined from the antagonism by these compounds of perforant path evoked responses (Koerner and Cotman, Brain Res., in press). Interestingly, APB appears to inhibit (competively) only the Ca++ dependent L-Glu sites. Thus, APB appears specific for a subpopulation of glutamate receptors.

In view of these observations, it is important to determine the regional distribution of the APB sensitive-Glu receptor. Nine rat CNS regions were dissected: spinal cord, brain stem, thalamus/hypothalamus, septum, hippocampus, caudate, cortex, and cerebellum. For these binding studies, a P2/P3 pellet was obtained and washed in 200 uM Hepes 4 times. The membrane fraction was assayed for inhibition of L-[3H]-Glu binding by 0.5mM APB in the presence of 2.5 mM Ca++. This concentration of APB gave maximal inhibition of Ca++ dependent binding sites, while having no effect on the binding in the absence of Ca++.

APB sensitive L-Glu binding sites showed a regional variation; high levels were found in brain stem and hippocampus, low levels in the cerebellum, and intermediate levels in the remaining regions. The obtained regional distribution was compared to other indices of glutamate transmitter activity.

Thus, the APB sensitive sites have a widespread distribution in the CNS and are of interest as potential receptors for glutamate using pathways. (Supported by fellowships from NATO and NIH, and by grants NS 08957 and MH 19691)

161.14 DEVELOPMENT OF CHOLINERGIC MUSCARINIC RECEPTORS IN RAT CNS: AUTORADIOGRAPHIC STUDIES. L. Charles Murrin, Dept. of Pharmacology, Univ. of Nebraska Medical Center, Omaha, NE 68105

Neurotransmitter receptors have been localized anatomically in the CNS in recent years through the use of autoradiography. We have developed conditions for labeling cholinergic muscarinic receptors for autoradiography with ^{3}H-1-quinuclidinyl benzilate (^{3}H-QNB; Amersham) in tissue slices from neonatal rats, using the procedure of Young and Kuhar (Brain Res. 179: 255, 1979). We here report preliminary studies on the ontogeny of these receptors. Sprague-Dawley strain pups were used. At various ages brains were fixed via cardiac perfusion with 0.1% formalin in PBS and 3-5 mm sections of brain were frozen to cryostat chucks in liquid N_2. The brains were sectioned at 6μ and thaw-mounted onto subbed slides. Binding was carried out in 170 mM Tris, pH 7.4 at 20°C for 60 min, which we found sufficient to reach equilibrium. Initially, ^{3}H-QNB was used at 3 x 10^{-9}M with 10^{-6}M atropine added to generate blanks. Using these procedures specific to non-specific binding ratios of 40:1 were obtained. The tissues were washed for 10 min in buffer at 20°C, then dipped briefly in distilled water to remove salts. ^{3}H-QNB was found to dissociate so slowly that there was no significant loss of specific binding with this procedure. Coverslips dipped in NTB-3 were apposed to the slides and exposed for two weeks. The slides were then developed, the tissue stained with Pyronin Y and examined by light microscopy. At birth autoradiographic grains were found in most areas having high concentrations of cholinergic muscarinic receptors in adult brain. The nucleus olfactorius of the olfactory bulb was heavily labeled. The cortex was labeled throughout but this labeling was uniform with no variation between layers. The striatum was also densely labeled with an uneven distribution of the labeling beginning about A8000 (Konig and Klippel, 1963) and continuing caudally. The least dense areas did not appear to correspond to fiber bundles. This uneven distribution was not as discrete as is seen with opiate receptors in striatum. By day 5 receptor levels in layer IV of the cerebral cortex were higher than in other layers. Density of binding had visibly increased in all labeled areas and continued to increase to day 21. In the striatum by day 11 fiber bundles could be seen while the uneven distribution of grains was still present. By day 21 the uneven distribution was gone while the striatum was clearly mottled by the fiber bundles passing through. In cortex at day 21 grain densities resembled those seen in adults with higher levels in layers 2,3,4 and 6. While much work remains, it is clear that this approach will be of great value in understanding the ontogeny of cholinergic systems in the CNS. Supported by the March of Dimes Birth Defects Foundation, MH 33390 and BNS 79-21105.

161.15 ESTROGEN MODIFICATION OF β-ADRENERGIC RECEPTOR DENSITY IN THE RAT HYPOTHALAMUS. H. Ryan Wagner and Elena Yablonskaya-Alter*. Dept. Neurology, College of P+S, Columbia Univ., NY, NY 10032.

Several lines of evidence suggest that estrogens modify the activity of noradrenergic neurons in the brain. Based on this, we have investigated the possibility that estrogen-induced changes in adrenergic function may be reflected at the receptor level. Hypothalamic membrane binding of the β-adrenergic radioligand, ^{3}H-dihydroalprenolol (DHA), was compared between male and cycling female rats and between age-matched female rats ovariectomized at least four weeks prior to the study. We also compared hypothalamic binding of ^{3}H-DHA in ovariectomized female rats following estrogen replacement and in pre-(25 day) and postestrous (60 day) female rats.

Hypothalamic ^{3}H-DHA binding was significantly elevated ($p \leq .01$) in female (F) rats relative to male (M) rats. Scatchard analysis showed a higher maximum receptor density in female animals (F, Bmax=89 fmols/mg; M, Bmax=80 fmols/mg) with no difference in ligand affinity (F, Kd=4 nM; M, Kd=5 nM). Binding capacity in ovariectomized female rats (O) was also significantly elevated ($p \leq .01$) over levels found in male rats (O, Bmax=96 fmols/mg) but did not differ significantly ($p < .1$) from levels in age-matched females without ovariectomy; ligand affinity was again unchanged (O, Kd=5 nM).

Assessing ^{3}H-DHA hypothalamic binding at a single ligand concentration (6 nM), we found no apparent age difference in binding between female rats at 25 and 60 days post partum (Day 25= 57±10 fmols/mg; Day 60=57±7 fmols/mg). Age was also not found to be a significant factor in male rats (Day 25=43±6 fmols/mg; Day 60=43±6 fmols/mg) although, ignoring age, binding capacity between male and female rats was again significantly different (F= 57 ±6 fmols/mg; M=43±4 fmols/mg). Treatment of ovariectomized female rats with estrogen (E) for four consecutive days (100 μg/kg, s.c.) increased hypothalamic ^{3}H-DHA binding capacity over levels found in vehicle injected control (C) rats (E=60+4 fmols/mg; C=51+3 fmols/mg). Results suggest that estrogens may elevate β-adrenergic receptor density in the rat hypothalamus, that such elevations occur before the 25th day post partum and that such changes, once present, are relatively permanent.

161.16 CHARACTERIZATION OF BENZODIAZEPINE BINDING AND ACTION ON RAT ANTERIOR PITUITARY CELLS. L. Grandison, Dept. of Physiology and Biophysics, Rutgers Medical School, College of Medicine and Dentistry of New Jersey, Piscataway, New Jersey 08854

As previously shown by this laboratory the benzodiazepines are potent inhibitors of prolactin secretion (Fed. Proc. 40:415, 1981). One observation demonstrated that diazepam blocked haloperidol induction of prolactin release. Since haloperidol stimulates prolactin release by binding to pituitary dopamine receptors to block the tonic inhibitory action of dopamine the above effect of diazepam suggests that benzodiazepines may act directly at the pituitary. This study sought to examine actions of benzodiazepines directly on the pituitary by determining the existence of benzodiazepine receptors in pituitary tissue and secondly by assessing the effects of benzodiazepines on prolactin release from dispersed pituitary cells maintained in tissue culture. Anterior pituitaries from male rats were enzymatically dispersed and maintained in culture for three to five days. For ligand binding studies the cells were kept in suspension culture. Using ^{3}H diazepam as the ligand specific binding to intact pituitary cells was found. This binding was saturable and scatchard analysis indicated one binding site with dissociation constant of approximately 10 nM and a binding maximum of 25 pmoles/10^6 cells. Displacement studies using unlabeled benzodiazepine analogues indicated a K_I of approximately 5 nM for RO5-4864 and a K_I of greater than 1 μM for clonazepam. For studies examining benzodiazepine action on prolactin release, dispersed pituitary cells were plated onto petri dishes and allowed to attach over a period of three days. During a 2 hour incubation the addition of diazepam to the medium over the dose range 10^{-9} - 10^{-6} M had no significant effect on spontaneous prolactin release. However, preincubation of the cells with diazepam for 24 hrs altered the responsiveness of the cells during a subsequent incubation. Benzodiazepine pretreatment potentiated the inhibition of prolactin release produced by GABA or apomorphine. These data suggest that benzodiazepines can act at the pituitary to alter hormone secretion. (Supported by NIAMDD Grant AM 26661).

162.1 BOMBESIN: CENTRAL NERVOUS SYSTEM (CNS) ACTION TO INCREASE GASTRIC MUCOSAL BARRIER IN RATS. Y.F. Taché. Pediatric Research Center, Ste-Justine Hospital, Université de Montréal, Montreal, Quebec, H3T 1C5.

We have previously shown that intracerebrally applied bombesin (1 µg dose) prevents gastric hemorrhagic lesions caused by stress and completely suppressed gastric acid secretion (Taché et al., Life Sci. 24: 1719, 1979; Taché et al., Proc. Soc. Natl. Acad. Sci. 77: 5515-5519, 1980). We report here that bombesin induced a CNS mediated increase in gastric mucosal barrier which may also contribute to explain its protective action against stress ulceration.

Saline or peptides were injected intracisternally (i.c.) in 24 h fasted male rats under light ether anesthesia and the pylorus was ligated. Conscious rats were decapitated two hours post injection (except in time-course study experiments) and the stomachs were removed. The estimation of mucosal barrier adhering to the everted glandular portion of the stomach was done using a dye binding procedure described by Corne et al. (J. Physiol. 242: 116, 1974). Bombesin (1 µg, i.c.) enhanced by 80%, whereas the mucolytic agent N-acetyl-L-cysteine (300 mg, per os) reduced by 89% the gastric mucosal barrier. The action of bombesin given i.c. is rapid in onset (22% significant increase is observed 15 min post injection), long acting (50% elevation is still observed 3h post injection), dose-dependent (minimal effective dose less than 50 ng), specific (as shown by the inactivity of β-endorphin, somatostatin, norepinephrine, serotonin, or dopamine 5-10 µg dose, i.c.) CNS mediated (since the peptide is inactive when infused into the jugular vein at 100 ng dose/min for 2 h), and not mimicked by other gastric acid inhibitor like atropin (2 mg/kg, i.v.). Indomethacin pretreatment (5 mg/kg, per os -1 h) did not affect bombesin induced increase in mucosal barrier indicating that peptide action is not mediated through prostaglandin release.

Supported by the Medical Research Council of Canada, Grant MA-6836.

162.2 ANALGESIC ACTIVITY OF NON-OPIATE NEUROPEPTIDES FOLLOWING INJECTIONS INTO THE RAT PERIAQUEDUCTAL GRAY MATTER. T. L. Sullivan* and A. Pert. NIMH, Bethesda, MD 20205

Injections of opiates into the periaqueductal gray matter (PAG), which is high in opiate receptors and opiate peptides, produce profound analgesia in the rat. Besides endorphins, the PAG also contains relatively high concentrations of other neuropeptides. Since this region of the brain appears to be critical for pain perception, it was of interest to ascertain whether any other neuropeptides might also have analgesic properties following direct microinjections. Rats were prepared with chronic indwelling cannulae guides through which various neuropeptides could be injected into the PAG. Analgesia was assessed with both the tail-flick and hot-plate procedures.

Of the opiates, β-endorphin exhibited the most potent analgesic effects in both the hot-plate and the tail-flick test. Both procedures revealed it to be approximately ten times as potent as either morphine or D-Ala^2-D-leu^5-enkephalin (DADL). D-Ala^2-met-enkephalin, on the other hand, appeared to be approximately one-third as potent as either morphine or DADL.

Bombesin, VIP and neurotensin all exhibited analgesic effects. Bombesin was the most potent non-opiate peptide analgetic in the hot-plate test, while VIP was the most potent in the tail-flick test. In general, all of these peptides were approximately three times more potent than morphine following PAG injections.

β-endorphin-induced analgesia was readily antagonized by naloxone. Analgesia induced by either bombesin, neurotensin or VIP, on the other hand, was not reversed by naloxone. Injections of β-endorphin and morphine into the mesencephalic reticular formation (MRF) produced considerably less analgesia than direct injections into the PAG. Injections of bombesin, VIP and neurotensin into the MRF also increased hot-plate latencies but had no effect on the tail-flick response. Injections of TRH, somatostatin, cholecystokinin 26-33 (non-sulfate) and bradykinin had no appreciable analgesic activity following PAG injections. Contrary to some reports, substance P was not found to have any substantial analgesic properties from a dosage range of 0.001-27 µg. Only the highest doses produced a very transitory (5 min post-injection) elevation of hot-plate and tail-flick latencies.

It is clear that there is considerable redundancy in the neurochemical coding of the endogenous pain suppression mechanisms at the level of the PAG and MRF. Experiments are underway to determine whether each system may respond selectively to different inputs.

162.3 CAPSAICIN-INDUCED ANALGESIA: CHARACTERIZATION AND A SITE OF ACTION. M.S. Miller*, S.H. Buck, I.G. Sipes* and T.F. Burks. Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, Arizona 85724.

Capsaicin (8-methyl-N-vanillyl-6-nonenamide), the principle pungent component of hot peppers, has been reported to produce an acute, localized nociceptive response in rats following subcutaneous administration. The acute response is followed by a long lasting desensitization to chemogenic nociceptive stimuli on all body surfaces and depletion of the putative peptide neurotransmitter substance P (SP) from the dorsal spinal cord (DC) and dorsal root ganglia (DRG). In this report we have characterized the sensory effects of capsaicin (C) and investigate the site of action for C-induced sensory deficits in the guinea pig, a species more sensitive to the actions of C than the rat. Hartley guinea pigs of either sex (300-400 g) were used in all studies. The sensory effects of C were investigated in animals treated with a single dose of C (50 mg/kg s.c.). Significant alterations in non-nociceptive heat, nociceptive heat and nociceptive chemical sensory modalities were detected. Pressure, cold and vibratory sense were unaltered. SP levels were significantly decreased in both the DC and DRG as determined by RIA in the absence of detectable changes in DRG somatostatin content. To investigate the site of action for C, animals received a single injection (8µg) of the radiolabeled C analog ^{3}H-dihydrocapsaicin (DHC) in the right front footpad. At various times after treatment (4 hrs-10 days) both forefeet were tested for thermal analgesia. Immediately following analgesia testing, right and left DRG (C_4-C_7) and footpad skin were collected. DRG SP levels, DRG DHC equivalents (DHCe), skin DHCe and skin unextractable DHCe content were then determined in tissues from the treated side and contralateral vehicle-injected control side of each animal. Treated feet demonstrated analgesia within 4 hrs with the effect lasting in excess of 10 days. Levels of SP and DHCe in DRG from treated sides were not different from contralateral controls throughout the experiment. Within 24 hrs of dosing, levels of DHCe in treated skin were not different from those in contralateral control skin. Levels of unextractable DHCe in treated skin were consistently 3-4 fold greater than levels in contralateral control skin throughout the 10 day experiment. It is concluded that in the guinea pig C produces chemogenic and thermal analgesia through a mechanism which does not involve SP depletion from the DRG or non-specific actions of C at the DRG. The site of action for C-induced analgesia may be peripheral to the DRG, possibly involving covalent binding of C to peripheral terminals of primary afferent thermal and chemogenic nociceptors. Depletion of SP from DRG appears to be mediated at a site more central to that which mediates C-induced analgesia. (Supported by USPHS NS15420, DA02163 and NIEHS ES82130).

162.4 INCREASED DRINKING RESPONSE TO INTRAVENOUS ANGIOTENSIN II AFTER LOW-POWER MICROWAVE EXPOSURE. D.L. Hjeresen* and J.B. Simpson. Department of Psychology, NI-25, Univ. of Washington, Seattle, WA. 98195 (Spon: R.D. Phillips, Battelle N.W., Richland, WA.)

Several recent research reports suggest increased permeability of the mammalian blood-brain barrier (BBB) following exposure to low power density (10 mW/cm^2). These studies noted reversibly increased permeability to tracers such as mannitol, Na-fluorescein, and horseradish peroxidase. We have infused a behaviorally active peptide following microwave exposure and determined the behavioral response.

The octapeptide Angiotensin II (AII) is dipsogenic following intravenous as well as intraventricular administration. It does not, however, enter the cerebrospinal fluid from the blood. We determined that 30 min exposure to 1 mW/cm^2 of continuous wave microwaves (918 MHz) enhances the drinking response to intravenous AII, perhaps by permitting its penetration into the brain

Male Long-Evans rats with indwelling jugular catheters were tested in one of four groups: 1) 30 min microwave exposure followed by 4 hr of AII infusion (2 ng/min/10 ul), N=8; 2) 30 min microwave exposure followed by isotonic saline infusion, N=16; 3) 30 min sham microwave exposure followed by AII infusion, N=9; 4) 30 min microwave exposure followed by no infusion, N=4. During the 4 hr post-exposure infusion, water consumption was measured at 30 min intervals and after 24 hr. These values were compared to an averaged daily (24 hr) baseline value taken over 5 days and a 4 hr baseline value taken after 30 min of sham microwave exposure while being infused with isotonic saline. The rats were exposed to 918 MHz, CW microwaves at an incident power density of 1 mW/cm^2 in individual, circularly polarized waveguides.

Both microwave exposure and AII affected 24 hr water consumption. Microwave/AII rats drank 14.9% above baseline consumption ($p < 0.05$, paired t) whereas sham-exposed/AII rats drank only 4.5% above baseline. Rats exposed to microwaves and infused with saline decreased their consumption 8.6% while microwave/non-infused rats differed from baseline by less than 1%. Four-hr consumption values were significantly higher than baseline for all groups except the microwave/non-infused control. However, at the end of 24 hr only the AII microwave group remained significantly elevated.

One interpretation of these data is that microwave exposure permitted penetration of the peripherally infused AII into brain ventricles and/or neuropil by opening the BBB to circulating AII. If this were true the AII might gain access to additional dipsogenic receptors, not accessible to blood-borne AII. However this conclusion awaits direct AII measurement in brain.

162.5 CENTRAL PRESSOR AND PERIPHERAL DEPRESSOR EFFECTS OF NEUROTENSIN IN CONCIOUS RATS C. Sumners*, M.I. Phillips and A. Camacho*. Dept. of Physiology, University of Florida, Gainesville, FL 32610

The tridecapeptide neurotensin (NT) elicits hypotension in rats when injected intravenously (IV) (Carraway et. al. J. Biol. Chem. 248: 6854, 1973), and is also known to have centrally mediated actions such as stimulation of hypothermia and antinociception. In order to examine whether the peripheral depressor effect of (NT) contains a central component, we have compared the effects on blood pressure of NT applied either i.v. or intracerbroventriculary (i.c.v.) in concious rats. Male 250g Sprague Dawley rats were implanted with a permanent lateral ventricle cannula under chloral hydrate anesthesia, and after a recovery period of 3-4 days both the femoral artery and vein were catheterised (under ether) for recording of blood pressure and i.v. injections respectively. The catheters were tunnelled under the skin, exteriorised through an incision on the back, and cemented into position. Rats were used the following day. Neurotensin (Sigma) injected i.v.t. (1 - 30 µg, in 1 - 3 µgl) caused dose related increases in arterial blood pressure ranging from 5-28mmHg (n=12 animals). The response latency was 30 secs and duration was up to 10 mins. Similar doses injected i.v. (in 0.1ml) caused a dose related depressor effect of 15 - 50 mmHg (n= 5 animals), with a duration of up to 90 min. The presser effect of i.v.t. NT was antagonised by i.v.t. phentolamine (10 µg), but not by the potent angiotensin II antagonist sar^1-ala^8-AII (10-20 µg). It was also shown that phentolamine (10 µg) antagonises the pressor effect of i.v.t. angiotensin II (100 ng). Results indicate that i.v.t. administered NT can cause a rise in blood pressure as distinct from its peripheral depressor action, and that this rise is mediated via an alpha adrenergic mechanism. Angiotensin receptors seem to play no role in this NT pressor response.

162.6 ANTIPYRETIC EFFECT OF CENTRAL AND PERIPHERAL ACTH (1-24) IN ADRENALECTOMIZED RABBITS. J.A. Zimmer* and J.M. Lipton. Physiology and Neurology Departments, University of Texas Health Science Center, Dallas, TX. 75235.

Intracerebroventricular (ICV) administration of ACTH (1-24) reduces fever induced by injection of leukocytic pyrogen (LP) in normal rabbits. This result suggests that central release of ACTH may normally limit fever (Glyn & Lipton, in press). However, because intra-hypothalamic injections of corticosteroids also reduce fever (Chowers, et al, 1968; Willies and Woolf, 1980), the antipyretic effect of central ACTH might be indirect and require stimulation of the adrenal cortex. To test this possibility ACTH (1-24) was injected ICV in 13 bilaterally adrenalectomized (ADX) rabbits made febrile by IV injections of LP. ACTH (250 ng) reduced fever when given simultaneously with LP in seven ADX rabbits and when given 30 min after LP in six others. This dose had a small hypothermic effect on body temperature when given to the same animals when they were afebrile. In order to evaluate the possibility that central ACTH can normally inhibit fever it was important to know if smaller non-hypothermogenic amounts of the peptide can reduce the febrile response. In experiments on seven ADX rabbits doses of ACTH averaging 50 ng reduced fever induced by IV LP, and 25 ng was antipyretic in some animals. Peripheral ACTH also reduces fever in man and rabbits (Kass and Finland, 1950), but it may be that this antipyresis depends upon an action of corticosteroids on the brain. To examine this possibility ACTH (2.5 ug) was given IV to ADX animals made febrile by IV LP. Fever was reduced when ACTH was given both simultaneously with and 30 min after LP injections. This dose of ACTH had no effect on body temperature when the animals were afebrile. The antipyretic effect of ACTH (1-24) is not peculiar to the rabbit since ICV injection of the peptide also lowered fever induced by IV administration of bacterial endotoxin in squirrel monkeys. From these results we conclude that (1) the release of adrenal corticosteroids and their subsequent action on the brain is not required for the antipyretic effect of ACTH (2) peripheral ACTH can enter the brain in quantities sufficient to reduce fever and, (3) the antipyretic effect of ICV ACTH (1-24) also occurs in primates. The findings suggest that release of endogenous central ACTH, and entry into the brain of the circulating ACTH known to increase in fever, limits the magnitude of the febrile response by influencing central temperature controls. (Supported by National Institute of Neurological Communicative Disorders and Stroke grant NG 10046.)

162.7 EFFECTS OF CENTRAL ADMINISTRATION OF VASOPRESSIN AND OXYTOCIN ON BODY TEMPERATURE OF THE RABBIT. J.R. Glyn* and J.M. Lipton. (SPON: H. Feit). Physiology and Neurology Departments, University of Texas Health Science Center at Dallas, TX. 75235.

The presence of vasopressin and oxytocin within brain sites outside the pituitary has evoked questions about their roles in extra-pituitary mediation of physiological functions. Previous research on these peptides suggested that they may influence or participate in central control of body temperature (Lipton & Glyn, 1980). In these earlier experiments intracerebroventricular (ICV) injections of arginine vasopressin (AVP) produced rapidly-developing hyperthermias which lasted 2.5-3.0 hr. Oxytocin produced hyperthermias of lower amplitude and longer duration. To examine further the nature of the central influence of these peptides, vasopressin and oxytocin were administered ICV to rabbits in cold (10°C) and hot (30°C) environments. Doses of 1.25-5.0 ug caused only small (0.2°C maximum) increases in body temperature in the cold; thus these peptides do not raise the central setpoint of temperature control. When 5 ug of AVP was given in the heat all rabbits showed significant increases in body temperature, and three had to be removed to a 23°C environment to prevent lethal hyperthermia. When these three animals were reintroduced into the 30°C environment their body temperatures again rose to life-threatening levels. In additional experiments AVP given centrally with 0.5 ug PGE_2 prolonged prostaglandin-induced hyperthermia. These combined results indicate that AVP and oxytocin inhibit heat loss and therefore have little effect on body temperature in the cold in which heat loss is already maximal.

Knowledge of the additivity of effects of centrally administered substances on body temperature can be used as an indication of whether the substances share common receptor sites (Glyn & Lipton, in press; Goodman & Gilman, 1975). Vasopressin and oxytocin (1.25 ug each), when combined in a single ICV dose, elicited a rise in body temperature greater than that produced by 2.5 ug of either peptide alone. This supra-additivity indicates that vasopressin and oxytocin act at different sites in the CNS temperature control pathways in the production of hyperthermia. Thus, the two peptides tend to raise body temperature when given centrally, without raising the central setpoint, by acting at least partially on different receptor sites. These findings open the possibility that endogenous central AVP and vasopressin are involved in CNS control of body temperature. (Supported by National Institute on Neurological and Communicative Disorders and Stroke Grant 10046).

162.8 RAPID INDUCTION OF TOLERANCE TO THE HYPOTHERMIC EFFECT OF β-ENDORPHIN (βE), BOMBESIN (BN), AND NEUROTENSIN (NT) AND LACK OF CROSS-TOLERANCE TO THE HYPOTHERMIC EFFECT OF ETHANOL (E). John Wenger*, Jeffrey Yusim*, Floyd Bloom and Marvin Brown. (SPON: Joseph Rogers). Peptide Biology Laboratory and Arthur Vining Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037.

Hypothermia results from the intracerebroventricular (icv) administration of βE, BN and NT. Peripheral E also causes hypothermia and tolerance develops to this effect. Studies were performed to determine whether tolerance can be induced to the hypothermic effects of these peptides given icv, and whether such tolerance would affect the hypothermic effect of E (3 g/kg i.p.).

Lateral ventricular cannulae were placed in male rats. Two days afer surgery they were then 1) tested for responsiveness to the hypothermic effect of a particular peptide, 2) if responsive, infused for at least 5 hours with that peptide to induce tolerance to it, 3) tested for tolerance to that peptide, 4) if tolerant, tested for tolerance to ethanol-induced hypothermia. Baseline temperatures were measured and injections and infusions given in a 22°C room. Following tolerance-test injections, the animals were placed immediately in a cold-room (4°C) for 1 hr.

βE (30 µg/10 µl) initially reduced rectal temperature (RT) to 33.78° C, a fall of 4.33 ± 0.34 °C (mean ± s.e.m.). Following at least 5 hr infusion with βE (3 µg/µl/hr), βE (30 µg/10 µl) resulted in a decrease in RT to 38.82, a fall of 0.06 ± 0.43°C thereby demonstrating tolerance. E then reduced RT to 34.22°C, a fall of 4.52 ± 0.43°C. E given to drug-naive controls reduced RT to 34.13 ± 0.41° C indicating cross-tolerance to E had not occurred.

BN (1 µg/10 µl) initially reduced RT to 34.35 ° C, a fall of 4.00 ± 0.20 ° C. Following an 18 hr infusion of BN (1 µg/µl/hr), BN (1 µg/10 µl) resulted in a decrease in RT to 37.13°C, a fall of 1.10 ± 0.28°C thereby demonstrating tolerance to BN. Immediate injection of E reduced RT 2.85 ± 0.36° C to 34.28 ± 0.15°C indicating cross-tolerance to E had not occurred.

NT (30 µg/10 µl) initially reduced RT to 35.84, a decrease of 2.56 ± 0.42°C. The same dose of NT following a 13 hr NT (3 µg/µl/hr) infusion resulted in a decrease of RT to 37.44, a decrease of 0.75 ± 0.33°C, thereby demonstrating tolerance to NT. Immediate injection of E reduced RT 3.00 ± 0.34°C to 34.44 ± 0.21°C indicating cross-tolerance to E had not occurred.

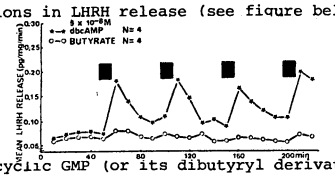
Animals tolerant to hypothermia induced by βE, BN and NT are not tolerant to the hypothermic effect of E. This suggests that ethanol-induced hypothermia is not dependent upon endogenous βE, BN or NT (Supported by ARC grant AA 03504).

162.9 DIBUTYRYL CYCLIC AMP INDUCES CYCLIC RELEASE OF LHRH FROM SUPERFUSED MALE RAT HYPOTHALAMI. Daryl E. Hartter* and V. D. Ramirez. Dept. of Physiology and Biophysics, Univ. of Illinois at Urbana-Champaign, Urbana, IL. 61801.

It is widely accepted that cyclic nucleotides (cyclic AMP and cyclic GMP) are intracellular messengers implicated in a variety of neuronal functions. The present study compares the effect of dibutyryl cyclic AMP (dbcAMP) and dbcGMP infusions on LH-releasing hormone (LHRH) release from male rat hypothalami superfused in vitro.

Two adult male Holtzman rats (per chamber) were killed after light ether anesthesia by heart bleeding; their mediobasal hypothalami (MBHs) were gently placed in a 500-µl. volume chamber kept at 37°C and superfused with a Kreb's Ringer phosphate medium (pH 7.40) with glucose (10mM), bacitracin (0.1mM) and bovine serum albumin (0.1%) at a flow rate of 60-70 µl/min. Theophylline (1mM) was added to medium. Ten-min. samples were collected on ice and later assayed for LHRH content by radioimmunoassay.

The pattern of in vitro LHRH release was clearly dependent on the mode of dbcAMP administration. A continuous infusion of 5 X 10^{-8}M dbcAMP for 2 hrs. produced a slow, steady increase in LHRH release, reaching eight-fold preinfusion values by the end of the infusion. Thirty- or 60-min. infusions were also effective in increasing LHRH release rate, producing irregular bursts in LHRH output. More strikingly, 10-min. infusions of dbcAMP given in an on-off pattern (at either 10-, 20- or 40-min. intervals) were extremely effective in generating a cyclic pattern of LHRH release from these MBH neurons; butyrate did not produce such cyclic variations in LHRH release (see figure below).



Furthermore, cyclic GMP (or its dibutyryl derivative) and the cAMP metabolite 5'-AMP did not modify LHRH release.

These experiments demonstrate that the LHRH neural release apparatus of superfused male rat hypothalami can be activated by cAMP but not cGMP, and, more importantly, that the pattern of LH-RH release is dependent on the mode of cAMP administration. Thus, it is tempting to speculate that cyclic release of LHRH is dependent on a regular generation of cAMP which periodically activates the LHRH release apparatus.

162.10 Central release of arginine vasopressin (AVP) in rabbit brain. Q.J. Pittman, T.J. Malkinson*, W.L. Veale & K. Lederis*. Depts of Pharmacology & Physiology, Univ. of Calgary, Calgary, Canada.

In addition to its hormonal actions on kidney water retention and peripheral vasomotor tone, recent observations indicate that AVP may be a putative neurotransmitter within the brain. Immunocytochemical studies have established the presence of immunoreactive AVP in neurons in the hypothalamus and in neural processes throughout widespread areas of brain. When injected into the brain, AVP has potent effects on many behavioral and physiological processes. We have sought evidence for AVP release within brain tissue in response to a stimulus which also activates pituitary secretion of this peptide into the circulation.

Male New Zealand white rabbits were fitted with stereotaxic headplates and chronic jugular catheters. Following a 5 day recovery period during which time the animals were habituated to the experimental surroundings, a push-pull cannula was lowered through the headplate so its tip was positioned in either the lateral septum or the amygdala. A sterile physiological solution was perfused through the cannula at 35µl/min for three 30 min periods; the perfusate was collected on ice and then frozen immediately at -70°C. After the first 30 min sample was collected, and concurrent with the beginning of the second collection period, 8 ml of sterile 3M NaCl was infused for 10 min into the jugular catheter. This amount of NaCl raises the blood osmolality to approximately 345 mOsmoles and constitutes a potent stimulas for AVP release from the pituitary. After termination of the second push-pull perfusion a period of 30 min elapsed before the third and final perfusion was started.

Perfusates were assayed for AVP using a sensitive radioimmunoassay which shows little cross-reactivity for other related peptides. In control perfusates, AVP levels varied from undetectable (<1.5pg/ml) to 135pg/ml. Following systemic injection of hypertonic NaCl, AVP levels in the second push-pull perfusate rose by 316% in the lateral septum (N=3) and by 299% in the amygdala (N=5). In the third and final perfusates AVP levels were still elevated above control levels.

Circulating AVP in physiological concentrations is not believed to cross the blood-brain barrier. Therefore, evidence for AVP release within rabbit brain is in keeping with the view that AVP could be a neurotransmitter in the brain. Further work is required to establish the specificity of the release in response to various stimuli and to explore other areas of the brain for their ability to release AVP.

162.11 NEUROCHEMICAL EFFECTS OF CAPSAICIN TREATMENT IN ADULT MALE WISTAR-KYOTO (WKY) AND SPONTANEOUSLY HYPERTENSIVE (SHR) RATS. Robert M. Virus*, Dennis Q. McManus* and G.F. Gebhart. Dept. of Pharmacology, University of Iowa, Iowa City, IA 52242

The effects of capsaicin (8-methyl-N-vanillyl-6-nonenamide) on the contents of substance P (SP) in central and peripheral nervous system tissues were investigated in adult male WKY and SHR rats. Capsaicin was subcutaneously administered in 3 successive daily 50 mg-kg^{-1} doses to lightly ether-anesthetized subjects. Subjects were sacrificed by decapitation 15 days after the last vehicle or capsaicin injection; brains, spinal cords and sympathetic ganglia were rapidly removed, frozen on dry ice, and stored at -80°C for subsequent assay of SP contents. SP contents were determined using a specific radioimmunoassay (Immuno Nuclear Corporation, Stillwater, MN). Selected brain nuclei were microdissected from 300 µm thick frozen coronal sections using the punch technique of Palkovits et al. (Brain Res., 77: 137-149, 1974; Brain Res., 79: 443-450, 1974; Brain Res., 80: 237-249, 1974).

Capsaicin treatment significantly increased the SP contents in the periventricular preoptic hypothalamic and medial amygdaloid nuclei only in rats of the WKY strain. SP contents of the raphe magnus, periventricular preoptic hypothalamic, and medial amygdaloid nuclei of vehicle-treated SHR rats were significantly greater than the SP contents of vehicle-treated WKY rats. Capsaicin treatment significantly reduced the content of SP only in the medial amygdaloid nucleus of SHR rats. No significant strain or treatment differences were observed in the SP contents of the solitary tract, locus coeruleus, and periaqueductal central gray.

The SP contents of spinal cords of vehicle-treated SHR subjects were significantly greater than those of vehicle-treated WKY subjects and capsaicin treatment significantly reduced spinal cord SP contents in rats of both strains. The amount of SP in both superior cervical and celiac sympathetic ganglia of vehicle-treated WKY rats was significantly greater than the SP content of these ganglia in vehicle-treated SHR subjects. Capsaicin treatment significantly reduced the SP contents of both ganglia in both strains.

These results indicate that differences between the WKY and SHR strains exist in the sensitivity to capsaicin-induced alterations in SP contents in a variety of central and peripheral nervous system structures. (Supported by NS-12114 and MH-15172).

162.12 HORMONAL REGULATION OF HIPPOCAMPAL SYNAPTIC PLASMA MEMBRANE PROTEIN PHOSPHORYLATION. Linda A. Dokas, Henk Zwiers* and Willem H. Gispen* Depts. of Biochemistry and Neurosciences, Medical College of Ohio, Toledo, Ohio 43699 and Inst. of Mol. Biol. & Rudolf Magnus Institute for Pharmacology, Utrecht, The Netherlands.

Hippocampal synaptic plasma membranes (SPM) were prepared in 10mM sodium acetate-10mM magnesium acetate-1mM calcium acetate, pH 6.5 and incubated in vitro for 20 sec with 7.5µM γATP^{32}. Under these conditions the major phosphorylated protein is of molecular weight 48,000. Addition of 10^{-5}M ACTH to the phosphorylation assay caused inhibition of SPM protein phosphorylation, including a 33% decrease in the phosphorylation of the 48K protein. Thus, hippocampal SPM contain an ACTH-sensitive protein kinase and its substrate protein, B-50. Hippocampal SPM were prepared from normal, sham-operated and adrenalectomized (ADX) rats. At all times following surgery, there was no difference in SPM protein phosphorylation between normal and sham-operated rats. At 3 and 4 days post-adrenalectomy (post-ADX), hippocampal SPM showed diminished protein phosphorylation in vitro. At 4 days post-ADX the decrease in B-50 phosphorylation was -36.0±2.9% compared to normal levels of phosphorylation. No difference was seen in hippocampal protein phosphorylation between normal and 14-day ADX rats. The time course of the effect following adrenalectomy suggests the inhibition of hippocampal SPM protein phosphorylation is not dependent upon the lack of adrenal steroids.

Comparison of SPM protein phosphorylation from the hypothalamus of normal, sham-operated and ADX rats showed no differences at either 3 or 14 days post-ADX. Hypophysectomy did not abolish the decrease in hippocampal SPM protein phosphorylation seen at 3 days post-ADX. The time course of the effect of adrenalectomy on hippocampal SPM protein phosphorylation and its regional specificity are consistent with the observation of Van Dijk et al (J. Endocr. 88:243-253, 1981) that endogenous levels of ACTH in the hippocampus are decreased at 3, but not 14 days, post-ADX. Previous work of Zwiers et al (Mechanism, Regulation and Special Functions of Protein Synthesis in the Brain, pp. 267-272, 1977), has shown that administration of ACTH in vivo leads to subsequent stimulation of incorporation of labeled phosphate from γATP^{32} in vitro into a SPM protein with the molecular weight of B-50 from subcortical (including hippocampal) tissue. In the present case, lowered ACTH levels in vivo would result in increased amounts of endogenous phosphate groups on SPM proteins, leading to decreased incorporation of P^{32} in a subsequent in vitro assay. Thus, our observation that adrenalectomy decreases hippocampal SPM protein phosphorylation most probably reflects a transient decrease in endogenous ACTH in the hippocampus following adrenalectomy. Supported in part by BRS RR 05700.

163.1 HIGH MOLECULAR WEIGHT SOMATOSTATIN SECRETION BY CULTURED BRAIN CELLS. Robert A. Peterfreund* and Wylie Vale. Department of Neurosciences, UCSD School of Medicine and Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Somatostatin-28 (SS-28) is a 28 residue, N-terminally extended form of the tetradecapeptide somatostatin-14 (SS-14). SS-28 has been characterized in brain and gut extracts and found to have biologic activities greater than or equal to the widely distributed SS-14. In order to clarify any possible extracellular role for SS-28, it is essential to determine whether intact cells secrete this peptide. We have investigated the chromatographic and immunologic behavior of the somatostatin-like peptides secreted by primary cell cultures of rat cerebral cortex and hypothalamus. Hypothalamic or cerebral cortical tissues from 18 day rat fetuses are dispersed with collagenase and maintained in a serum supplemented medium. The cells from both tissues exhibit a basal secretion of 100-300 pg of somatostatin as measured by radioimmunoassay with antibody S201. Depolarizing agents elicit a calcium dependent secretion of up to 1 to 4 nanograms of somatostatin per 10^7 cells. Hypothalamic cultures secrete somatostatin in response to administration of 8-BrcAMP or IBMX. Both drugs have lesser effects on secretion by cerebral cortical cells. The secretory product elicited by high potassium medium was collected in acid plus protease inhibitors, heated for five minutes at greater than 95° C, lyophilized, redissolved in 6 M guanidine-HCl in 3 N HOAC and applied to a Sephadex G50 column eluted with 3 N acetic acid at room temperature. For both types of cultures, two main peaks of somatostatin were detected by RIA using antiserum S201 which is directed against the center of SS-14. These peaks comigrated with synthetic SS-28 and SS-14 respectively. Radioimmunoassay with antiserum S39 which reads the amino terminus of SS-14 and does not detect synthetic or native SS-28 failed to detect the peak corresponding to SS-28. For cortex cultures, 23% of the recovered somatostatin comigrated with the SS-28 peak. Twenty-two percent of the hypothalamic product migrated as SS-28. Both hypothalamic and cortical elution profiles had a third, minor peak near the void volume. This peak could correspond to an even larger form of somatostatin. When considered with the high potency of SS-28 in the central nervous system, these results indicate that SS-28 or a somatostatin-like moiety of similar size may be a significant secretory product of cerebral cortical and hypothalamic cells.

163.2 BRAIN TSH AND GH: EVIDENCE FOR SEPARATE POOLS OF BRAIN AND PITUITARY IMMUNOREACTIVE AND SYNAPTOSOMAL ASSOCIATION OF BRAIN GROWTH AND THYROID STIMULATING HORMONES. S. Hojvat*, G. Baker*, L. Kirsteins* and A. M. Lawrence* (SPON: I. Held). Biochem. Neuroendocrinol. Lab., VA Hospital, Hines, IL 60141, and Biochem. Dept., Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153.

Pituitary-like peptides with immuno- and biologic activity similar to, if not identical with, hormones from the pars distalis have been shown to be present in discrete areas of the rodent and primate central nervous system (CNS), particularly within the hypothalamus and limbic system. These include ACTH, luteinizing hormone (LH), thyroid-stimulating hormone (TSH), and growth hormone (GH)-like peptides. Several lines of evidence indicate these are not of pituitary origin. Levels of these peptides remain unchanged following hypophysectomy. Dispersed brain cells produce these materials in tissue culture. Studies reported here, utilizing differential ultracentrifugation, demonstrate TSH and GH-like immunoreactivity associated with synaptosomal fractions of whole brain homogenate. Whereas significant changes in the concentration of GH and TSH in the brain and in the pars distalis can be evoked by removal of the thyroid and gonads or by the administration of supraphysiologic doses of thyroxine, these changes, in general, vary inversely. For example, rat brain GH levels rise significantly following thyroidectomy while pituitary and serum levels drop significantly. Pituitary and serum TSH rise dramatically after thyroidectomy; there was no change in brain TSH. Pituitary and serum TSH dropped significantly when supraphysiologic doses of thyroxine were administered while TSH in the brain remained unchanged. Castration caused a rise in hypothalamic TSH and a significant fall in pituitary levels. Whereas TSH and GH rise during development of the pituitary, from prepartum values to levels at puberty, brain GH and TSH rise dramatically 24 hours before birth, drop precipitously and reappear at the time of puberty. Conclusion: Immunoreactive GH and TSH-like peptides in the brain are synaptosomally associated; changes following target gland ablation or after administration of supraphysiologic amounts of thyroxine show a pattern quite different from that observed in serum and pituitary. Unique profiles in the development of fetal, neonatal, young adult GH and TSH in the brain and in the pituitary indicate their apparent independence from each other. This data suggests these brain-based peptides play no role in regulation of pituitary hormone secretion, but because significant and consistent changes followed thyroidectomy and castration, it may still be that these brain peptides are involved in overall neuroregulation of the organism's endocrine physiology.

163.3 VASOPRESSIN CONTENT OF INTRA AND EXTRAHYPOTHALAMIC NUCLEI OF RAT BRAIN. D.M. Dorsa* and M. Raskind* (SPON: W. Crill). GRECC, VA Medical Center, Seattle, WA 98108.

Although extrahypothalamic projections of vasopressin (AVP) containing fibers have been visualized using immunocytochemical techniques, successful quantitative measurements of AVP contents of these brain nuclei have not been reported. Since AVP has been shown to influence conditioned avoidance behavior when locally applied to areas in the septum, thalamus, and locus coeruleus, we have established methods for quantitation of AVP in discrete microdissected brain nuclei to further examine the possible involvement of vasopressin containing neuronal systems in CNS processes.

Male Sprague-Dawley (SD) rats (n=7-11) and homozygous (HODI, n=5) and heterozygous (HEDI, n=5) Brattleboro rats (hereditary diabetes insipidus) were killed by decapitation and their brains and neurointermediate lobe (PNI) of the pituitary were rapidly removed and frozen on dry ice. Selected nuclear brain regions were "punched" according to the method of Palkovits, frozen, sonicated in 0.1N HCl at 4°C, then centrifuged, aliquoted and lyophilized. A highly sensitive and specific radioimmunoassay was performed on these samples using an antiserum to AVP kindly provided by Drs. D.A. Fisher and H. Artman. Pituitary and brain nuclear contents in μU/μg protein for the 3 groups were as follows:

Area	SD	HEDI	HODI
median eminence	122.9±19.1	51.2±16.9	N.D.
supraoptic N.	12.87±4.23	3.74±0.59	N.D.
suprachiasmatic N.	3.75±0.76	2.25±1.12	N.D.
paraventricular N.	1.16±0.21	1.38±0.51	N.D.
OVLT	0.63±0.18	0.32±0.03	N.D.
ventral tegmental N.	0.31±0.13	0.29±0.07	N.D.
medial preoptic N.	0.19±0.14	0.14±0.01	N.D.
lateral septum	0.10±0.02	N.D.	N.D.
locus coeruleus	0.06±0.006	0.17±0.05	N.D.
frontal cortex	N.D.	N.D.	N.D.
PNI (n=1)	1005.5	576.6	N.D.

N.D. = not detected

These data confirm quantitatively the presence of vasopressin in low but significant amounts in extrahypothalamic behaviorally sensitive brain nuclei. The lack of immunoreactivity in HODI PNI and brain indicates the specificity of these measurements for AVP and supports the contention that AVP deficiency in HODI underlies their behavioral deficits. Quantitative measurements of AVP content of specific brain nuclei will allow us to examine the regulation of activity of these neurons and their physiologic importance in CNS function.

163.4 COMPARATIVE STUDIES OF PLASMA AND BRAIN ANGIOTENSINOGEN IN THE RAT. Anthony Vitto and Morton P. Printz*. Division of Pharmacology (M-013), Department of Medicine, Univ. Calif., San Diego, La Jolla, CA 92093.

There is much evidence that distinct renin-angiotensin systems exist in the plasma and the brain of a variety of animal species. Angiotensinogen (renin substrate), the precursor protein from which the angiotensin peptides are derived, is a key element in this system. We present studies that distinguish plasma angiotensinogen from brain angiotensinogen in the Sprague-Dawley rat. A rapid and efficient purification of stable renin substrate was carried out using high-salt precipitation, hydrophobic interaction chromatography (Phenyl-Sepharose), and gel filtration (Ultrogel AcA 34). Essentially one protein-staining band was observed on native polyacrylamide gel electrophoresis. Plasma and brain forms of angiotensinogen are similar in molecular size as determined by gel filtration and dodecyl-sulfate polyacrylamide gel electrophoresis. However, whereas a molecular weight in the 60,000 dalton region of migration was observed on polyacrylamide gels, a molecular weight of 100,000 was observed on gel filtration. This apparent overestimation of molecular weight suggested the presence of carbohydrate. The glycoprotein nature of angiotensinogen was confirmed by differences in heterogeneity on isoelectrofocusing polyacrylamide gels that could be altered by treatment of renin substrate with neuraminidase prior to electrofocusing. However, neuraminidase failed to convert the plasma and brain forms of angiotensinogen to a single identical form. Distinctions between plasma and brain angiotensinogen were also made on the basis of differential binding to various lectin-gel columns. Differences in primary sequence, if any, remain to be determined. Current projects underway involve the production of antibody directed toward each form of renin substrate and the immunohistochemical localization of angiotensinogen within various brain regions.

163.5 PROPERTIES OF NEW HYBRID CELL LINES. T. Amano and Y. Kudo, (SPON: H. Kawamura) Mitsubishi-Kasei Inst. of Life Sci., Minamiooya, Machida-shi, Tokyo, Japan 194.

New hybrid cell lines between mouse neuroblastoma N115TG3 and rat glioma C6Bul (NG115-301, NG115-401), hybrids between neuroblastoma N18TG2 and pheochromocytoma PC12 (NP-1A, NP-3A, NP-4), and hybrids between PC12 and C6Bul(PG-1D, PG-2A, PG-3A) were made by using polyethlene glycol #1000. Hybrids were selected in HAT medium and identified by the presence of both marker chromosomes of the parents. Some of the hybrids exhibited high choline acetyltransferase activities independent of low activities of parent cell lines. NP series hybrid cells had both dense and clear vesicles resembling to the parent PC12 cells under electron microscope. On the other hand PG-1D cells had only clear vesicles characteristics to acetylcholine.

NG115-301 cells responded to dopamine (1-100 μM) by elevating intracellular cyclic AMP to 30-fold. NG115-401 cells responded to dopamine by inhibiting intracellular cyclic AMP accumulation. NG115-401 cells had 100 pmoles/min/mg protein of choline acetyltransferase activities together with significant amount of substance P like immunoreactivity(SPLI) ranging 500-1,000 pg/mg protein. Acetic acid extract (0.1 M) of the cells showed SPLI in fractions corresponding to 26K molecular weight by Biogel column (H. Hatanaka and T. Amano, Brain Res. in press). Acid/acetone extract revealed SPLI corresponding to the fractions of authentic substance P. The extracts showed biological activities by contracting guinea pig ileum in the presence of atropine (10^{-6} M) and chlorpheniramine (10^{-6} M). Electron micrographs showed dense cored vesicles suggesting secretory activities of the cells. Rat spinal ganglions derived from 30-day-old Lewis rat as reported substance P positive tissues also had low but significant amount of choline acetyltransferase activities (10 pmoles/min/mg protein). These findings provide the evidences of the presences of the activities of substance P and choline acetyltransferase in a new neuronal cell line. These cell lines may provide usefull models for the physiological study and biochemical processing of substance P.

163.6 CHARACTERIZATION AND DISTRIBUTION OF MOTILIN-LIKE IMMUNOREACTIVITY IN THE RAT CENTRAL NERVOUS SYSTEM. T. L. O'Donohue*, M. Beinfeld,* W. Y. Chey,* and D.M. Jacobowitz. Lab. of Clin. Sci., NIMH, Bethesda, MD 20205 and The Genesee Hospital, Rochester, N.Y. 14607.

A number of reports have suggested the presence of motilin immunoreactivity in the central nervous system of various species. The distribution and identity of motilin immunoreactivity in rat brain was investigated in this study. Using two C-terminally directed motilin antisera, approximately 1.5 ng and 0.4 ng of motilin were detected in the rat forebrain and cerebellum, respectively. The rat brain immunoreactive material, as characterized by Sephade G-50 chromatography, consisted of a large high molecular weight peak eluting near the void volume and a smaller lower molecular weight peak eluting near the elution volume of synthetic porcine motilin. Further characterization of the low molecular weight peak by reverse phase high pressure liquid chromatography indicated that this peptide was distinct from synthetic porcine motilin. Furthermore, one N-terminally directed antiserum poorly detected immunoreactive material in brain while another N-terminal antisera failed to recognize brain motilin. Therefore, chromatographic and immunological data distinguish the immunoreactive material in brain and synthetic porcine motilin.

The distribution of motilin-like immunoreactivity was investigated by immunofluorescence and radioimmunological procedures. Nerve terminals containing motilin immunoreactivity were primarily distributed throughout the hypothalamus with the greatest density in the median eminence. Perikarya-containing motilin immunoreactivity were also primarily localized in the mediobasal hypothalamus. Moderate concentrations of immunoreactive motilin were also contained in extrahypothalamic regions. The data reported here demonstrate that a peptide distinct from, but perhaps related to, motilin is present in neurons in rat brain.

163.7 SECRETIN IN RAT BRAIN: LOCALIZATION, CHARACTERIZATION AND BEHAVIORAL EFFECT. C.G. Charlton,* T. L. O'Donohue,* R. L. Miller,* J.N. Crawley and D. M. Jacobowitz (SPON: A. M. Laties). Lab. of Clinical Science, NIMH, Bethesda, MD 20205 and Dept. of Pharmacology, Coll. of Med., Howard Univ., Washington, D.C.20059.

Secretin is a basic polypeptide of 27 amino acids. Secretin-like bioactivity in extracts of porcine brain has been reported. This report will further describe the localization and characterization of brain secretin and its possible role as a neuroregulator.

Secretin-like immunoreactivity (SLI) has been identified and characterized in acid extracts of rat and pig brain utilizing a highly specific radioimmunoassay and fractionation on a reverse phase high pressure liquid chromatographic system. SLI of rat brain coeluted precisely with SLI of rat duodenum, but slightly ahead of SLI of pig brain and duodenum and synthetic porcine secretin. The difference in elution pattern suggest that secretin in the rat is slightly different from secretin in the pig.

Gross dissection revealed a wide distribution pattern of SLI throughout the rat brain. The highest concentrations were observed in the pineal and pituitary glands, followed by the thalamus, hypothalamus and olfactory bulb. Lower concentrations were observed in the cerebellum, midbrain, septum, striatum and hippocampus. The medulla-pons and the cerebral cortex contained the lowest concentrations.

Intraventricular injection of secretin (5μg) reduced open field activity and decreased the number of novel-object-approaches in rats. Secretin also decreased ventilation rate in anesthetized rats and increased defecation in awake rats.

The detection of SLI in the rat brain, combined with the fact that intraventricular injections of the peptide produced behavioral and physiological changes, may indicate that secretin is another of the growing number of neuroregulatory peptides.

163.8 STUDIES ON AN α-MSH ACETYLATING ENZYME IN THE RAT AND FROG. M.C. Chappell,* T.L. O'Donohue,* Y.P. Loh, R.L. Miller* and D.M. Jacobowitz. Lab. of Clin. Sci., NIMH, Bethesda, MD 20205 and Dept. of Pharmacology, Howard University, Washington, D.C. 20059.

Both deacetylated and N-acetylated α-MSH are present in proopiomelanocortin neurons in the rat and human brain and rat pituitary gland and the N-acetylated form is much more behaviorally active than the deacetylated peptide (Neuroscience Abstracts, 1981). Since the N-acetylation reaction appears to be a key step in the regulation of the behavioral activity of α-MSH, the enzymatic process regulating this conversion was investigated.

The enzyme assay involved incubating an 8000xg tissue supernatant with acetyl-(^{3}H)-coenzyme A and deacetylated α-MSH. The enzymatically synthesized (^{3}H)-α-MSH was isolated by a combination of ion exchange and high pressure liquid chromatography and counted. The enzyme was distributed unevenly with a 50-fold gradient between the highest and lowest activity in the pituitary gland and brain.

Highest activities were found in the pituitary gland. Similar activities were found in the anterior lobe (1.7 pmole/5 min/mg wet wt) and the neurointermediate lobe (0.96 pmole/5 min/mg wet wt). Enzyme concentrations in the brain were, on the average, about 30-fold lower than that found in the pituitary gland. The relative activities were olfactory bulb > hypothalamus, septum, cerebellum > striatum, cortex > thalamus, midbrain, brain stem > hippocampus. The regional distribution of enzyme activity did not parallel the distribution of α-MSH concentration in brain and pituitary. It is therefore unlikely that the enzyme is solely restricted to α-MSH synthesizing cells of the pituitary gland.

To determine if the α-MSH N-acetylating enzymatic activity is linked to α-MSH biosynthesis, enzyme activities were determined in pituitary glands of frogs (Xenopus laevis) housed in either chronic light to suppress α-MSH synthesis or chronic dark to induce α-MSH synthesis. Frogs housed in chronic darkness had significantly higher acetylating enzyme activities in both the anterior and neurointermediate lobes of the pituitary than did frogs housed in chronic light. The results of these studies indicate that although the α-MSH acetylating enzyme may not be solely localized to α-MSH synthesizing cells, it does appear to play an important role in the physiology of the α-MSH neuron or cell as 1) physiological alteration of α-MSH biosynthesis also alters acetylating enzyme activity and 2) N-acetylation markedly potentiates the behavioral actions of α-MSH.

163.9 REGIONAL CONCENTRATIONS OF INSULIN IN THE RAT BRAIN.
D. G. Baskin*, D. M. Dorsa*, and D. Porte, Jr.* (SPON: S. D. Hauschka). Depts. of Biological Structure, Pharmacology, and Medicine, Univ. Washington School of Medicine, Seattle, WA 98195, and Veterans Administration Medical Center, Seattle, WA 98108

Insulin has been found in extracts of rat brain, but the concentrations of insulin within various regions of the brain have not been clearly established. Therefore, we measured the concentrations of immunoreactive insulin (IRI) in different regions of the brain of fed, adult male Wistar rats (300g). Brains were removed after decapitation and dissected into various portions, which were frozen on glass slides in contact with CO_2 ice. The brains (N = 4) were perfused with Krebs Ringer phosphate prior to decapitation. Frozen brain tissue was homogenized in 10 vols. of ice cold 0.2M HCl/75% ethanol and shaken overnight at 4°C. Aliquots (5 and 10 µL) were taken for protein determination by the Lowry assay. The homogenates were centrifuged at 30,000 g for 20 min. at 4°C. Supernatants were evaporated to 5% of original volume at room temperature. The concentrates were resuspended in 5 vols. 0.05M ammonium carbonate containing 1% BSA, and neutralized with ammonium hydroxide. The samples were then centrifuged at 30,000 g for 20 min. at 4°C and the supernatants were lyophylized and frozen until radioimmunoassay. The sensitivity of the radioimmunoassay was 0.04 ng per tube. The results from 5 rats are shown in the Table ($\bar{x} \pm$ sem). Measurements from a single unperfused brain gave comparable values and are included.

Region	Total IRI (ng)	Total protein (mg)	IRI/protein (ng/g)
Amygdyla	0.394 ± 0.018	6.4 ± 0.5	65.3 ± 9.1
Hypothalamus	0.168 ± 0.009	4.9 ± 0.4	36.5 ± 4.2
Hippocampus	0.258 ± 0.009	7.0 ± 0.3	37.4 ± 2.6
Olfactory bulb	0.188 ± 0.011	4.0 ± 0.5	49.2 ± 4.3
Cortex	0.458 ± 0.041	5.9 ± 0.5	78.8 ± 4.8
Midbrain	0.829 ± 0.027	18.7 ± 1.5	46.5 ± 5.6

The results indicate that insulin concentrations are very low in these portions of the brain. Although the amount of insulin per ng protein varied slightly among the regions examined, the total amount of insulin detected in each region appeared to reflect the relative size of the extracted portion. Compared to neuropeptides that are known to be a product of brain neurons and exhibit large regional differences in concentration, insulin is more diffusely and evenly distributed in the brain. The results suggest that most of the insulin in the rat brain is probably not produced by local neuronal systems but very likely originates from the endocrine pancreas. (Supported by NIH Grant AM 17047 and the Veterans Administration).

163.10 DISTRIBUTION OF SUBSTANCE P IN EMBRYONIC RAT BRAIN.
M.L. Swenberg* and W. Lovenberg* (SPON: C.E. Creutz). Section on Biochem. Pharmacol., Natl. Heart, Lung and Blood Inst., Natl. Inst. of Health, Bethesda, Maryland 20205.

Neurons containing Substance P(SP) are present in many regions of brain, but the physiological functions under their regulation remain to be defined. In this study we have examined the regional content of SP during prenatal and postnatal development.

Radioimmunoassay (RIA) was used for all SP determinations. Antibodies were raised in New Zealand white rabbits, injected subcutaneously with SP coupled to bovine albumin (BSA-SP) at doses equivalent to 50 µg SP per rabbit. SP antiserum was also obtained as a gift from Dr. William Campbell, University of Texas. SP was iodionated with ^{125}I Bolton Hunters reagent. RIA was carried out in phosphate buffer containing saline (PBS) at pH 7.4; and the bound and free SP were separated by the Dextran-charcoal method.

Brain tissue was dissected and homogenized in 500 µl of 20 mM HCl. An aliquot of homogenate was removed for protein assay by the Bradford method and the remaining homogenate was extracted for 10 minutes in a boiling water bath, cooled and centrifuged at 10,000 rpm for 10 minutes. The supernatant fluid was lyophilized and stored at -20°C until assay.

SP was present in brain by the 15th day of gestation at a relatively low level; 233 ± 50, 430 ± 50, 348 ± 120 pg/mg protein (pg/mg p) for the forbrain, cerebellium, and midbrain respectively. The levels for comparable regions on the 20th-21st day of gestation were: 438 ± 100, 972 ± 200, and 1454 ± 100 pg/mg p; and 1034 ± 200 pg/mg p for hypothalamus. However, 1 day after birth the levels appeared to decrease.

We conclude that SP neurons are significantly developed by the 15th day of gestation and continueously develop until birth. We are presently completing a more detailed study of the developmental pattern and the function of SP in rat brain.

163.11 FEVER-INDUCED CHANGES IN CENTRAL α-MSH CONCENTRATIONS IN THE RABBIT.
W.K. Samson,* J.M. Lipton, J.A. Zimmer* and J.R. Glyn*. (SPON: Sami I. Said). Physiology and Neurology Departments, University of Texas Health Science Center, Dallas, TX. 75235.

Body temperature in fever rarely exceeds 41.1°C even though man and other homeotherms have the capacity to raise temperature even higher (DuBois, 1949). The regulatory mechanism that underlies this phenomenon may depend upon central α-MSH, a peptide which reduces fever when administered centrally (Glyn & Lipton, in press). To test this idea leukocytic pyrogen (LP) was injected into the lateral ventricle of adult NZW rabbits. Once maximal fever was reached (~41.0°C), the animals were decapitated, and brains quickly frozen on dry ice. Control animals did not receive LP but were similarly handled and sacrificed. Discrete brain regions were microdissected and extracted in 1 ml iced, 2.0 N acetic acid containing 500 KIU trasylol. Antiserum to synthetic α-MSH (Drs.C. Oliver and R.L. Eskay) employed for RIA at an initial dilution of 1:3,000 generally bound 30% of total iodinated trace and provided a range of assay sensitivity from 2.0-500 pg α-MSH. Aliquots of tissue extracts from all areas where α-MSH was detected displayed dose displacement curves that parallel that of the synthetic peptide. Additionally, extracts of rabbit pituitary, median eminence and septum comigrated with synthetic α-MSH on column chromatography (G-25, 0.9 x 96.0 cm). Immunoreactive α-MSH (ir α-MSH) recovered in these column fractions also displayed parallel dose displacement RIA curves. No significant differences in ir α-MSH content ($\bar{x}$ ± SEM, pg/ug protein) were detected in pyrogen-injected rabbits (n=9) versus controls (n=17) in the following areas: Paraventricular area of hypothalamus (2.94 ± 0.42 vs 3.13 ± 0.40), median eminence (5.41 ± 0.82, 4.90 ± 0.63), midbrain central grey (2.46 ± 0.28, 2.32 ± 0.19), arcuate nucleus (7.15 ± 1.07, 10.33 ± 1.29), preoptic/anterior hypothalamic area (6.36 ± 0.76, 6.78 ± 0.93), pineal (7.87 ± 1.95, 7.71 ± 1.26) or whole pituitary (86.5 ±10.0, 89.5 ± 11.9 ng/ug protein). Less than 0.05 pg ir α-MSH/ug protein was detected in cerebral cortex and thalamus. A significant difference ($p < .01$) did exist in the septal extracts of control rabbits (0.54 ± 0.04) when compared to pyrogen injected animals (0.81 ± 0.10). These punches of rabbit septum were unilateral and included portions of both the medial and lateral divisions. The finding that LP-induced fever was associated with an increase in levels of a CNS-peptide (α-MSH) that has been implicated in the central control of thermoregulation lends support to the theory that CNS peptides act as neuromodulators at discrete CNS sites to control this vital physiologic function. (Supported by NINCDS Grant 10046).

164.1 TRIMETHYLTIN PRODUCES SOMATOSENSORY DYSFUNCTION. R. S. Dyer, W. E. Howell and T. J. Walsh. Neurotoxicology Division, US Environmental Protection Agency, Research Triangle Park, NC 27711.

Trimethyltin (TMT) is a neurotoxic alkyltin which produces selective neuronal damage within the limbic system (Brown et al., 1979) and a unique behavioral syndrome characterized by spontaneous seizures, hyperreactivity, and tail mutilation (Dyer et al., 1980). Observed tail mutilation suggested somatosensory disturbances. To study this, the following tests were performed: (1) heat pain threshold; (2) peripheral mixed nerve threshold and conduction velocity; and (3) the somatosensory evoked response (SER). Male Long-Evans hooded rats were implanted with ground, reference, and somatosensory cortex electrodes. Prior to receiving an i.p. injection of either 0 (saline vehicle) or 7 mg/kg TMT chloride, animals were tested on each of the three tests, and re-tested on days 1 and 4 following dosing. Sensitivity to heat was measured by placing each animal on a hot plate (51.0°C) and recording the latency to lick the hind paw. Animals were then anesthetized and placed on an apparatus permitting immersion of the tail in warm paraffin oil (37.5°C). Prior to immersion three needle electrode pairs (two stimulating-one recording) were inserted near the left dorsal caudal nerve. The tail was allowed to equilibrate to bath temperature before testing was begun (5 min). Mixed nerve conduction velocity was determined by supramaximally stimulating (5 Hz, 0.1 msec) proximal and distal electrode pairs (100 mm separation) and recording the compound nerve action potential at a distant tail location. The SER was elicited by stimulating the proximal electrode pair (1 Hz, 0.1 msec) at an intensity sufficient to produce a maximal compound action potential from the nerve. A mean of 64 responses was obtained for each animal and the peak-to-peak amplitudes and latencies of the resulting averaged response were measured. TMT exposure produced a significant increase in the latency to hind paw lick, thus indicating impairment in the somatosensory system. The absence of TMT-induced alterations in conduction velocity and mixed nerve threshold suggested that the deficit was not due to peripheral nerve dysfunction. Analysis of the SER data revealed that TMT induced a statistically significant increase in P2 latency. The absence of alterations in late SER peaks, and the absence of any amplitude changes implies that the dysfunction reflects timing of somatosensory information. Whether this timing dysfunction results from impaired central conduction, synaptic function or synchronization will be addressed in future studies.

164.2 2-DEOXYGLUCOSE MAPPING OF THE GUINEA PIG AUDITORY PATHWAY USING STIMULI WHICH ELICIT TINNITUS IN HUMANS. J.S. Kauer, L.Babitz* J.W. Nemitz, C.T. Sasaki*. Sections of Neurosurgery, Neuroanatomy and Oto-Rhino-Laryngology. Yale University School of Medicine, New Haven, CT 06510.

We have used the 14C 2-deoxyglucose (2DG) technique to examine changes in metabolic activity in the auditory pathway of 52 guinea pigs after removal of the cochlea, removal of the middle ear ossicles, and after treatment with acetylsalicylic acid (aspirin). Three experiments were performed. In the first series we examined the levels of neuronal activity at 2½ hrs to 42 days after asceptic uni- and bilateral cochlear ablations. In this series we observed a spontaneous increase in activity which appeared at 2-14 days in those regions having major connections with the ablated cochlea when compared with the background levels of activity seen when tested immediately after surgery.

In the second series we performed asceptic uni- and bilateral removal of the middle ear ossicles. These manipulations, in contrast to cochlear removal, caused little or no spontaneous increase in activity on the side connected to the lesion when examined at either one day or 21 days. This suggests that the increased activity seen several days after cochlear removal was due to the process of deafferentation per se and not to the deafness which was caused by both the cochlear and ossicle removals. These findings are consistent with the possibility that the spontaneous increase in metabolic activity seen after cochlear removal may be a reflection of the subjective sensation of tinnitus experienced by humans after cochlear damage or VIII nerve section.

In the third experimental series we administered acetylsalicylic acid 30-50 mg/da for 3-7 days to animals which had had uni- or bilateral ossicle removals 9-21 days prior to 2DG testing. This experiment was designed to examine whether moderate levels of a salicylate known to produce tinnitus in humans, could elicit increased activity in those animals which would normally show no spontaneous return of neuronal activity after experiencing a conductive hearing loss. In the three animals examined to date under these conditions an increase in 2DG uptake was observed after aspirin administration. These preliminary data are consistent with the findings seen after cochlear ablation and further suggest that this increased activity may reflect a tinnitus-like phenomenon in this experimental animal. We believe the findings from these three sets of experiments may form the basis for the development of an experimental animal model for the study of a profound otologic problem about which there is virtually no pathophysiological information. Supported by the Deafness Research Foundation and USPHS grant NS 16288

164.3 DIFFERENTIAL EFFECT OF ISCHEMIA ON ACTIVE UPTAKE OF DOPAMINE, GABA AND GLUTAMATE. Jesse Weinberger* and Gerald Cohen. Dept. Neurology, Mount Sinai School of Medicine, N.Y., N.Y., 10029

Unilateral cerebral ischemia was induced in the Mongolian gerbil by left carotid ligation. Energy-dependent, active uptake of ^{3}H-dopamine, ^{3}H-GABA and ^{14}C-glutamate was measured in isolated synaptosomes as a paradigm of neuronal membrane function in ischemia. Synaptosomes were prepared by differential centrifugation in 0.3M sucrose. Uptake was carried out in Krebs-Ringer-phosphate buffer, pH 7.4, at concentrations of 5×10^{-9}M for dopamine and 8×10^{-6}M for GABA and glutamate. Synaptosomes were separated from the incubation medium by filtration through.65 micron Millipore filters for subsequent scintillation counting of radioactive tracer within the synaptosomes. The uptake at 10 min into the ischemic (Left) and control (Right) hemispheres was expressed as the L/R ratio.

Significant decrease in uptake did not occur until 16 hours after carotid ligation. No change was evident at 1, 4 and 8 hours. The extent of reduction of uptake at 16 hours is shown in the following table (mean ± SEM):

	Dopamine	GABA	Glutamate
Ischemic L/R Uptake	.152 ± .048	.280 ± .059	.475 ± .035
Sham Control L/R Uptake	.956 ± .063	.991 ± .095	.977 ± .068

The greater reduction in uptake of dopamine compared to glutamate was significant ($p < .001$).

Potassium stimulated release was evaluated by adding KCl to the medium to a final concentration of 60 mM and measuring the radioactive tracer remaining in the synaptosomes after 3 min. Release, expressed as a % of the amount taken up, was not affected even when uptake was markedly reduced. This indicates that uptake took place into normally functioning synaptosomes and that the decrease in uptake was probably due to loss of nerve terminals.

In separate experiments, uptake was studied in striata dissected from ischemic and control hemispheres to evaluate whether the difference between dopamine and glutamate was due to regional variation or intrinsic differences in the nerve terminals. The L/R uptake ratio in the striatum at 16 hours was .347 ± .140 for dopamine and .649 ± .142 for glutamate ($p < .02$).

These findings indicate that loss of active uptake of putative neurotransmitters after ischemia is a delayed process and that the dopaminergic synapse is more sensitive to ischemic damage than the glutamate synapse.

164.4 REDUCED SYMPATHETIC NERVOUS SYSTEM ACTIVITY IN RATS WITH DIETARY INDUCED OBESITY. B. E. Levin, J. T. Triscari*, M. B. Finnegan*, A. C. Sullivan*, Dept. Neurosci., N.J. Med. Sch., Newark, NJ 07103, VA Med. Ctr., E. Orange, N.J. 07019, and Dept. Pharm. II, Hoffmann-LaRoche Inc., Nutley, NJ 07110.

The sympathetic nervous system plays an important modulatory role in the control of many metabolic systems which function abnormally in obesity. The genetically obese Zucker rat has abnormal sympatho-adrenal function (Levin, B. E., et al., Pharm. Biochem. Behav. 13: 107, 1980), although it is uncertain if this is the cause or effect of obesity. We therefore fed 4-5 mo old, male Sprague-Dawley rats on a highly palatable diet consisting of rat chow admixed with 10% corn oil and condensed milk for 3 mo. These rats over-ate and developed diet-induced obesity (DIO) with a 97% greater weight gain than chow-fed controls. DIO was associated with a 31% increase in cardiac tyrosine hydroxylase activity and decreased cardiac (18%) and interscapular brown adipose tissue (27%) dopamine-β-hydroxylase activity. DIO rats also had reduced norepinephrine (NE) levels in their adrenals (25%), hearts (46%), aortas (68%) and epididymal white adipose tissue pads (38%). Turnover rates for NE, assessed by tyrosine hydroxylase inhibition with α methyl-p-tyrosine, were also significantly reduced in the hearts (73%), aortas (50%), pancreases (46%), and white adipose depots (51%) of DIO rats. No changes occurred in NE levels or turnover in brown adipose tissue of DIO rats, however. Therefore, while the mechanism is uncertain, DIO is associated with decreased peripheral sympathetic function which may contribute to the reduced ability of obese animals to expend calories as heat.

164.5 STRIATAL ^{3}H-SPIPERONE BINDING AND SPONTANEOUS PERIORAL MOVEMENTS IN THE RAT DURING AND AFTER WITHDRAWAL FROM 6 MONTHS PHENOTHIAZINE TREATMENT. John L. Waddington, Stephen J. Gamble* and Rachel C. Bourne*. Division of Psychiatry, M.R.C. Clinical Research Centre, Northwick Park Hospital, Harrow, Middlesex. HA1 3UJ, U.K.

It is commonly believed that the pathophysiology of 'tardive dyskinesia' resides in the functional supersensitivity of dopamine (DA) receptors in the basal ganglia induced by neuroleptic drugs. We have investigated the incidence of spontaneous perioral movements during and after withdrawal from 6 months continous phenothiazine treatment in rats and have sought to relate these phenomena to in vitro binding indices of DA receptor function.

Rats were treated with fluphenazine decanoate (FPZ-D) by i.m. injections or with trifluoperazine HCl (TPZ) via drinking water. After 6 months of FPZ-D injections (5 mgm at 2-3 week intervals), but not at 7 days after a single FPZ-D injection, there was an excess incidence of spontaneous jaw movements (70%) in comparison with controls (12.5%). Injections of FPZ-D were then terminated and over the next 6 month period these incidences ranged from 50-80% in FPZ-D animals and 17-50% in controls. Striatal ^{3}H-spiperone binding was unaltered after 6 months of withdrawal. After 6 months but not 1 week of oral TPZ treatment (3.8 mg/kg/day) there was a 40% incidence of such movements (16% in controls). At 2½ months after TPZ withdrawal the incidence was 83% (18% in controls) yet striatal ^{3}H-spiperone binding was unaltered.

6 months phenothiazine treatment was associated with an excess incidence of spontaneous perioral movements, enhancing a pre-existing disposition. The pathophysiology did not appear to involve those DA receptors exemplified by striatal ^{3}H-spiperone binding.

164.6 PHENYLKETONURIA (PKU), TETRAHYDROISOQUINOLINES (TIQS) AND NEUROLOGICAL DAMAGE. M. Druse-Manteuffel, M.A. Collins, D.Tonetti*, C.Waddell* & P.Patel*. Dept. Biochem. & Biophys., Loyola Med.School, Maywood, IL 60153

Recently Lasala & Coscia(Sci.203:283,1979)reported that the TIQ, desoxynorlaudanosoline-1-carboxylate (DNLCA), an endogenous product of dopamine and phenylpyruvate, was elevated in brains of adult hyperphenylalaninemic rats and in urines of children with PKU. Based on DNLCA distribution and enzyme inhibitory studies, a neuropathological role for the TIQ was implied. To test this idea we examined the effects of DNLCA on myelin proteins and the biogenic amines in the brains of normal neonatal rats.

DNLCA(in sterile saline)was given intracerebrally to rats on days 6(20 µg), 8, 11, 14 & 16(10 µg/day). Controls received saline only. On day 18, rat pups were decapitated. Some brains were used for the preparation of purified myelin and separation of myelin proteins by SDS polyacrylamide gel electrophoresis(Druse et al. Brain Res.76:423,1974). Other brains were used to quantitate brain region content of biogenic amines by reverse phase HPLC(with electrochemical detection). Repeated injections of DNLCA produced a slight (6%) reduction in brain weight and did not affect brain protein content or the composition of myelin proteins. However, DNLCA exhibited a potent and perhaps selective toxicity toward the serotonin(5-HT)system and was found to be toxic to CNS myelination. Both the content and concentration of myelin protein were significantly reduced (41% & 39%, respectively). Levels of 5-HT in the striata of TIQ-treated 18-day-old pups were ∿80% below normal, but dopamine and DOPAC levels were unchanged. This effect on brain 5-HT resembles that seen earlier with another carboxylated TIQ (Hannigan & Collins, Drug Alc.Depend.4:235,1979). It is well-known that the two processes, myelination and biogenic amine dynamics, are disrupted in the brain during PKU. Several other phenylalanine metabolites (i.e. phenylacetate) have toxic effects on myelination, but effects on the biogenic amines are not prominent. Our data in neonatal rats indicate that a more complex metabolite, a TIQ alkaloid, has selective actions on both processes which certainly could be important in the neuropathology of PKU.

We thank Dr. Coscia for the DNLCA. Supported by Loyola BRSG and USPHS.

164.7 PLATELET 5-HYDROXYTRYPTAMINE CONCENTRATIONS IN PSYCHIATRIC PATIENTS AND CONTROL SUBJECTS. H.L. Jackman and H.Y. Meltzer, Dept. of Psychiatry, University of Chicago and the Illinois State Psychiatric Institute, Chicago, Illinois.

The role of 5-hydroxytryptamine (5-HT) in the etiology of schizophrenia and the affective disorders has been studied by examining 5-HT in blood platelets. Several investigators have reported increased 5-HT levels in platelets from schizophrenic patients. In this preliminary study, we report the concentration of 5-HT in platelets from 59 psychiatric patients and 30 control subjects.

Five ml of venous blood from controls or patients was put into polypropylene tubes containing ACD anti-coagulant. Platelet-rich-plasma (PRP) was prepared by centrifugation at 600 g for 2.5 minutes and the number of platelets per ml of PRP was determined electronically. A platelet pellet was formed by centrifugation, frozen at -40°C, and assayed within two weeks. The platelet 5-HT was assayed spectrofluorometrically and reported as ng 5-HT per 10^8 platelets (U). Patient diagnoses were established by the Research Diagnostic Criteria.

The number of patients in each diagnostic group and their mean platelet 5-HT concentration ± SD are as follows: 11 paranoid schizophrenics, 91 ± 38 U; 7 undifferentiated schizophrenics, 87 ± 39 U; 5 schizoaffective depressed (mainly schizophrenic), 95 ± 13 U; 8 unipolar depressed, 53 ± 13 U; 12 bipolar depressed, 62 ± 27 U; 7 schizoaffective depressed (mainly affective), 62 ± 23 U; 5 bipolar manics, 58 ± 17 U; 4 schizoaffective manics (mainly affective), 82 ± 28 U. The concentration of 5-HT in platelets from 30 control subjects was 62 ± 16 U. A two way ANOVA was performed on the data and revealed a significant diagnostic effect; paranoid schizophrenics have a significantly higher platelet 5-HT concentration than controls ($P < .01$). The 5-HT in platelets from schizoaffective depressed (mainly schizophrenic) and undifferentiated schizophrenics also tended towards higher concentrations than that found in platelets from controls. No sex effect or interaction between sex and 5-HT content was detected. Neuroleptic treatment produced no significant effect on platelet 5-HT levels.

While a great deal of overlap in platelet 5-HT concentration values exists, our data is in agreement with previous findings of a greater than normal concentration of 5-HT in platelets from some schizophrenic patients. This finding supports the hypothesis that an abnormality in 5-HT metabolism may contribute to the pathophysiology of schizophrenia.

164.8 ^{3}H-GABA BINDING IN GALACTOSAMINE-HCl INDUCED HEPATIC ENCEPHALOPATY IN RAT: A DENERVATION SUPERSENSITIVITY PHENOMENON. M.Baraldi*, M. L. Zeneroli*. (SPON:F VARGAS). Istituti di Farmacologia e di Semeiotica Medica°, Modena University, 41100 Modena, Italy.

Fulminant hepatic failure (FHF), characterized by massive necrosis of the liver, is associated with unclear brain changes resulting in hepatic encephalopathy (HE). Our approach to study HE was to investigate GABA receptor characteristics. FHF was obtained in rats by the injection of Galactosamine-HCl and the degree of HE was evaluated with visual evoked potentials. The kinetics of Na^+-independent ^{3}H-GABA binding of fresh or frozen three times Triton X-100 treated P_2 membranes from brain of controls and comatose rats were studied. Scatchard analysis of the saturation curve in freshly prepared membranes revealed only one receptor with low affinity for GABA ($GABA_1$) in both situations; hovewer the affinity of GABA to membranes from comatose rats (K_d=122±3 nM) was significantly increased in comparison with that of controls (K_d=193±7 nM). In frozen, Triton treated and repeatedly washed membranes, two receptor components, one ($GABA_1$) with low affinity (K_d=192 nM, B_{max}=7.6 pmol/mg prot.) and one ($GABA_2$) with high affinity (K_d=20 nM, B_{max}=2.1 pmol/mg prot.) were found in control while in membranes from brain with HE only the high affinity site ($GABA_2$) was present (K_d=25 nM, B_{max}=1.8 pmol/mg prot.). This result was confirmed performing the same ^{3}H-GABA binding studies in different brain areas.

The relative increased affinity found in the freshly prepared membranes from rats with HE could be interpreted as a supersensitivity phenomenon due to a degeneration of Gabaergic neurons associated with a decrease of endogenous inhibitors of GABA binding. Hovewer it is impossible to completely evaluate this phenomenon in fresh membranes because of the still present endogenous GABA and endogenous protein inhibitor (GABA modulin). The treatment with Triton seems to completely remove the endogenous inhibitor from the HE membranes and to leave only the high affinity binding sites.

The present study provides evidence that $GABA_1$ and $GABA_2$ receptors are two different entities and that the mechanism of HE due to FHF could be related to an induced $GABA_1$ receptor degeneration.

164.9 PROLINE-LEUCINE-GLYCINAMIDE (PLG) PREVENTS NEUROLEPTIC DRUG-INDUCED DOPAMINE RECEPTOR SUPERSENSITIVITY IN STRIATUM. Ram K. Mishra*, S. Chiu* and C.S. Paulose*, Neuropharmacology Lab., Depts. of Psychiatry and Neurosciences, McMaster Univ., Hamilton, Ontario, L8N 3Z5, Canada. (SPON.: E. Werstiuk).

The potential anti-Parkinsonian and antidyskinetic properties of PLG have recently been recognized. There is evidence in the literature suggesting that neuropharmacological profile of activity of PLG may be mediated through interacting with central dopamine receptors. In the present study we have examined the effect of PLG on neuroleptic drug-induced supersensitivity in rats. Various groups of animals received: PLG (10 mg/kg), Haloperidol (3 mg/kg), Chlorpromazine (20 mg/kg), Haloperidol + PLG, and Chlorpromazine + PLG. The control group received the vehicle solution. The drugs were administered subcutaneously for 3 weeks. After 5 days of last injection, the animals were sacrificed and striata dissected out for ^{3}H-spiroperidol binding assay. The spiroperidol binding to tissue preparation was carried out as previously described (Brain Res. 170, 381, 1979). As reported earlier, neuroleptic drugs increased the spiroperidol binding sites significantly in the striatum, Haloperidol caused a mean increase of 58% in the B_{max} whereas chlorpromazine produced a mean increase of 67%. PLG at two different doses (10 mg/kg and 20 mg/kg) prevented neuroleptic drug induced increase in spiroperidol binding sites. PLG by itself had no significant effect on binding sites. These results suggest an interaction of specific PLG receptors with dopaminergic mechanisms in the CNS and may explain the beneficial effect of PLG in tardive dyskinesia. We have recently reported the presence of specific PLG receptors in various discrete regions of brain tissue obtained from several mammalian species including humans (Fed. Proc. 39, 625, 1980). The interaction between PLG and neuroleptic dopamine receptors and modulation of dopaminergic system by PLG remains an interesting topic for future research. (This work was supported by the Ontario Mental Health Foundation).

164.10 TETRABENAZINE MODEL OF DEPRESSION: CHANGES IN CEREBRAL FLUID DYNAMICS AND REVERSAL BY AMITRIPTYLINE. T. Kent*, S. Preskorn, R. Glotzbach*, and G. Irwin*. Depts.of Psychiatry & Pharmacology, Univ. of Kansas Sch. of Med., Kansas City, KS 66103.

The central adrenergic vasoregulatory hypothesis postulates that this neuronal system has as one of its functions the regulation of brain permeability (PS) and blood flow (CBF). We found that the blood:brain barrier becomes more permeable to compounds, such as water, at high $PaCO_2$. This finding is consistent with the hypothesis: high $PaCO_2$ stimulates an increase in the firing rate of central adrenergic neurons which should lead to the observed increase in PS. Moreover, treatment with amitriptyline(AMI)--an indirect acting adrenergic agonist--doubled the increase in PS observed at high $PaCO_2$ (Table I).

In this experiment, the effect of tetrabenazine (TBZ)--a catecholamine depleting agent--was studied on the increase in PS observed with increasing CBF. Using a dual label radioistope technique previously described, changes in the cerebral extraction of ^{3}H-water (E_w), brain permeability to water (P_wS), and CBF were measured in rats. The animals were anesthetized, paralyzed, and passively ventilated.

TBZ is a standard screen for potential antidepressant drugs. 20mg/kg of TBZ administered (i.p.) produces autonomic and behavioral changes. These effects occur within 45 mins., persist for over 3 hours, and coincide with drug-induced depletion of central catecholamines. Reversal of these effects is a predictor of antidepressant activity in man. In our hands, these behavioral effects were produced by TBZ and were reversed by AMI. We tested the effect of TBZ on the apparent adrenergic-mediated, $PaCO_2$-induced increase in PwS. (Note: The effect of experimental treatments can be expressed either as a change in the slope of PwS vs. CBF or vs. $PaCO_2$.) At 45 min., coincident with maximal central catecholamine depletion, TBZ essentially abolished the $PaCO_2$-induced increase in PwS (Table I). AMI reversed the effect of TBZ (Table I).

Group	PwS versus CBF	r	n	Dose
Controls	$.8\bar{x}+0.28.$	.98	3	
*Controls	$.9\bar{x}+0.34$	.98	12	
*AMI	$1.83\bar{x}+0.01$	.96	15	17.5mg/kg i.p.
TBZ	$.24\bar{x}+1.67$	.65	13	20mg/kg i.p.
TBZ+AMI	$.76\bar{x}+1.03$	.87	17	

*from Preskorn, et al., Sci. 1981

These results support the central adrenergic vasoregulatory hypothesis. Moreover, a functional change occurred in central adrenergic innervation of the blood:brain barrier in this pharmacological model of affective illness--a disease long thought to be related to disturbances in central adrenergic mechanisms. *(Supported by MH-00272 and NS-17252).

164.11 IN VIVO ASSESSMENT OF PRESYNAPTIC ADRENERGIC α-2 RECEPTOR FUNCTION IN RHESUS MONKEYS AND HUMANS. D. S. Charney*, G. R. Heninger, D. S. Sternberg*, and R. H. Roth. Yale University School of Medicine, New Haven, CT 06508.

There is considerable evidence that presynaptic α-2 adrenergic receptors regulate the release of norepinephrine (NE) through negative feedback mechanisms. The present investigation was undertaken to develop methods for assessing in vivo the sensitivity of this receptor because of the potential for providing important new information on the regulation of the NE system in intact experimental animals and humans. Alpha-2 adrenergic antagonists and agonists increase and decrease, respectively, brain NE turnover and 3-methoxy-4-hydroxyphenelethyleneglycol (MHPG) production. Plasma-free MHPG had been found to reflect brain MHPG in a variety of experimental situations (Elsworth, J.D. et al, Neuroscience Abstracts 6:140, 1980). In the present study, the effect on plasma-free MHPG of an α-2 adrenergic antagonist (yohimbine) and agonist (clonidine) were studied in rhesus monkeys, normal humans, and in depressed psychiatric patients. Plasma was obtained from blood samples drawn through an indwelling intravenous catheter, both before and at a variety of time periods following drug administration. Plasma MHPG was determined by gas chromatography and mass spectrometry. In four rhesus monkeys tested twice, clonidine (3 μg/kg IV over 5 min.) reduced plasma MHPG by 36% ($P < .01$), and yohimbine (1 mg/kg IV over 5 min.) increased MHPG by 78% ($P < .01$) with the maximum effect for both drugs occurring 2 hrs. following the dose. The mean difference between the 1st and 2nd test in each monkey was less than 1/3 the mean change produced by either yohimbine or clonidine. In 12 normal human volunteers, clonidine (5 μg/kg p.o.) decreased plasma MHPG by 14% ($P < .05$) and in five other volunteers, yohimbine (10 mg p.o.) increased plasma MHPG by 31% ($P < .01$), with the maximum effect for both drugs occurring 4 hrs. following administration. Clonidine (5 μg/kg p.o.) was administered to 15 depressed patients before and during chronic treatment with desipramine (N = 10) and amitriptyline (N = 5). Desipramine, but not amitriptyline, significantly attenuated the effect of clonidine on plasma MHPG and blood pressure. This is consistent with findings in laboratory rats, where chronic desipramine, but not amitriptyline attenuates the effects of clonidine on brain MHPG. These results indicate that this method could be of considerable utility in the study of adrenergic α-2 receptor regulation of the NE system in neurologic and psychiatric illness. (Supported by MH-18949, MH-25642, and MH-30929).

164.12 BIOCHEMICAL DEMONSTRATION OF REDUCED DOPAMINE TURNOVER WITH LOW-DOSE APOMORPHINE IN SCHIZOPHRENIC PATIENTS.
N.R. Cutler,* D.V. Jeste,* F. Karoum, N.H. Kalin,* S.C. Risch,* and R.J. Wyatt, Adult Psychiatry Branch, National Institute of Mental Health, Washington, D.C. 20032.

Apomorphine, a partial dopamine agonist, has been previously demonstrated to improve psychotic symptoms in some chronic schizophrenic patients (Tamminga, C.A. et al., Science 200: 567, 1978). The antipsychotic effect of apomorphine has been attributed to a reduction in central dopamine turnover through an autoreceptor action. Yet, to our knowledge, there has been no direct demonstration in man of such an hypothesized reduction in dopamine turnover with low-dose apomorphine. In a double-blind study, we evaluated behavioral, biochemical, and neuroendocrine effects of apomorphine, 0.005 mg/kg, in schizophrenic patients.

METHODS: Five young chronic schizophrenic patients, three males and two females, diagnosed by the Research Diagnostic Criteria, participated. Subjects had been maintained on stable doses of neuroleptics (mean daily dose equivalent to 1067.5 mg of chlorpromazine) for at least one month. Subjects were given apomorphine and placebo subcutaneously on two different days, in a random order. All subjects were at bedrest the night before and during the study. Brief Psychiatric Rating Scale (BPRS) Score, temperature, and blood pressure were assessed and blood samples collected 20 minutes before the injection and every 20 minutes thereafter for a total of two hours.

RESULTS: Analysis of the total BPRS scores showed marked but temporary clinical improvement in two patients. Overall, the most significant changes were noted in ratings of depression and anxiety. Plasma homovanillic acid (HVA) concentrations, measured by mass fragmentography, showed significant decrease following apomorphine as compared to placebo ($t=5.1$; $p<.009$). All five patients had reduced plasma HVA concentrations as early as 20 minutes following apomorphine; in some patients the plasma HVA concentrations had not returned to their baseline values, even at 100 minutes. Plasma cortisol and human growth hormone concentrations did not change significantly.

CONCLUSIONS: A small dose of apomorphine (.005 mg/kg) given to medicated schizophrenic patients produced a significant drop in plasma HVA concentrations. Studies by Bacopoulos, N.G. et al. (Eur. J. Pharmacol. 56: 225, 1979) and Swann, et al. (Life Sci. 27: 1857, 1980) suggest that drug-induced changes in plasma concentrations of dopamine metabolites reflect changes in dopamine metabolism. Our findings, therefore, indicate that a low dose of apomorphine significantly reduces dopamine turnover in schizophrenic patients. This is consistent with the postulated action of low-dose apomorphine on dopaminergic autoreceptors. Further implications of our findings will be discussed.

164.13 EFFECTS OF CHRONIC HYPERTENSION ON ALPHA-ADRENERGIC, SEROTONERGIC AND HISTAMINERGIC RECEPTORS IN ISOLATED CEREBRAL ARTERIES. C. Estrada*, M.V. Conde*, B. Gomez*, and S. Lluch*, (SPON: R.E. McCaman), Department of Physiology, Fac. de Medicina, Universidad Autonoma, Madrid, Spain.

Direct measurements of cerebral blood flow in unanesthetized chronic hypertensive goats have shown an increase in cerebrovascular resistance during the hypertensive state. In order to study the mechanisms underlying this phenomenon, the responsiveness to vasoconstrictor agents acting on different vascular receptors was tested in isolated cerebral vessels from normotensive and hypertensive goats. Chronic hypertension was induced by unilateral renal artery constriction. Values for mean arterial pressure were 102±2 mmHg in normotensive goats and 136±3 mmHg in hypertensive ones. The middle cerebral arteries from 20 normotensive and 7 hypertensive goats were dissected out and isometric contraction of 5 mm length segments was measured in a standard way. Cumulative concentration-response curves for norepinephrine (NE, 10^{-8} - 10^{-4} M), tyramine (TYR, 10^{-6} - 10^{-3} M), serotonin (5HT, 10^{-8} - 3×10^{-6} M), and histamine (HIS, 10^{-8} - 3×10^{-5} M) which were obtained for arteries from both groups of animals were compared. The maximum effect (E_{max}) of NE and TYR was increased in vessels from hypertensive goats (150% of normotensive control), but the EC_{50} values were unchanged. The concentration-response curve to 5HT was shifted to the left in arteries from hypertensive animals, indicating an increase in sensitivity (EC_{50}, 3×10^{-7} M in normotensive goats versus 10^{-7} M in hypertensive ones), but the E_{max} was not significantly different. The responsiveness to HIS was similar in arteries from both groups of animals. The increase in response to NE and 5HT, transmitters thought to be present in nerve endings in the cerebral vessels, may explain the increased cerebrovascular resistance seen during chronic hypertension. The responses obtained after stimulation of alpha-adrenergic, serotonergic and histaminergic receptors were altered in different ways during hypertension. This suggests that the increased cerebrovascular responsiveness involves specific changes at the receptor level. Supported in part by Comisión Asesora Cientifica y Técnica.

164.14 PLATELET ALPHA-2 RECEPTOR BINDING BY ^{3}H-YOHIMBINE IN NORMAL HUMAN VOLUNTEERS AND PSYCHIATRIC PATIENTS. S.M. Stahl, D.J. Woo*, P.A. Berger and R.D. Ciaranello. Lab. of Developmental Neurochemistry, Stanford U. Med. Ctr., Stanford, CA. 94305

Alpha-2 adrenergic receptors on intact human platelets were characterized by ^{3}H-yohimbine, a potent alpha-2 adrenergic antagonist. ^{3}H-yohimbine binds specifically and with high affinity to alpha-2 adrenergic receptors of human platelets. We have adapted a rapid and reliable method for determining K_D and B_{MAX} of platelet alpha-2 receptors in 30 ml of blood from human donors. This method employs intact human platelets rather than platelet membranes, as well as the Corrash method for isolating the full population of intact platelets. ^{3}H-yohimbine had the same binding characteristics in Corrash-isolated platelets as in platelets isolated after a single centrifugation. Total binding was 2-5% of total ^{3}H-yohimbine added. Non-specific binding using phentolamine (1.5×10^{-6}M) varied between 10-20% of total binding. The association and dissociation kinetics were rapid and linear at 30°, and the binding is of a single order with the k_{-1}/k from pooled normal human volunteers of 0.51 nmolar. Tissue binding curves showed that at least 1.5×10^8 total platelets per tube were needed for linear kinetics.

^{3}H-yohimbine binding displaced by phentolamine was determined in 10 medicated and 12 unmedicated patients of various psychiatric diagnoses, and in 14 normal volunteers. Scatchard analysis showed that K_D for ^{3}H-yohimbine binding in normal human volunteers was 2.00 ± 0.49 nM and B_{MAX} was 107 ± 42 binding sites per platelet. The results of K_D and B_{MAX} values as a function of psychiatric diagnosis and psychotropic medication will be discussed.

165.1 CORRELATION OF FIRING THRESHOLD TO MEMBRANE POTENTIAL IN SCIATIC AXONS. Kenneth J. McLeod and Stephen A. Raymond. Research Laboratory of Electronics, MIT, Cambridge, MA 02139.

The three phase variation in excitability that follows impulses in axons (Raymond, J. Physiol. 290:273, 1979) was compared to intracellularly recorded afterpotentials to ascertain the relationship between membrane potential and firing threshold.

Action potentials and afterpotentials were recorded in excised sciatic nerve of frog using silanized microelectrodes. Axons selected for study maintained a resting potential of at least -65 mV for a period of at least one hour, and produced action potentials of at least 70 mV peak amplitude.

Following impulse bursts of 1 to 1000 spikes at 5 ms intervals all axons exhibited a brief afterhyperpolarization of 3 - 15 mV. Short bursts were marked by a subsequent depolarizing wave that decayed over 200-500 ms. A lingering hyperpolarization could be seen after this wave that was larger and persisted longer in proportion to the duration of the conditioning burst. Halftimes for this hyperpolarization, PTH, depended strongly on the activity, typically ranging from 0.5 sec after bursts of 16 impulses to 2 min. after bursts of 1000 impulses at 5 ms intervals. The total time course of the afterpotential variations in each axon corresponded closely to the total time of the combined refractory, superexcitable and depressed phases for any given stimulus pattern as measured concurrently using threshold hunting. Membrane voltage changes of less than 1 mV were observed under conditions where threshold had changed by a factor of 2 or more. Superexcitability was consistently seen during the first few hundred ms following a spike or a burst whether or not the membrane was hyperpolarized. After short bursts or single spikes the depolarizing wave resulted in a net depolarization. As conditioning activity was increased, the wave appeared on top of a more and more dominant PTH. After a very long tetanus the depolarizing wave could not be seen in the superexcitable phase.

These results are consistent with the idea that superexcitability is not mediated by the membrane potential but by the direct influence of the raised extracellular K concentration immediately following activity. Depression appears to be strongly correlated to intracellular loading with Na.

Additional experiments using steady depolarizing and hyperpolarizing currents indicated that resting threshold levels are logarithmically related to the membrane potential. This observation and the results showing the dependence of threshold on ion concentration suggest that firing threshold may be mediated by a surface reaction.

165.2 A MECHANISTIC INTERPRETATION OF INTERMITTENT RESPONSIVENESS TO REPETITIVE STIMULATION OF MYELINATED FIBERS. Stephen A. Raymond and Dinah Sah*. Research Laboratory of Electronics, MIT, Cambridge, MA 02139.

Studies of the relation between impulse activity and threshold have shown why fibers subjected to long trains of repetitive electrical stimuli respond in bursts and gaps ('intermittent responsiveness'), but the ionic and molecular basis of the changes in threshold produced by activity remains obscure. The following hypothesis has been useful in efforts to find a mechanistic interpretation of the empirical relations: superexcitability is mainly caused by the aftereffects of an impulse on external K, and depression is proportional to the rate of sodium pumping.

Here we mention several findings bearing on this hypothesis. Diffusion of K away from the external surface of nodal membrane was modeled by assuming that the myelin sheath is impermeable to K and that a net 7.5×10^{-13} mmoles of K are exchanged per impulse. We assumed that the diffusion constant for K in the matrix is that in H_2O. Kinetics of K concentration taken at the membrane surface showed a high correspondence in relative amplitude and time course to the superexcitability following single spikes and bursts. Both build up over bursts and show a significant increase that lasts over 1 s.

Longitudinal diffusion within the axon of Na accumulating at the node was also calculated. For the 2 sigma boundary of excess post-impulse Na to extend through the internode (1000 μ) would require more than 10 minutes. Recovery from depression is known to be prolonged by extending the duration of activity-induced depression (Raymond, J. Physiol. 290, p. 294, 1979). We suggest the prolongation occurs because the sodium pump current remains augmented while pump sites located at the nodes extract the extra Na that has diffused into the internodes during the long exposures to repetitive activity. Cohen (Neurosci. 6: 301, 1980) has found that at any given firing rate fibers having the greater degree of depression appear to have a greater rate of sodium pumping. One expects such fibers to exchange more quickly the Na accumulated during a burst and to show a faster recovery from depression. We analyzed oscillatory firing patterns during intermittent responsiveness in frog axons, and found that more depressible fibers showed more strongly periodic response with briefer recoveries.

Though the diffusion kinetics match superexcitability nicely, the present experiments do not indicate that the diffusing substance is K. Afterpotentials change less dramatically than the threshold (McLeod, these proceedings) and do not have a Nernstian relation to K ratios. As suggested by R. Grossman (J. Physiol. 295: 307, 1979), K may have a direct effect on excitability without altering membrane voltage.

165.3 PHASE LOCKING, PERIOD DOUBLING BIFURCATIONS AND CHAOS IN PERIODICALLY DRIVEN NEURAL AND CARDIAC OSCILLATORS. Leon Glass* and Michael R. Guevara*. Department of Physiology, McGill University, 3655 Drummond St., Montreal, Quebec H3G 1Y6.

A simple mathematical model for the periodic pulsatile stimulation of spontaneously active neural and cardiac oscillators displays rich dynamics as a function of the frequency and amplitude of the periodic stimulation. The autonomous oscillator may become phase locked to the periodic stimulus in a variety of regular periodic patterns (i.e., 1:1, 3:2, 4:3, 4:2, 2:2, where N:M represents N periodic stimuli to M action potentials of the driven oscillator). In addition apparently aperiodic patterns which are not phase locked are found in numerical simulations of the model system. The irregular aperiodic dynamics observed in the numerical studies are analogous to "chaotic" dynamics observed in finite difference equations (Li, T.-Y, Yorke, J.A., Am. Math. Monthly,82:985, 1975; May, R.M., Nature, 261:459, 1976). Over limited ranges of stimulus amplitude one observes the following sequence of phase locking patterns as the stimulation frequency is increased 1:1, 2:2, 4:4, ..."chaos". This sequence arises as a consequence of period doubling bifurcations similar to those observed in physical systems (Physics Today, March, 1981, p. 17). The implications of this work for the experimental and clinical observation of period doubling bifurcations and chaos will be discussed. (Supported by the National Science and Engineering Research Council of Canada and the Canadian Heart Association).

165.4 SUPRACHIASMATIC NUCLEUS ABLATION: EFFECTS ON RAT BRAIN NEUROTRANSMITTER RECEPTOR RHYTHMS. M. S. Kafka, R. Y. Moore and P. J. Marangos. NIMH, Bethesda, MD 20205 and Dept. of Neurology, Sch. of Med., SUNY, Stonybrook, NY 11794

Circadian rhythms in the number of α-adrenergic, β-adrenergic, muscarinic acetylcholine (ACh), and benzodiazepine (BDZ) receptors have been demonstrated in the brains of rats entrained to a light:dark cycle (12:12). The rhythms (measured October, 1979) persisted after 48-72 hours in continuous darkness (Kafka et al., Brain Res. 207: 409-419 [1981]). As the suprachiasmatic nuclei (SCN) of the hypothalamus appear to regulate a number of circadian rhythms in the rat (Moore, Frontiers in Neuroendocrinology 5: 185-206 [1978]), the effect on the receptor rhythms of suprachiasmatic nucleus ablation was studied (June, 1980).

SCN lesions were made electrolytically and the rats permitted to recover for 17 days in a controlled light:dark cycle (L:D, 12:12). After 36 h in continuous darkness (D:D) 8 lesioned rats and 8 sham-operated controls were sacrificed at 4-hour intervals over a 24-hour period. Forebrains (all brain rostral to the cerebellum except striatum) were dissected and quickly frozen. The number of α-receptors was measured in these brains by the specific binding of [^{3}H]WB4101; β-receptors, by [^{3}H]dihydroalprenolol; ACh receptors, by [^{3}H]QNB; and BDZ receptors, by [^{3}H]diazepam.

The 24-hour mean number of each receptor was unaltered by ablation of the SCN suggesting that the SCN do not regulate the total number of a receptor, but only the diurnal changes in its magnitude. Controls exhibited an apparent circadian rhythm (i.e., with a period of approximately 24-hours) in BDZ receptor and α-receptor number, whereas the rhythms in β-receptor and ACh receptor number appeared ultradian (i.e., with a period less than 24 hours), the periods of each approximating 12 hours. Only control BDZ receptor and α-receptor rhythms (D:D) were circadian in both October and June. The β-receptor and ACh receptor rhythms in brains from rats with SCN lesions were similar to those in brains from controls. In contrast, the rhythms in BDZ receptors and α-receptors in brains from rats with SCN lesions were distinctly different from rhythms in controls. The circadian rhythm in BDZ receptor number was either markedly damped or absent, and the circadian rhythm in α-receptor number was clearly absent, with ultradian rhythms manifest in the number of both receptors. In this study, SCN lesions appear to affect selectively rhythms in brain receptor numbers that are clearly circadian in control animals, whereas rhythms in receptors that are ultradian in brains of controls are unaffected by SCN lesions.

165.5 ACTIVITIES OF INHIBITORY INTERNEURONES IN FICTITIOUS SCRATCHING. R. Cueva-Rolón* and E. J. Muñoz-Martínez. Dept. Physiol. Facultad de Medicina. Universidad de Guadalajara. Guadajalara, Jal. MEXICO and Dept. Physiol. & Biophys. Centro de Investigación y de Estudios Avanzados. Apdo. Post. 14-740, México 14, D.F. MEXICO. (SPON: G. Massieu).

Motoneurones activities during the scratching reflex begin with a prolonged flexor discharge followed by cycles of discharges of the flexor and the antagonistic extensor motoneurones. Flexor activity coincides with extensor inactivity and vice versa. In the present experiments we investigated: a) whether the initial event in the generation of scratching activity consists of selective flexor excitation or whether the extensor motoneurones are also subliminally excised, b) whether the periods of inactivity result from deactivation or from inhibition and c) whether Renshaw cells or Ia inhibitory interneurones participate to determine the inactivity periods.

Fictitious scratching was produced in descerebrated cats. Electroneurograms were recorded from the tibialis anticus and from a filament of the medial gastrocnemious nerve. In some experiments recordings were taken from spinal neurons. Reflex excitability of motoneurones was tested by stimulation of the deep peroneal and the triceps surae nerves. Also, extensor neurones were subliminally activated in some experiments by passive stretch of the triceps surae muscles.

Our results showed that extensor motoneurones were subliminally activated before the initial flexor discharge and always inhibited during the periods of flexor activity. Correspondingly, flexor motoneurones were inhibited during the periods of extensor activation. Intracelullar recordings revealed membrane hyperpolarizations during the inhibition periods. Antidromic stimulation of flexor and extensor motor axons did not significantly changed the scratching discharges; thus, Renshaw cells do not apparently contribute to the generation of rhythmic discharges. Passive stretch of the extensor muscles may reduce the duration of the flexor discharges or supress the fictitious scratching; similar effects were obtained by electric stimulation of low threshold muscle afferents. Stimulation of cutaneous afferents caused prolonged flexor discharges and disappearance of extensor activity. Our results indicate that Ia inhibitory interneurons participate in the generation of scratching reflex.

165.6 EFFECT OF DIBUTYRYL CYCLIC-AMP ON ELECTRICAL EXCITABILITY, $^{45}Ca^{2+}$-UPTAKE AND β-ENDORPHIN SECRETION FROM AtT-20/D16-16 PITUITARY CELLS. M. Adler, S. Sabol*, M. Jackson*, N. Busis and M. Nirenberg. Lab. Biochem. Genetics, NHLBI, Lab. of Biophys., NINCDS, NIH, Bethesda, MD 20205, and Lab. of Preclinical Studies, NIAAA, Rockville, MD 20852.

We have recently shown that clonal AtT-20/D16-16 (D16) mouse anterior pituitary cells can generate Na^+ and Ca^{2+} action potentials and secrete β-endorphin and ACTH. Although all well-impaled control cells were electrically excitable, many cells were injured by microelectrode penetration (3 M KCl, 40-80 M Ω). This was indicated by findings of low and unstable resting potentials. Spontaneous action potentials were rarely observed with untreated D16 cells, but were found frequently with cells exposed to 1 mM dibutyryl cyclic-AMP (Bt_2cAMP) for $\geq$ 9 days (treated). Since treatment of D16 cells with Bt_2cAMP also resulted in increases in the resting potential, input resistance, and cell volume, the higher incidence of spontaneous activity in treated cells could reflect either a reduction in microelectrode-induced damage or a change in ion channel properties. To distinguish between these possibilities, experiments were performed using extracellular microsuction pipettes (3-5 M Ω). With extracellular recordings, 19 of 20 Bt_2cAMP-treated cells and an almost equal number of control cells (18 of 20) were spontaneously active. The spontaneous action potentials were abolished in control cells when intracellular impalement was attempted, whereas in treated cells spontaneous activity persisted after impalement. The effects of Bt_2cAMP also were examined on $^{45}Ca^{2+}$ uptake and β-endorphin secretion from D16 cells. In both control and treated cells $^{45}Ca^{2+}$ influx increased rapidly when the K^+ concentration was changed from 5 to 80 mM and attained equilibrium within 30 sec. K^+ dependent $^{45}Ca^{2+}$ uptake by control and Bt_2cAMP-treated cells were 2.0 and 0.9 nmol/0.5 min/mg protein, respectively. β-Endorphin and β-lipotropin secretion was determined by radioimmunoassay employing an antiserum against β-endorphin. Rates of secretion of immunoreactive β-endorphin were 0.60 and 0.23 pmoles/min/mg protein from control and 21-day treated cells, respectively, in medium containing 5.4 mM KCl. Upon addition of 80 mM KCl, the rate of release increased 33-fold in control cells during the first two min of exposure, then returned to the basal rate. Treated cells underwent a 23-fold depolarization-dependent increase in β-endorphin secretion before returning to the basal rate. These results indicate that Bt_2cAMP treatment of D16 cells depresses $^{45}Ca^{2+}$ uptake and hormone secretion but does not alter specific ion conductances.

165.7 DOSE-RELATED EFFECTS OF INTRACELLULAR CYCLIC ADENOSINE-3':5'-MONOPHOSPHATE INJECTIONS IN IDENTIFIABLE ARCHIDORIS NEURONS. P.E. Hockberger and J.A. Connor. Dept. of Physiol. & Biophys., and Neural & Behav. Biol. Program, Univ. of Illinois, Urbana, IL 61801.

Liberman et. al. (Biofizika 20(3):451, 1975) reported that iontophoretic injection of cyclic adenosine-3',5'-monophosphate (cyclic AMP) into unidentified Helix neurons resulted in a transient depolarization in a considerable number of cells. In addition they noticed that this response was sometimes followed by "packets of pulses"-i.e. bursts of action potentials, in otherwise silent neurons. We report here that iontophoretic or pressure injections of cyclic AMP into members of a group of fourteen identifiable Archidoris neurons resulted in similar membrane potential changes. Injections of cyclic AMP into 131 cells elicited an instantaneous depolarization in 130 with subsequent bursting in 37 of these cells. Comparable injections of adenosine-5'-monophosphate (5'-AMP) were without effect in 15 of 17 cells.

Although these responses were independent of cell type, they appeared to be related to the amount of cyclic AMP injected. Iontophoretic injections lasting several minutes often transformed a transient depolarizing response into a sustained depolarization. After a delay of approximately ten to fifteen minutes, this sustained depolarization frequently included bursts of action potentials. Such bursts were preceded by a sudden, progressive increase in size of subthreshold membrane oscillations. Bursting and oscillatory behaviors were not present prior to cyclic AMP injections. Once these behaviors were induced, they persisted for hours.

A quantitative estimate of the dose-related nature of these responses was attempted using a dye injection procedure. This involved monitoring the optical absorbance of a cell during pressure injections of buffered solutions (pH=7.4) containing 0.2M cyclic AMP and 10 mM arsenazo III. Cells injected in this manner (n=32) exhibited transient depolarizations following doses between 50 and 500 µM cyclic AMP. No single dose was found which could routinely induce bursting (or oscillatory) behavior, although some cells exhibited such an effect following multiple injections totaling less than 1000 µM cyclic AMP.

We also examined the possibility that pressure injections may result in cellular swelling and thereby alter membrane properties. Injections of either 5'-AMP or buffered internal saline which increased cell volume by 6% were found to be without effect on membrane excitability or resting potential (n=9). Saline injections greater than 20% of cell volume resulted in a transient depolarization of 10mV in two cells tested. In contrast, cyclic AMP injections which caused 10mV depolarizations were achieved with injections totaling less than a 0.2% increase in cell volume (n=4).

165.8 EFFECTS OF GAMMA-AMINOBUTYRIC ACID ON HIPPOCAMPAL RHYTHMIC SLOW ACTIVITY AND ACETYLCHOLINE UTILIZATION. C.N. Allen and I.L. Crawford. Depts Pharmacology and Neurology, VA Med. Ctr. and Univ. Texas Hlth. Sci. Ctr. at Dallas, Tx. 75216.

Neurophysiological experiments suggest gamma-aminobutyric acid (GABA) is an important neurotransmitter in the medial and lateral septum. Septal GABA may be part of the phasing mechanism necessary for generation of atropine sensitive hippocampal rhythmic slow activity (RSA). Electrophysiological studies were designed to test the hypothesis that GABA in the medial septum may contribute to hippocampal rhythmic slow activity generation. Neurochemical experiments were designed to determine if GABA affected the activity of septo-hippocampal cholinergic neurons.

Rats (300 ± 25 gm) were implanted with an indwelling cannula directed at the medial septum, other rats also had bilateral intraventricular polyethylene cannulae. For physiological recording bipolar electrodes were positioned on the surface of the hippocampus, bilaterally. Animals were allowed to recover three days for neurochemical experiments and ten days for electrophysiological studies. Electrical activity recorded from awake unanesthetized rats was amplified and analyzed by a time histogram computer. For neurochemical assessment of cholinergic neuronal activity muscimol (100 ng), bicuculline (3 ng) or saline (all in 0.9% saline 0.5 µl) were injected into the medial septum; hemicholinum-3 (HC-3, 5 µg) was injected into each lateral ventricle 30 min prior to sacrifice by microwave irradiation focused on the head. Acetylcholine (Ach) in discrete brain regions was extracted in formic acid/acetone then assayed radiochemically.

Muscimol reduced (41%) the incidence of 5.9-9.1 Hz electrical activity recorded from the hippocampal surface. This decrease lasted 90 min and was antagonized by prior injection of bicuculline. Intraventricularly injected muscimol (100 ng/10 µl) had no effect on hippocampal RSA. Intraseptal saline injection was also without effect. These observations provide evidence of a direct septal gabaminergic influence on hippocampal RSA. Twenty minutes after muscimol (100 ng) intraseptally ACh levels increased (8.2 ± 2.4 to 17.3 ± 5.2 mmol/g wet wt ± S.D.) in the hippocampus, indicating a decreased utilization. Bicuculline antagonized this effect and saline was without action. These data suggest a correlation between GABA inhibition of hippocampal rhythmic slow activity and a decrease in hippocampal cholinergic neural activity.

166.1 PASSIVE ELECTRICAL CONSTANTS IN THREE CLASSES OF HIPPOCAMPAL NEURONS. Thomas H. Brown, Russell A. Fricke and Donald H. Perkel. Div. of Neurosciences, City of Hope Research Institute, Duarte, CA 91010, Dept. of Anatomy, Emory University Medical School, Atlanta, GA 30322 and Dept. of Biological Sciences, Stanford University, Stanford, CA 94305.

The hippocampus contains several spatially segregated classes of morphologically distinct neurons. Using the guinea pig in vitro slice preparation, we have examined the passive electrical constants of three classes of cells: pyramidal neurons of regions CA3 and CA1 and granule cells of the dentate gyrus.

Hyperpolarizing constant current steps were injected into the cell soma and the transient and steady-state current-voltage(I-V) relationships were analyzed. There was usually a linear range in the I-V curves between the resting potential and more hyperpolarized potentials. The electrical constants were analyzed within this linear range. The input resistance (R_N) was determined from the slope of the I-V curve and the membrane time constant (τ_0)was obtained by fitting the terminal portion of the charging curve with an exponential function. The slope of the charging curve was measured and analyzed to estimate two cable-theory parameters of the neurons, based on a simple Rall model: the electrotonic length (L) of the equivalent dendritic cylinder and the conductance ratio (ρ) of the dendrites to that of the soma. Three methods (see Brown, et al. J. Neurophysiol. 45, 1-15, 1981) were used to estimate L and ρ. The four electrical constants, R_N,τ_0, L and ρ were then used in an eigenfunction expansion to generate the theoretical charging curves of the Rall model.

The experimentally derived charging functions were accurately predicted by the Rall model we used, while certain alternative models were unable to account for the data. Mean ($\pm$ S.E.) values for the four electrical constants are summarized below. There were statistically significant differences in the τ_0 values for the three classes of cells, suggesting proportionate differences in the specific membrane resistivity. We conclude that hippocampal neurons are electrically compact,and that the passive membrane constants differ markedly from those of the more extensively studied spinal motor neurons. (Supported by a McKnight Foundation Scholars Award & NIH grants NS-16576, NS-09744 & NS-12151).

Electrical Parameter	CA3 Pyramid (N = 8)	CA1 Pyramid (N = 12)	Granule Cell (N = 10)	Overall (N = 30)
R_N (MΩ)	39.0 ± 3.6	42.6 ± 3.6	38.4 ± 3.0	40.2 ± 1.9
τ_0 (msec)	19.3 ± 1.8	15.2 ± 1.2	11.6 ± 1.5	15.1 ± 1.0
L	0.93 ± 0.09	0.90 ± 0.08	0.94 ± 0.08	0.92 ± 0.05
ρ	1.2 ± 0.4	1.3 ± 0.2	1.5 ± 0.2	1.4 ± 0.1

166.2 ELECTROPHYSIOLOGICAL CHARACTERIZATION OF REMOTE CHEMICAL SYNAPSES. N.T.Carnevale and D.Johnston. Neurology Division, VAMC, Northport, N.Y.; Neurology Department, HSC T12 Rm020, SUNY, Stony Brook, N.Y. 11794; and Neurology Department, Baylor College of Medicine, Houston, Texas.

We present a new approach to the analysis of linear electrotonus, which yields practical methods for estimating the coupling between an intracellular recording site and the locus of synaptic input. This approach is free of those preconditions which limit the applicability of previous methods based on continuous cable or compartmental models, viz.: detailed knowledge of neuronal geometry or assumption of an idealized branching pattern; spatial uniformity of the electrical properties of axoplasm and cell membrane; restriction to synaptic inputs with brief time course. We require only that: membrane current depends linearly on membrane potential; the experimenter be able to elicit a pure epsp or ipsp; membrane potential can be recorded while current is injected; and, for some measurements, that the composition of the extracellular fluid can be altered.

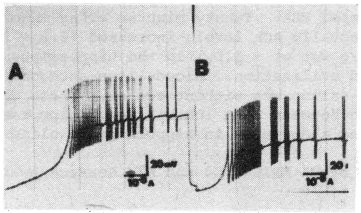
The neuron is depicted as a linear two-port network, with the location of synaptic input at one port and the site of the recording electrode (for convenience called the soma) at the other. Measurements of current, charge and potential fluctuations at the soma are related to current flow, charge entry and potential fluctuations at the synaptic region by two coupling coefficients. The first, k_{12}, defines: the steady state voltage decay from soma to synapse; charge transfer from synapse to soma; and the steady current decay from synapse to soma when the soma is voltage clamped. It can be determined empirically by measuring the change in reversal potential as a function of ionic composition of the extracellular medium. The second coefficient, k_{21}, defines: the steady state voltage decay from synapse to soma; and the charge transfer and current decay from soma to synapse. It can be estimated by driving the synaptic input to summation and measuring the potential change at the soma. A third coefficient, k^2, provides a lower estimate of the first two. It can be determined by measuring the change of synaptic potential or current amplitude as a function of membrane potential at the soma.

Our conclusions will be compared with the results of previous treatments of linear electrotonus. Typical values of these coupling coefficients will be provided, based on anatomical and electrophysiological data.

166.3 RESPONSES OF THE HYPOXIC RESISTANT APLYSIA R_{15} NEURON TO TTX, SUBSTITUTION OF EXTERNAL Ba^{2+} FOR Ca^{2+}, AND LOW PO_2's. P.E. Coyer. Lab. of Neurophysiology and Cerebrovascular Research, Dept. of Neurology and the Neurosciences Program, Univ. of Alabama in Birmingham, The Medical Center, Birmingham, AL 35294.

Using voltage-current records obtained from the neuron R_{15}, the effects of low oxygen (measured as a PO_2 of $<$ 20 torr in the suffusate) on its membrane potential and slope resistance were tested. R_{15} responded to hypoxia by increasing its membrane resistance in the non-linear portion of the anomalously-rectifying, voltage-current curves while undergoing a concomitant hyperpolarization. Figures A & B below show the effects of hypoxia (B) compared to normoxia (A).

The effects of hypoxia on R_{15} were reversible (not shown) as indicated by a return to a similar anomalously-rectifying, voltage-current curve following reoxygenation of the bath as shown in A. It can be inferred from these voltage-current records that during TTX (10^{-4}M) and Ba^{2+} (10mM) administration the events leading to an increase in the membrane slope resistance were associated with the IK(Ca) current. In other words, hypoxia may have increased the amount of inward calcium current leading to inactivation and hyperpolarization resulting from an increase in gK. Unless the membrane conductance changes were effected by a TTX-insensitive Na channel, the observations of an increased membrane slope resistance with hypoxia were present during TTX administration, a procedure which blocked spike generation but which had no effect on the voltage-current record. Substitution of Ba^{2+} for Ca^{2+}, a procedure which is known to partially block IK(Ca), produced a more linear voltage-current curve in the depolarizing direction and seemed to cause changes in the observations of R_{15}'s membrane potential and slope resistance during exposure to hypoxia. The effects of Ba^{2+} substitution on the voltage-current curves before, during, and after hypoxia are being investigated in R_{15}. Supported in part by NINCDS NS 08802 and NS 07123.



166.4 ACTIVE AND PASSIVE MEMBRANE PROPERTIES OF ISOLATED HORIZONTAL CELLS FROM THE CATFISH RETINA. Dominic Man-Kit Lam and Daniel Johnston, Neuroscience Program, Baylor College of Medicine. Houston, TX 77030

Horizontal cells in the intact retina are interconnected through a complex network of chemical and electrical synapses. The electrotonic interactions between horizontal cells make it difficult to determine the active and passive membrane properties of individual cells. In general, recordings from horizontal cells in situ have indicated extremely low input resistances and primarily passive membrane responses to current injection or light. In an attempt to investigate the active and passive membrane properties of horizontal cells, we have dissociated catfish retinae and recorded from identified isolated cone horizontal cells.

Retinae were dissociated using previously described techniques (Lam, Nature 69: 1987, 1975). Intracellular recordings were made with 30-50 megohms KCl-filled micropipettes and a 3-kHz time-share single-electrode clamp system (Johnston, Cell. Molec. Neurobiol. 1: 41, 1981). Each cell was photographed prior to recording.

Depolarizing and hyperpolarizing current pulses revealed nonlinearities in the steady-state voltage-current (V-I) relationships of most cells. The nonlinearities probably represent delayed and anomalous rectification as described in other types of neurons. Furthermore, depolarizing current pulses revealed a regenerative voltage response as defined by an increasing positive slope in the membrane potential transient. This regenerative voltage response was TTX insensitive, blocked by 10 mM Mn, Co or Ni and, therefore, is most likely calcium dependent. In order to determine the specific membrane properties of these cells, the surface area of each cell was measured from an enlarged image. The input resistance was determined from the slope of the V-I plot, and the membrane time constant calculated from small depolarizing and hyperpolarizing voltage transients. Only the cells meeting the criteria for isopotentiality were used in the analysis. For seven cells the average input resistance was 164 megohms, the average membrane resistivity ranged from about 5000-20,000 ohm-cm^2 (mean of 13,500 ohm-cm^2) and the average membrane capacity was 1.3 ± 0.3 microfarads/cm^2.

It is concluded that with the exception of an apparent lack of TTX sensitive sodium channels, the active and passive membrane properties of cone horizontal cells appear similar to those described in a variety of other neurons. {Supported by NIH grants 15772, 11535 (DJ) and EY02423 (DMKL).}

166.5 POTENTIAL DEPENDENT TRANSPORT PROCESSES IN ISOLATED RETINAL NEURONS. George S. Ayoub and Dominic Man-Kit Lam, Baylor College of Medicine, Houston, Texas 77030.

In the goldfish and catfish retinas, H1 horizontal cells which receive input predominantly from red sensitive cones, possess a high-affinity uptake system for γ-aminobutyric acid (GABA) with a K_m of about 20 μM. Lam and Steinman (PNAS 68:2777) have shown that accumulation of GABA by these neurons is enhanced by light stimulation of the retina. The cellular mechanisms controlling this stimulation-dependent process were examined by dissociating fish retinas into single cells and obtaining a fraction enriched with horizontal cell somas and axons that contain few or no synaptic endings (Lam, Nature 254:345). These cells were collected on transparent Nuclepore filters (3 μm pore size) and incubated in Ringer's solution containing radiolabeled GABA. The filters were then washed, dried, and the radioactivity measured with liquid scintillation counting. As reported earlier (Ayoub and Lam, Soc. of Neurosci. Abst. 6:54), the GABA transport mechanism remain active in these isolated horizontal cell somas. Depolarization of these cells with the Na^+ ionophore, monensin, results in a decreased accumulation of GABA, which is dependent upon the monensin concentration. To study the dependence of this GABA transport mechanism upon the membrane potential of these neurons, the permeant lipophilic cation, tetraphenylphosphonium (TPP), was employed. This ion distributes itself across the plasma membrane according to the transmembrane potential of the cell, allowing a measurement of the membrane potential of a population of cells. Using ^{3}H-TPP and ^{14}C-GABA, we were able to simultaneously determine the membrane potential and rate of GABA uptake in the same horizontal cells. The resting potentials of -70 to -90mV observed agree with intracellular recordings of these cells (Johnston and Lam, Soc. of Neurosci. Abst., 1981). The data from this double label experiment imply that GABA uptake is likely dependent upon the membrane potential of the horizontal cells in an exponetial fashion. Kinetic analysis of this transport process under hyperpolarizing and depolarizing conditions has been correlated with the rate of uptake in these states, and found to be consistent with the hypothesis that GABA uptake into somas of H1 horizontal cells increases with hyperpolarizing and decreases with depolarization. This work was supported by NIH grant EY02423 and the Retina Research Foundation (Houston).

166.6 INTERPRETATION OF VOLTAGE-CLAMP MEASUREMENTS IN HIPPOCAMPAL NEURONS. Daniel Johnston and Thomas H. Brown. Dept. of Neurology, Baylor College of Medicine, Houston, TX 77030 and Div. of Neurosciences, City of Hope Research Institute, Duarte, CA 91010

Recently it has become possible to apply voltage-clamp techniques to pyramidal neurons from in vitro hippocampal slices (Johnston, et al, Nature, 286, 1980; Johnston and Brown, Science 211, 1981), an achievement of potential importance in aiding our understanding of the synaptic physiology and active membrane properties of these cells. However, to interpret properly the voltage-clamp measurements, it is necessary to assess the influence of nonisopotentialities within the neuron on the measured current amplitude and time course. Using experimental data combined with analog simulations, we have addressed this problem for hippocampal CA3 pyramidal neurons. We were particularly interested in the mossy fiber synaptic input, which is known to be anatomically proximal to the cell soma.

We constructed an analog neuronal model consisting of nine compartments, where compartment 1 represents the cell soma and compartments 2 through 9 represent the equivalent dendritic cylinder. The values for the parallel resistor and capacitor of each compartment and for the coupling resistor between adjacent compartments were selected (Brown, et al, J. Neurophysiol. 45, 1981) so as to mimic the typical passive membrane properties and electrotonic structure of CA3 pyramidal cells (Johnston, Cell. Molec. Neurobiol. 1, 1981; Brown, et al, Neurosci. Abstr. 7, 1981). A conductance mechanism, consisting of a battery in series with an electronically-controlled variable resistance, was placed in parallel with one of the nine compartments. Two types of conductance changes were introduced into the various compartments--one was sinusoidal and the other mimicked a synaptic event. A voltage clamp was applied to the soma compartment, using a standard 30 MΩ microelectrode and a single-electrode clamp system (550 Hz frequency response). We devised several criteria for assessing the adequacy of the voltage clamp as a joint function of the frequency or waveform of the conductance change and the compartment in which it occurred.

The measurement errors associated with the various conductance changes in each of the compartments will be described. For sinusoidal conductance changes between 10 and 400 Hz and for synaptic events with realistic conductance waveforms, we find that adequate voltage-clamp measurements can be made only in compartments 1 and 2. By comparing experimental data for the mossy fiber synaptic current waveform with the results of our simulations, we can conclude that the mossy fiber synaptic input is located no farther from the cell soma than compartment 2. This particular synaptic input is therefore suitable for voltage-clamp analysis. (NS11535, NS15772, NS16576 and a McKnight Scholar's Award)

166.7 THE IMPLICATION OF THE SURFACE NEGATIVE WAVE OF CEREBRAL CORTEX EVOKED BY THE ANTIDROMIC ACTIVATION OF THE BETZ CELL. S.F. Fan* and S.L. Hu*(SPON: R.G. Butler). Shanghai Institute of Physiology, Academia Sinica, Shanghai, China.

In the previous work we have found that the cortical responses of Betz cell to the antidromic stimulation of the pyramidal tracts in medulla contains a clear surface negative component of short latency with no sign of postsynaptic activities. As judged from other criteria, however, the impulse does not travel upward to the terminal portion of the apical dendrite. Thus it seems to exist an obvious contradiction, since it is commonly held that when an impulse ceases to conduct further somewhere along the nerve tissue placed in a volume conductor, the segment further on would only serve as a current source and around which only a positive potential change could be recorded. The results presented in this paper, both from the qualitative calculation according to the volume conductor theory and from the model experiment done with peripheral nerve show that, if the membrane properties of the segment which the impulse has not invaded are somewhat different from those of the segment which the impulse has just passed through, either the membrane potential of the former is lower and/or the membrane resistivity is higher, a negative potential change could be recorded around the inactivated segment. Therefore, it is likely that the terminal portion of the apical dendrite must possess lower membrane potential and/or higher membrane resistivity as compared with the soma and the basal portion of the apical dendrite.

166.8 INTRACELLULAR IMPEDANCE ANALYSIS INDICATES RELATIVE PROXIMITY OF MEMBRANE CONDUCTANCE CHANGES. S.E. Fox and C.Y. Chan*, Dept. of Physiology and Dept. of Anatomy and Cell Biology, Downstate Medical Center, SUNY, Brooklyn, N.Y. 11203.

In identifying the synapses responsible for an event in neurons whose various afferents occupy distinct proximal/distal zones it is valuable to locate zones of changing conductance. Using cable equations, we modelled neurons to predict impedance as measured by sinusoidal current injected into the soma. The model showed that distal changes in conductance have a much smaller effect on impedance (as seen from the soma) at high frequency than do proximal changes, given the same change in impedance at low frequency (cf. fig.). This effect is due to capacitive shunting of high frequencies in the proximal region so that little current reaches the distal cellular zones.

The results from the mathematical model were verified both with an RC circuit model of a neuron and in spinal neurons in vitro. A single electrode bridge amplifier was modified to pass sinusoidal current at up to 400 Hz through electrodes of up to 100MΩ while faithfully recording the voltage drop across the cell. Measurements on the RC circuit agreed with the mathematical model. The somata of embryonic chick spinal neurons in culture were impaled with K-acetate-filled micropipets (40-80MΩ). Sinusoidal currents (0.1 to 1.0 nA p-p) were passed while recording the membrane potential. Iontophoretic application of GABA (75 to 750 nA, 200 to 700 msec) produced localized conductance increases, either on the soma or up to 200 μm out on the neurites. The figure shows the effect of GABA applied to the soma (proximal) or 50 μm out on a neurite (distal) for a cell which was typical of the six cells tested. The change in the magnitude of the impedance as a percentage of the change for DC (100 msec pulses) is plotted for the four frequencies tested, dropping more abruptly for distal conductance changes. Another fascinating effect which was also predicted by the models is the apparent increase in impedance at high frequency (arrow) with increased conductance in the distal processes. 166.9 ELECTROTONIC STRUCTURE OF THE RAT SYMPATHETIC POSTGANGLIONIC NEURONS. Barbara K. Henon, Thomas H. Brown and Donald A. McAfee, Div. of Neurosciences, City of Hope Research Institute, Duarte, CA. 91010.

The superior cervical sympathetic ganglion is often used *in vitro* as a model system for chemical synaptic transmission. We have evaluated the passive electrical constants of the postganglionic neuron in order to estimate their influence on measurements of synaptic transmission and integration.

Single microelectrode techniques were used for bridge-balanced voltage measurements of randomly selected postganglionic neurons. We measured the magnitude and time course of the voltage change across the cell membrane in response to a hyperpolarizing current step. Thus we were able to compute the input resistance R_N and the passive electrical constants described below. Within 2 ms after the onset of the current step, the voltage changed as a single exponential function and was subjected to regression analysis to determine the membrane time constant τ_0 and its coefficient C_0. In 9 of 12 cells studied the charging curves deviated from the extrapolated regression line during the first 1 or 2 ms. This deviation was peeled and fit by a second exponential function to give the first equalizing time constant τ_1 and its coefficient C_1. The time constants and their coefficients were used to estimate two cable theory parameters of the neuron based on a simple Rall model: L, the electrotonic length of the equivalent dendritic cylinder and ρ, the conductance ratio of the dendrites to that of the soma (Brown et al., J. Neurophysiol. 45:1-15, 1981). The constants R_N, τ_0, L and ρ were used in an eigenfunction expansion to generate the theoretical charging curves of the Rall model.

There was precise agreement between the actual data points and the theoretically derived charging functions. In spite of the substantial dendritic conductance indicated by our values for ρ, the value of L is relatively small and we conclude that the sympathetic neuron is electrotonically even shorter than either the hippocampal or spinal motor neurons. 167.1 ABSENCE OF ELECTRICAL COUPLING IN DYE-COUPLED PYRAMIDAL CELLS IN THE CA1 REGION OF GUINEA PIG HIPPOCAMPUS. Paul G. Funch, W. Douglas Knowles and Philip A. Schwartzkroin, Dept. of Neurological Surgery, University of Washington, Seattle, WA.

One proposed substrate for the synchronization of hippocampal neuronal activity is direct electrical connections between pyramidal cells (PCs) via gap junctions. Others have recently used dye-coupling as evidence supporting the existence of electrical coupling in mammalian neocortex, hypothalamus, and the CA3 region of the hippocampus. We have found no evidence for electrical coupling in the CA1 region using two electrophysiological methods: 1) with simultaneous intracellular recordings from PC pairs, subthreshold current injection through one microelectrode never produced a membrane potential change measurable with the second (except when the two electrodes were in the same PC); 2) antidromic stimulation rarely activated short latency depolarizations (SLDs), and in no case were the SLDs resistant to collision with action potentials elicited by brief intracellular current injections. Nevertheless, intracellular injections of Lucifer Yellow (LY) into single CA1 PC somas usually resulted in the staining of 2 to 4 PCs. In contrast, intradendritic injections of LY rarely resulted in the staining of more than a single PC. We thus conclude that dye-coupling can artifactually overestimate the extent of electrical coupling between neurons.

167.2 DYE-COUPLING BETWEEN CA1 PYRAMIDAL CELLS IN RAT HIPPOCAMPAL SLICES. R. D. Andrew, C. P. Taylor*, R. W. Snow, and F. E. Dudek. Dept. of Physiol., Tulane Univ. Sch. of Med., New Orleans, LA 70112.

Several lines of evidence indicate that some hippocampal neurons are electrotonically coupled. In the present studies 3% Lucifer Yellow (LY), a fluorescent dye known to cross gap junctions between electrotonically coupled cells, was injected (1-3 nA hyperpolarizing current) into CA1 pyramidal cells to determine whether these neurons are dye-coupled.

In transverse slices of rat hippocampus, multiple staining of CA1 cells was observed in approximately 45% of the cases (n = 11) after dye was injected intracellularly into single cells which had action potentials $\geq$ 50 mV throughout the injection. Using the same procedures, multiple staining was never observed in neurons of sliced superior cervical ganglia (n = 11). Dye-coupling was also present in saline with 4-8 mM Mn^{2+} and 0.05-0.5 mM Ca^{2+}. Field potentials were monitored to confirm that chemical transmission was blocked. This indicates that dye transfer is not mediated by chemical synapses and strongly supports the hypothesis that dye-coupling in CA1 cells results from LY transfer directly between neurons rather than indirectly through an extracellular route.

Diffusion of LY from thin-walled micropipette tips could occasionally stain CA1 cells, even during a brief impalement. Such staining was rare and faint, but potentially could lead to an overestimation of the number of dye-coupled cells. Experiments are in progress to evaluate which factors contribute to this problem, and these results will be discussed.

Maximum separation between dye-coupled cells in transverse and longitudinal directions was measured to evaluate whether a specific orientation exists for dye-coupling within the CA1 area. Somata of coupled cells ($\sim$8 x 10 µm) were within 35 µm of each other (not corrected for shrinkage during fixation). No preferential orientation of coupling was detected.

Intracellular recordings were analyzed to determine whether the presence of fast prepotentials (FPPs) was correlated with dye-coupling. Although FPPs occurred spontaneously or to orthodromic stimulation in dye-coupled cells, they were also observed in brightly stained cells with no dye-coupling. Therefore, either some electrotonically coupled pyramidal cells are not dye-coupled, or some FPPs are not coupling potentials.

167.3 PHYSIOLOGICAL EVIDENCE FOR ELECTROTONIC COUPLING BETWEEN CA1 PYRAMIDAL CELLS IN RAT HIPPOCAMPAL SLICES. C. P. Taylor* and F. E. Dudek. Dept. of Physiol., Tulane Univ. Sch. of Med., New Orleans, LA 70112.

The hippocampus is well-known for its susceptibility to seizures and synchronous afterdischarge. Physiological and anatomical evidence indicates that some hippocampal neurons are electrotonically coupled, which hypothetically could mediate synchronization of epileptiform events. Antidromic stimulation was used to determine whether some CA1 pyramidal cells are electrotonically coupled.

Transverse slices of rat hippocampus were prepared by conventional techniques. Chemical synaptic transmission was blocked with saline containing 4-8 mM Mn^{2+} and 0.05 - 0.5 mM Ca^{2+}, which completely eliminated orthodromic field potentials.

In two intracellular recordings out of 28, antidromic stimulation revealed short latency depolarizations (SLDs) which were clearly resistant to collision by action potentials evoked with current injection through the intracellular electrode. For the SLDs in these two cells the latency from the antidromic soma spike (87 and 75 mV) was 250 and < 100 µsec, and amplitude was 8.7 and 11 mV. Smaller SLDs were observed during these experiments, but could not be analyzed reliably on the falling phase of the current-evoked spike. Possible reasons for the low percentage of cells exhibiting SLDs will be discussed. Because SLDs were resistant to Mn^{2+} and collision, they were most likely electrotonic coupling potentials from spikes in other pyramidal cells.

After prolonged incubation (1-4 hr) in a solution containing 0.5 mM Ca^{2+} and 8 mM Mn^{2+}, intense stimulation of the alveus not only evoked an antidromic population spike, but also large synchronous afterdischarges of up to 30 spikes lasting up to 650 msec. Occasionally additional population bursts occurred for up to 10 sec after the stimulus. Both intracellular and extracellular recordings during stimulation of the alveus and stratum radiatum confirmed that chemical synaptic transmission was still blocked. Simultaneous intracellular and extracellular recordings during the afterdischarges occasionally revealed subthreshold depolarizations which were similar in waveform to SLDs (above) and were also synchronous with extracellular population spikes. Therefore, synchronous afterdischarges can be evoked when Ca^{2+} influx and chemical synaptic transmission are blocked with Mn^{2+}. These results provide evidence supporting the hypothesis that electrotonic coupling in the hippocampus, independent of any chemical synaptic interaction, mediates synchrony during epileptiform activity.

167.4 FORMATION OF ELECTRICAL COUPLING BETWEEN XENOPUS EMBRYONIC MUSCLE CELLS IN CULTURE. I.Chow*, M.H.Chow* and M-m.Poo. Dept. of Physiology and Biophysics, Univ. of California, Irvine, CA 92717.

Low resistance pathways, detectable by electrophysiological methods, are known to be present in a variety of embryonic systems. They are generally accepted to be associated with gap junctions and have been shown to disappear at later stages of development. However, it is unclear how the cells regulate this capability for electrical coupling throughout development. The present study has investigated the mechanisms involved in the decrease of coupling with age in Xenopus embryonic muscle cells in culture. Our findings suggest that such decrease is mediated by extramembranous factors, since high coupling capability can be restored in older cells after treatment with colchicine and Ca^{++}-Mg^{++}- free medium (CMF).

Cultured Xenopus myotomal cells were manipulated into contact 12 to 72 hours after plating. After various contact intervals, electrotonic propagation of acetylcholine-induced depolarizations between the cells were recorded and the coupling ratios were determined. The results show that cells less than 24-h old in culture established measurable coupling within 30 min of contact (95% of the recorded cell pairs). The percentage of electrically coupled pairs decreased with culture age, so that by 24-36 hours 83% of the pairs were coupled. Cells older than 36 h did not establish coupling within the first half-hour of contact;however, the 2-day old cells were capable of establishing electrical coupling if left in contact for longer periods and by 2 h about half of the cell pairs were found to be coupled.

Pretreatment of 2-day old cells with colchicine (1 h), known to disrupt microtubules, and with CMF (0.5 h), which removes cell coat material, induced the onset of electrical coupling at least one-half hour earlier than in control cells. After 30 min of contact about 80% and 25% of the cell pairs pretreated with colchicine and CMF, respectively, had detectable coupling, whereas the controls were not coupled. The average coupling ratio of the pretreated cells was also higher than the control values. One and one-half hours after contact, the colchicine pretreated cells had an average coupling ratio twice that of the control pairs, and the CMF pretreated pairs had a value three times as large as the controls.

This recovery of coupling capability suggests that the decreased extent of coupling found in 2-day old cultured cells is not due to alterations in the intrinsic plasma membrane components, e. g. a loss of precursor molecules for the formation of intercellular channels.

168 SYMPOSIUM

Cytoskeletal Determinants of Neuronal Form and Function. R.J. Lasek (Chairman, CWRU) S.L. Palay (Harvard), M.L. Shelanski (NYU), F. Solomon (MIT), R.L. Gulley (NIH).

The functional properties of a neuron are determined in great part by its general shape and by its structural details such as the presence and location of dendritic spines. What is the structural basis of the varied forms which neurons express? How can these forms be stable and yet undergo the changes which contribute to the plasticity of the nervous system? Answers to these questions and others are beginning to emerge from the study of cytoskeletons. Although most of the progress in the study of cytoskeletons has occured within the realm of cell biology, the time is ripe for this information to be integrated into neurobiology (see Lasek and Shelanski et al., Neurosci. Res. Prog. Bull. 19:1-153, 1981). The purpose of this symposium is to provide an introduction to the structural and biochemical properties of the cytoskeletal elements. The speakers will attempt to relate the cytoskeleton to the dynamic events that occur during the development of the nervous system and in specialized regions such as the synapse.

The symposium begins with Sanford L. Palay who will provide a contemporary picture of cytoskeletons in the nervous system. Our image of the cytoskeleton is a product of both the most recent electron microscopic observations as well as the classical metallic stains that depict the cytoskeleton in the light microscope. Michael L. Shelanski follows with a brief review of the molecular properties of microtubules, intermediate filaments and microfilaments. In addition he will explore the molecular interactions between these polymers and their possible roles in the integral properties of the cytoskeleton. Frank Solomon will describe his studies on intracellular determinants of cell shape. More specifically, he will explore the possibility that cytoskeletal organizing centers convey structural information from one cell generation to another and that this information can influence the shape of the progeny. Raymond J. Lasek will discuss environmental factors that may influence the axonal cytoskeleton as it moves from the cell body to the axon terminal. The final speaker, Robert L. Gulley, will analyze the recent advances in our understanding of the structure of the synapse. Emphasis will be placed on the relationship between the cytoskeleton and the plasma membrane, particularly at the synaptic junction. The presentations will be followed by an open discussion.

169 SYMPOSIUM

PARALLEL AND SERIAL PROCESSING IN VERTEBRATE VISUAL PATHWAYS. C. Enroth-Cugell (Chairman; Northwestern Univ.), R.M. Shapley* Rockefeller Univ., R.W. Rodieck, (Univ. of Washington), P. Lennie* (Univ. of Sussex, England).

In the last century, Ramon y Cajal demonstrated that the retinas in every vertebrate class contain a variety of different morphological types of ganglion cells. Recent concurrent developments in physiology and anatomy have clarified the different ganglion cell types in certain species, with regard to function, morphology and central projection. These findings point to the importance of parallel processing in the visual pathway.

R.W. Rodieck will describe the different morphological and functional types of ganglion cells that have been identified in the cat and monkey, and will trace their central destinations.

R.M. Shapley will then describe the receptive field mechanisms that characterize specific ganglion cell classes and the cells upon which they terminate in the lateral geniculate nucleus. The development of our understanding of these mechanisms has been an outgrowth of our recently increased knowledge of the physiological heterogeneity of ganglion cells.

Finally, P. Lennie will discuss possible visual roles of the physiologically distinct classes of cell. Although some psychophysical observations on man, (e.g. distinct thresholds for perceiving patterns and movement) have been thought to reveal characteristic properties of two of the major physiological classes, recent physiological observations in cat and monkey make such simple ideas less attractive.

170 WORKSHOP

THE GROWING RELEVANCE OF GAP JUNCTIONS AND ELECTROTONIC SYNAPSES TO NEUROBIOLOGY. M.V.L. Bennett (Chairman, Albert Einstein Col. of Med.), D.C. Spray (Albert Einstein Col. of Med.), R. Weingart (Univ. Bern), R.B. Hanna and T.S. Reese (SUNY Syracuse and NINCDS) J.A. Raper and C.S. Goodman (Stanford), F.E. Dudek (Tulane).

This workshop was inspired by new developments with respect to electrotonic synapses and their morphological substrate, gap junctions. 1)Junctional conductance in embryonic tissues can be readily and reversibly altered by a number of experimental manipulations. Increase in cytoplasmic H ion concentration to 0.1 μM strongly depresses conductance; much higher concentrations of Ca ion (c.1 mM) are required to produce the same effect. Thus, H ion is a more likely candidate for physiological control. Effects of other agents suggest the existance of at least two gating mechanisms. A specific junctional blocker is not yet available, but diversity of mechanisms of block may allow separation of actions on junctions from those on other cell properties. 2)Junctions in cardiac muscle exhibit a similar sensitivity to cytoplasmic H ion, and action of H ion is not mediated through Ca ion. Normal intracellular pH can reside at an intermediate point where junctional conductance can be modulated up or down by pH changes. Thus, junctional conductance provides a logical site for pharmacological and physiological actions on cardiac function. 3)High resolution techniques for freeze fracture reveal new aspects of junctional structure. The hypothesized intercytoplasmic channel and the oligomeric nature of the intramembrane particle are apparently resolved. Decreasing junctional conductance by cytoplasmic acidification produces a small change in particle structure, but no immediate change in particle spacing. 4)During neurogenesis in the grasshopper dye coupling can be transient and exhibit a high degree of spatial as well as temporal specificity. Precise mechanisms for formation and removal of junctions are presumably involved. The specificity suggests a possible role in information transfer underlying determination of cell type and navigation by growing fibers. 5)Electrotonic synapses defined by electrotonic coupling, dye coupling, and presence of gap junctions are being found in new regions of the mammalian central nervous system. Some of these synapses may synchronize neuronal firing and lead to rhythmic activity or mass release of neurohormone. The pathological synchrony of epilepsy may also be mediated by electrotonic synapses.

171.1 THE RELATIVE CONTRIBUTIONS OF CORTICAL SITE AND SIDE IN THE CONTROL OF PRAXIC AND SPATIAL BEHAVIOR. B. Kolb, R. J. Sutherland, and I. Q. Whishaw. Department of Psychology, Univ. of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4.

Studies of the localization of function in the cortex have shown that both the site as well as the side of damage are important in understanding the neural control of complex motor (praxic) and spatial behavior of humans. The frontal and parietal lobes appear to participate in certain aspects of these behaviors and may do so differently in the two hemispheres. In the present study we compared the relative contributions of cortical site (frontal vs. parietal) and side (left vs. right) in the performance of spatial and complex motor tasks by rats.

In the first experiment, rats with bilateral aspiration lesions of the medial frontal cortex, orbital frontal (sulcal) cortex, parietal cortex, or all of the neocortex (decorticate) were tested on three spatial tasks (Morris water maze, radial arm maze, Grice box) and four tasks requiring complex motor movements including: 1) opening puzzle latches, 2) traversing a narrow beam, 3) grooming, and 4) food hoarding. The results showed that the frontal and parietal cortex both participate in spatial and praxic behaviors but they do so in different ways. On the spatial tasks sulcal lesions impaired performance of the water maze and Grice box but not the radial arm maze; medial frontal lesions impaired performance of the water maze but not the other two mazes; and parietal lesions impaired performance of the radial arm maze and Grice box but not the water maze. Decortication impaired performance on all the mazes. Sulcal lesions had little effect on the motor tests whereas medial frontal lesions impaired the opening of latches and abolished food hoarding. Parietal lesions produced a mild deficit on the puzzles and a severe deficit on the beam. Decortication severely impaired all four motor tasks.

In the second series of experiments, rats with large unilateral lesions of the left or right frontal cortex or total unilateral removal of the left or right hemisphere were tested in the same spatial tasks as above, and similar rats will be tested on the motor tests. To date, the results show that removal of the left hemisphere produces a more severe deficit in acquisition of the water maze than a similar removal of the right hemisphere.

The data show that the cortical control of spatial and praxic behaviors can be dissociated in the rat and that both the site and side of lesion are important in understanding the neural control of praxic and spatial behavior in the rat.

171.2 POSTURAL ASYMMETRY IN THE NEWBORN WISTAR RAT AND IMPLICATIONS FOR BRAIN LATERALITY. G.D. Rosen*, M. Hofmann*, J. Stockler*, J.S. Gall*, D.A. Yutzey*, and V.H. Denenberg. Dept. Biobehav. Sci., Univ. Connecticut, Storrs, CT 06268.

Newborn female Sprague-Dawley rats have a rightward population asymmetry in tail position that is also a reliable predictor of later rotational asymmetry (Ross, Glick, and Meibach, Neurosci. Abs., 1980). Male pups had a non-significant bias toward the left. Other work has demonstrated a rightward bias among adult females in a rotometer as well as a two-lever operant conditioning apparatus (Glick and Ross, Dev. Br. Res., in press). Conversely, Purdue-Wistar rats from our colony have shown a leftward turning preference in the open field (Sherman et al., Br. Res., 192, 1980). If the findings of Ross et al. can be generalized to other rat strains, the prediction is that Wistar rats would exhibit a left tail bias in infancy.

Our results are summarized in Table 1. Significantly more pups exhibited a leftward tail posture in both males and females. In addition, females are more biased in the leftward direction than the males. There are also significantly more males than females who show a neutral tail position.

Thus, the differences between our results and those of Glick's group appears to be due to strain differences in postural asymmetry and consequent spatial bias, with the Wistar rat asymmetrical to the left while the Sprague-Dawley is rightward biased.

TABLE 1

Direction of Postural Asymmetry
(percentages in parenthesis)

	LEFT	NEUTRAL	RIGHT
MALES	445 (50.6)	102 (11.6)	302 (38.8)
FEMALES	473 (57.5)	58 (7.1)	291 (35.4)

171.3 EXPERIENCE INDUCED ASYMMETRIES AFFECT THE RETENTION OF A TASTE AVERSION IN RATS. M. Hofmann*, J.A. Garbanati*, G.F. Sherman*, G.D. Rosen*, D.A. Yutzey*, and V.H. Denenberg (SPON: E.B. Thoman) Dept. Biobehav. Sci., Univ. Connecticut, Storrs, CT 06268.

Previous research has found that stimulation in infancy can produce an asymmetrical brain organization in the rat. In addition, Denenberg et al.(Brain Res. 200:123, 1980) have shown that a conditioned taste aversion (CTA) may be asymmetrically processed by the intact rat brain. Following CTA induction, rats received unilateral hemidecortication. When tested subsequently for retention of the aversion, animals with a left hemidecortication (L) in general retained the aversion longer than those with right hemidecortication (R) or intact brains (I). In this study we wish to test the capacity of a single intact hemisphere to form and retain a CTA both with and without the benefit of extra stimulation in early life.

Rats were handled (H) or left undisturbed (NH) for the first 20 days of life. For the next 30 days, half of each group were either housed in an enriched environment (EE) or a standard lab cage (LC). At approximately 110 days of age, animals were given a R, L, sham lesion (S), or were not lesioned (C). At approximately 200 days of age, animals were introduced to a sweetened milk solution followed by an injection of an isotonic LiCl solution. For the next 25 days, animals were presented the sweetened milk for 30 min. to test the acquisition and retention of the aversion.

A preliminary analysis revealed no differences between the S and C groups, so they were pooled (I). In the NH-LC group, both R and L differed from I over trials ($p<0.01$), while not differing from each other. In the NH-FE group, only the L vs. I comparison was significant over trials ($p<0.01$). No individual comparisons are significant in the H-LC condition, whereas in the H-FE condition, L was significantly different from I ($p<0.01$) and R ($p<.01$) over trials, while the I and R groups did not differ.

These data indicate that stimulation in early life can produce an asymmetrical brain organization. Unilateral hemidecortication in normally reared laboratory rats produces an increased retention of a CTA regardless of the laterality of the lesion. With respect to the I group, H decreases the retention of R and L groups, and EE decreases the retention of the R group without demonstrating a clear asymmetry between the hemispheres. However the combination of H and EE acts to reduce the retention of the R, while not affecting the retention of the L group. These results support and extend the prior results on the effects of early experiences and cerebral asymmetry in rats with regard to activity, muricide, and CTA.

171.4 RECIPROCAL CONNECTIONS OF LATERAL ORBITOFRONTAL CORTEX WITH BASAL FOREBRAIN, HYPOTHALAMUS AND BRAINSTEM IN CAT. S.J. Wiegand and J.L. Price Dept. Anat. and Neurobiol., Washington University School of Medicine, St. Louis, Mo. 63110

The prefrontal cortex is involved in the regulation of complex behaviors and autonomic responses requiring interaction with diverse subcortical structures. This study demonstrates extensive direct connections between lateral orbital portions of frontal cortex and the basal forebrain, hypothalamus and brainstem in the cat. Cortical areas on the medial bank of the presylvian sulcus and posterolateral gyrus proreus were stereotaxically injected with 100 nl of HRP conjugated to wheat germ agglutinin (1%) and/or ^{3}H-leucine (50μCi/μl). Electrophysiological recording was used to guide the placement of injections.

Within the ipsilateral basal forebrain labeled neurons are present in the nucleus of the diagonal band and nucleus basalis. In the hypothalamus, retrogradely labeled neurons are present in the lateral and dorsal hypothalamic areas and the perifornical region at the level of the tuber cinereum, but not more rostrally. Caudally labeled cells are found in the tuberomammillary and supramammillary nuclei and the adjacent lateral and posterior hypothalamic areas. Labeling of caudal hypothalamic structures is more extensive in experiments in which cells of the mediodorsal nucleus of thalamus are heavily labeled, compared to cases where retrograde thalamic labeling is predominant in the submedial or ventromedial nuclei. Within the brainstem labeled cells are usually found in the central tegmental area, medial and dorsal raphe and central gray. Occasional labeled neurons are located in the substantia nigra, locus coeruleus, parabrachial nucleus or reticular formation. Light retrograde labeling of the contralateral hypothalamus and brainstem is frequently observed.

Anterograde connections are demonstrated by both HRP and autoradiographic methods. In the basal forebrain anterograde label is present in the ipsilateral diagonal band. More caudally label is frequently observed in the far lateral hypothalamus, bordering the ipsilateral cerebral peduncle. In experiments in which the submedius nucleus of thalamus is heavily labeled, bilateral anterograde label is noted in the medial ventral part of lateral hypothalamus. Within the brainstem anterograde label is present in the ipsilateral ventral tegmental area extending dorsolaterally over the substantia nigra, and bilaterally in the medial pontine nuclei and ventrolateral central gray.

Supported by Grants NS09518 and T32NS07507.

171.5 A RE-EXAMINATION OF THE ORGANIZATION OF THALAMIC-PREFRONTAL PROJECTIONS IN MONKEY. M.L. Weber-Levine and J.S. Stamm. Depts. of Psych., Morehouse College, Atlanta, GA 30314 and SUNY at Stony Brook, Stony Brook, NY 11790.

Early investigations of prefrontal lobe functions in monkeys demonstrated the existence of two distinct areas in this cortex, an orbitofrontal and a dorsolateral region. Anatomically these regions were shown to receive projections from three distinct zones in the nucleus medialis dorsalis (MD) in thalamus. Later behavioral studies have shown the existence of more than one functional region within the dorsolateral convexity. The region of sulcus principalis has been shown to be important for tasks involving a spatial delay, whereas the surrounding non-principalis cortex is related to tasks in which the animal must respond in a direction opposite to the cue in order to obtain a reward. On the basis of the behavioral data this study was undertaken in an attempt to determine if there exists a scheme of projections from MD which would lend anatomical support to the functional dissociations. A series of lesions involving behaviorally defined subareas of the dorsolateral cortex was made. In addition to total dorsolateral cortex ablations these lesions included the following: removal of; sulcus principalis, both complete and partial, non-principalis dorsolateral cortex, complete and partial, and frontal pole.

The resulting retrograde degeneration in MD clearly indicates a topographical arrangement of projections from MD to prefrontal cortex. The projection system suggested here differs from those of earlier studies. It is concluded that there exists in MD a dorsoventral arrangement of projections corresponding to the dorsoventral axis of the cortex. These projections form dorsoventral planes along the anterior-posterior axis in MD, with the greatest amount of projections emanating from the more anterior regions of MD. No evidence was found to support previous suggestions for the existence of a core projection from MD to the frontal pole. The variation in the density of degeneration following total or partial lesions lends support to the concept of sustaining projections from each region of MD to the different regions of cortex. This concept also helps to explain the lack of complete dissociation of function following lesions of the behaviorally defined subareas of dorsolateral cortex.

171.6 AREA 5 IS INVOLVED IN VISUAL NEGLECT IN THE CAT. Robert Sinclair* and Simon Horenstein. Departments of Neurology and Psychology, Saint Louis University, Saint Louis, Missouri 63104.

Ablation of a portion of area 5 on the mesial surface of the cat brain resulted in modification of a visually dependent learned task. Previous findings indicated that ablation of auditory area Ep in the posterior ectosylvian gyrus modified preference to double simultaneous visual stimulation (DSS). Ablation of AI and AII in the auditory cortex and SII in the somatosensory cortex did not. Clinical cases of sensory neglect are often trimodal. Therefore, a somatosensory analogue of Ep is implicated.

A common cortococortical projection point (Vss) between Ep and visual cortex exists in the mid suprasylvian gyrus. AI and AII project to each other and to Ep, but not to Vss. SI and SII likewise project to each other and to area 5 but not to Vss. Area 5 has been called a third somatosensory area, and a portion of area 5 projects to mid suprasylvian cortex (Mss), apparently overlapping Vss. Area 5 is therefore a possible analogue for the somatosensory system of auditory Ep.

The present study evaluated the functional role of area 5. Three cats were appetitively conditioned in a specially designed "Y" maze (Toga, A.W. et al., Psychological Reports, 40:1071-4, 1977) equipped for visual stimulation. On unilateral stimulation animals were required to move into the sole lighted arm of the maze and on DSS to move into either of two in order to obtain food reward delivered from a feeding cup at the end of each. Each animal established its own lateralization pattern to DSS. After training, unilateral subpial resection of area 5 in the anterior lateral gyrus and mesial surface in the longitudinal fissure was performed, and the animal tested from the 1st to 10th postoperative days. After intracardiac saline-formalin perfusion, brains were removed for anatomic study. Lesions imposed no apparent postural bias or lateral preference to unilateral stimulation. A significant decrease in turns toward the side affected by the lesion to DSS was found in one animal with lesion restricted to the mesial portion of area 5, and another animal with a lesion extending over both the mesial and lateral portion of area 5. In a third animal with lesion restricted to the lateral portion of area 5, no significant change in lateral preference to DSS was found. This suggests that the mesial portion of area 5 is critical for producing neglect, while the lateral portion is less or not at all important.

Results suggest that area 5 may indeed function within the somatosensory system in a manner analogous to that of Ep in the auditory. Ep and area 5 may integrate information about their respective sense modalities. Their projections to Vss possibly enter multimodal processing which in turn determines the direction of the orienting response.

171.7 EFFECTS OF NEONATAL SECTION OF THE CORPUS CALLOSUM ON INTERHEMISPHERIC TRANSFER OF VISUAL PATTERN DISCRIMINATIONS IN THE CAT. M. Ptito, F. Lepore, B. Cardu and M. Lassonde. Dépt. de Psychologie, Univ. du Québec à Trois-Rivières, Trois-Rivières, Québec and Univ. de Montréal, Montréal, Québec

Numerous studies have shown that early interventions in the visual system of both animals and men can result in its permanent alteration. Moreover, the interhemispheric transfer of visual pattern discriminations in the adult cat depends on the integrity of the forebrain commissures, and especially the corpus callosum, since its transection generally abolishes the ability of an animal to transfer this information across the hemispheres. The aim of the present experiment was to determine whether the neonatal section of the callosum might result in the greater utilization of the secondary commissures such that these become sufficient to mediate this type of transfer in the adult.

Six cats were used in the experiment: two control cats underwent the mid-line transection of the callosum and optic chiasma when they were adults; two had their callosum sectioned at 6 weeks post-natally, namely, after callosal myelinization but before the end of the critical period when the visual system is still susceptible to modifications; the callosum of the other two subjects was sectioned at 21 days of age, when myelinization is still supposedly incomplete. These 4 subjects were then raised in the animal colony until they were 7 months old, at which time their chiasmas were sectioned, followed by behavioral testing. This consisted of learning various pattern discriminations in a Thompson-like two-choice box with one eye and testing for transfer using the other eye.

Results indicated that the control group, as expected, did not transfer, requiring as many trials to learn the discrimination with the second eye as with the first. This was also the case with the subjects whose callosum was split at 6 weeks. The subjects whose callosum was sectioned at the earlier age (21 days) did not show complete transfer, although they did show some saving on a number of pattern discriminations. The results, though inconclusive, do point to some possible greater utilization of the extra-callosal commissures in early operated animals.

172.1 GANGLIOSIDES ENHANCE MEMORY CONSOLIDATION IN RAT PUPS. S.E. Karpiak and M.M. Rapport. Div. of Neuroscience, New York State Psychiatric Institute and Depts. of Psychiatry and Biochemistry, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

Injection of antibodies to brain ganglioside into the CNS of the adult rat has been shown to inhibit consolidation phases of learning(1). Further, the injection of antibodies to ganglioside into the neonate rat pup (PN Day 5) results in subtle learning deficits in the mature animal accompanied by decreased levels of ganglioside in the CNS and alterations in spines of cortical pyramidal cells(2). The following study was undertaken to determine if the administration of gangliosides into neonatal rat pups might alter learning behavior. There is evidence that gangliosides in contact with cells in vitro are functionally incorporated into the cell membrane, and the addition of gangliosides to some neuronal cell cultures leads to more rapid maturation of the cells(3).

Rat pups from 5 to 15 days after birth were given daily sub.cu. injections of 2.5 mg of total brain ganglioside (in 25 µl of saline). Control rat pups received saline injections only. On PN Days 11,12 and 14 pups were trained on a multi-directional avoidance paradigm using 20 shock-escape trials, and latency to escape the shock was recorded (as a measure of performance). Both groups of rats acquired the task equally well on Day 11. Their performance on Day 12 improved significantly (50% reduction in the latency scores). However when the rats were tested on PN 14 (skipping one day of training) those injected with ganglioside showed no difference in performance as compared to Day 12, whereas the control animals had increased latency scores (+50% to 60%; $p<0.01$) indicating poorer retention. The results show that administration of gangliosides enhances consolidation phases of learning as determined by better retention of an acquired task. This enhancement may be due to an increase in the levels of ganglioside in neuronal membranes or to more rapid maturation of neurons. Preliminary data show some enhancement of learning behavior (retention) in these rats at maturity.

172.2 INHIBITION OF GLUTAMATE RELEASE CORRELATES WITH AMNESTIC POTENCY OF PROLINE ANALOGS. Elizabeth Keller*, Richard M. Pico* and Joel L. Davis. Addiction Res. Lab., and Aging and Behavioral Biol. Res. Lab., VA Med. Center, Sepulveda, CA, 91343.

Van Harreveld et al., (Pharmacol. Biochem. and Behavior. 12: 533-541, 1980) have described the procedure for determining the amnestic potency of various amino acids. Briefly, chicks are injected intracerebrally with 10 µl/hemisphere of 300 mM amino acids, 1 min. after one-trial training to suppress the peck responce to a bead. Suppression was conditioned by coating the bead with an aversant (methyl anthranilate). Impaired memory was noted, 24 hr later, when animals with certain amino acids showed a higher peck rate than the control chicks when presented with an uncoated bead.

Memory processing, by correlation with spreading depression, is hypothesized to be caused by the effects of glutamate released into extracellular space. This glutamate effect is inhibited by L-proline and several of its analogs (Van Harreveld et al., Pharmacol. Biochem. and Behavior. 12: 533-541, 1980). It is proposed that proline's amnestic potency is due to postsynaptic competition for glutamate receptors on dendritic plasma membranes (Cherkin and Van Harreveld, Brain Res. 156: 265-273, 1978). Alternatively, it has been suggested that the mechanism may involve the inhibition of glutamate released from presynaptic compartments (Keller et al., J. Neurochem., in press). The following study was initiated to strengthen this hypothesis by establishing a correlation between the amnestic potency of proline analogs and their potency as glutamate release inhibitors.

To determine the effect of proline analogs on glutamate release minislices of ectostriatum from white leghorn chicks (strain B-300, 3 days old, 35 grams) were superfused with physiological salt solution containing suitable concentrations of proline analogs and depolarized with 45 mM K^+. Efflux was collected before and after stimulation and the released endogenous glutamate measured by an enzymatic assay (Graham and Aprison, Analyt. Biochem. 15: 487-497, 1966).

These studies show that D-proline has no effect on glutamate release, that L-proline inhibits release by approximately 50% and DL-3,4-dehydroproline inhibits glutamate release by about 75%. This very closely approximates the relative changes in retention scores that measure memory impairment, thus suggesting that L-proline's amnestic potency is related to inhibition of glutamate release.

172.3 ACTIONS OF 4-OH AMPHETAMINE ON ACTIVE AVOIDANCE CONDITIONING AND REGIONAL BRAIN CONCENTRATIONS OF NOREPINEPHRINE AND DOPAMINE. Joe L. Martinez, Jr., Koichi Ishikawa*, Tracy J. Hannan*, K.C. Liang*, Beatriz J. Vasquez, Robert A. Jensen, Debra Sternberg, Cathy Brewton* and James L. McGaugh. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717, U.S.A.

Previously, we reported that 4-OH amphetamine (4-OH AMPH) enhanced retention of an inhibitory avoidance response (Neurosci. Abs., 1978, 4, 261) and that this effect was abolished by adrenal demedullation (Neurosci. Abs., 1979, 5, 320). The purpose of these experiments was to investigate the enhancing effect of 4-OH AMPH on memory in a one-way active avoidance task and to measure the effect of 4-OH AMPH on brain catecholamine concentrations.

Male ARS Sprague-Dawley rats (90 days old), either sham-operated (SHAM) or adrenal demedullated (ADMX), were given eight trials of training in an active avoidance task on Day 1 (640 µA footshock). Immediately after training, the rats received either SAL, .41, or .82 mg/kg 4-OH AMPH, i.p. A dose of .82 mg/kg significantly enhanced the number of avoidance responses made by the SHAM animals on Day 2 ($p<.02$). Neither dose of 4-OH AMPH had an effect in the ADMX rats. Thus, as in inhibitory avoidance conditioning, the enhancing actions of 4-OH AMPH on memory mechanisms are dependent on the integrity of the medulla.

In the second experiment, normal rats were administered either SAL, .82, or 8.2 mg/kg 4-OH AMPH i.p., and were sacrificed either 10, 30 or 60 min following injection. Regional brain and adrenal concentrations of norepinephrine (NE), dopamine (DA), and epinephrine (E) were determined by means of high performance liquid chromatography with electrochemical detection. A dose of .82 mg/kg 4-OH AMPH significantly reduced concentrations of DA in the amygdala ($p<.05$) and hippocampus ($p<.05$) 60 min following injection. The higher dose of 8.2 mg/kg 4-OH AMPH reduced concentrations of DA at the 60 min time point in the amygdala ($p<.01$), cortex ($p<.01$), striatum ($p<.01$), and hippocampus ($p<.01$). NE was significantly reduced in the amygdala ($p<.01$), cortex ($p<.01$), hypothalamus ($p<.01$), hippocampus ($p<.05$), midbrain ($p<.05$), and adrenal glands ($p<.05$). With the high doses of 4-OH AMPH, E was also reduced in the adrenals ($p<.01$), 60 min after treatment.

These results suggest that 4-OH AMPH affects both brain and adrenal catecholamines and that the behavioral effects of 4-OH AMPH may be due to a dual action on both central and peripheral catecholamine systems.

172.4 RELATIONSHIPS AMONG AMPHETAMINE-INDUCED MEMORY IMPROVEMENT, AFFECT, AND MOTOR BEHAVIOR Geoff Carr* and Norman White, Department of Psychology, McGill University, 1205 Dr. Penfield Ave., Montreal H3A 1B1 Canada.

The dopamine (DA)-containing neurons with cell bodies in pars compacta have been implicated in the mediation of the retention of learned behavior, affect (reward and aversion), and motor behavior. Amphetamine (AM), a drug which facilitates DA neurotransmission, also influences memory, affect and motor behavior. Therefore, we used AM to study the relationship among these putative behavioral functions of the DA neurons. In Experiment 1 rats were given the training trial of a retention test (pairing of tone and shock) followed by an IP injection of 2 mg/Kg d-amphetamine sulphate. They were then placed into an observation cage where general activity was measured by photocells and stereotypy was measured by observation. Next day the rats were tested for retention (conditioned suppression of licking). The AM-injected rats showed significantly better retention than saline-injected or 1 hour delay, AM-injected control rats. The degree of improvement in retention produced by the AM was significantly correlated with the amount of stereotypy produced by the same injection ($n=22$, $r=0.43$), but not with the amount of increase in general activity ($r=-0.25$). In Experiment 2 water-deprived rats that drank a novel-tasting solution, were injected with AM, and their motor behavior measured. Next day the AM-injected rats drank significantly less solution than saline-injected or water-paired, AM-injected control rats. The strength of the conditioned taste aversion (negative affect) produced by the AM injection was significantly correlated with the increases in general activity produced by the same injection ($n=36$, $r=0.32$), but not with the amount of stereotypy ($r=0.07$). These data link the stereotypy-motor and the retention-improving actions of AM, and they link the general activation and negative affective actions of the same drug. AM-produced stereotypy has been associated with DA terminals in caudate, and increases in general activity with DA terminals in nucleus accumbens. To test the hypothesis that AM produced the pairs of correlated effects by acting on DA terminals in these two brain areas, rats were prepared with chronic cannulae aimed at lateral caudate or accumbens and tested for the effects of intracerebral AM (10ug in 1uL over 30 sec) in the Retention and CTA experiments. AM in accumbens produced significant increases in general activity, but only small increases in stereotypy. AM in caudate produced significant increases in stereotypy, but only small increases in general activity. Neither group showed a CTA. AM in accumbens had no effect on retention. AM in caudate significantly improved retention compared to controls, and the degree of improvement was negatively correlated with stereotypy ($n=8$, $r=-0.54$), and with general activity ($r=-0.25$). These data suggest that the pairs of linked effects we observed with peripheral injections of AM may not be mediated by the same neural mechanisms.

172.5 EFFECTS OF PHENCYCLIDINE ON SENSORY, MOTOR, MOTIVATIONAL, LEARNING, AND MEMORY FUNCTIONS. John D. Hardy* and Raymond P. Kesner (Spon: B. Grosser). Dept. of Psychol. Univ. of Utah, Salt Lake City, UT. 84112.

Phencyclidine (PCP) in humans has been shown to have marked effects on sensory, perceptual, motivational, mnemonic, and cognitive functions. Because of the paucity of data on the effects of PCP in humans and because of ethical concerns, it was deemed of importance to develop an animal model of PCP effects. Thus, the present study was designed to investigate systematically the effects of PCP on a variety of behaviors. Under the influence of different doses of PCP (4-24 mg/kg, i.p.) different groups of rats were tested for (a) ability to detect odors, visual square, touch, and pain, (b) ability to perform placing, righting, and grasping reflexes, (c) activity level, emotionality, and habituation in an open field, (d) illness effects and water intake, (e) acquisition and retention of active avoidance, and (f) performance on an 8-arm radial maze.

Data showed that low doses of PCP (4, 8 mg/kg) have profound effects on learning, memory, and activity level. Specifically at doses of 4 mg/kg there was (a) an increase in activity level which appeared to be a function of impaired habituation, and (b) an impairment in active avoidance learning. At doses of 8 mg/kg there was (a) no effect on pain threshold to shock, (b) a marked reduction in activity level, but no changes in emotionality, (c) a profound deficit in active avoidance learning, but no effect on subsequent retention with injections prior to training, immediately after training or prior to the retention test, and (d) a profound disruption of errorless performance on the radial arm maze.

Data also indicated that higher doses of PCP (12, 16, 24 mg/kg) produce disruption of sensory, motor, and motivational function. More specifically, at doses of 12 mg/kg, there were marked disruptive effects in detection of odors, visual square, and touch as well as performance of placing, righting, and grasping reflexes. At doses of 16 and 24 mg/kg there was a decrease in water intake, but no illness effects. In conclusion, PCP has a myriad of behavioral effects. Furthermore, it has been possible to demonstrate that higher-order behavioral functions (i.e., learning, and habituation) are affected by low doses of PCP, whereas detection of sensory input and motor reflexes are affected only by high doses of PCP.

172.6 THE EFFECTS OF ATROPINE AND BENACTYZINE ON SHORT-TERM MEMORY IN THE MONKEY. J.H. McDonough and D.M. Penetar*. U.S. Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

Cholinergic mechanisms have been implicated in both long and short-term memory (Bartus and Johnson, Pharm. Biochem. and Behav., 1976, 5, 39-46; Davis et al., Science, 1978, 201, 272-274). Scopolamine disrupts short-term memory in a dose-related fashion. Scopolamine's effects were potentiated by increasing retention intervals. The effects of other anticholinergics have not been systematically explored.

Dose-response curves for the anticholinergics atropine and benactyzine were generated on a delayed matching-to-sample task in rhesus monkeys. Subjects initiated trials by responding on a center lever for brief flashes of the sample (colors of red, blue or green) on a backlit key. Match stimuli appeared on three additional backlit keys after delays of 0, 4, 8 or 16 sec. Placement of match stimuli and delays were randomized. Session length was 200 food reinforced trials. The doses of atropine were 0.014, 0.044, 0.14, 0.25, and 0.44 mg/kg. The doses of benactyzine were 0.057, 0.18, 0.57 and 1.8 mg/kg. The preinjection times were equated for onset of central effects. Atropine was injected (i.m.) 45 minutes prior to the session while benactyzine was injected (i.m.) 15 minutes prior. Dependent variables were percent correct matches for each delay and session time.

Under baseline and saline control conditions, retention accuracy ranged from 92% at the 0 sec delay to 76% at the 16 sec delay. Atropine produced a graded effect on accuracy at all delay intervals. The highest dose tested produced severe memory deficits. Performance was reduced to 51% at the 4 sec delay, 45% at the 8 sec and 34% (chance) at the 16 sec delay. For all doses tested, animals responded steadily but at a reduced rate. Session lengths revealed dose-related increases of up to 6 hrs.

Benactyzine produced dose-related effects on short-term memory but only at the 4, 8 and 16 sec delays. Benactyzine's effects were much less severe than atropine's. The highest dose produced 66% correct responses on the 16 sec delay. Additionally, the nature of benactyzine's effects appear to be dissimilar. Benactyzine produced an initial response suppression followed by a period of responding similar to baseline performance.

At this time it is not known whether the differences between the two drugs are due to the relative differences in duration of action or possibly to differences in their anticholinergic mechanisms of action.

172.7 CENTRAL CHOLINERGIC FUNCTION AND SHORT-TERM MEMORY IN THE RAT. D. G. Spencer. Dept. of Psychology, Indiana University, Bloomington, IN 47405.

Systemic administration of scopolamine (a cholinergic muscarinic receptor antagonist) and hippocampal lesions are quite similar in behavioral effect. Performance on memory procedures is particularly sensitive to these treatments. Since the hippocampus has a high concentration of muscarinic receptors, the goal of the present study was to examine the interaction between systemically administered scopolamine and selective hippocampal muscarinic blockade on performance of a short-term memory task.

Sixteen male Sprague-Dawley rats were trained on a continuous non-matching to sample (CNM) task in which lever pressing was reinforced on 5 sec discrete trials on which the brightness of a panel light was different from that of the previous trial. Intervals between successive trials (retention intervals) varied between 2.5, 5, and 10 sec. Lever presses were analyzed for effects on the signal detection theory variables of sensitivity (performance accuracy) and bias (degree of responsiveness). Eight other rats were trained to perform on a superficially similar discrimination task in which lever presses were reinforced only during trials with one particular panel light brightness.

All rats were then bilaterally implanted with stainless-steel cannulae in one of three locations: dorsal hippocampus, ventral hippocampus, or caudate nucleus. After performance stabilized, all subjects received both systemic and central drug administration. The former consisted of i.p. injections of saline, scopolamine hydrobromide (0.125, 0.25, and 0.50 mg/kg), and d-amphetamine sulfate (0.50 and 1.0 mg/kg). The latter consisted of two 1 uL bilateral injections: one of 10 ug/uL scopolamine in Ringer's solution and one of Ringer's solution alone.

Whether given systemically or centrally in either hippocampal location, scopolamine decreased sensitivity to an equal extent on trials following all three retention intervals in both CNM and discrimination tasks. Scopolamine did not affect bias except at the highest systemic dose (0.50 mg/kg) and when injected into the caudate nucleus. In both cases bias decreased, however this effect produced by caudate injection was not accompanied by decreased sensitivity. Systemic injections of d-amphetamine at both doses increased bias and the higher dose (1.0 mg/kg) decreased sensitivity as well.

These results have two major implications. First, since scopolamine equally disturbed performance following the three retention intervals in both tasks, it interferes with performance by disrupting processes other than retention. Second, the hippocampal muscarinic receptors are specifically involved with the short-term memory effects produced by systemic scopolamine.

172.8 FOLLOWING SCOPOLAMINE INJECTIONS, SHORT-TERM AND LONG-TERM HABITUATION IS INTACT AS MEASURED BY THE DURATION OF INVESTIGATION OF A NOVEL OBJECT BY GERBILS. MaryLou Cheal. Neuropsychology Laboratory, McLean Hospital and Harvard Medical School, Belmont, MA 02178.

Mongolian gerbils allowed to investigate a novel object for one minute show significant habituation on a second trial. Habituation is shown whether the second trial occurs 60 seconds later or up to four weeks later. Thus, this paradigm, stimulus-elicited investigation, allows the study of both short-term and long-term habituation. In gerbils given scopolamine hydrobromide (0.01-10.0 mg/kg S.C.) 20 minutes before Trial 1, habituation of the duration of investigation was observed on Trial 2. Habituation was observed when Trial 2 occurred 60 seconds after Trial 1 and when Trial 2 was 24 hours later. Therefore, intact memory can be inferred.

However, by also measuring the number of approaches to the stimulus, it is possible to provide an additional interpretation of the data. The number of approaches to a cup was greater in gerbils given 0.1, 1.0, or 10.0 mg/kg scopolamine than in those treated with lower doses or vehicle. The larger number of approaches was seen on the first trial after drug injection, on a second trial 24 hours later, and in gerbils habituated to the cup before drug injection. Frequency and duration measures of 24 hour habituation did not differ across doses in gerbils given methyl scopolamine (0.1-10.0 mg/kg), indicating a central effect of scopolamine on the frequency of habituation 24 hours after treatment.

In scopolamine-treated gerbils, the number of approaches was greater with no difference in total duration, resulting in a shorter mean duration per approach. The shorter duration per approach suggests a decreased ability to maintain attention. A parsimonious interpretation of much controversial data in the literature is that animals can choose and respond to stimuli following scopolamine injections, but are unable to maintain attention long enough to do so when the stimulus requires more than a minimal amount of time and effort. Thus, in this simple paradigm of investigation of an object, habituation can be demonstrated in scopolamine-treated gerbils.

172.9 ADMINISTRATION OF ENKEPHALIN ANALOGUES INTO THE AMYGDALA CENTRAL NUCLEUS: EFFECTS ON PAVLOVIAN CONDITIONED HEART RATE IN RABBITS. M. Gallagher, B. S. Kapp, J. P. Pascoe* and C. D. Applegate*. Depts. of Psychology, Univ. of North Carolina, Chapel Hill, NC 27514 and The Univ. of Vermont, Burlington, VT 05405.

Previous results from our laboratory demonstrated that administration of opiate agents into the amygdala central n. altered the acquisition of Pavlovian conditioned heart rate in rabbits (Soc. Neurosci. Abstr. 6, 168, 1980). Whereas opiate agonist administration impaired conditioned heart rate responding, opiate antagonist administration alone augmented conditioned responding. Since opioid peptides are highly concentrated within the central n. of the amygdala, the effects of opiate antagonist administration into this region may be due to blocking endogenous enkephalin activity. Consequently, the effects of enkephalin analogue administration into the central n. on conditioned heart rate were assessed.

New Zealand rabbits were surgically prepared with cannulae positioned at the dorsal surface of the central nucleus. Two weeks later all animals were trained using a standard Pavlovian conditioning procedure. Drug injections were delivered in a 1.0 µl volume immediately prior to the conditioning session. Two opioid peptides were used, D-Ala^2, Met^5-enkephalin (DALA) and D-Ala^2, D-Leu^5-enkephalin (DLEU).

Conditioned heart rate responses for UNOPERATED and VEHICLE-injected control groups did not significantly differ. Compared to the VEHICLE group, administration of DALA (2.0 or 1.0 µg) significantly attenuated conditioned heart rate responding. This effect of DALA (2.0 µg) was blocked by concurrent administration of the opiate antagonist naloxone. Statistical analysis performed on the conditioned response data for the VEHICLE group and the groups which received injections of DLEU (2.0 or 1.0 µg) revealed no significant differences among these groups.

Previous studies have indicated that the DLEU analogue preferentially labels delta receptors found in high concentration within the central n. of the amygdala (Chang et al., Mol. Pharm. 16, 91-104, 1979; Goodman et al., Proc. Nat. Acad. Sci. USA 77, 6239-6243, 1980). Since the effects on conditioning observed in this study following DALA administration were not observed following comparable doses of DLEU, it appears that delta receptor activity within the central n. may not contribute to conditioning processes. The possibility that mu receptor activity may play a role in conditioning processes is consistent with the present findings as well as our previous report that administration of opiate agents alters the acquisition of conditioned heart rate.

Supported by NIMH grant R01-MH35554.

172.10 DIFFERENT EFFECTS OF 1,4- and 1,5-BENZODIAZEPINES ON ECS-INDUCED AMNESIA IN A PASSIVE AVOIDANCE TASK. F.J. Hock*, H.J. Kruse* and U. Schindler*. (SPON: J.-P. EWERT). HOECHST AG, CASSELLA AG, D-6230 Frankfurt 80, Germany.

1,4-benzodiazepines have been reported to induce anterograde amnesia in humans. Therefore we investigated the effect of diazepam, a 1,4-benzodiazepine in an one-trial dark avoidance paradigm in mice and compared it with clobazam, a 1,5-benzodiazepine. The apparatus consisted of a light (L) and dark (D) compartment, connected by a guillotine door. During the acquisition trial (AT) an unavoidable footshock (FS, 1 mA, 1.0 sec) was delivered immediately after entering D, followed by a maximal electroconvulsive shock (ECS, 15 mA, 0.2 sec). The retention trial was run 24 hrs later. The latency time for entering D was measured during the acquisition and retention period (cut-off time: 300 sec). Drugs were administered orally 90 min prior to both AT and RT.

Diazepam at 1 and 2 mg/kg caused a decrease in latency time during the retention trial by 39 and 33 % respectively, while clobazam at 12.5 and 25 mg/kg brought about a marked increase by 187 and 196 % over control. Lower doses of both drugs had no effect.

In other tests on protection against hypoxia in mice (induced by sodium nitrite, brevatonal, or asphyxia) both drugs were active, diazepam being even more potent than clobazam. The ED50 values for the prolongation of asphyxia survival time was 3.8 mg/kg for diazepam and 22 mg/kg for clobazam after oral administration.

The results indicate that memory consolidation and/or retrieval in mice may be impaired by diazepam but not affected or enhanced by clobazam. Protective effects of tranquilizers against hypoxia may be due to sedation and/or anxiolytic activity.

172.11 PHARMACOLOGICAL PROTECTION AGAINST HYPOXIC AND ELECTRO-BRAINSHOCK DISRUPTION OF AVOIDANCE RETRIEVAL IN MICE. E. Gamzu and L. Perrone* Dept. of Pharmacology, Hoffmann-La Roche Inc., Nutley, N.J. 07110

Deficits of learning and memory are common to many clinical problems ranging from minimal brain dysfunction in children to senile dementia in the elderly. The present studies were designed to establish a model of one aspect of clinical amnesia - retrieval failure - by using two distinct disruptors, hypoxia and subconvulsive electro-brainshock (EBS), and to determine whether clinically used compounds such as magnesium pemoline (MP), piracetam (P), and vincamine (V) protected against these disruptors.

Naive male CF1 mice received 10 training trials at one minute intervals. On each trial a mouse was placed into the apparatus. After 10 seconds, an electric shock (1mA) was applied via the grid floor for 15 seconds. The mouse could either avoid or escape the shock by entering a second unshocked compartment through a small opening. Twenty-four hours later drug or vehicle was given orally 60 min. before 10 trials of retention testing. Hypoxia, EBS or sham treatment preceded the retention test by 5 min. Hypoxia consisted of 8 seconds exposure to pure CO_2 (normal air for shams). EBS (10 mA,, 10 mS, 60 Hz for 200 mS) was applied transcorneally via a DC stimulator (the power was turned off for shams).

At testing, the mean % avoidance response for shams was 80% (the means for groups of 5 ranged from 74-90%). The mean for mice receiving EBS was 24% and for hypoxia 40%. Control experiments have shown that the disruption is not the result of motor deficits, since learning is not affected.

MP and P protected dose-dependently against both types of disruption. The doses (in mg/kg) at which peak % recovery occurred after EBS and hypoxia, respectively, were MP-(30) 91%, (30) 86%; P-(1000) 89%, (1000) 92%.

The following compounds were inactive against EBS disruption and were not tested against hypoxia: amphetamine, chlorpromazine, clonidine, diazepam, hydergine, imipramine, and physostigmine. V produced a 43% recovery of function against EBS disruption at a single dose.

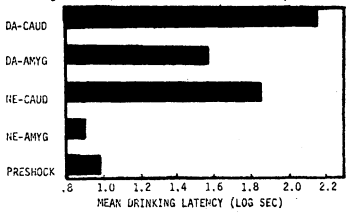
Neither stimulant nor anticonvulsant activity alone is sufficient for the effect. The procedures appear useful for evaluating potential memory enhancers.

172.12 NOREPINEPHRINE AND DOPAMINE: DIFFERENTIAL EFFECTS OF MANIPULATION OF THE AMYGDALA AND CAUDATE ON AVERSIVE INFORMATION PROCESSING. Maureen E. Ellis and Raymond P. Kesner (SPON: S.W. Miller). Dept. of Psychology, Univ. of Utah, SLC, UT 84112.

Based on substantial evidence from the electrical brain stimulation (EBS) and the lesion literature, both the amygdala and the caudate have been implicated in the processing of aversive information. EBS and lesion techniques might disrupt memory processes by influencing neurotransmitter function within the particular brain substrate. Two closely related transmitters, norepinephrine (NE) and dopamine (DA), are differentially distributed in the amygdala and caudate. Since recent evidence has also implicated the importance of central catecholamine systems in learning and memory, the present study was designed to investigate the effects of manipulation of the NE and DA systems of the amygdala and caudate on retention of a passive avoidance training experience.

Water deprived rats were trained to enter a goal box in order to drink from a tube containing water. After reaching a predetermined latency criterion, rats were given a single 3 sec, 3 mA footshock and then tested for retention 24 hr later. Immediately following footshock, all rats were injected with either NE (1 ug) or DA (1 - 10 ug) via bilateral, chronic, stainless steel cannulus implanted in either the amygdala or the caudate. Retention was evaluated as an increased latency to approach the drinking tube relative to pre-shock latency.

Rats injected with 1 ug NE in the amygdala did not demonstrate retention (amnesia) when tested in the goal box 24 hr following footshock. In contrast, rats treated with DA in the amygdala or with either NE or DA in the caudate displayed excellent retention in the 24 hr test. Furthermore, the data suggested that the DA-caudate group had enhanced retention when compared to the DA-amygdala rats. The overall results support a crucial role for the NE, but not the DA, system of the amygdala in aversive information processing. Conversely, DA, but not NE, in the caudate may have some function in passive avoidance learning.



172.13 DRUG EFFECTS ON THE DELAYED MATCH-TO-SAMPLE PERFORMANCE OF SQUIRREL MONKEYS. E. Schwam*, L. Rumennik*, J. Sepinwall, and L. Cook*, Dept. of Pharmacology, Hoffmann-La Roche Inc., Nutley, N.J. 07110

The search for pharmacological agents for treatment of human cognitive dysfunctions necessitates the development of preclinical research strategies and methods for evaluating drug effects on non-human learning and memory. Two such strategies have been to identify drugs that will either enhance performance under normal conditions or protect against induced deficits in performance. Compounds considered important to study in this regard include certain stimulants, muscarinic agonists, cholinesterase inhibitors, anti-hypoxic agents, cerebral metabolic agents and hypothalamic and pituitary peptides.

The effects of eight representative compounds were examined on the three-choice match-to-sample performance of highly trained adult male squirrel monkeys under normal conditions. Each trial of the task consisted of two successive components. First, animals were required to select the choice stimulus that matched the simultaneously presented sample stimulus. Following two consecutive correct matches all keys were darkened for a fixed interval (less than 30 sec.) after which the three choice keys only were illuminated. Responding to the correct choice key after the delay interval (delayed matching) resulted in food presentation.

All drugs were orally administered with one dosing per week. d-Amphetamine improved performance at the lowest dose tested (0.05 mg/kg) but severely disrupted performance at the highest doses tested (0.60 and 0.80 mg/kg). Increases in accuracy were seen with strychnine (at 0.25 and 0.50 mg/kg) but these were not consistent.

Diazepam and the anticholinergic scopolamine produced relatively few deviations from baseline at the lowest doses tested (0.625 and 0.0125 mg/kg, respectively) but progressively decreased matching accuracy as the doses were increased. No consistent effects have been seen thus far during a preliminary evaluation of the cholinesterase inhibitor physostigmine (0.0013-0.04 mg/kg).

The purported "nootropic compounds" piracetam (100-300 mg/kg) and Hydergine (a combination of three hydrogenated ergot alkaloids; 6.25-50 mg/kg), and the anti-hypoxic agent phenformin (1.88-7.5 mg/kg) failed to improve performance.

172.14 THE EFFECTS OF PIRACETAM, VINCAMINE, AND d-AMPHETAMINE ON MONKEY ELECTROCORTICOGRAM & VI 60 LEVER RESPONSE RATE. K.L. Keim and T. Smart*. Dept. Pharmacology, Hoffmann-La Roche Inc., Nutley, N.J. 07110.

We have shown drug-specific frequency changes in the electrocorticogram (ECoG) of unrestrained squirrel monkeys and have regarded these as measures of selective drug action (Keim et al., Neurosci. Abstr. 6: 366, 1980). Our present study compares the effect of 800, 1600, & 2400 mg/kg piracetam (PIRC; 2-pyrrolidinone acetamide) and 5 & 10 mg/kg vincamine (VINC; an alkaloid obtained from *Vinca minor*), and 0.1, 0.3, & 1.0 mg/kg d-amphetamine (AMPH) on the ECoG during an operant task. The "nootropic agents" have had clinical application in treating cerebral insufficiencies, senility, etc.; d-amphetamine is a known psychostimulant.

Drugs were administered intragastrically 60 min prior to testing food-restricted monkeys (80% ad lib wt) on a VI 60 sec schedule of food reinforcement. The session was 90 min. Telemetered ECoG activity from the anterior cortex was quantified and the 0-32 Hz range was subdivided by computer into 8 bands for spectral frequency analysis. Each monkey 2-6 per dose) was run on two consecutive days: vehicle (5% acacia) was given on Day 1 and drug on Day 2. Data are reported as the difference between drug and vehicle runs.

The 0-32 Hz wideband ECoG was not significantly altered by either PIRC, VINC, or AMPH. PIRC had little effect on the distribution of ECoG frequencies within the 0-32 Hz range, however, there was a tendency to lessen 4-8 Hz and augment 8-16 Hz activity. 10 mg/kg VINC significantly decreased 4-8 Hz and increased 20-32 Hz ECoG activity. In contrast, 1 mg/kg AMPH significantly decreased 2-4 Hz and increased 4-12 Hz ECoG activity.

PIRC enhanced and VINC attenuated VI response rate, but not significantly. Emesis was observed in 1 of 4 and in 3 of 6 monkeys following 5 or 10 mg/kg VINC, respectively. AMPH disrupted behavior following 0.3 and 1.0 mg/kg which markedly decreased VI response rate.

We found significant changes in the spontaneous EEG of primates following treatment with vincamine, but the changes were not of large magnitude. The VINC-induced ECoG alterations differed qualitatively the encephalotropic effects produced by the psychostimulant AMPH. This nondeficit animal model - shown to be sensitive to many other types of pharmacological agents - appears to be meaningful though may not be the most sensitive for evaluating the central effects of such compounds generally classified as "nootropics."

172.15 THE EFFECTS OF TRIMETHYLTIN ADMINISTRATION ON PASSIVE AVOIDANCE CONDITIONING IN RATS. E. Bostock*, T. J. Walsh, M. Gallagher, and R. S. Dyer (SPON: R. Musty). Dept. of Psychology, Univ. of North Carolina, Chapel Hill, NC 27514, and Div. of Neurotoxicology, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Trimethyltin (TMT) is a neurotoxic organotin compound. Human exposure to TMT has been reported to induce a variety of behavioral changes including memory deficits, hyperactivity, anorexia, visceral pain, and generalized seizure activity (Fortemps et al., Int. Arch. Occup. Environ. Hlth. 41:1-6, 1978). Recent studies of TMT toxicity report that this compound produces brain damage with a high degree of selectivity for limbic system structures (Dyer et al., in press; Brown et al., Am. J. Path. 97:59-82, 1979). The purpose of the present study was to examine the effects of TMT administration on behavioral measures sensitive to limbic system damage.

TMT was administered by gavage to male Long-Evans hooded rats. Rats were administered either 0 (n=8), 5 (n=8), 6 (n=11), or 7 (n=6) mg/kg TMT in 0.9% saline. Twenty-one days following TMT administration rats were tested on a passive avoidance task using a 0.6 mA, 1 sec footshock following the procedure described by Gallagher et al. (Sci. 198:423-425, 1977). Approximately 1 week later jump flinch shock thresholds were determined.

A Kruskal-Wallace one-way analysis of variance of passive avoidance retention latency data revealed a significant difference among groups ($p<.001$). Doses of 5, 6, or 7 mg/kg TMT produced significant retention latency deficits compared to controls (Mann-Whitney U, two-tailed, $p's<.02$). A Kruskal-Wallace one-way analysis of variance performed on jump flinch thresholds revealed no significant difference among groups.

The results of jump flinch threshold tests and information from a previous study (Dyer et al., in press) indicate that retention latency deficits are probably not produced by a change in sensitivity to sensory stimuli. The reported limbic system toxicity of TMT (Dyer et al., in press; Brown et al., Am J. Path., 97:59-82, 1979) suggests that passive avoidance retention deficits may be attributable to damage to limbic system structures. This premise is further supported by our observations that TMT treated rats exhibit deficits in radial arm maze performance (Walsh et al., Soc. Neurosci. 1981).

The effects of TMT administration on an active avoidance task will be studied to further elucidate the behavioral correlates of TMT toxicity.

172.16 ENVIRONMENT - SPECIFIC CONDITIONED ACTIVITY WITH d-AMPHETAMINE AS THE UNCONDITIONED STIMULUS. R.J. Beninger and B.L. Hahn* Dept. of Psychology, Queen's University, Kingston, K7L 3N6, Canada.

Several Studies have shown that the unconditioned increase in behavioral activity produced by the stimulant drug, d-amphetamine can be conditioned to stimuli associated with injections (e.g. Tilson & Tech, Pharmacol. Biochem. Behav. 1973, 1, 149-153). However, the precise stimuli that control this conditioned responding (for example, temporal stimuli, stimuli associated with preinjection handling, the injection itself, or stimuli from the test environment) remain unclear. The present study was undertaken to test the role of environmental stimuli in conditioned activity. Two environments (E_1 and E_2; 40 x 50 x 41 cm high), differed in floor texture, level of illumination and color (black vs. white); their floors were demarcated into 10 cm squares. Forty-eight male Wistar rats received a one hr habituation exposure to one environment on two consecutive days; half received E_1 then E_2 and half received the other order. On each of the next 5 days, each rat received two 30-min sessions; the first was an habituation session in one environment and the second was a conditioning session in the other. Again, half received one order of environments and half the other. Conditioning sessions were preceded by i.p. injection with saline (n=24), 2.5 mg/kg (n=12) or 5.0 mg/kg (n=12) d-amphetamine sulphate. On the next day, all animals received a saline injection prior to the one test session; half of each group was tested in the conditioning (same) and half in the other (different) environment. Dependent measures were number of squares entered and stereotypy rating taken during a 30 sec observation period at 5, 10, 20 and 30 min into the session by two "blind" raters. Results revealed significantly greater number of squares entered and higher stereotypy ratings in the same vs. the different environment for the d-amphetamine groups at the 10 min observation period; the saline animals showed no environment effect at this time. These results suggest that environmental stimuli play an important role in mediating conditioned activity with d-amphetamine as the unconditioned stimulus. (Supported by the MRC.)

173.1 POST-TETANIC DEPOLARIZATION OF FROG PRIMARY AFFERENT FIBERS. R.A. Davidoff and J.C. Hackman. Neurology Service, V.A.M.C. and Department of Neurology, University of Miami School of Medicine, Miami, FL 33125.

Tetanization of a frog dorsal rool (DR) results in a sustained negative shift of potential followed by a hyperpolarization of the fibers contained in an adjacent (passive) DR (Davidoff and Hackman, J. Physiol. 302:297, 1980). Our present experiments show that when sucrose gap recordings are made from the stimulated (active) DR of the isolated, hemisected frog spinal cord superfused with HCO_3^-- buffered Ringer's solution (15°C), an additional potential change is found--the sustained negative shift is succeeded by a slow (5 to 60 sec), large (5 to 12 mV) depolarizing after-potential (DAP). A long-lasting (1 to 4 min, 2 to 6 mV) hyperpolarization follows the DAP.

The DAP could be produced by tetanic electrical stimulation of a lumbar DR at frequencies ranging from 10 to 100 Hz, for durations of 5 to 30 sec provided that the DR was stimulated with voltages greater than 3X the threshold for producing a detectable dorsal root potential. Both the magnitude and duration of the DAP were monotonically related to the stimulation frequency, stimulating current strength, and tetanus duration.

The DAP originated in the cord since it was eliminated by sectioning the cord between the entrance of the DR and the primary afferent terminals. It did not result from a GABAergic effect since it was increased by GABA blockers. On the other hand, the magnitude and amplitude of the DAP were proportional to $[K^+]_o$ as measured with K^+-sensitive microelectrodes. And it was sensitive to procedures which altered $[K^+]_o$. For example, it was increased by picrotoxin and bicuculline which increase K^+ efflux, and was decreased by pentobarbital which reduces K^+ efflux; its amplitude and duration were augmented when K^+ clearance was reduced by blocking the Na^+ pump (ouabain, cooling, substitution of Li^+ for Na^+); it was increased by perfusion with Ringer's solution containing OmM K^+. That at least part of the responsible rise in $[K^+]_o$ is Ca^{++}-dependent is suggested by the finding that low concentrations of Mn^{++} (50 M) reduced or abolished the DAP.

These observations show that repetitive stimulation of primary afferents is followed by a long-duration depolarization of the stimulated fibers. The results are consistent with the view that this potential change is at least partly a consequence of a transient excess of $[K^+]_o$. (Supported by VAMC Funds, MRIS 1769).

173.2 SPINAL CORD ASYMMETRIES FOLLOWING PARTIAL DEAFFERENTATION. H. Richard Koerber, Dept. of Physiology, West Virginia Univ. Medical Ctr., Morgantown, WV 26506.

In recent years it has become apparent that quite substantial interanimal variation can be observed in the dorsal horn somatotopic map. It is very difficult, therefore, to identify any possible plastic changes in dorsal horn somatotopy following partial deafferentation when combining data from many animals. Recent studies have concluded that projections from cutaneous nerves and single cutaneous afferents from symmetrical locations on the skin project to symmetrical locations in the spinal cord laminae III and IV. Others indicate that dorsal horn cells with receptive fields from symmetrical locations on the hindlimbs are located in relatively symmetrical locations in the spinal cord.

This study was designed to examine in detail the symmetry of the postsynaptic somatotopic map, and determine what asymmetries exist following partial deafferentation. Parallel electrode penetrations were made every 250 um across the width of the spinal cord. Single units were isolated and their receptive fields recorded on one of three standard cat leg drawings. Once the receptive field was recorded the position of the electrode tip was marked by passing 1 uA of AC current for 30 sec. Once the electrode tracks had been reconstructed the dorsal horns were divided into 10 bins using decile lines drawn through the laminar boundaries. Recording sites located in symmetrical bins at the same rostrocaudal level were used as "matched pairs" for statistical tests of symmetry.

Results from unoperated animals indicate a very high degree of symmetry with respect to receptive field areas, (cm^2), receptive field positions (distance from toes, cm) and receptive field geometries (length/width ratios). In chronically deafferented animals in which L6 and L7 dorsal roots were sectioned 30 days or >150 days prior to recording experiments, asymmetries were apparent. The major contribution to the asymmetries observed was the appearance of silent areas in the denervated dorsal horn. Asymmetries between responsive areas in the spinal cord can all be accounted for simply by the loss of afferent input from the severed roots.

This work was supported by USPHS grant NS12067 to P. B. Brown.

173.3 PATTERN OF CATECHOLAMINE DISTRIBUTION IN THE LUMBAR SPINAL CORD. G. D. Peca-Vogelsang, C. J. Hodge, Jr., R. T. Stevens, A. V. Apkarian, J. Franck, and O. M. Brown* Depts. of Neurosurgery and Pharmacology, Upstate Medical Center, Syracuse, NY 13210.

Most catecholamine containing terminals in the spinal cord are from suprasegmental sources. This study was undertaken to further elucidate the pattern of catecholamine (CA) distribution in the lumbar spinal cord using both glyoxylic acid induced histofluorescence (HF) and high performance liquid chromatography (HPLC).

Control lumbar spinal cords of cats were cut serially in five sections, L3-L7. Lesions placed between L3 and L4 included unilateral and bilateral ventral quadrant section, unilateral hemisection in conjunction with a mid-lumbar sagittal section and complete transection. The spinal cord segments were analyzed by HPLC as whole and either sagittally or horizontally hemisected pieces. To observe the orientation of the CA terminals, the spinal cord was cut at various angles and examined using HF.

In control animals, noradrenaline (NA) content increased 200-300% in the more caudal lumbar segments when compared to L3. In segments halved horizontally, the increase appeared more exaggerated in the dorsal horn. There was no obvious difference with HF between rostral and caudal segments. Distinct differences are seen, however, between the laminae of the spinal grey. Bilateral ventral quadrant section caused a large decrease in NA concentration. The segment above the lesion remained relatively the same. Unilateral ventral quadrant section produced a large decrease ipsilaterally and a substantial decrease contralaterally. L3 hemisection and a more caudal sagittal section left the cord ipsilateral to the hemisection completely depleted of NA but only had a moderate decrease in NA content contralateral to the caused lesion. Transection caused a complete depletion of NA below the lesion as measured by HPLC, although HF was still able to detect small quantities of NA associated with blood vessels along the median fissure.

These results indicate that there is a higher NA content in the more caudal lumbar segments, that descending NA fibers are located primarily in the ventral quadrant, and that there is substantial segmental crossing of descending NA fibers.

173.4 DORSAL ROOT POTENTIALS ELICITED BY LOCUS COERULEUS STIMULATION - DEPENDENCE ON INTACT NORADRENALINE STORES. A. V. Apkarian, C. J. Hodge, Jr., J. Franck, R. T. Stevens, and G. Peca-Vogelsang. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Nucleus locus coeruleus (LC) contains noradrenergic (NA) cells, some of which project to the spinal cord. The LC cells constitute a major source of NA terminals within the lumbar spinal cord. Electrical stimulation of the LC pontine area causes strong modulatory effects on most lumbar dorsal horn interneurons receiving cutaneous input. This study was undertaken to investigate the effects of LC stimulation on afferent dorsal root terminals.

Cats were anesthetized with chloralose, the lumbar enlargement exposed and dorsal rootlets of L7-S1 mounted on bipolar Ag-AgCl recording wires. LC was located both stereotaxically and by recording from the mesencephalic trigeminal nucleus. The brain stem stimulation parameters used were: stimulus trains of 50 msec, biphasic constant current pulses lasting 200 usec with a 100 Hz frequency and amplitudes varying from 50 to 200 uA. The LC stimulation evoked dorsal root potentials (DRP) were compared with the DRP's evoked by stimulating the hindlimb either electrically or by touch.

The brain stem stimulation evoked negative DRP's were of longest duration when the stimulating electrode was in LC as compared to other positions within the brain stem. The latency of the LC stimulation evoked DRP's was about 50 msec. Advancing the stimulating electrode deeper into pontine reticular formation gave rise to DRP's with 10 to 20 msec. latency. Hindlimb stimulation evoked DRP's had latencies of only a few milliseconds. Both IV and topical application of alpha adrenergic blockers (phentolamine and phenoxybenzamine) abolished the LC evoked DRP but not the reticular or hindlimb evoked DRP's. Application of the beta adrenergic blocker propranolol had no effect. IV injection of an MAO inhibitor (imipramine) increased the duration of LC evoked DRP with no change in the latency and without affecting the hindlimb stimulation evoked DRP.

These results suggest that LC stimulation causes NA dependent primary afferent depolarization through alpha adrenergic receptors.

173.5 CATECHOLAMINE VARICOSITIES IDENTIFIED IN CAT DORSAL ROOT GANGLION AND SPINAL VENTRAL ROOTS. R. T. Stevens, C. J. Hodge, Jr., A. V. Apkarian, and G. D. Peca-Vogelsang. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

During an investigation of the catecholamine (CA) innervation of spinal grey matter, dorsal root ganglia and ventral roots were examined using the glyoxylic acid histofluorescence technique. Fibers containing CA were found in both the ventral roots and dorsal root ganglion at all spinal levels but not within the dorsal roots. The CA fibers in this region were classified into two types. One form was a single, fine, varicose fiber. The other form was a bundle of intertwined fibers which collectively produced an intense fluorescence. This type was generally associated with blood vessels and was presumed to be sympathetic in origin. Both forms of these CA nerve fibers were also present in the grey matter of the spinal cord.

To examine the source of these CA varicosities, lesions were made. These included a lesion of the spinal root distal to the DRG or a total spinal transection. In both cases, CA varicosities of both types remained in both the DRG and the ventral roots. Occasionally CA fibers were observed entering the DRG accompanying blood vessels.

Catecholamine varicosities of central origin present in DRG and ventral root have been described in the rat[1], however the source and function of these fibers is, as yet, unknown.

(1) A. Dahlstrom and K. Fuxe. Evidence for the existence of an outflow of noradrenaline nerve fibers in the ventral roots of the rat spinal cord. Experientia 21:409 (1965).

173.6 POSSIBLE SOURCES OF CATECHOLAMINE TERMINALS IN THE LUMBAR SPINAL CORD OF THE CAT. C. J. Hodge, Jr., R. T. Stevens, G. D. Peca-Vogelsang, A. V. Apkarian, and J. I. Franck. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

The grey matter of the lumbar spinal cord is rich in catecholamine (CA) terminals in areas linked to the modulation of sensory and motor processes. Following lumbar injections, horseradish peroxidase (HRP) and Evans Blue (EB) retrograde transport were combined with glyoxylic acid induced CA histofluorescence to identify those areas of the brain stem which project to the cord and which also contain CA cell bodies. The use of EB allowed determination of those cells that both contained CA and projected to the cord.

The most rostral CA cell groups, A8, 9, and 10, which include substantia nigra, contained little or no retrogradely transported marker, and therefore do not contribute to lumbar CA innervation. The pontine areas of locus coeruleus, the subcoerulear area, the parabrachial nuclei and the Kolliker-Fuse nucleus are comprised in part of CA containing cells and cells that project to the lumbar cord. However, using the EB double labeling techniques, it was seen that most of the LC cells that project to the cord are not catecholaminergic. The more ventral areas of the subcoerulear nucleus, the parabrachial nuclei, and the Kolliker-Fuse nucleus have a much higher percentage of CA containing cells that project to the lumbar cord and likely are the major source of spinal CA.

The CA containing cells of the medulla are relatively sparse and retrograde labeling was absent or very light with the exception of the area corresponding to A1 in the rat.

These results indicate that the primary source of lumbar spinal NA is from the dorsolateral pons in the caudally projecting nuclei ventral to locus coeruleus.

173.7 A LIGHT AND EM ANALYSIS OF IMMUNOREACTIVE GLUTAMIC ACID DECARBOXYLASE (GAD) IN THE SPINAL AND TRIGEMINAL DORSAL HORN OF THE CAT. Allan I. Basbaum, Ellyn J. Glazer and Wolfgang Oertel*, Dept. of Anatomy, Univ. of California, San Francisco and Dept. of Neurology, Technische Univ., Munich, Germany.

Segmental and supraspinal control of dorsal horn nociceptors involves complex interactions among a variety of putative neurotransmitters. To analyze the contribution of GABA to this control, we have examined the distribution of immunoreactive GAD, the biosynthetic enzyme for GABA. Cats were perfused with 4% para/0.2% glut., in 0.1M phosphate buffer. To generate GAD cell body labelling, colchicine (20µg/µl) was injected 48 hours prior to perfusion, either intrathecally (10µl) or intracisternally (6µl). Sections through the lumbosacral enlargement and the trigeminal nucleus caudalis were sectioned either transversely or sagitally on a Vibratome and processed for GAD immunoreactivity with the PAP method using a sheep anti-GAD antiserum (Oertel et al, Neuroscience, 1981). Sections for LM were pretreated with 10% methanol/3%H_2O_2 to enhance antibody penetration. Sections for EM were osmicated and flat embedded in Epon-Araldite. Control sections were incubated in preimmune serum; all controls were negative.

GAD terminals are most dense in the superficial dorsal horn, laminae 1 and 2, (the substantia gelatinosa, sg). Much less staining is found in the nucleus proprius, lamina 3, 4 and 5. A dense region of GAD staining was also present in medial lamina 7 and adjacent to the central canal. GAD cell body staining was generally confined to the soma. GAD cells are found in most layers of the dorsal horn, but are most numerous in lamina 3. Many are found in the inner sg, somewhat fewer in the outer sg. A few, small fusiform cells (5x10-15µ) are found in the marginal zone. Most of the GAD cells are oval or round, measuring 5-10x10-20µ.

EM analysis reveals a variety of synaptic relationships. GAD terminals are presynaptic to dendrites in lamina 1 and 2, to somata and proximal dendrites of lamina 1 and to axons, including a population of central axonal terminals. Many of the latter are presumed to be of primary afferent origin. Occasionally, vesicle-containing GAD profiles are postsynaptic to unlabelled axon terminals.

Given the presence of numerous GAD cells, but the paucity of GAD terminals in lamina 3, this study indicates an important contribution of these lamina 3 cells to the control of superficial dorsal horn nociceptors of I and II. Moreover, despite electrophysiological similarities, lamina 3 and 4 are probably functionally distinguishable. Supported by NS 14627, 00364, DA-01949 BNS 78-247621 and the Sloan Foundation.

173.8 ELECTRON MICROSCOPIC ANALYSIS OF PACINIAN CORPUSCLE AFFERENT FIBER TERMINALS IN CAT DORSAL HORN. K. Semba, P. Masarachia*, S. Malamed*, M. Jacquin*, S. Harris* and M. D. Egger. Dept. of Anat., CMDNJ-Rutgers Med. Sch., Piscataway, N.J. 08854.

Intra-axonal injections of horseradish peroxidase (HRP) into afferent fibers from the glabrous skin of the cat's hind paw made possible observation of functionally identified terminals at the electron microscopic level (Egger et al., Brain Research, 207: 157-162 (1981)). We have now begun to characterize terminals of fibers innervating Pacinian corpuscles. Analysis of micrographs of HRP-filled boutons in Rexed's laminae III, IV and V indicated: (1) HRP-filled boutons, ranging from 1.0 to 3.5 µm in longest dimension, contained clear, round vesicles, approximately 40 nm in diameter. From lamina III to lamina V, the number of synaptic zones per bouton decreased. (2) Both axo-dendritic and axo-axonic specializations were observed, with axo-dendritic profiles predominating in laminae III and IV (about 70%), whereas axo-axonic profiles predominated in lamina V (about 60%). We observed no axo-somatic profiles. (3) HRP-filled boutons formed both asymmetrical and symmetrical synapses with dendritic profiles, with asymmetrical synapses predominating (about 80%). The longest dimension of the postsynaptic dendritic profiles ranged from 0.5 to 3.5 µm. (4) All the axons with which HRP-filled boutons had synaptic contacts contained clear, elliptical or pleomorphic vesicles, 40-50 nm in major diameter. A few of these unlabelled axons contained dense-core vesicles as well. About 40% of the axons in contact with the HRP-filled boutons were identified as postsynaptic, with the synaptic type clearly seen to be asymmetrical. The complexity of the neuropilar organization of the HRP-filled boutons was revealed by serial sectioning labelled afferent collaterals in lamina IV which included 19 boutons. One of the boutons synapsed with 5 dendrites and 5 unlabelled axons; 3 of the 5 unlabelled axons in turn synapsed with 3 of the 5 dendrites that were postsynaptic to this labelled bouton, forming a glomerulus. Some boutons were interconnected by extremely thin axon collateral segments, which in places appeared to be only 25-60 nm in diameter. HRP-filled boutons frequently gave origin to thin HRP-filled sheets which curled along the bouton, but which appeared to be distinct, --and separated by membranes,--from glial elements in the vicinity of the boutons. The predominance of axo-dendritic synapses in laminae III and IV, combined with the fact that all the HRP-labelled boutons contained clear, round vesicles, suggests that activating the Pacinian corpuscles in the glabrous skin should produce strong excitatory drive on postsynaptic dorsal horn cells. 173.9 MORPHOLOGIC ANALYSIS OF NEURONS OF THE CAT SUBSTANTIA GELATINOSA INTRACELLULARLY STAINED WITH HORSERADISH PEROXIDASE.
M.A. Clendenin and G.E. Goode, Department of Anatomy, Eastern Virginia Medical School, Norfolk, VA 23501

Small neurons of the substantia gelatinosa (SG) in the lumbar dorsal horn of the cat were targets for intracellular recordings and enzyme labelling. Some cells were labelled by intracellular iontophoresis while other neurons were studied following incorporation of extracellular marker protein. No more than three "injury filled cells" appeared in our serial reconstructions of 100 micron Vibratome sections reacted with DAB, in contrast to intracellular injections when the enzyme was limited to the cell from which physiologic recordings were made. We studied the size, shape and location of the perikarya as well as dendritic and axonal shape, length, and patterns of termination. Two different cell types were labelled in the superficial zone of the substantia gelatinosa. The cells near the marginal-SG interface have small oblong or rounded soma. Their dendrites radiate to form small spherical fields within a hundred microns of the perikaryon, whereas their distal dendrites form longitudinal arrays for several hundred microns within a cord segment. Proximal dendrites are tortuous, highly branched arbors with distinct beaded dilations along their length. A variety of complexes of short spines as well as long thin pedicles with spine heads project from these proximal dendrites. The larger diameter, long longitudinal distal dendrites of these cells are relatively spine free until at their distal tips they branch into thin pedicles with multiple spine heads. One neuron in our collection may represent a subpopulation of neurons as its distal dendritic pattern was oriented from a lateral to medial direction across the SG.

The morphology of these neurons in the superficial SG is in contrast to labelled cells in lamina IV. Their larger cell bodies are stellate, their dendrites form larger spherical fields proximally, and their large distal dendrites project dorsally through lamina III, II and I into the dorsal root entry zone. These dendrites are relatively aspinous. The morphology of labelled neurons will be discussed with regards to their physiology and ultrastructure in an attempt to uncover a common denominator for the modulation of nociceptive information in the interneuronal pool of the SG. (Support by USPHS General Research Support Grant 218).

173.10 SYNAPTIC INPUTS ON THE DORSALLY DIRECTED DENDRITES OF AN HRP-FILLED LAMINA IV DORSAL HORN NEURON IN THE SUBSTANTIA GELATINOSA OF ROLANDO: AN EM ANALYSIS.
S. Gobel, G. J. Bennett, Z. Seltzer*, M. J. Hoffert and E. Humphrey*. Neurobiology and Anesthesiology Branch, National Institute of Dental Research, National Institutes of Health, Bethesda, MD 20205.

In Golgi studies of perinatal animals, Ramon y Cajal showed that the deeper parts of the dorsal horn contain neurons with either pyramidal or multipolar cell bodies which send some of their dendrites dorsally into the substantia gelatinosa of Rolando (Rexed's laminae I and II). From our Golgi studies in adult cats, it has become clear that such neurons constitute an important source of the dendrites in laminae I and II. In these Golgi studies, two kinds of neurons which send dendrites into laminae I and II have been found in Rexed's laminae III and IV. One of these has very spiny dendrites while the other one has relatively smooth aspiny dendrites. Recently, we have intracellularly filled one of these neurons with smooth dendrites in the adult cat lumbar cord with horseradish peroxidase (HRP). This neuron has its cell body close to the IV/V border. In addition to giving rise to dendritic branches in laminae III,IV, and V, this neuron sends numerous dendritic branches dorsally into laminae I and II as well as into Lissauer's tract and the dorsolateral funiculus. An EM analysis of the HRP-filled dorsal dendrites showed that numerous small dome-shaped axonal endings in lamina I, Lissauer's tract and the dorsolateral funiculus synapse on these dendrites at single short axodendritic synapses which can be either symmetrical or asymetrical. One of these endings contains a mixture of different sized small oval agranular vesicles with appreciable numbers of highly flattened ones while the other one contains only small oval vesicles. Occasional dense-core vesicles are seen in both endings. These two kinds of axonal endings resemble the D1 and D2 dome-shaped serotonergic endings respectively which were shown in other studies to take up [^{3}H]5HT and the serotonin neurotoxin 5,6 dihydroxytryptamine (Ruda and Gobel, Brain Res. 184(1980) 57-83). In their passage through laminae I and II, the HRP-filled dendrites were not observed entering any glomeruli, i.e., those structures in which the axonal endings of primary neurons are found. These observations suggest that many of the neurons in the deeper laminae of the dorsal horn which send some of their dendrites dorsally into laminae I and II may recieve appreciable input from descending aminergic axons on these dorsal dendrites but very little input from the primary axons which arborize in these laminae.

173.11 INTRACELLULAR RECORDING FROM DORSAL HORN NEURONS IN THE RAT SPINAL CORD SLICE PREPARATION.
K. Murase* and M. Randić (Spon: W. G. Van Meter). Dept. of Vet. Physiol. Pharmacol., Iowa State University, Ames, IA 50011.

Utilizing transverse rat spinal cord slices and extracellular recording it has been shown that substance P (SP), somatostatin (SS) and methionine-enkephalin (ME) modify activity of the dorsal horn neurons by acting directly on postsynaptic sites (Miletić and Randić, Neurosci. Abstr., 6: 624, 1980). By using intracellular recording technique in vitro in a horizontal spinal cord slice preparation we have now investigated membrane actions of SP and SS.

Rats (5-12 days old) were anesthetized with ether and, following a laminectomy, about 1 cm long segment of lumbosacral spinal cord with attached dorsal rootlets was quickly removed and immersed in oxygenated Krebs-Ringer solution at 6°C and further sectioned with an Oxford vibratome to yield about two horizontal 300 µm-thick dorsal horn slices. The slices were incubated in Krebs-Ringer solution at room temperature for about 1 hr. Then they were transferred to the recording chamber and continuously perfused with oxygenated Krebs-Ringer solution at 37°C at a flow rate of about 2 ml/min. Intracellular recordings were performed with micropipettes filled with 1-3 M K-acetate having D.C. resistances of 60-100 MΩ. Good intracellular recordings from slices could be obtained for 6-8 hrs after isolation of the spinal cord. Electrical stimulation of the dorsal rootlets with a glass-coated platinum wire electrode was used to synaptically activate dorsal horn neurons. A high-input impedance bridge amplifier was used to inject current through the recording microelectrode. The amplitude of the recorded voltage produced by hyperpolarizing current pulses was used as a measure of the membrane input resistance. Effects of bath-applied SP and SS (10^{-4} to 10^{-6} M) were studied on spontaneous activity, membrane potentials and input resistance, and on synaptic and action potentials.

In 29 dorsal horn neurons, mean resting potential and membrane input resistance were -67.4 ± 5.9 mV, and 41 ± 12 MΩ respectively. The amplitudes of the evoked action potentials up to 85 mV were recorded. SP produced a reversible and dose-related depolarization, while SS weakly hyperpolarized the membrane of most dorsal horn neurons. Both effects appeared to be associated with decrease in membrane input resistance, although the sample of tested units is relatively small. More extensive intracellular studies of the membrane actions of SP, SS and ME and analysis of their ionic mechanisms are currently in progress. (Supported by NSF grant BNS 23871 and U.S. Dept. of Agriculture).

173.12 EVALUATION OF THE SPONTANEOUS SPINAL ELECTROGRAM AS A MEASURE OF DESCENDING SPINAL CORD FUNCTION FOLLOWING TRAUMA.
J. T. Molt. Dept. of Physiology. Hahnemann Med. Col., Philadelphia, PA 19102

In the study of experimental spinal cord trauma objective tests of cord function are necessary for the evaluation of the degree of injury and the efficacy of treatments. The most commonly employed method of electrophysiological assessment is the somatosensory evoked potential. Tests of descending cord pathways are less frequently employed even though these tracts represent a large percentage of the cross sectional area of the cord and it is their interruption that results in the loss of motor activity.

In this investigation the spontaneous electrical activity of the spinal cord (spontaneous spinal electrogram or SEG) was analyzed as a method to assess descending cord function. The SEG consists of low voltage background activity (25 µV) upon which occur spontaneous, random, large voltage (75-300 µV) negative potentials termed negative sharp waves (NSWs) which are 20-40 msec in duration. NSWs are inhibited by activity in descending cord pathways. This fact was used as a rationale to test the hypothesis that surgical interruption of descending pathways that remain functionally intact 48 hours following spinal cord trauma in the cat will result in an increase in the occurrence of NSWs that will inversely correlate with both the intensity of the injury and the histologically determined extent of the trauma-induced lesion.

Anesthetized cats were injured by dropping a 25 gram weight variable distances onto an impounder resting on the dura of the L2 cord. The change in momentum (impulse) of the weight was measured. 48 hours later the cat was rendered decerebrate under ether anesthesia. The SEG was recorded caudal to the site of injury. The mean amplitude of NSWs was determined and the mean number/min exceeding this value was determined. The cord was then surgically transected rostral to the trauma-induced lesion and recording continued. The average number/min of NSWs passing the previously determined threshold was determined as was the mean amplitude. The percentage of cross sectional area showing lesions was determined histologically.

The results show that there was a significant inverse correlation between percent change in count following surgical transection and both impulse and lesion size confirming the hypothesis and indicating that the SEG may be a valuable tool in assessing trauma and treatment in experimental spinal cord injury. In addition the results show that the mean pretransection count correlated positively with both impulse and lesion size suggesting that the level of SEG activity may give insight into cord functional status, an important result in terms of possible human application. Supported by Biomed. Res. Suppt Grant 5-SO7-RR05413.

173.13 SITES OF ACTION OF SEGMENTAL AND SUPRASPINAL INPUTS INHIBITING IMPULSE TRANSMISSION ALONG THE PATHWAYS MEDIATING PAD OF Ia FIBERS. P. Rudomín, I. Jiménez*, M. Solodkin* & S. Dueñas*. Centro de Investigación del I.P.N. México 14 D.F.

Impulse transmission along the pathways mediating primary afferent depolarization (PAD) may be inhibited by segmental and supraspinal stimulation. However, the site of action of these inhibitory inputs has not been yet determined. Previous work suggests that at least two interneurons are interposed in the PAD pathway to group I fibers and that intraspinal microstimulation (ISMS) produces PAD probably by direct activation of the last order interneuron. Now we are using the ISMS technique to detect inhibitory actions on this interneuron. Cats were anesthetized with pentobarbital, paralyzed and maintained with artificial respiration. PAD was inferred from the changes in the threshold current necessary to keep a constant probability of antidromic firing of single fibers. A conditioning train to group Ia fibers in the biceps-semitendinosus (BST) nerve usually decreased the activation threshold of single Ia fibers in the gastrocnemius (GS) nerve. This effect was inhibited by preceding sural (SU) conditioning. The PAD of Ia GS fibers produced by ISMS applied either in the intermediate nucleus (IN) or in the motor nucleus (MN) was not affected by SU conditioning. Stimulation of the magnocellular reticular formation (RF) could reduce the PAD of Ia GS fibers produced either by BST stimulation or by ISMS to the IN, but not the PAD produced by ISMS to the MN. It thus appears that SU inhibition acts on the first order interneuron. RF inhibition appears to act on the last order interneuron which is located within the IN and makes axo-axonic contacts with the Ia fibers ending both in the IN and in the MN.

The inhibition produced by RF stimulation on the BST induced PAD was usually abolished by sectioning the ipsi. dorso-lateral fasciculus in the thoracic spinal cord, but sometimes it was also necessary to cut the contralateral half of the cord. Not unfrequently RF stimulation reduced the activation threshold of Ia GS fibers (classified as such because SU conditioning reduced the BST induced PAD). This depolarizing action was mediated by fibers running in the ipsi. ventromedial fasciculus. This suggests that the facilitatory and inhibitory actions produced by RF stimulation are mediated by independent descending fiber systems which may be coactivated by the electrical stimulation.

174.1 DESCRIPTIVE MEASURES OF THE INNERVATION OF THE CORNEAL EPITHELIUM IN RABBIT. A.J. Rózsa and R.W. Beuerman, Division of Ophthalmology, Stanford University Medical Center, Stanford, CA 94305

All forms of supraliminal stimulation of the cornea are perceived as noxious. Although sensory receptors of the corneal epithelium are known to be morphologically unspecialized or "free nerve" endings, there have been no adequate descriptions of the organizational design or of the density of the innervation of corneal epithelium.

Both corneas of 24 albino rabbits (2-2.5 kg) were stained with a modified gold chloride technique. Cross-sections (15 µm thick) and flat-mounts (100 µm thick) were prepared for light microscopical (400X-1000X) examination.

Cross-sections, used for determining neural density, were apportioned into 100-µm samples, and the number of axonal endings, their branching pattern and mode of termination were assessed. Averaging terminal counts from 248 samples confirmed the notion that the corneal epithelium was densely innervated. A normal rabbit corneal epithelium with a surface area of 213 mm^2 was calculated to contain about 1.4 million terminal endings. This meant that the fine filament of an esthesiometer (0.13 mm dia.), when contacting the surface of the epithelium, could stimulate approximately 100 terminal endings. A combination of serial cross-sections and horizontal flat-sections enabled the reconstruction of the three-dimensional organizational geometry of axon terminals within the epithelium. After penetration of the epithelium, axons branched in characteristic patterns of "leashes" containing 4-50 terminals. These "leashes" often coursed together for several hundred micrometers within the basal cell level of the epithelium. Vertical branches rising from the "leashes" at irregular intervals formed a dense and complex arrangement of terminal endings at all levels of the epithelium. A practical method for assessing relative changes in innervation showed that neural density at all levels in the epithelium increased as a function of the distance from the limbus to the center. This observation agreed well with the psychophysical finding that corneal sensibility to mechanical stimulation increased as its center was approached.

Based on psychophysical evidence and the results of these studies, the cornea suggests itself as an excellent model for the neurobiological investigation of experimental pain.

174.2 PRURITUS EVOKED BY ELECTRICAL, CUTANEOUS STIMULATION, R.P. Tuckett, Department of Physiology, University of Utah, Med. Ctr., Salt Lake City, Utah 84108

Only polymodal nociceptors have been found to respond to cowhage (Tuckett, R.P., Neurosci. 6:428, 1980), a potent itch producing agent; however, the same receptors also respond to levels of heat and to chemicals that produce pain. It is possible that by producing different firing patterns, a single neuron is able to signal both pain and itch to the central nervous system.

The skin of 25 human subjects was stimulated at frequencies varying from 2 to 100 Hz, with a pulse width of 7 ms. One electrode (2x3 cm) was placed on the volar aspect of the wrist and the other either about 18 cm proximal on the forearm or on the ankle. At the beginning of the experiment, the nature of the procedure was explained and the subject's informed consent obtained, with the understanding that the subject could drop out of the experiment at any time. Subjects were randomly presented with pairs of stimuli and were asked to compare the intensity of the test to the control stimulus within the pair. The control stimulus was 10 Hz. All but two (93%) reported pruritus that increased in intensity with increased frequency of stimulation through 40 Hz. The intensity diminished and was more variable at 100 Hz, probably due to fatigue of the sensory neurons. The quality of the sensation did not change from itch to pain over the range of frequencies presented.

Afterwards, cowhage was applied to the wrist that had not been electrically stimulated. All subjects felt itching. Twenty-one (84%) said the itching was very similar to that from electrical stimulation. Their verbal description of the two experiences were also quite similar. The remainder reported the quality of itch to be different for the two types of stimuli.

In addition, discharge patterns of individual polymodal neurons in cat to heat (45-50°C) and cowhage were used to trigger the stimulator in double-blind experiments. Subjects were unable to distinguish any differences in the quality of the evoked sensations. (All reported itching.) It was concluded that the experimental evidence did not support the possibility that the quality of the noxious sensation elicited by electrical stimulation is dependent on the stimulus frequency. (Supported by USPHS Grant NS15102.)

174.3 THE ROLE OF MUSCLE AFFERENTS IN RELIEF OF PAIN FOLLOWING PERIPHERAL NEUROTRAUMA: CLINICAL AND EXPERIMENTAL STUDIES. A. Rabin* and R.A. Levy. Department of Pharmacology, University of Illinois College of Medicine, Chicago, IL 60680.

Although electrical stimulation of the skin is a common procedure for the treatment of chronic muscle pain syndromes, stimulation of muscles to relieve burning pain from skin has not yet been explored. During the course of clinical observations[1] we noticed that cutaneous burning pain and pain paroxysms following peripheral neurotrauma could be relieved by tensing of muscles having afferent inputs segmentally congruent with those of denervated skin. We found, in patients with denervation of the upper extremity, that referred sensation could be induced in the hand and forearm by stimulation of the shoulder girdle muscles. Thus, there exists a close topographical relationship in the central representation of these muscles and the distal part of the extremity. We succeeded in relieving burning pains in the hand in such patients by electrical stimulation of those muscles or by physical exercises.

Experiments in rats with full or partial section of the brachial plexus were carried out to support these observations. The animal model of autotomy (Wall et al., 1979; Wiesenfeld and Lindblom, 1979), which has been associated with painful sensation, was used to determine the role of the shoulder girdle muscles in prevention of autotomy of the paw. The degree of autotomy after denervation of the upper extremity, by section of the brachial plexus in the subclavicular area, was markedly intensified by additional denervation of the shoulder girdle muscles.

These data support the notion that activation of partially deafferented sensory centers through overlaping muscle inputs may be effective in relieving chronic pain syndromes.

Supported by NIH grant DE 5390.

[1]Clinical data obtained at City Hospital #67, Moscow, USSR.

174.4 IMMUNOHISTOCHEMISTRY OF RAT SPINAL DORSAL HORN TREATED WITH INTRATHECAL CAPSAICIN, KAINATE AND PIPERINE. T. Yaksh, P. Micevych and R. Elde (Spon. by F.W.L. Kerr), Dept. of Neurosurgery, Mayo Fdn., Rochester, MN 55905 and Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

Intrathecal capsaicin (60 µg), a homovanyllic acid derivative has been shown to produce a significant elevation of the thermal nociceptive threshold in rats as measured by the tail flick and hot-plate assays. This thermal analgesia is coincident with a 40-70% depletion of substance P (sP) levels in the spinal cord as measured by radioimmunoassay (RIA). Intrathecal piperine (60 µg) and kainic acid (60 µg) also produce a significant depletion (50%) of spinal sP as measured by RIA but do not produce a significant elevation of thermal nociceptive threshold. Using immunohistochemistry we examined a series of rats which received intrathecal capsaicin (70 µg), piperine (70 µg), kainic acid (70 µg) or drug vehicle (50% dimethyl sulfoxide). The drug doses were sufficient to show significant depletion of spinal sP assayed in a parallel series of animals, but in the vehicle control rat spinal cord no changes were observed. The drug treated rats, vehicle controls and normal rats were allowed to survive 7 days and then sacrificed by transcardial perfusion. Ten micron cryostat sections were incubated with antibodies raised against sP, cholecystokinin (CCK), somatostatin (SOM), methionine-enkephalin (M-ENK) and serotonin (5-HT), and processed for indirect immunofluorescence. The most striking effects of intrathecal capsaicin, piperine and kainic acid were localized in laminae I, II and III (Rexed). The table below summarizes our findings on the effects of these agents on the immunofluorescence of these dorsal laminae.

	sP	CCK	SOM	M-ENK	5-HT
Capsaicin (7)	-	-	+	+	+
Kainic Acid (5)	+	+	+	-	+
Piperine (2)	-	+	+	+	+

n = ( ); + = no change from normal; - = profound reduction of immunofluorescence.

The sP, CCK and SOM in laminae I, II and III has been reported in small diameter primary afferents, ENK has been localized in intrinsic neurons and 5-HT is present in a descending system of fibers. Our observations imply that capsaicin depletes sP and CCK, and piperine depletes sP from primary afferent fibers. Kainate depletes the intrinsic ENK neurons but does not have an effect on the primary afferent fibers. None of the drug treatments affected the scattered 5-HT-immunoreactivity fibers in the dorsal horn. The kainic acid depletion of spinal sP measured by RIA has not been confirmed by this study. (NS 16541 and Mayo Fdn.)

174.5 RELEASE OF SEROTONIN AND NOREPINEPHRINE INTO SUPERFUSATES OF THE RAT SPINAL CORD FOLLOWING ELECTRICAL STIMULATION OF THE NUCLEUS RAPHE MAGNUS. Donna L. Hammond, Gertrude M. Tyce and Tony L. Yaksh, Dept. of Physiology and Neurosurgery Research, Mayo Foundation, Rochester, Minnesota 55905.

Axons of serotonergic neurons contained within the nucleus raphe magnus (NRM) terminate in the spinal cord. The present study examined the ability of electrical stimulation of the NRM to increase the efflux of endogenous serotonin (5HT) and norepinephrine (NE) into superfusates of the rat spinal cord. Male Sprague Dawley rats were pretreated with 10 mg/kg fluoxetine, anesthetized and prepared for superfusion of the spinal cord subarachnoid space. Artificial CSF was delivered at 0.1 ml/min to the caudal intrathecal space and, after superfusing the entire spinal cord, was collected at the level of the cisterna magna in iced sampling tubes. 5HT and NE in the same sample of superfusate were separated using column chromatography and their concentrations were determined using HPLC with electrochemical detection. The spinal cord was superfused for three consecutive 25 min intervals. The first sample was used to monitor the recoveries of added standard 5HT and NE. The second sample of superfusate was used to determine the basal concentrations of 5HT and NE. During the collection of the final sample of superfusate, the NRM was stimulated at 30 Hz using 0.5 msec monophasic square waves. Current intensity was varied from 150 to 250 μA, but remained constant during the period of stimulation in any one animal. This final sample of superfusate was used to determine the levels of the evoked release of 5HT and NE. The stimulation sites were localized histologically in all animals. Basal efflux of 5HT and of NE was 0.60 ng/ml (SE = 0.13) and 0.23 ng/ml (SE = 0.03), respectively. Following electrical stimulation of the NRM, levels of 5HT increased to 1.14 ng/ml (SE = 0.27) and those of NE increased to 0.41 ng/ml (SE = 0.09) ($p < 0.05$, Student's t-test; each amine). Electrical stimulation of sites located outside the NRM failed to increase 5HT and NE levels. The release of 5HT into spinal cord superfusates following electrical stimulation of the NRM is in agreement with the anatomical and biochemical data which indicate that serotonergic neurons of the NRM project to the spinal cord. The concomitant release of NE may reflect the activation of noradrenergic axons of passage or the ability of NRM neurons to modulate the activity of noradrenergic neurons which project to the spinal cord. Finally, the results of this study suggest that the elevation of nociceptive threshold produced by electrical stimulation of the NRM may be mediated by the release of both 5HT and NE in the spinal cord. (Supported by NS 16541 to TLY and the Mayo Foundation).

174.6 PROPERTIES OF A LONG LATENCY RESPONSE EVOKED IN DORSAL HORN NEURONS BY NOXIOUS THERMAL STIMULI IN DECEREBRATE CATS. K. C. Kajander*, D. C. Tam*, T. J. Ebner, and J. R. Bloedel. (SPON: G. King) Depts. of Neurosurgery and Physiology, Univ. of Minnesota, Minneapolis, 55455.

These experiments were designed to study the characteristics of the long latency response of dorsal horn neurons to noxious thermal stimuli. Specifically the extent to which this response can discriminate between different noxious temperatures was examined using signal detection theory. Also the effects of activating descending pathways on these measurements were determined. Experiments were performed in unanesthetized, decerebrate cats in which the lumbosacral region of the spinal cord was exposed by a laminectomy and stimulating electrodes were placed in the nucleus raphe magnus and the periaqueductal gray. Noxious thermal stimuli were applied to the ipsilateral hind footpad of the cat using a thermoelectric module capable of producing a 10°C rise in temperature in approximately 2 sec. Dorsal horn neurons selected for this study responded to maintained thermal stimuli at a temperature of 45°C and increased their discharge when the temperature was raised to noxious levels. The response of each neuron was assessed in the following manner. Transient thermal stimuli 10 and 12°C in magnitude were applied to the footpad from each of two baseline temperatures (42 and 45° C). The response of the neuron to each stimulus was analyzed individually. Based on plotted data from the individual trials, the time of onset (latency) and the duration of the average discharge rate of the neuron during a selected response period were then calculated. The mean frequency and standard deviation of the response evoked during several trials at each of the two transient temperature stimuli were used to calculate the parametric discriminability measure d'. The responses of most dorsal horn neurons had latencies greater than two seconds and durations which significantly outlasted the period of heating. The calculation of d' revealed that the responses to the two transient thermal stimuli were significantly different. Electrical stimulation to the periaqueductal gray and nucleus raphe magnus could attenuate the mean frequency of the response. However, its effect on d' was variable as d' was shown to increase or decrease. These data indicate that, based on an analysis of firing frequency, some dorsal horn neurons can discriminate between two transient noxious temperatures. In addition, the activation of descending pathways can alter the magnitude of the responses to each temperature pulse independent of their effect on discriminability. This research was supported by NIH Grant #5 RO1-NS13002.

174.7 COMPARISON OF RESPONSES OF ROSTRAL AND CAUDAL TRIGEMINAL BRAINSTEM NEURONES TO ELECTRICAL AND THERMAL STIMULATION OF TOOTH PULP IN CATS. J.W. Hu, G.J. Ball and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Toronto, Canada M5G 1G6.

The subnucleus caudalis of the trigeminal brainstem sensory nuclear complex is generally implicated as the brainstem site vital for the relay of orofacial nociceptive information, yet paradoxically a large number of presumed nociceptive primary afferents from the tooth pulp has been shown in anatomical and electrophysiological investigations to project to more rostral parts of the trigeminal brainstem complex such as subnucleus oralis. However, since electrophysiological evidence for the latter projection is largely based on the activation of low-threshold mechanosensitive (LTM) neurones in oralis by electrical stimulation of the tooth pulp, we wished to test the response of oralis neurones to both electrical and natural (thermal) stimulation of the tooth pulp and compare it, in the same animals, with the response of caudalis neurones to both forms of pulp stimulation.

The activity of single neurones electrically driven from the ipsilateral canine tooth pulp was recorded in caudalis and oralis of anaesthetized cats. The neurones were functionally identified as LTM or cutaneous nociceptive neurones on the basis of criteria recently described (J. Neurophysiol., 45: 173, 1981). The effects on these neurones of controlled heating or cooling of the tooth crown were then examined.

In accordance with our earlier observations (e.g. Brain Res., 117: 211, 1976), we noted many LTM neurones in subnucleus oralis which had orofacial mechanoreceptive fields but which could also be driven at short latency by pulp electrical stimulation. However, none of 39 of these oralis neurones tested responded to heating (50-55° C) or cooling (0-5° C) of the tooth pulp. In contrast, 12 of 18 caudalis nociceptive neurones excited by facial noxious stimuli and pulp electrical stimulation responded also to tooth heating. The most vigorous and reproducible responses to heating were noted in those nociceptive neurones located in the superficial layers of caudalis. A weak response to thermal stimulation was seen in 4 of 28 LTM caudalis neurones that could be electrically driven from the pulp.

These findings raise uncertainties about the functional role, if any, played in tooth pulp nociception by those LTM neurones which can be excited by a synchronous barrage of impulses initiated by a pulpal electrical stimulus but not by a natural stimulus of the pulp. These neurones appear to predominate in subnucleus oralis.

Supported by NIH grant DE04786.

174.8 SYNAPTOLOGY OF CORTICOTRIGEMINAL PROJECTIONS. R.C. Dunn, Jr., L.E. Westrum and K.L. Chong*. Div. of Neurosurgery and Dept. of Anatomy, St. Louis Univ. Sch. of Med., St. Louis, Mo. 63104 and Dept. of Neurosurgery, Univ. of Wash. Sch. of Med., Seattle, Wash. 98195

Cortical input to the spinal trigeminal nucleus produces both presynaptic depolarization and hyperpolarization of trigeminal afferent fibers (Sessle, B.J., Dubner, R., Br. Res. 22:121, 1970). However, little is known about the synaptology of these cortical projections which are important in modification of facial sensation. To clarify these structural-functional relationships, an electron microscopic (EM) study of the corticotrigeminal projection is being made. Fourteen adult cats received either large sensorimotor region (6) or small coronal gyrus (8) cortical excisions. After survival periods from 30 hrs. - 21 days, animals were perfused and wafers of brainstem including p. interpolaris and p. caudalis were processed for EM. At 30 hrs., occasional small (1.6 μm) thinly myelinated axons are undergoing degeneration. Terminal degeneration is rarely seen at this time. By 72 hrs. widely separated electron dense terminals are encountered. Most are small (1 to 1.2 μm) and contain round vesicles (R-type terminals) but occasional small boutons with pleomorphic vesicles (NR-type) are also seen. Degenerating boutons frequently contact small (1.2 μm) dendritic shafts and spines. While the R terminals contact dendrites at asymmetrical membrane specializations, the NR-terminals may have symmetric contacts. Bouton degeneration is most pronounced at 4-5 days; even at this time, however, altered terminals are widely scattered. Although small degenerating axons are numerous at 7-8 days survival, dense terminals have become less frequent, essentially disappearing after 14 days. By 21 days the major remnants of the cortical injury are engulfed masses of electron dense axon fragments. Of particular interest at 3-5 days survival are occasional cortical boutons which appear to be post-synaptic to NR terminals. This arrangement may be the anatomic substrate for presynaptic depolarization of corticofugal fibers by trigeminal afferents (Dubner, R. et al: Nature 223:72, 1969). No cortical terminals have been found presynaptic to other terminals within interpolaris. From this study we conclude: 1) the corticotrigeminal boutons are small and sparse; 2) at least two categories of boutons are present, R and NR; 3) the NR boutons may be R boutons undergoing degeneration, but the symmetric contact of some argues for a separate category of corticotrigeminal afferent; 4) some corticofugal afferents appear to participate in axoaxonic arrangements.

174.9 NON-SEROTONERGIC CELLS AT THE ORIGIN OF THE DORSOLATERAL FUNICULUS (DLF) IN RAT MEDULLA. J.N. Johannessen*, L.R. Watkins* & D.J. Mayer (SPON: M.C. Boadle-Biber). Dept. of Physiology, MCV/VCU, Richmond, VA 23298.

Descending pathways within the spinal cord DLF have proved important in the production of analgesia. The medullary nucleus raphe alatus, (NRA - n. raphe magnus & n. reticularis paragigantocellularis), which gives rise to fibers which descend in the DLF, is a sensitive site for the production of analgesia by electrical & pharmacological methods. Indirect evidence suggests that descending serotonergic fibers from area B3 may play a role in descending inhibition. The cells of B3 show a similar distribution to those of NRA, however, there is no direct evidence that serotonergic fibers from B3 descend in the DLF.

The cell bodies of NRA were retrogradely labeled with HRP by implanting a small piece of HRP-gel (Griffin et al., Brain Res., 168 (1979) 595-609) unilaterally into the cervical DLF. Two days later, the method of Bowker et al. (Neurosci. Abstr., 6 (1980) 101) was used to simultaneously visualize both retrogradely labeled cells & cells exhibiting serotonin-like immunoreactivity (SLI).

Extremely few double labelled cells were seen. Retrogradely labelled cells of NRA exhibited a different distribution from SLI cells. The SLI cells of B3 lie ventral to NRA. Some intermingling of retrogradely labelled cells and SLI cells was seen, especially near the midline. At the level of the facial nucleus, 25 retrogradely labelled cells & 55 SLI cells were seen in a typical hemisection, while no more than two double labelled cells could be identified.

Quantitative comparisons of SLI cells in the retrogradely labelled & non-labelled halves revealed no difference in the number of SLI cells, ruling out the possibility that the retrograde staining prevented or obscured SLI. Conversely, most cells retrogradely labelled from the DLF were found in an area devoid of SLI on the controlateral side, indicating a differential distribution of SLI cells & retrogradely labelled cells. Furthermore, sections from a single brain which were processed for retrograde labelling, but not SLI, showed similar patterns and numbers of labelled cells to those sections processed for both. Heavy double labelling of serotonin-like cells could be seen after a liquid injection of HRP (4 ul - 40%) into the fourth ventricle.

These results suggest that serotonin is not a major component of the DLF projection which originates in the NRA. This is consistent with evidence indicating that a descending serotonergic projection is unnecessary to elicit analgesia. (Johannessen et al. Neurosci. Abstr., 6 (1980) 247).

174.10 RELATIVE EFFECTS OF DESCENDING INHIBITION ON A-FIBER AND C-FIBER INPUTS TO SPINAL CORD DORSAL HORN NEURONS IN THE CAT. Bruce G. Gray and Jonathan O. Dostrovsky, Dept. of Physiology, Univ. of Toronto, Toronto, Ont. M5S 1A8, Canada.

It is now generally accepted that stimulation of certain brainstem regions can activate a descending inhibitory system whose major effect is to reduce the transmission of nociceptive information. This concept is supported by studies showing that the C-fiber (primarily nociceptive) induced excitation of dorsal horn neurons is more powerfully inhibited than the A-beta (non-nociceptive) induced excitation. However since suprathreshold stimuli sufficient to excite C-fibers produce a very intense and synchronous activation of low threshold A-beta fibers it is difficult to obtain a meaningful comparison of the relative effects of the descending pathways on these two responses. In order to overcome this problem, the present study examined the relative degree of descending inhibition on the responses produced when each fiber group was excited to a comparable level.

Single unit recordings were obtained from the lumbar spinal cord of barbiturate anesthetized adult cats. Bipolar stimulating electrodes were stereotaxically implanted into the periaqueductal gray (PAG), lateral reticular formation (LRF), nucleus raphe magnus (NRM) and nucleus gigantocellularis (NGC). Stimulation sites were subsequently verified histologically. Only cells classified as wide dynamic range and which received both A-fiber and C-fiber inputs were studied. To test for inhibitory effects the brainstem conditioning stimuli were delivered 130ms. prior to the response of the particular fiber input under study and consisted of a 100ms., 500Hz train of 0.1ms. pulses. Cells were excited using electrical skin stimuli or an air-jet to just suprathreshold levels by A-fiber input and the intensity of the threshold current applied to PAG,LRF,NRM and NGC needed to inhibit this response recorded. Then after raising the stimulus intensity to levels just suprathreshold for obtaining the C-fiber input the intensity of the threshold current necessary to inhibit this response noted. Using this method it was found that the current thresholds necessary to inhibit these responses were similar in 4 cells but in the remaining 3 tested, the threshold current for inhibiting the C-fiber input was markedly lower. Another method was to use suprathreshold stimuli and construct PSTH's. Through inspection of the distribution of spike activity from C-fiber input one could create a similar distribution for the A-fiber input by using low intensity natural or electrical repetitive stimuli. When comparing the relative magnitude of inhibition following stimulation to a given brainstem structure only in 1 of 5 cells was there a more powerful inhibition of the C-fiber input. These experiments have shown that in many cases there is no preferential inhibition of C-fiber input and thus the apparent selectiveity previously reported is probably due to the unequal synaptic drive produced by the two fiber groups.

174.11 EFFECT OF LESIONS OF THE N. RAPHE MAGNUS & SURROUNDING AREAS ON SYSTEMIC & MICROINJECTION MORPHINE ANALGESIA. E.G. Young*, L.R. Watkins* & D.J. Mayer (SPON: R. Costanzo). Dept. of Physiol., MCV/VCU, Richmond, VA 23298.

Previous studies have implicated several medullary nuclei in descending inhibition of pain. Foremost of these are n. raphe magnus (NRM) & n. reticularis paragigantocellularis (NRPgc). It has recently been suggested that the combined NRM/NRPgc area, referred to as n. raphe alatus (NRA), forms the actual functional unit for descending pain inhibition (Br Res, 181:1, 1980). The question arises as to the relative involvement of these areas in systemic & microinjection morphine analgesia (MA). In Exper. 1, the effect of NRA, NRM, NRPgc & control lesions were tested for systemic MA. Pain sensitivity was measured (tail flick test) prior to & 40 min after 6 mg/kg morphine (i.p.) at 2 days prior to surgery and 5, 12 & 19 days after surgery. Lesions were made by passing 0.15-1.0 mA (DC) for 10 sec through a stainless steel pin insulated to 0.5 mm of the tip. Significant reduction in systemic MA was observed for NRM, NRPgc & NRA groups, compared to controls. A progressive reduction of MA occurred, wherein systemic MA decreased from 100% (pre-lesion) to 50-70% by 12 days after NRM, NRPgc & NRA lesions. Our NRM results differ from Proudfit's (Neurosci, In press) in that no change in baseline pain sensitivity was seen. In Exper. 2, MA was produced by 5 μg/0.5 μl morphine injected into the periaqueductal gray. The effect of NRM, NRPgc & control lesions was assessed as in Exper. 1. In contrast to the effects for systemic MA, NRM lesions abolished microinjection MA by 5 days post-lesion. Preliminary results indicate a comparable reduction of MA for NRPgc lesions.

It is known that MA involves a descending pathway in the dorsolateral funiculus (DLF) of the spinal cord. Supraspinal areas which project via the DLF may potentially be involved in pain inhibition. If axons from such areas pass through NRA, they would be destroyed by lesions in this area. To determine if such an axon-of-passage problem existed, horseradish peroxidase (HRP) in slow-release gel was implanted bilaterally in the cervical DLF of NRM, NRPgc, NRA & control rats. Comparison of HRP labelled nuclei in these 4 groups showed that no such axon-of-passage problem occurred; all areas which normally project via the DLF are still present after NRM, NRPgc & NRA lesions.

This work demonstrates that analgesia elicited by morphine microinjected into the periaqueductal gray can be abolished by lesions within the NRA. In contrast, these same lesions have a much smaller effect on systemic MA, indicating that multiple sites are involved in this opiate analgesia. This research was supported by Grant DA-00576 to DJM.

174.12 THE ORIGIN OF BRAIN STEM SEROTONERGIC AND NEUROTENSIN PROJECTIONS TO THE RODENT NUCLEUS RAPHE MAGNUS. A.J. Beitz. Dept. Anat., School of Med., Univ. of South Carolina, Columbia, SC. 29208.

The distribution of serotonin (5HT) and neurotensin (NT) immunoreactive cell bodies which project to the nucleus raphe magnus (RM) was localized in the brain stem of the rat utilizing the combined retrograde transport - immunohistochemical technique of Bowker et. al., (Brain Research, 1981). Twelve adult Sprague-Dawley rats were stereotaxically injected with horseradish peroxidase by means of either iontophoresis or pressure injection. One to 3 days later the rats received an intraventricular injection of colchicine (60μg in 6μl NaCl). The animals were subsequently perfused with 3.8% paraformaldehyde followed by a 25% sucrose-PBS solution. The brains were removed, and 40μm sections were processed for HRP histochemistry using $CoCl_2$ in the reaction to yield a black reaction product. Alternate sections were then incubated in antisera to 5-HT or NT and further processed for PAP-immunohistochemistry using the method of Sternberger (1974). Neurons which both contain 5-HT or NT and project to the RM were identified by the presence of both brown and black reaction product in the same cell. 5-HT immunoreactive cells which project to the RM were localized in the nucleus (N) reticularis paragigantocellularis, the ventrolateral periaqueductal gray and the medial aspect of the n. cuneiformis. A few double labeled 5-HT cells were also present in the n. raphe dorsalis. Several brain stem nuclei were found to contain double-labeled NT cells. The majority of NT immunoreactive neurons projecting to the RM were observed in the N. solitarius, the midbrain periaqueductal gray, the nucleus cuneiformis and the locus coeruleus. A few double labeled neurons were also evident in the parabrachial nuclei and the ventral most portion of the trigeminal nucleus caudalis. These results demonstrate several sources of 5-HT and NT input to the raphe magnus. Of notable importance is the demonstration of both a 5-HT and NT projection from the periaqueductal gray to the RM. It is possible that these projections subserve the descending pain control system and thus deserve further study. (Funded by NSF BNS 7906486. I thank Dr. Robert Elde for the anti-5-HT serum).

174.13 ANTAGONISM OF INHIBITIONS OF NOCICEPTIVE NUCLEUS RETICULARIS VENTRALIS NEURONES (NRV) EVOKED BY PERIAQUEDUCTAL GREY STIMULATION (PAG) BY MICROIONTOPHORETIC NALOXONE, IN RATS SHOWING STIMULATION EVOKED ANALGESIA (SEA). R. Morris* and R.G. Hill* (Spon: D.W. Lincoln), Department of Pharmacology, University of Bristol, Bristol BS8 1TD, U.K.

Under sodium pentobarbital anaesthesia 47 male rats were chronically implanted with teflon coated stainless steel, twisted wire, bipolar electrodes targeted on the PAG. After a 4-8 day postoperative recovery period the current thresholds for the production of explosive escape behaviour (EEB) (observed in an open field) and SEA (measured using the reflex responses to noxious thermal or mechanical stimulation of the tail) were assessed. In 35 animals EEB was observed, which included all the animals in which SEA was present. Six animals showed reproducible analgesia, which was clearly antagonised by naloxone (10 mg/kg, i.p.), at thresholds lower than those which produced EEB in these animals, a further 8 animals showed variable analgesia at an identical threshold to that producing EEB.

All the animals (N=14) showing some degree of analgesia were used in subsequent acute experiments. The animals were anaesthetised with urethane and conventional six barrelled microiontophoresis electrodes were used to record action potentials and apply drugs within the NRV. The stimulation parameters producing the behavioural changes (50 Hz, trains of 0.5 ms duration, 50-300 μA, square wave positive pulses applied for 5-10 s) had a predominantly inhibitory effect on NRV neurones which responded to noxious peripheral stimulation (N tested = 56, 57% inhibited, 13% excited, 30% no influence). In a condition-test paradigm these PAG evoked inhibitions powerfully suppressed the nociceptive excitations for poststimulation periods up to 2 min. Microiontophoretically applied naloxone was tested against 21 of these inhibitions and partial antagonism was observed in 14 units and no influence in the remaining 7 units. These data suggest that an endogenous opioid system may be acting on caudal reticular neurones during stimulation evoked analgesia but, alternatively, these results may be related to the explosive escape behaviour which was much more consistently evoked from PAG stimulation in these experiments (supported by the Wellcome Trust).

174.14 ACTIVATION OF PRIMATE SPINOTHALAMIC TRACT CELLS FOLLOWING INTRACARDIAC BRADYKININ INJECTION AND DURING CORONARY ARTERY OCCLUSION. R.W. Blair, R.N. Weber*, H.R. Holmes*, and R.D. Foreman. Dept. of Physiology, Okla Univ Hlth Sci Ctr, Oklahoma City, OK 73190

Neural impulses mediating the pain of angina pectoris are conducted through sympathetic afferents. Since the spinothalamic tract (ST) is known to convey impulses signalling pain to the brain, we have examined whether sympathetic afferents from the heart can activate ST neurons. Previously we demonstrated that electrical stimulation of these afferents could excite ST cells. The goal of the present study was to determine if stimuli applied directly to the heart could activate ST neurons. Extracellular potentials of ST cells of primates anesthetized with alpha chloralose and Na pentobarbital were recorded from gray matter in the T_3 to T_5 segments of the spinal cord. The cells were antidromically activated by stimulating their axons in the contralateral ventral posterior lateral nucleus. Although visceral input onto ST cells is emphasized in this study, all the ST cells also received somatic input. Bradykinin (BK) was injected (1-10 μg/kg) into the heart via a catheter placed in the left atrial appendage. Coronary artery occlusion (CAO) was produced by tightening a snare around the main left coronary artery. Of 20 ST cells tested for a response to intracardiac BK, 15 increased their discharge rate from an average of 13.2 ± 3.4 to 29.6 ± 4.5 (SE) Hz. The latency to onset of cells' responses to BK ranged between 4 and 20 seconds after BK injection; peak responses occurred 11 to 56 seconds after injection. Five cells were unaffected by BK. Injections of similar doses of BK into the descending aorta or femoral vein produced little or no change in cell activity, indicating that BK's effect on ST cells originated from the heart. The responses of 8 cells to CAO were determined. Four cells were excited (from 17.8 ± 9.1 to 24.3 ± 9.7 (SE) Hz), but the other four were unaffected by CAO. The 4 cells excited by CAO and 3/4 of cells unresponsive to CAO were excited by BK. In the 4 cells responsive to both stimuli, BK caused the ST cells to fire at a higher rate than did CAO. These results demonstrate that presumably noxious stimuli applied to the heart can excite some ST cells. Thus, the pain of angina pectoris may be conveyed via the spinothalamic tract. (Supported by NIH grant #22732).

174.15 THE CORTICAL PROJECTION OF THE NUCLEUS SUBMEDIUS IN THE CAT. A.D. Craig, Jr., S.J Wiegand and J.L. Price. Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110

Recent results have indicated that the dorsal portion of the nucleus submedius (Sm) in medial thalamus is a major spinothalamic terminus, receiving input virtually exclusively from the marginal zone (Craig and Burton, J. Neurophysiol., 45: 443, 1981); although the sources of afferent input to the remainder remain unknown, the preceding observations suggest that at least part of Sm may be involved in specific nociception. Conflicting reports have been published regarding the efferents of Sm in the cat and the rat; the present experiments have identified a discrete zone of orbitofrontal cortex in the medial wall of the presylvian sulcus and the adjacent posterolateral gyrus proreus as the Sm cortical field in the cat.

Anterogradely transported label was observed in cats which had received 50-100 nl injections of tritiated amino acids (50-100 uCi/ul). In three of these cases, bilateral injections were placed in caudal Sm and rostral Sm on each side, respectively. Retrogradely transported label was observed in cats which had received unilateral 100 nl injections of 1% HRP conjugated with wheat germ agglutinin. Analysis of these cases indicates that Sm projects topographically onto layer 3 of a discrete agranular orbitofrontal cortical field; the postero-dorsal portion of Sm projects to the postero-dorsal portion of the cortical field, and the antero-ventral portion of Sm to the antero-ventral portion of the Sm cortical field. A diffuse layer 1 projection to the Sm cortical field may also arise from Sm neurons; however, a dense projection to superficial layer 1 of Sm cortex appears to arise from VM neurons immediately subjacent to Sm. Sm is reciprocally connected with its cortical field; a moderate cortico-thalamic projection to contralateral Sm is also present. The Sm cortical field is cytoarchitectonically distinguished from adjacent areas by a diminished cell size in layer 5 and an expanded layer 3. It extends anteriorly almost to the frontal pole, attains its greatest dorso-ventral extent at the level of the junction of the olfactory peduncle, and extends caudally into the fundus of the rhinal sulcus to the level of the agranular insular cortex. The evidence indicates that the feline Sm cortical field may be homologous to the ventrolateral orbital field of the rat (Krettek and Price, JCN, 171: 157, [1977]), since both are adjoined by areas receiving input from MD and VM.

These results indicate that a distinct orbitofrontal field may be involved with nociception. (Supported by NS09809 [to H. Burton], NS09518 and T-32-NS07507.)

174.16 NEONATAL INTRASPINAL 6-HYDROXYDOPAMINE OR 5,7-DIHYDROXYTRYPTAMINE: SEXUALLY DIMORPHIC EFFECTS ON NOCICEPTION BUT NO EFFECTS UPON MORPHINE ANALGESIA. B. A. Pappas, R. Ings and D. C. S. Roberts. Carleton University, Ottawa, Canada, K1S 5B6.

Intrathecal administration of both alpha noradrenergic (NE) and serotonergic (5-HT) antagonists in the adult rat reportedly lower nociceptive thresholds. It is not clear, however, whether spinal NE or 5-HT systems mediate the antinociceptive effects of morphine (e.g., Yaksh & Wilson, J. Pharmacol. Exp. Ther., 1979; Reddy, Maderhut & Yaksh, J. Pharmacol. Exp. Ther., 1980; Proudfit & Hammond, Brain Res., 1981). To selectively deplete spinal NE and 5-HT, newborn rats were injected intraspinally on days one and two with either 6-hydroxydopamine (6-OHDA, 10 μg) or 5,7-dihydroxytryptamine (5,7-DHT, 8 μg) after desmethylimipramine pretreatment to deplete spinal NE or 5-HT, respectively. We tested these animals for basal nociception and morphine analgesia during adulthood. Intraspinal 6-OHDA depleted only spinal NE by 81, 78 and 87% in cervical, thoracic and lumbar cord, respectively. The 5-HT depletions after 5,7-DHT were 60, 55 and 66% in corresponding regions. There were no monoamine depletions in the brain — in fact, elevations of NE and 5-HT, respectively, were observed in the brainstems of the 6-OHDA and 5,7-DHT groups, presumably reflecting sprouting from the supraspinal origins of the damaged spinal terminals.

Nociceptive thresholds were determined immediately prior to and at 20 min. intervals after either s.c. saline, 1, 3 or 7.5 mg/kg morphine sulphate. Latency to tail flick after immersion of the distal tail in water (55°C) was recorded. The 6-OHDA and 5,7-DHT injections produced sex dependent effects on baseline nociceptive thresholds — tail flick latencies were significantly lowered in the spinal NE depleted females but normal in their male counterparts. Conversely, thresholds were significantly elevated in the spinal 5-HT depleted males but normal in their female counterparts. No sex differences were found, however, in the monoamine depletions after the 6-OHDA or 5,7-DHT treatments. While we do not as yet have an explanation for this sexual dimorphism, it may account for some conflicting reports of the role of spinal monoamines in nociception.

Neither spinal NE nor 5-HT depletion affected the antinociceptive effect of morphine at any of the three doses. Females were generally less affected by morphine, especially at the highest dose. Thus, while normal nociception requires intact spinal NE or 5-HT terminals in females and males, respectively, these terminals may not be necessary for the analgesic action of morphine in either sex.

175.1 NON-LINEAR HAIR CELL MODEL GENERATES SUMMATING POTENTIALS. T. McMullen*, D. C. Mountain* and E. Sanchez* (SPON: H. VOIGT). Depts. of Biomed. Engr. and Otolaryngology, Boston University, Boston, MA 02215.

Computer simulation was employed in an attempt to gain more understanding of the mechanisms responsible for the generation of the summating potential. Recent studies have shown that the operation of vertebrate hair cells is non-linear in at least two respects: (a) membrane conductance is voltage sensitive (Corey, D. and Hudspeth, A., Nature, 281: 625-627, 1979); and, (b) the relation between hair bundle displacement and the resulting conductance change is asymmetric and sigmoidal (Hudspeth, A. and Corey, D., Proc. Natl. Acad. Sci., 74: 2407-2411, 1977).

Prior to simulation of a model which included both of these elements, equivalent circuit models which simulated each of these phenomena separately were studied. Acoustic stimuli were modeled by time-varying modulations in the transducer resistance, and both intracellular and extracellular responses were examined. The variation in reponses to acoustic stimuli of various frequencies and amplitudes and, also, for different levels of endocochlear potential (EP) were compared to experimental data.

175.2 MUSCARINIC ACETYLCHOLINE RECEPTOR BINDING IN THE COCHLEA OF THE GUINEA PIG. William James, Mary Ann Cheatham* and William L. Klein. Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201

Cell membranes from the guinea pig cochlea have saturable, specific binding of the potent muscarinic antagonist 3H-quinuclidinyl benzilate (QNB). Cochlear turns, dissected free of stria vascularis, were removed from Urethane-anesthetized animals, stored frozen until use, then sonicated in phosphate buffer. The homogenate was centrifuged at low speed to remove debris. Within a nanomolar range of 3H-QNB concentrations, half of the atropine-sensitive binding sites were filled at 0.7 nM and saturation was shown with 0.8 to 1.5 nM. Scatchard analysis revealed only one class of binding sites, with a maximum number at saturation of 41.7 fmol/mg protein. Muscarinic cholinergic compounds specifically blocked 3H-QNB binding sites at low concentrations. Binding of 3H-QNB was reduced by 50% (IC50) at these concentrations: acetylcholine (ACh) at 6 uM, atropine at 5 nM and oxotremorine at 0.4 uM. With a nicotinic antagonist, curare, the measured IC50 was 100 uM. Since curare is pharmacologically active at the micromolar range in the superfused system (Konishi, Acta Oto-laryng. 74, 1972), it is likely that nicotinic ACh receptors also are present in the cochlea.

Efferent innervation is maximal in the base of the cochlea, and receptor numbers show a similar distribution. In separate measurements on pooled first and second or third and fourth turns, we found 0.34 fmol/apical turns and 1.1 fmol/basal turns.

Our findings represent the first measurement of any neuroreceptor binding site in the cochlea, and are consistent with the use of ACh as a transmitter by the olivocochlear bundle.

175.3 THE EFFECT OF NOISE EXPOSURE ON DEOXYGLUCOSE UPTAKE IN THE INNER EAR OF THE MOUSE. Jochen Schacht and Barbara Canlon*. Kresge Hearing Research Institute, The University of Michigan, Ann Arbor, MI 48109.

Deoxyglucose trapping in peripheral and central auditory structures was determined by microdissection of tissues and scintillation counting of the radioactive tracer. CBA mice received a pulse of ^{3}H-deoxyglucose into the tail vein (5 mCi/kg body weight) and blood samples and organs were taken after various time intervals. Prior to dissection, enzymatic activities were arrested by microwave irradiation. Radioactivity and protein concentrations were determined in homogenates of 1) organ of Corti, consisting of the auditory receptor cells as well as supporting cells; 2) lateral wall tissues, a combined preparation of stria vascularis and spiral ligament; 3) cochlear portion of the VIIIth nerve; 4) inferior colliculus. Radioactivity in all inner ear tissues was maximal at 45 to 60 min and the steady-state ratio of deoxyglucose-6-phosphate to deoxyglucose was 60:40. Animals were exposed to noise (white noise, free field) ranging from 25 dBA (anechoic chamber) to 115 dBA (acoustic overstimulation). There were no effects on serum glucose levels or serum kinetics of deoxyglucose. In all auditory structures examined deoxyglucose uptake increased 4 to 5-fold between 25 and 85 dBA and decreased by 25-50% between 85 and 115 dBA. Exposure and pulse times of 15 to 180 min were studied, and the effects were most clearly evident at 60 min. The increased uptake is consistent with analogous findings in the central nervous system and should represent increased metabolism and local blood flow. The finding that the lateral wall tissues which are devoid of neural innervation also respond to noise stimulation points to a close coupling of metabolism in the cochlea. It could indicate a regulation of cochlear blood flow at the modiolar level. The reason for the decreased uptake at high intensities remains speculative and may be related to vasoconstriction of cochlear vessels. It is interesting to note that electrophysiological responses of the ear follow a similar pattern as observed for deoxyglucose trapping: the cochlear microphonic potential rises with increased stimulus intensity and decreases with overstimulation. Likewise, firing rate of single auditory fibers in various species is maximal at moderate stimulation of 60 to 80 dB. Thus, deoxyglucose utilization in the auditory periphery is well correlated with the pattern of the electrophysiological response.

175.4 EFFECTS OF SHORT-TERM ANOXIA ON THE INTRACELLULAR POTENTIALS FROM COCHLEAR INNER HAIR CELLS. M.C. Brown, A.L. Nuttall*, R.I. Masta* and M. Lawrence*. Kresge Hearing Research Institute, The University of Michigan Medical School, Ann Arbor, MI 48109.

Intracellular recordings were obtained from inner hair cells in the guinea pig cochlea. Short-term anoxia was induced in these paralyzed animals by turning off the respirator for brief periods. A 30 second anoxia induced a rapid and profound decrease in the DC receptor potential response to low intensity tone bursts at the characteristic frequency of the hair cell. Frequencies different from the characteristic frequency evoked smaller receptor potentials which showed proportionally less reduction during anoxia. The resting membrane potential was little affected during the anoxic period.

Other cochlear potentials were also affected by short-term anoxia. A large reduction was observed in the click-evoked compound action potential recorded from the round window. The percent reduction of the endocochlear potential was smaller in magnitude than the reduction of the DC receptor potential while the 4 kHz cochlear microphonics were least affected. These results suggest that the large effect of anoxia on the auditory neural potentials may be the result of oxygen depletion at elements peripheral to the nerve fibers.

175.5 REFLEX INHIBITION AUDIOMETRY AS AN INDEX OF OTOTOXICITY. J.S. Young* and L.D. Fechter (SPON: W.R. Millington). The Johns Hopkins University, School of Hygiene and Public Health, Department of Environmental Health Sciences, Division of Toxicology, Baltimore, MD 21205

Attempts to provide a functional assessment of toxic damage to the auditory system face substantial constraints. The methods of traditional animal psychophysics are exquisitely sensitive, but require a substantial investment of time and effort in subject training. This limits the number of subjects which can be tested. Reflex procedures (e.g. Preyer's reflex, startle reflex) provide a much more rapid assay of hearing function, but are markedly less sensitive, with thresholds 50-60 dB above the detection threshold.

We have determined pure-tone audiometric functions in Long-Evans hooded rats, for stimuli between 2.5 and 40 kHz, in a procedure based on measuring the modulation of the startle reflex by weak stimuli which precede a startle-eliciting stimulus. No subject training is required for these determinations. Tone prestimuli of varying frequency and intensity are presented according to the psychophysical method of constant stimuli, and tone detection is assessed by comparing the amplitude of the whole-body startle response on trials containing a tone prestimulus to startle amplitude on interspersed trials on which only the startle stimulus is presented. We have further examined the effects of combined injections of an aminoglycoside antibiotic (neomycin) and aminooxyacetic acid, a treatment previously shown to produce rapid and severe hair cell damage (Cronin-Schreiber, R. et al., Soc. Neurosci. Abstr., 6:42, 1980).

We have found thresholds of startle inhibition to be quite similar to absolute detection thresholds as measured by operant techniques (e.g., Kelly, J.B. & Masterton, B., J. Compar. Phys. Psych., 91:930, 1977). Increases in the thresholds of startle inhibition of the treated subjects were noted within a few days of the combined injections.

Our results indicate that startle inhibition audiometry provides a rapid, sensitive index of hearing function, and of toxic insult to the auditory system. In addition, they provide a behavioral corroboration of the anatomical and electrocochleographic effects reported for combined administration of aminoglycosides and aminooxyacetic acid.

175.6 STIFFNESS MEASUREMENTS OF STEREOCILIARY BUNDLES IN FROG CRISTA AMPULLARIS. S. Orman* and A. Flock* (SPON: J. Hind) Dept. of Neurophysiology, Univ. of Wisconson, Madison, WI, and Dept. of Physiology II, Karolinska Institute, Stockholm, Sweden.

Single stereociliary bundle displacements resulting from a small jet of frog's Ringer's solution of known velocity, have been measured in the sensory hair cells of the frog's crista ampullaris. The bundle stiffness -- the ratio of the fluid drag force to the angular displacement -- has been calculated to be approximately 4.6×10^{-11} N/rad .

The crista was dissected free from the ampulla of the posterior vertical canal and positioned in a fluid filled chamber where individual stereociliary bundles could be viewed with differential interference contrast optics. A 50 µm micropipette was brought into close approximation with an individual bundle allowing delivery of a fluid jet from a specially constructed microsyringe apparatus. The displacements were recorded on 16 mm film and both the angle of deflection and the time for the return to the stereocilia's resting position were measured on the film. The deflection curves reveal that the stereociliary bundles of the frog crista are highly overdamped and obey a Hooke's law type equation, i.e., the restoring torque returning the bundles to the resting position after the fluid jet was stopped was proportional to the angle of displacement. This supports the model that stereociliary stiffness restricts bending to a hinge region at the apical surface of the hair cell.

To determine if Ca^{2+} could influence the mechanical properties of the stereociliary bundles through action on their actin protein component, the calcium ionophore A 23187 was added to the Ringer's solution bathing the crista preparation. When the ionophore was added to a calcium free Ringer's bath no change was seen in the bundle's response to the fluid jet. When the ionophore was added to the normal Ringer's solution (2 mM Ca^{2+}) an immediate decrease in the deflection response to the fluid jet was observed. The resulting increase in bundle stiffness, due to the calcium, was calculated to be in the range of 20-25 %. The modulatory role of calcium in hair cell transduction through an active mechanical control mechanism will be discussed.

175.7 HAIR CELL ORIENTATIONS IN THE GRAVISTATIC ORGANS OF THE BLACK TETRA, A CHARACIN FISH. Christopher Platt. Dept. Biological Sciences, Univ. Southern California, Los Angeles, CA 90007.

The inner ear of the black tetra, Gymnocorymbus ternetzii, is interesting for two reasons. First, this is one of the few teleost fishes for which we know gravistatic functions of parts of its inner ear (von Holst, Z. vergl. Physiol. 32:60, 1950; Schoen, & von Holst, Z. vergl. Physiol. 32:552, 1950). Second, the black tetra represents the characins, a major family within the ostariophysines, a large group of teleosts with good hearing, from which only carps and catfish have had their ears examined. I have now mapped the tetra's inner ear sensory surfaces using scanning electron microscopy. Before removal from the head, the vestibular membraneous pouches were nicked for precise spatial orientation marks. Each sensory hair cell has an apical ciliary bundle, with an asymmetrically placed single kinocilium that gives each cell an observable orientation corresponding to its peak directional sensitivity.

Black tetras 30-35 mm long have roughly 10,000 hair cells in the utricle, their major gravistatic otolith organ. The cup-shaped sensory macula faces upward; its narrow posterolateral extension, the lacinia, is covered only by otolithic membrane. The striola of the main macula is a broad arc of cells with large prominent bundles; it courses almost 270° anteriorly around the macula, from the medial side to the base of the lacinia. Utricular hair cells form two oriented populations. From the central medial side, cell orientations radiate outward in a fanlike pattern. More marginal cells of the anterolateral side have orientations opposed to the central group, and so face radially inward. A line drawn between the two populations does not bisect the macula, but curves along the middle of the striola and lacinia. Thus a single utricle is asymmetrical, with a majority of cells oriented facing ipsilaterally.

The lagena is the tetra's other gravistatic otolith organ. Its macula is on its vertical medial wall, and contains a prominent anterior and posterior patch of large-bundled hair cells, both within a large oval area of small-bundled cells. Cells in the dorsal region face generally ventrally, while those ventral face dorsally. These two opposing populations form a boundary that runs near the middle of the macula from the rostral tip, then curves downward toward the caudal end.

These orientation patterns show that the unilaterally operated fish of von Holst and others indeed are left with asymmetric unequal populations of opposing cells in the remaining ear. The receptor patterns in all the tetra's inner ear surfaces, including also the saccule, macula neglecta and semicircular canal cristae, are extremely similar to those in other ostariophysines.

176.1 HYPERPLASIC GANGLIA AND THEIR INNERVATION PATTERNS IN FROGS WITH EARLY DORSAL ROOT GANGLION REMOVALS. M. Davis and M. Constantine-Paton. Dept. Biol., Princeton Univ., Princeton, N.J. 08544.

The problem of how sensory neurons project to appropriate CNS and peripheral regions can be studied by experimental alteration of the size of the target area. Increases in the periphery have been achieved by early removal of hindlimb dorsal root ganglia (DRG) in Rana pipiens tadpoles. The procedure has been reported to result in an increase in cell number (hyperplasia) in the adjacent ganglion relative to an equivalent ganglion on the opposite side (Bibb,H.,1977,J.Exp.Zool.200:265-275). We have further investigated the hyperplasic response to determine whether the size and position of the denervated region are consistently related to the increase in sensory cell number. We also asked whether the hyperplasic ganglia actually innervate the denervated central and peripheral areas.

Various combinations of tadpole hindlimb DRG were removed, and the animals were permitted to survive past metamorphosis. DRG cell counts were then used to assess the extent of hyperplasia. This information was combined with either physiological maps of hindlimb nerve receptive fields or with anatomical examinations of central and peripheral innervation. Examination of these areas was done by 1) ^{3}H-proline injections into the ganglion followed by autoradiography on the spinal cord, or 2)applications of horseradish peroxidase (HRP) to the cut sciatic nerves for determination of labeled cell numbers in ganglion 10(defined by Ecker,1889).

The location and degree of hyperplasia were highly variable. Although hyperplasias were found in the ganglia adjacent to those removed, some animals showed hyperplasia in non-adjacent ganglia. In these cases intervening ganglia were either normal in cell numbers or hyperplasic. Non-adjacent hyperplasias occurred most frequently in ganglion 10 which normally sends only a small branch to the hindlimb. Our HRP studies show that a hyperplasic #10 has many more labelled cells coursing through the sciatic nerve than contralateral #10. Receptive field mapping of hindlimb nerves shows that hyperplasic ganglia increase their peripheral fields.Autoradiography suggests no appreciable increase in the central terminations of hyperplasic ganglia compared to controls.

Thus, although the location of ganglionic hyperplasia cannot be reliably predicted from the type of tadpole ganglion removal, ganglia showing hyperplasia are often associated with increases in peripheral area. We conclude that the peripheral addresses of hindlimb DRG are not rigidly defined. The central processes of these same DRG do not show an equivalent capacity to expand their segmental spread within the spinal cord.

176.2 TIME-COURSE FOR RECEPTIVE FIELD PLASTICITY OF DORSAL HORN NEURONS IN HEMISECTED CATS. Gene L. Brenowitz. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

We have recently demonstrated a reorganization of cutaneous input to dorsal horn neurons following partial spinal cord hemisections (T 13, sparing the dorsal columns) in cats (Brenowitz and Pubols, Soc. Neurosci. Abstracts 6:847). The most striking change observed was a large increase in the size of light tactile, proximal hindlimb receptive fields in a discrete zone in the lateral dorsal horn ipsilateral to the lesion in animals with chronic (3-6 mo.) but not acute (6h-5d) survivals.

The present study was aimed at establishing when between 5d and 3 mo. the increase in receptive field size occurs. The sizes of light tactile, proximal hindlimb receptive fields (plotted with a 1gm vonFrey hair) and somatotopic organization, in general, of L7 dorsal horn neurons were studied in methoxyflurane anesthetized cats partially hemisected (T13, sparing the dorsal columns) 7-30d prior to recording.

Enlarged proximal hindlimb receptive fields were found in animals surviving 14d after a hemisection. The largest field observed extended from the dorsal midline, down the lateral leg, to a point midway down the lateral foot. The enlarged fields seen at this survival time were as large as those found in animals with 3-6 mo. survivals. These results indicate that by 14d the reorganization of cutaneous input responsible for this change is virtually complete and remains stable for at least 6 mo. Animals with 7-12d survivals did not have enlarged proximal hindlimb receptive fields, although it is difficult to detect subtle changes in field size.

The results of this study indicate that between 12 and 14d following a partial hemisection, increases in the size of light tactile, proximal hindlimb receptive fields become detectable and reach their maximum. These fields remain enlarged over the next 6 mo. The process or processes responsible for this reorganization may well begin earlier than 14d, going undetected until this time. In the future, this time-course for receptive field size changes should help differentiate between several alternative explanations for such plasticity.

176.3 Ultrastructural Features of Dorsal Column Unmyelinated Fibers After Acute Injury of the Rat Spinal Cord and DMSO Treatment. P.K. Hill, J.C. de la Torre, S.M. Thompson,* S. Rosenfield-Wessells* and M.L. Beckett.* Department of Anatomy, Eastern Virginia Medical School, Norfolk, Virginia 23501 and Department of Neurosurgery, University of Miami School of Medicine, Miami, Florida 33101.

The project was conducted to elucidate the ultrastructural features of the adult rat dorsal funiculi unmyelinated fibers following acute injury and dimethyl sulfoxide (DMSO) treatment. Three groups of animals were included in the study: Group I (6 adult rats) received L-1 laminectomy, no contusion and 4 days of saline-filled Alza mini-pump implantation. Group II (6 adult rats) received L-1 laminectomy, contusion of L1-2 with a force of 0.17640 Newtons and 4 days of saline-filled Alza mini-pump implantation. Group III (6 adult rats) received L-1 laminectomy, contusion of L1-2 with a force of 0.17640 Newtons and 4 days of DMSO-filled Alza mini-pump implantation. Group II and III animals also received an intraperitoneal injection of saline and 1.5 gm/Kgm. body weight of DMSO, respectively, 3 times daily for 4 days in order to maintain systemic levels of the drugs. Qualitative ultrastructural examination of the right and left dorsal columns was performed at the lesion site (L1-2) as well as 1 centimeter proximal (T 11-12-13) and distal (L3-4-5).

The general trend of unmyelinated fiber response to DMSO treatment is that the usual clustering arrangement is better preserved at the lesion site as well as proximal and distal to that area when compared with control tissue. In both saline and DMSO treated tissues, clusters of small and medium-sized unmyelinated fibers remained intact to a greater extent than larger unmyelinated terminals. In Group III distal to the lesion, however, larger terminals consistently retained synaptic contacts and axoplasmic constituents to a greater extent than those in Group II.

The significance is that unmyelinated fibers of all sizes are better protected ultrastructurally from degenerative changes during acute injury in DMSO treated animals than are those of the saline treated group. Since functional return after experimental spinal cord injury as facilitated by DMSO treatment has been documented as a prognostic indicator of subsequent motor function return (J.C. de la Torre, et. al. Ann. N.Y. Acad. Sci. 243:362-389, 1975), structural preservation of unmyelinated dorsal column fibers may provide the initial step for potential recovery.

176.4 CENTRAL NEURAL TASTE RESPONSES IN PREPUBERTAL AND ADULT RATS. D.L. Hill, R.M. Bradley, and C.M. Mistretta. Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

To determine whether there are functional changes in responses from central taste neurons after weaning in rats, electrophysiological recordings were made from chemosensitive units in the nucleus of the solitary tract (NST) in the medulla. Twenty-three single units were studied in rats aged 25-35 days (prepubertal) and 28 units in adults. Chemical stimuli applied to the anterior tongue were 0.1M and 0.5M NH4Cl, NaCl, LiCl, and KCl. Neural activity was measured for the first 5 sec after stimulation of the tongue; a comparable period of pre-stimulus spontaneous activity was subtracted to yield response frequencies.

For each stimulus, response frequencies in rats aged 25-35 days were lower than those in adults. However, only response frequencies to NaCl and LiCl were different at a statistically significant level ($p < 0.05$); response frequencies to these two salts in prepubertal rats were at least 50% lower than adult frequencies. Further differences were apparent when neurons were categorized on the basis of responding maximally to 0.1M NH4Cl, to 0.1M NaCl/LiCl, or equally to all 0.1M salts; no NST neuron responded maximally to 0.1M KCl. The percentage of neurons within each category are presented in the table.

	Maximally Effective Stimulus (% Neurons)		
Age	NH4	Na/Li	Equally
24-35 days	48	9	43
adult	14	22	64

Most younger neurons responded maximally to NH4Cl or equally to all salts; very few responded maximally to NaCl or LiCl. In adult rats, neurons generally responded equally to all salts, with about the same distributions in NH4 versus Na/Li categories.

We conclude that taste responses of rat NST neurons change after weaning. As in peripheral taste neurons, striking differences are found in responses of central neurons to NaCl and LiCl. Major response frequency changes to NaCl and LiCl in peripheral fibers, however, occur before weaning. Maturation of taste responses may be progressively delayed in more central neural structures, and adult rats would presumably differ from younger rats in behavioral responses to some taste stimuli. 176.5 ANATOMICAL AND HISTOCHEMICAL STUDY OF THE ACCESSORY OLFACTORY BULB OF MOUSE. F. Miragall* and P.P.C. Graziadei. Biology, Florida State University, Tallahassee, Fla 32306

Recent studies have stressed the importance of the vomeronasal (VN)-accessory olfactory bulb (AOB) system in the sexual behavior of rodents. Anatomical observations, however, are mostly centered on the main olfactory bulb (MOB) while the AOB has received so far little attention.

The present investigation provides preliminary information on the morphological and chemical aspects of the AOB.

Light microscope observations with silver methods specific for the demonstration of the nervous tissue show that the glomeruli of the AOB stain in a characteristic blue-purple color as opposed to the pale red color of the MOB glomeruli. The same silver methods stain selectively the mitral and tufted cells of the MOB while they fail consistently to stain the same cells in the AOB. The differential stainability of the two centers is presently further investigated.

With immunohistochemical methods for the demonstration of the olfactory marker protein the AOB glomeruli show a faint yellow stain as opposed to the deep brown color of the MOB glomeruli.

The glomeruli of the AOB are arranged in a large, globose mass where the individual glomerular profiles are indistinct and the periglomerular cells are sparse. In the MOB the glomeruli are more discretely arranged and their profiles are separated by layers of periglomerular cells. In the AOB the external plexiform and mitral cell layers are not discretely arranged.

The above features will be illustrated together with the ultrastructural details of the organ.

176.6 DEVELOPMENTAL DIFFERENCES IN THE BIRTH DATE OF OLFACTORY BULB PROJECTION NEURONS IN THE GOLDEN HAMSTER. Marjorie R. Grafe, Dept. of Neuroscience, Univ. of Florida, Gainesville, FL 32610

The golden hamster is born after an extremely short gestational period of 16 days. Although neonatal hamsters can respond to odors, their olfactory system undergoes many anatomical and functional changes in the first three weeks postnatally. We have previously reported a developmental change in the distribution of cells in the olfactory bulb (OB) which contribute axons to the lateral olfactory tract (LOT) (Grafe and Leonard, 1981). Cells which send efferents from the OB in the first week of life are concentrated in the medial quadrant of the bulb. The present study was undertaken to determine if there was a corresponding topographical gradient in the time of origin of these cells.

Pregnant hamsters were injected with ^{3}H-thymidine on gestational days 10 (E10), 11, 12, 13 and 14, and pups on postnatal days 1 (P1) and 2 (E16=P0). The pups were sacrificed at about P30, and heavily labeled mitral cells (MC) and tufted cells (TC) were plotted and counted from coronal sections of the OB. No MC or TC were heavily labeled after injections on E10. MC were formed only on days E11-12. TC were formed on E11-14. When classified according to their positions in the external plexiform layer (EPL), we found that inner tufted cells (ITC) were formed on E11-12, while middle and outer tufted cells (MTC and OTC) were formed on E12-14. By P1, the only heavily labeled neurons in the OB were granule cells. The projection neurons of the OB can be broken down into two groups on the basis of their birth dates: 1) the early-formed MC and ITC, and 2) the later-formed MTC and OTC. The time of origin of the MC and TC is much more compressed than in the mouse, which has a longer gestational period of 19 days. Hinds (J.Comp.Neurol.134:287,1968) found MC and TC originating on E10-18, with a fairly distinct progression from MC to ITC to OTC.

We found no consistent topographical gradients in the time of origin of MC and TC other than the depth distribution in the EPL. There was, however, a distinct tendency for labeled cells to cluster in small groups, sometimes widely separated from other labeled cells, suggesting a possible common origin of these cells. Studies are currently in progress combining thymidine labeling with retrograde transport of HRP to determine if there is a direct correlation between time of origin of OB cells and the arrival of their projections into olfactory cortex.

176.7 BIOCHEMICAL CONTROL OF OLFACTORY NEURON REPLACEMENT. C. Camara and J.W. Harding. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164.

Sectioning of the primary olfactory nerve is known to cause retrograde degeneration and death of the primary olfactory neurons in vertebrates. These neurons, unlike others in mature mammals, can be replenished from an undifferentiated stem cell population called basal cells. This replacement process, which is accelerated following injury, also occurs on a regular basis imparting to these neurons a finite lifespan. Using ^{3}H-thymidine incorporation into DNA to quantitatively assess mitotic activity and autoradiography to identify the actively dividing cell population, the mitotic activity of basal cells in olfactory epithelium was monitored at various times following olfactory nerve section. The mitotic rate increased dramatically after surgery, reaching a maximum at four days, at which time a 15-fold increase in mitotic rate was measured. Subsequently the rate declined, returning to control level by day 10. The rate of mitosis of basal cells appears to be controlled by the dipeptide carnosine, which is contained specifically within the mature neurons and its amino acid component, β-alanine. These compounds have antagonistic effects with carnosine acting as a powerful inhibitor and β-alanine working as a strong activator of ^{3}H-thymidine incorporation. The primary olfactory pathway makes an excellent model system to study the endogenous control of mitogenesis. The usefulness of this system is further amplified by the fact that the primary olfactory neurons represent the only neuronal population which is replaced on a regular basis in vertebrates.

176.8 OLFACTORY GRANULE CELL DEVELOPMENT IN NORMAL AND HYPERTHYROID RATS. P. C. Brunjes, W. T. Greenough and H. D. Schwark*. Dept. of Psychol. and Program in Behav. and Neural Biol., Univ. of Illinois, Champaign, IL 61820.

Neonatal hyperthyroidism results in accelerated anatomical maturation in many neural regions and in precocious functional capabilities, including early development of odor sensitivity (Brunjes & Alberts, Horm. & Behav., 14: 76, 1980). This study was designed to determine whether cellular maturation in the olfactory bulb parallels that of chemosensory abilities. The granule cell was investigated because its late formation and maturation suggested particular susceptibility to hormonal treatment. On the day after birth (Day 1), litters were trimmed to 8 rats (4♂, 4♀). Two males and 2 females received i.p. injections of L-thyroxine sodium (1 µg/gm body weight) on Days 1-4, while control pups received vehicle only. Eight littermate pairs (4♂, 4♀) were sacrificed at 7, 14, 21, and 60 days of age, their brains processed via Golgi-Cox techniques and sectioned at 120 µm. Fifteen internal granule cells were drawn (500x) per brain, using a camera lucida and criteria which maximized areas sampled. Tissue was coded to prevent experimenter bias during all stages of data collection. Measurements included: width and length of external plexiform layer portions of dendrites, number of 10 µm "Sholl" ring intersections, number and length of branches per order, and spines/dendritic length.

Development in both groups followed a similar course, with overproduction of dendritic material followed by subsequent regression. Nearly every measure (width of dendritic field, total dendritic length, total number of branches, ring intersections) exhibited peak values on Days 14-21, and decline thereafter. Similar "inverted U-shaped" curves of cellular, dendritic and synaptic development have been reported in several neural regions (Purves & Lichtman, Science, 210: 153, 1980) suggesting that the sequence may be a general feature of neural maturation.

Hyperthyroidism did not accelerate dendritic maturation in 7-day-old animals, the age at which precocious odor sensitivity was reported, and did not grossly affect development in older age groups. The results are striking because the bulb exhibits similarities with region in which major hormone-induced changes have been demonstrated (e.g. cerebellum, hippocampus). While our findings may be due to strain/dose differences, perhaps the bulb is relatively resistant to hormonal fluctuation. Nevertheless, the results are intriguing given that hyperthyroidism accelerates odor sensitivity but not the early anatomical maturation of the olfactory bulb.

176.9 REGIONALLY SPECIFIC ALTERATIONS IN THE GROWTH OF OLFACTORY CORTEX FOLLOWING NEONATAL BULBECTOMY IN GOLDEN HAMSTERS. T. Schoenfeld, J.V. Corwin*, and C.M. Leonard. Department of Neuroscience, University of Florida College of Medicine, Gainesville, FL 32610

When the olfactory bulb is removed in the neonatal rat, intracortical (association) projections in the adult to the deafferented piriform cortex, normally restricted proximally, fill most of Layer I (Price et al., 1976; Westrum, 1975). However, the adult width of Layer I is reduced unless deafferentation occurs within 2 days of birth (Friedman & Price, 1978). We examined the generality of these findings for various parts of the olfactory cortex and for another rodent species, the golden hamster. The left olfactory bulb was aspirated in hamsters 5 (P5) or 19 (P19) days old, and the hamsters were sacrificed as adults 7-9 months later. The width of Layer I was measured bilaterally in the olfactory tubercle (OT), anterior piriform cortex (APC), and posterior piriform cortex (PPC).

Deafferentation at P5 produced a reduction in Layer I of the lateral OT of about 35% when compared to standard values from intact brains ($p<.05$). Deafferentation at P19 produced no change in the width of Layer I in the lateral OT. In the APC lateral to the lateral olfactory tract (LOT), a moderate 20% reduction relative to intact values (statistically ns.) was observed following bulbectomy at either age. Little or no alteration in the width of Layer I was seen in the medial OT, PPC, or APC deep to the LOT. Although terminals of the intracortical system (arising from APC, visualized with degeneration techniques) were found to extend to the pial surface in all three areas after bulbectomy at either age, regional differences in the growth of Layer I following deafferentation suggest that, in some cases of neonatal bulbectomy, the laminar distribution of intracortical innervation may represent some sprouting of terminals superficially while, in other cases, it may represent maintenance of a proximally restricted terminal field.

Of particular interest was the finding that bulbectomy at P19 but not P5 produced an expansion of Layer I in the contralateral lateral OT and the APC deep to the LOT (greater than intact, $p<.05$). This regional specificity in the expansion of Layer I suggests a role for the anterior olfactory nucleus (AON). Removal of AON terminals with a bulbectomy may result in an expanded arborization of AON terminals in other areas which the AON normally innervates, i.e., the lateral OT and the APC deep to the LOT. Expanded terminal arborization could then produce laminar expansion if synaptic density remained nearly normal. This expansion in olfactory cortex may represent another demonstration of the conservation of terminal arborization described by Schneider.

Supported by NIH grant NS 13516, NSF grant BNS 7924680, and NIH postdoctoral fellowship NS 06402-02 to J.V.C.

176.10 NORMAL AND ABNORMAL AUDITORY CORTICOTECTAL PROJECTIONS IN RATS. L. L. Rose*, P. W. Land and A. R. Harvey* (SPON: N. S. Buckholtz). Department of Anatomy, Medical University of South Carolina, Charleston, South Carolina 29425

We examined the projections from the auditory cortex to the inferior colliculi (IC) of normal rats and rats which had received unilateral auditory cortex lesions at birth. Newborn rats were anesthetized with ether and the caudal and lateral portions of one cerebral hemisphere were removed by aspiration. Four months later, a lesion was made in the auditory cortex of the intact hemisphere. After a 4 day survival, animals were perfused with 4% paraformaldehyde and frozen sections through the brains were stained with the method of Fink and Heimer. The brains of several normal adult rats with acute unilateral auditory cortex lesions received similar treatment.

In normal adult rats, degeneration resulting from unilateral auditory cortex lesions was distributed in a pattern similar to that described for the cat. Coarse degenerating fibers interspersed with fine granules of degeneration spread over the dorsal, lateral and caudal aspects of the ipsilateral IC. This degeneration was largely confined to a narrow lamina of cells corresponding to the pericentral nucleus of the cat but also extended to some extent into the external nucleus. In addition, moderate to heavy degeneration extended into the dorsomedial portion of the central nucleus (dorsomedial nucleus). A light but consistent projection was traced through the commissure of the IC, and sparse degeneration extended into the dorsomedial portion of the contralateral central nucleus.

Lesions of the intact auditory cortex of rats with unilateral cortical ablation at birth produced patterns of degeneration in the ipsilateral IC which were similar to control animals. In contrast to normal rats, numerous fascicles of degenerating fibers occurred in the commissure of the IC of these animals and both coarse and fine granules of degeneration could be traced throughout most of the pericentral and external nuclei of the contralateral IC. Moreover, degeneration in the dorsomedial portion of the contralateral central nucleus was much denser than in control animals, and in some cases appeared denser than the degeneration in the corresponding portion of central nucleus ipsilateral to the lesion.

These results show that, as with other corticofugal pathways, the normal pattern of the auditory corticotectal projection is achieved, in part, through some cooperation between populations of axons from both hemispheres. However, since the projection from the auditory cortex is normally bilateral to a portion of the IC, while that from the visual cortex to the superior colliculus is exclusively ipsilateral in rat, there are likely to be other factors which influence the laterality of cortical projections to the mesencephalon. (Supported by USPHS grant EY03414 and Anatomy Department development funds to P.W.L.)

176.11 NEURAL TUNING MATURES FIRST AT HIGH CHARACTERISTIC FREQUENCIES IN COCHLEAR NUCLEUS NEURONS. Nigel K. Woolf and Allen F. Ryan*. Otolaryngology Research Laboratory, University of California at San Diego Medical School and San Diego VA Medical Center, San Diego, CA 92103.

Anatomical evidence indicates that the cochlea matures sequentially in a basal to apical direction. As a consequence of this, it would be expected that maturation of high frequency physiologic function would precede that for lower frequencies. The occurrence of neurones with high frequency CFs (characteristic frequencies) at the onset of hearing has not previously been reported and consequently this prediction has not been tested. In order to test the hypothesis, response properties of single neurons in the cochlear nuclei (CN) of Mongolian gerbils (Meriones unguiculatis) were examined by conventional extracellular recording techniques at postnatal ages 10,12, 14, 16, 18, 30, 60, 90 (young adult) days after birth (DAB),and adult. This range of chronological ages included the onset of neonatal hearing through achievment of mature auditory system characteristics.

Single neuron recordings in the neonatal gerbil CN revealed clear ontogenetic trends. At 10 DAB none of the neurons recorded from within the CN responded to acoustic stimulation. At 12 DAB only a small percentage of the neurons encountered were responsive. For subjects 14 DAB, or older, the vast majority of neurons isolated in CN were responsive to acoustic stimulation. Based upon data taken from neurons which were responsive, it was evident that with increasing chronological age threshold sensitivity rapidly and monotonically increased at all CFs. In contrast, the maturation of tuning in neurons with high-CF was quite different from that of neurons with low-CF. With increasing chronological age the frequency tuning curves for neurons with CF below 3 kHz exhibited a systematic increase in sharpness of tuning (Q10dB) and an increase in slope for both the high and low frequency boundaries for their tuning curves. This trend is consistent with previous reports. However, for neurons with high-CF ($CF \gg 3$ kHz) the sharpness of tuning (Q10dB), at all ages, can approximate normal adult values. That is, tuning at 12 DAB for high-CF neurons can be as sharp as that at maturity in spite of CF threshold disparities of 100 dBSPL or more. The existence at the onset of auditory function of neurons with high-CF and sharp neural tuning is a novel finding. This report thus supports the hypothesis that physiologic functional maturation in the central auditory nervous system is closely correlated with anatomic maturation in the cochlea.

Supported by NIH grants NS00176 and NS14945 from the NINCDS and by the Research Service of the Veterans Administration.

176.12 MORPHOLOGICAL DEVELOPMENT OF RAT COCHLEAR NUCLEI AND AGE-DEPENDENT EFFECTS OF ACOUSTICAL DEPRIVATION. J. Coleman, B.J. Blatchley, and J.E. Williams*. Departments of Psychology and Physiology, Univ. of South Carolina, Columbia, SC 29208.

The goal of this study was to examine changes in volume of the dorsal and ventral cochlear nuclei (DCN and VCN) during different stages of development and to determine the morphological effects of acoustically depriving groups of animals from various ages.

To determine the normal development of the cochlear nucleus, albino rats were sacrificed at 10, 16, 24, 36 or 70 days of age. Sections were drawn on a microprojector and the volumes of DCN and VCN were calculated from planimetric measurements. The volume of VCN increased as a function of age, with the greatest increase occurring between 10 and 16 days of age ($\alpha = .05$). Age-dependent volume differences of VCN were as follows: 71% between 10 and 70 days, 50% between 16 and 70 days, 33% between 24 and 70 days, and 17% between 36 and 70 days; the DCN also increased in size but the slope of expansion was less than for VCN.

The external auditory meatus was ligated in groups of rats at 10, 16, 24, or 36 days after birth and the animals allowed to survive to 70 days. The effects of monaural sound attenuation upon volume of the cochlear nuclei and upon the size of large spherical cells within the ACVN were then studied. The VCN of rats deprived from all ages were reduced in volume ($\alpha = .01$) with the largest difference in volume occurring between 10 and 16 days of age. VCN volume decreased for deprived groups relative to 70 day old normals by the following respective percentages: 43% for 10 day olds; 32% for 16 day olds; 24% for 24 day olds; and 20% for 36 day olds. Large spherical cells, which receive direct input from the auditory nerve, were smaller in the early deprived animals than those from normal cage-reared animals ($\alpha = .05$). Cell area differences between deprived animals and 70 day olds were: 36% for 10 day olds; 21% for 16 day olds; 17% for 24 day olds; and 15% for 36 day olds.

These results demonstrate that the most dramatic period of development for VCN and DCN occurs between 10 and 16 days in rat. The effects of acoustical deprivation on VCN and DCN volume and on large spherical cell area are most pronounced when deprivation is initiated within this same period of development. These findings concur with observations that there is increased auditory nerve activity during this stage of development in rat. (Supported by the Deafness Research Foundation.)

176.13 EARLY AUDITORY EXPERIENCE MODIFIES SOUND LOCALIZATION IN THE OWL. Phyllis F. Knudsen* and Eric I. Knudsen. Dept. of Neurobiology, Stanford University, Stanford, CA. 94305

Young barn owls were plugged in one ear and later tested to determine if they could accurately locate sounds. The owls compensated for the abnormal acoustic conditions created by the plugs and localized sounds without error.

Two barn owls (age 28 and 30 days) were monaurally occluded with foam rubber ear plugs. These owls and one unplugged owl were trained at approximately 8 weeks of age to turn their heads and fixate on sound and light stimuli delivered to them in an anechoic chamber. Owls naturally orient to sounds and lights but this behavior was positively reinforced to reduce habituation to the task. The sounds were repetitive noise bursts of various durations; the light was a light-emitting diode located at the center of the speaker cone. The speaker moved on a semicircular track that pivoted around a horizontal axis so that the speaker could be positioned nearly anywhere around the owl. Since an owl's eyes are stationary, the owl must turn its head to fixate an object visually. The experiments were performed in the dark and the owl's head movements were monitored with an infrared sensitive monitor.

For the behavioral experiments the speaker was moved to a random location, the sound or light stimulus was turned on, and the owl's orientation response was recorded. Forty to fifty responses to sound and light were collected from random locations around the owl. For each trial the owl's response, relative to the actual location of the speaker, was computed. Sound localization error was defined as the difference between the mean orientation to lights and the mean orientation to sound. In normal owls this error is less than 2° in azimuth and elevation.

The two experimental owls were tested after they had been plugged 110 days. Their respective localization errors were right 1.9°, down.8° and right 1.8°, down.5°. Thus, they localized sound with normal accuracy. We then removed their ear plugs and measured their sound localization error. The initial error of one owl, the day her plug was removed, was 6.7° left, 18.4° down. Over the next few weeks her error decreased and after 24 days her error was 1° left and 2° down. The second owl showed a similar pattern of compensation. His initial error was right 12.4° and up 7.6°. After 15 days his localization error was less than 2° in both azimuth and elevation.

We conclude that the auditory system of owls is capable of modifying its sound localization mechanism based on experience in early life.

176.14 TOUCH DOMES AND THEIR MERKEL CELLS IN THE DEVELOPING AND MATURE RAT. J. Diamond, C.A. Nurse and B. Visheau. Dept. of Neurosci., McMaster Univ., Hamilton, Ontario L8N 3Z5.

In an accompanying Abstract (Nurse et al.) we show that epidermal mechanosensory target cells, the Merkel cells, can be labelled with the fluorescent dye quinacrine. Here we use this technique to follow the appearance of the quinacrine fluorescent cells (QFC) in the developing touch domes of rat skin. The density of dome "primordia" (DP) and the distribution of QFC per DP_2 were determined in rectangular strips of epidermis (10-40 mm^2). In animals < 2 weeks old, touch domes are not readily visualized structures, but in epidermis that is mechanically separated from the dermis following ½ hr incubation in 3 mg/ml dithiothreitol, the sites of the DP can be easily recognized by the flat elliptical annuli of QFC scattered across the basal epidermis. At day 1, the average density (σ) of DP was consistently higher on the dorsal (D) than on the ventral (V) trunk skin; the mean σ_D was about 1.3 DP/mm^2 and the mean σ_V was about 0.9 DP/mm^2. Both σ_D and σ_V subsequently decreased, and by two weeks they were usually <0.6 DP/mm^2. We are examining the likelihood that the DP are all established by birth or shortly thereafter, and then simply become further separated as the animal grows. The number of QFC per dome varied in both dorsal and ventral skin, from a low range of 3-50 QFC through an intermediate range of 51-100, to a high range of >100 QFC. At day 1, 50-75% of DP had QFC in the low range in both dorsal and ventral skin, although in the latter, about 10% had QFC in the high range as compared to 0-2% in the dorsal skin. Preliminary indications are that by day 7, the proportion of DP in the high range had increased in both the ventral (ca. 25%) and the dorsal (ca. 10%) skin. We are extending these studies to include embryos and older animals. Analysis of excised domes from adults indicates that often these have 50-170 QFC. This is surprising, since estimates based on nerve terminal counts have suggested that there are only about 25 Merkel cells per adult dome (Smith, J. Comp. Neurol. 131: 459, 1967). Electronmicroscopic (E.M.) examination of domes excised from animals even a few weeks old reveals, in addition to normal Merkel cells, abnormal ones, "transitional" cells (English et al., J. Comp. Neurol., 194: 475, 1980) and an occasional "dead" Merkel cell; any of these might have normal, abnormal or no nerve endings. We are attempting to combine nerve terminal staining with quinacrine fluorescence, together with E.M. examination of touch domes, to clarify the intriguing "modelling" that seems to be occurring within these sensory structures.

176.15 DEVELOPMENT OF THE TRIGEMINAL PATHWAY IN THE MOUSE. D. Durham and T.A. Woolsey. Dept. Anat./Neurobiol., Washington U. Sch. Med., St. Louis, MO 63110.

The large mystacial vibrissae on the faces of rodents are represented within the sensory trigeminal pathway in discrete segregated loci, the pattern of which can be demonstrated with Nissl stains and/or the succinic dehydrogenase (SDH) histochemical technique. Damage to the vibrissae during the 1st postnatal week results in an anatomical alteration of the whisker representations, which decreases in severity with the age at the time of the lesion. In mice, a "critical period" for susceptibility to peripheral damage was determined from Nissl stained material to end on postnatal day (PND)-5 in the cortex and PND-3 in the thalamus (birth = PND-1). Using the SDH method, which apparently demonstrates the patterns of terminals, Killackey and Belford (1980) examined the vibrissae representations in rats damaged on various PND's and concluded that the cortical and thalamic "sensitive periods" were synchronous.

In the present study, various rows of vibrissae were damaged in timed litters of mice on PND 1,2,3,4, or 5. The animals were sacrificed on PND 15 60 and their brains prepared for SDH histochemistry. Paraffin sections of the muzzles were prepared to assess peripheral damage. We examined the 5 vibrissae representations for the pattern and density of the SDH stain.

In the brainstem trigeminal system, the appearance of representations in the principal sensory nucleus and spinal nuclei interpolaris and caudalis was similar regardless of the day of damage. Portions of the representations connected to damaged whiskers showed a relative paling of SDH stain density with no gross distortions of the overall pattern. We conclude that the critical period for the brainstem nuclei ends on or before birth and that the low SDH stain density is a result of the degeneration of 1° afferents from the damaged follicles. In the ventrobasal thalamus, we observed a graded response to damage, including "compensation" by the areas flanking the damaged zone, suggesting a critical period ending on PND-3. The results in the cortex parallel those seen in Nissl stained material with slightly more segmentation within the representations for a row; and the critical period ends on PND-5.

Taken together, our data suggest a sequential development along the whisker pathway, such that more peripheral stations could "instruct" the next central one.

176.16 SHORT-TERM CHANGES IN THE FUNCTIONAL ORGANIZATION OF SOMATOSENSORY (SmI) CORTEX OF ADULT RACCOONS AFTER DIGIT AMPUTATION. A.M. Kelahan and G.S. Doetsch. Depts. of Physiology and Surgery (Neurosurgery), Med. Coll. Ga., Augusta, GA. 30912.

Amputation of a forepaw digit in neonate and adult raccoons has profound long-term effects on the functional organization of SmI cortex (Carson et al., 1981; Kelahan et al., in press). Electrophysiological study of barbiturate-anesthetized animals about one year after amputation revealed that the cortex was responsive, in a non-topographic fashion, to stimulation of large regions of the forepaw including the digit stump. Compared with normal cortex, the receptive fields (RFs) of neurons in chronically deafferented cortex (1) were larger and commonly included more than one digit, (2) often involved both glabrous and hairy skin, (3) were sometimes discontinuous and (4) were extremely variable in location as a function of recording distance across the cortical surface and of depth within cortical tissue; only minor changes were detected in neuronal submodality sensitivity and none in the distribution of tactile stimulus thresholds. The observed effects tended to be more pronounced in neonatal than in adult amputees. No such reorganization could be found immediately after amputation in barbiturate-anesthetized animals.

In the present study, the short-term effects of amputating forepaw digit 3 were studied in adult raccoons sedated with nitrous oxide, paralyzed and treated with local anesthetics. Extracellular recordings from single neurons and small clusters of neurons within the deafferented cortex revealed a shift in afferent drive from digit 3 to the adjacent digits and palmar pads within 30-60 minutes after amputation; the efficacy of this input gradually increased over time. In most respects, the short-term cortical changes were similar to the long-term changes: (1) novel RFs were larger than normal, comparable in size and location to those of long-term amputees; (2) no somatotopic organization was evident, i.e. RF location seemed to be unrelated to the cortical site of recording; (3) no major changes were found in neuronal submodality sensitivity. In contrast, following acute amputation (1) fewer neurons responsive to cutaneous stimulation could be found, (2) RF boundaries were more difficult to delineate and (3) neurons had somewhat higher stimulus thresholds than those of both normal animals and long-term amputees.

These results indicate that the local cortical reorganization following amputation does not require the development of new anatomical connections — unmasking and strengthening of pre-existing latent or weak off-focus inputs may suffice to account for the observed cerebral plasticity. These findings have important implications for the sensory phenomena associated with phantom limbs in human amputees.

176.17 POSTNATAL DEVELOPMENT OF THE ANTERIOR VENTRAL COCHLEAR NUCLEUS IN THE C57BL/6 MOUSE. Dept. of Anatomy, New York Med. Coll., Valhalla, N.Y. 10595.

The cytoarchitecture of the anterior ventral cochlear nucleus (AVCN) was analyzed with Nissl stain and Golgi-Kopsch or Rapid Golgi impregnations at 0,5,10,20 and 30 days in the standard planes. 30 and 20 day AVCN exhibit all the organization present in the mature mouse. Its rostral tip is capped by layers of granule cells which continue around dorsal and dorsolateral surfaces of AVCN. A characteristic cell type is the spherical (12-17 μm) cell with a dark staining nucleus and light staining cytoplasm. These cells are arranged in rostrocaudal and mediolateral rows among the ascending fibers. The dorsal area of AVCN lacks this arrangement. Occasional large multipolar (25-30 μm), spherical (25-30 μm), small (15 μm) and large fusiform (25-32 μm) are present. 10 day old AVCN has a homogenous cellular distribution while 5 and 0 day old AVCN have greater numbers of spherical but very few large neurons.

Golgi impregnations illustrate the following: 30 and 20 day old AVCN: Multipolar cells with 3 radiating primary dendrites, few 2° branches, distal varicosities and numerous short spines. Large spherical cells have 3 to 4 1° dendrites oriented rostrocaudally, few 2° branches, but many distal spines and varicosities. Ovoid neurons have thin and delicate dendrites caudorostrally oriented, few spines, some varicosities and little higher order branching. Larger and most numerous, spherical cells have 1 large 1° dendrite which branches profusely to give a "bushy" appearance. Spines and varicosities are present. 10 day old AVCN: Multipolar, spherical and fusiform cells have similar dendritic arrangements except the somata have appendages and dendritic processes. Some distal dendritic tips have expanded areas with projections. 5 and 0 day old AVCN: Have mostly spherical cells but various specific cell types are difficult to distinguish. The dendritic pattern for the spherical cells is more elaborate but there are no stereotype dendritic orientations. Supported by Grants No. 1-78-6 IN-A-P002R (NIA), 41-979-1 (NIH) and the Anatomy Department.

176.18 ABSOLUTE VISUAL THRESHOLD IS DETERMINED BY THE PROPORTION OF STIMULATED RODS IN THE GROWING GOLDFISH RETINA. Maureen K. Powers and Carl J. Bassi,* Department of Psychology, Vanderbilt University, Nashville, TN 37240.

New neurons are continually added to the retina of the adult goldfish in such a way that the density of rods remains constant while the density of all other cells decreases with age (Johns and Easter, J. Comp. Neurol. 176: 331, 1977). Thus, the receptive fields of ganglion cells in older fish contain more rods. We tested the effect of the relative increase in rods on the sensitivity of the rod system by measuring absolute threshold in three different sizes of goldfish. Small (3.3 ± 0.2 cm standard length), medium (9.5 ± 0.4 cm) and large (15.6 ± 1.4 cm) fish were classically conditioned to respond to a diffuse 532 nm stimulus that covered approximately the same number of ganglion cells in each fish. Threshold, determined by means of a staircase procedure, was defined as the intensity to which a given fish responded on 50% of the trials. We found that the retinal irradiance (q/sec per cm^2) required at threshold was the same in all three sizes of fish, and since double hits were unlikely (see Powers and Easter, Vision Res. 18: 1137, 1978), this result means that the proportion of rods stimulated at threshold was the same for all fish. However, because the stimulus occupied a larger retinal area in larger fish, a larger number of rods were stimulated at threshold in larger fish. The increase in the number of rods stimulated at threshold closely matches the increase in the convergence ratio of rods to ganglion cell fibers (computed from Easter, Rusoff, and Kish, J. Neurosci., in press). We infer that the steadily increasing convergence ratio in growing goldfish does not result in enhanced visual sensitivity with age; on the contrary, the goldfish maintains constant visual sensitivity despite its continually changing visual system.

176.19 ACUITY AND PATTERN DISCRIMINATION IN YOUNG GERBILS. Frances E. Wilkinson and Leonard Gordon*. Department of Psychology, McGill University, Montreal, Quebec, Canada H3A 1B1.

The gerbil possesses a number of characteristics which should make it an excellent subject for behavioral studies of visual development. Locomotor competence, eye opening and weaning all occur within a period of a few days and the young animals display a high level of visual attentiveness and curiosity. The present study is an initial attempt to assess the pattern discrimination abilities and visual acuity of the developing gerbil.

Eight adolescent gerbils (48-58 days of age) from 2 litters were trained on a brightness discrimination followed by 1 of 3 pattern discrimination problems. A ninth animal from one of the same litters was tested for visual acuity in the same behavioral paradigm and the same conditions of illumination. Four adult gerbils (7-8 mo.) were also trained on the brightness and one pattern problem.

A Lashley jumping stand with food reinforcement was employed for behavioral testing. One or 2 20 trial sessions were given daily depending on motivation level. Acuity was assessed by having the animal discriminate vertical square-wave gratings from matched grey stimuli. The pattern problems used with the young gerbils were 3 pairs of Lie figures: (1) concentric circles vs. radiating line (N = 2); (2) vertical vs. horizontal gratings (N = 4); (3) oblique vs. upright sets of hyperbolae (N = 2). All 4 adults learned Problem 2.

A visual acuity measure of 1c/deg. was obtained under our test conditions (distance - 24 cm). Thus our pattern discrimination stimuli (single bar width: 2-8°) were well above threshold. Brightness discrimination was acquired in a mean of 106 trials. No difference was seen between BLACK + and WHITE + groups or between adolescents and adults. All 3 Lie pattern problems were solved very quickly. Average trials to criterion for adolescents: (1) circles vs. lines, 35; (2) vertical vs. horizontal, 48. (3) hyperbolae, 90; for adults: vertical vs. horizontal, 30. Transfer tests including contrast reversals rule out luminous flux and local brightness cues and suggest that gerbils in both groups rely on "pattern" information. The trend toward increasing difficulty from problems 1-3 is the same as that seen in kittens (Nature, 1980, 284: 258-9). The relation between our acuity measure and adult acuity, and the significance of the Lie pattern discriminations to models of visual system functioning will be discussed.

176.20 LATE EMBRYONIC DEVELOPMENT OF AMACRINE CELLS, DISPLACED AMACRINE CELLS, AND GANGLION CELLS IN THE MOUSE RETINA: AN ELECTRON MICROSCOPIC, SERIAL SECTION ANALYSIS. J. W. Hinds and P. L. Hinds*. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

At embryonic day 15 (E15) amacrine cells (AC) appear to develop from cells in the ganglion cell layer (GCL) which lose their axon and migrate outwards to the future amacrine cell layer (ACL) - Hinds and Hinds '78 J. Comp. Neur. 179: 277. The present study examines AC and GC development at E17, the first day when an obvious inner plexiform layer (IPL) occurs between GCL and ACL. Many GC's resemble those at E15 in having an axon and dendrites in the optic nerve layer (ONL), but the ones with somata in the outer GCL now have well developed branching dendrites in the IPL. AC's with somata in the ACL also have dendrites arborizing in the IPL, but they are generally thinner and more tortuous. Unlike E15 a clear transitional series from ventricular cells (VC) to AC's occurs; intermediate elements are bipolar shaped cells with arborization in the IPL. An unequivocal daughter cell pair of immature AC's in the future ACL confirms the direct origin of some AC's from mitotic VC's at E17. In contrast, the development of displaced amacrine cells (DAC) closely resembles that described for AC's at E15: derivation from "ganglion cells" by loss of the axon and transformation of the cell. Three lines of evidence support this conclusion. (1) As at E15 cells resembling GC's but containing only an apparent axon remnant occur, but now their somata are restricted to the IPL and adjacent inner GCL; transitional cells that more closely resemble typical AC's at E17 are also found in the IPL. (2) One cell was found with an axon which morphologically appeared to be in the process of breaking up and degenerating. (3) The fraction of anaxonic cells that had somata in the GCL and IPL (2/79 (3%) in GCL; 12/90 (13%) in GCL plus IPL), even if all end up in the GCL, is too small to account for the large fraction (probably at least 35%) of DAC's found in the adult mouse (Dräger and Olsen '81 Inv. Ophth. 20: 285) ($P<0.001$). Autoradiographic studies show that few additional cells will join the GCL after E17, so the additional DAC's that occur in the adult must mostly be derived from cells that at E17 have axons that enter the ONL and resemble GC's. The present results suggest a natural explanation for the Golgi results of Perry and Walker ('80 Proc. Roy. Soc. 208: 415) that the 6 types of AC's with the widest field dendrites are found with somata on both sides of the IPL, but the 3 types with narrower fields have somata only in the inner nuclear layer: perhaps the former are derived by loss of an axon and become trapped on one side or the other of the forming IPL, while the latter generally are later arising cells that form directly from VC's. (Supported by NIH Grant EY 01398).

176.21 CORTICAL ACTIVATION OF CELLS IN TECTAL TRANSPLANTS IN RATS. G. T. Golden, A. R. Harvey* and R. D. Lund, Department of Anatomy, Medical University of South Carolina, Charleston, South Carolina 29425

In previous studies we found that tectum taken from fetal rats and transplanted adjacent to the superior colliculus of newborns continues to mature and forms connections with the host brain. Anatomical studies indicate a substantial projection from the host occipital cortex to the transplants. Frequently, both cerebral cortices contribute to this pathway, however the projection from the cortex ipsilateral to the side with which the transplant connects is the heaviest and most consistent. In this study we have investigated whether the cortical projection is capable of physiologically activating cells in the transplant.

Three to nine months after transplantation, rats were anesthetized with urethane and ketamine. An array of 6 stimulating electrodes was placed in the left occipital cortex spanning areas 17 and 18a. Single units were recorded in transplants with varnished or glass-coated tungsten microelectrodes. Small electrolytic lesions were made during the recording penetrations to allow subsequent reconstruction of electrode tracks. Brains were fixed after recording for histology.

A total of 20 electrode penetrations were made in 7 transplants. Four of these transplants connected with the left and three transplants connected with the right superior colliculus. Of the 124 transplant units tested with electrical stimulation, 20 (16%) were orthodromically activated from host cortex. A higher proportion of cells was driven in the transplants connected ipsilaterally to the stimulated cortex. Minimum latencies after cortical stimulation ranged from 3.5 to 300 msec., however all but three transplant units had latencies less than 15 msec. The mean latency for these 17 cells was 7.2 msec. For any individual unit the latencies fluctuated over a range from 3 to 5 msec. Most units responded to about 50 to 70% of the shocks applied to the host cortex.

The results indicate that cells in transplants are indeed driven by host cortical afferents, however the activation seems less secure than that found in the corticotectal pathway in normal animals. (Supported by NEI grant EY 03327 and MUSC postdoctoral fellowship)

176.22 CORTICAL EVOKED POTENTIAL AND SINGLE UNIT ACTIVITY TO VISUAL AND AUDITORY STIMULI IN MATURE AND IMMATURE FERRETS (MUSTELA PUTORIUS). G. H. Rose*. (SPON: R. J. Ellingson). Department of Psychology, Bowdoin College, Brunswick, ME 04011.

The ferret is a comparatively inexpensive, easily obtained, relatively tame carnivore with a cat-like gyrencephalic brain. Used fairly extensively in endocrinology, reproductive physiology and virology studies, its use in brain research is limited to animal models of CNS birth defects induced by neurotoxins administered during pregnancy. With the exception of a study on the cerebeller center (Llinas et al., J. Neurobiol., 4, 69-94, 1973), virtually no information is available on the structure and functions of the mature or immature CNS in spite of the above mentioned advantages. It is of particular interest from a developmental viewpoint since it is extremely immature at birth. Eyes in ferrets open at 30 days of age in contrast to 4-7 days of age in kittens. The neurophysiological results obtained appear to be the first reported regarding the sensory cortex of this species.

The cortical topography and other parameters of evoked potential and single unit activity in response to visual and auditory stimuli were delineated in 10 adult and 15 immature ferrets (3-10 weeks of age). Records were obtained from anesthetized and unanesthetized subjects. Unique species typical data, in terms of VEP waveform, unusually short latency regions (visual), and late developmental onset (25-30 days after birth) of electrocortical responses, were obtained. The data are contrasted with developmental neurophysiological findings prevalent in other species.

177.1 DEVELOPMENT OF THORACIC MUSCLES IN MUSCLE-SPECIFIC MUTANT AND NORMAL DROSOPHILA MELANOGASTER. Walter J. Costello and John B. Thomas*. Dept. of Biol., Yale Univ., New Haven, CT. 06511

Using anatomical, physiological, and genetic techniques, we have been studying the interaction between nerve and muscle in developing motor systems of D. melanogaster. The specific systems examined are those involved in escape-the jump response and subsequent flight. The jump is mediated by the tergo-trochanteral muscle (TTM),a tubular muscle; flight is accomplished by two opposing sets of fibrillar type muscles, the dorsal longitudinal (DLM) and the dorso-ventral (DVM).

Several mutations affecting these motor systems are expressed by highly specific phenotypes. One set of mutations disrupts only the jump system, while another set affects solely the flight motor system.

Jump Response Mutants: two mutants, nj 42 and 45T (latter isolated by L. Salkoff), disrupt only the TTM. In the adult, the TTM is almost wholly missing, though the indirect flight muscles, DLM and DVM, are normal.

Flight Response Mutants: the mutant allele stripe (sr) affects only the DLM (Costello,1979,Neurosci.Abstr.5:243). With only one copy of the mutant allele (genotype sr/Df(3)sr; one chromosome carries sr, the other has a deletion at that locus), no DLMs are present in the adult; The DVMs and TTM are unaffected. In nj 307, only the DVMs are affected. Wild-type flies have 6 sets of DVMs (3 per side). In nj 307, one set of DVMs is missing; the adjacent DVMs, DLMs, and TTM are normal.

The development of these muscles during pupation was studied. In every mutant, the affected muscle was at first present, and only subsequently degenerated in mid- to late pupal stages. In normal and mutant flies, we found that in late prepupal and early pupal stages, the myocytes giving rise to DLM,DVM, and TTM appear to migrate from the everted 2nd leg disc, complementing earlier findings (Shatoury,1956,J.embryol.exp.morphol. 4:228). Also, the nerves innervating the larval muscles which serve as substrates for DLM/DVM apparently persist, becoming the adult motoneurons supplying DLM/DVM. The adult myocytes migrate along these nerves in early pupae to reach the larval muscles where they commence differentiation into adult muscles. Thus these nerves might provide orientation for the migrating myocytes to reach their proper destination.

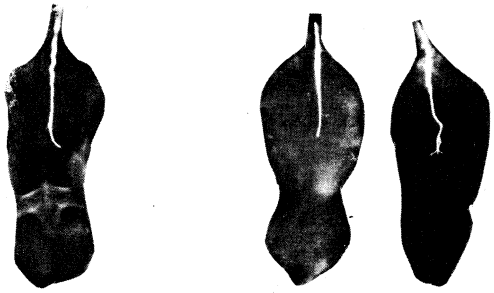
177.2 A SINGLE GENE MUTATION ALTERS THE MORPHOLOGY OF THE GIANT FIBER IN DROSOPHILA. John B. Thomas* (SPON: Robert J. Wyman) Dept. of Biology, Yale Univ., New Haven, CT 06511.

An X-linked recessive mutation, nj262, has been isolated in D. melanogaster which alters the terminal bend of the giant fiber (GF). In mutant flies the GF cell body position and dendritic morphology is indistinguishable from wild-type and each of the two GFs descends unbranched to the thoracic ganglion. In wild-type flies the GF always bends laterally before ending abruptly (Koto et. al., Brain Research , in press). However, the GF in nj262 flies fails to make this characteristic bend and either terminates before making the bend or sends out numerous abnormal branches from the tip (see fig.). At the terminus of the bend the GF normally contacts the TTM motorneuron. This synapse is disrupted physiologically in the mutant.

However, the GF does drive the TTM in the mutant, perhaps by a different pathway. The TTM can be driven by the GF only at extremely low frequencies (0.5 Hz vs. the normal 200 Hz) and its response latency is abnormally long (3.0 msec vs. the normal 1.0 msec). In contrast, the DLM is driven normally by the GF in nj262. This is a disynaptic pathway in wild-type mediated by the PSI interneuron which the GF contacts before making its characteristic bend (King and Wyman, J. Neurocytol., in press).

Supported by USPHS #NS-07314 to R.J. Wyman.



WILD-TYPE NJ262

Lucifer Yellow fills of wild-type and mutant GFs.

177.3 ANALYSIS OF MUTANTS WITH INCREASED MEMBRANE EXCITABILITY IN DROSOPHILA MELANOGASTER. B. Ganetzky,* A.-X. Liu,* and C.-F. Wu. (SPON: D. Murphy). Lab. of Genetics, Univ. of Wisconsin, Madison, WI 53706, and Dept. of Zoology, Univ. of Iowa, Iowa City, IA 52242.

Three genes (Sh, bas^{MW1}, and Eag) involved in the regulation of nerve membrane excitability in Drosophila melanogaster were studied using the larval neuromuscular preparation. Mutations in any of these genes results in enhanced nerve excitability and neuromuscular transmission. Double mutants exhibit striking synergistic interactions suggesting close functional relationships among these three genes.

In Sh, single nerve stimuli evoke excitatory junctional potentials (ejps) of increased amplitude and duration even at 0.1 mM $[Ca^{2+}]_o$ which are associated with repetitive spikes in motor axons (Jan et al., Proc. Roy. Soc. Lond. B. 198:87, 1977; Ganetzky and Wu, Soc. Neurosci. Abstr. 6: 569, 1980). In bas^{MW1}, several stimuli at 10Hz trigger a train of nerve spikes accompanied by a prolonged ejp. Nerve evoked ejps are normal in Eag(0-2mV at 0.1 mM$[Ca^{2+}]_o$). However, Eag differs from normal and the other two mutants in causing the ocurrence of spontaneous ejps ($\sim$ 5Hz). These ejps have normal time course and amplitude.

Double mutants display additional defects not found in any of the single mutants:

1. Duration of evoked ejps is increased at least 10 fold.
2. Spontaneous ejps of this duration occur even at 0.1 mM$[Ca^{2+}]_o$.
3. Both evoked and spontaneous ejps correlate with repetive firing of the motor axon.
4. Nerve terminals sustain very prolonged synaptic transmission upon electrotonic stimulation even when axonal conduction is blocked by TTX.

Mutations such as these can provide the material to analyze the molecular mechanisms of membrane excitability.

Supported by NIH grants NS15390 to B. G. and NIH grants NS15350 and NS15797 to C.-F. W.

177.4 THE TRANSPLANTATION OF EYES TO GENETICALLY EYELESS SALAMANDERS. W.A. Harris*. (Spon: A.I. Selverston). Dept. of Biology, UCSD, La Jolla, CA. 92093.

The eyeless axolotl was discovered as an autosomal recessive mutant (Humphrey, R., Anat. Rec. 163: 306, 1969). Hibbard and Ornberg (Exp. Neurol. 50: 113, 1976) showed that vision could be restored to such animals by embryonic transplantation of eye primordia. The experiments presented here describe several new findings on eyeless animals to which eyes have been transplanted. These are: 1) The central projections of such eyes, as traced with autoradiography or HRP, may be bilateral or ipsilateral to the optic centers of the midbrain and thalamus, or down the spinal cord. The probability of each of the different classes of projection is correlated with the site of nerve entry as in eye transplants to normal animals (Harris, W.A., J. Comp. Neurol. 194: 303, 1980) and is not therefore influenced by the host's eyes (contrary to Giorgi, P.P. and Van der Loos, H., Nature 275: 746, 1978; and Schwenk, C. and Hibbard, E., Exp. Neurol. 55: 498, 1977). 2) Somatosensory serotonergic input to the tectum which is restricted to the deep neuropil in normal animals, and is superficial in eyeless mutants, becomes normally deep in genetically eyeless tecta innervated by transplants. 3) Acetylcholinesterase staining in the tectum, which is limited to the superficial optic neuropil in normal animals, and is largely absent in eyeless mutants, is restored by transplantation. 4) The transplanted retinas make topographic maps on the host tecta, either normal or rotated depending on the orientation of the transplant, even though these transplants were performed before stage 34, the supposed time of "retinal specification" in these animals (Stone, L.S., J. Exp. Zool. 145: 85, 1960), and even though the optic fibers take abnormal routes to the tectum. 5) Whereas in normal animals the axes of the visual and somatosensory projections to the tectum are in topographic register, in eyeless animals to which a rotated eye has been transplanted, these axes are not in register. Thus, the visual map does not orient the somatosensory one.

177.5 K^+-RESISTANT MUTANTS OF PARAMECIUM TETRAURELIA FAIL TO "ADAPT". C. L. Shusterman and C. Kung* Lab. Molecular Biology and Dept. of Genetics, University of Wisconsin, Madison, WI 53706.

A class of behavioral mutants of Paramecium tetraurelia was obtained by a nonbehavioral selection, and used to study the membrane events involved in "adaptation". 35 mM K^+ added to the culture medium kills wild-type P. tetraurelia. The mutants were obtained by adding 35 mM K^+ to mutagenized, autogamized cultures, and isolating the cells that grew. At least 27 independent K^+-resistant mutants resulted, and some survive at up to 80 mM K^+. Paramecia grown in non-lethal levels of K^+ (15 mM) show a behavioral deficit called adaptation. Wild-type P. tetraurelia grown overnight in 15 mM K^+-supplemented medium fails to respond when challenged with Ba^{++} or a thermal gradient. However, the K^+-resistant mutants show little or no such adaptation. The K^+ resistance and lack of adaptation occur together in all of the mutants and cosegregate in genetic crosses. Genetic complementation tests define at least four complementation groups, and the degrees of non-adaptation and K^+ resistance are correlated within the groups.

The mutants have been studied electrophysiologically in an investigation of the membrane phenomena involved in adaptation. Mutants from three different complementation groups and a double mutant of two of these were studied with current clamp and voltage clamp in comparison with the wild type. The mutants are not significantly altered in their resting, depolarization-sensitive or hyperpolarization-sensitive g_K's. One of the mutants has a reduced calcium activation and inward current, indicating a reduction in g_{Ca}. The double mutant, which shows the "pawn" behavioral phenotype (lack of avoiding reactions to any stimulus) has a complete loss of calcium activation and zero inward current. These results indicate that adaptation in Paramecium is a membrane phenomenon involving a change in the membrane conductance to Ca^{++}. Supported by P. H. S. grant GM22714 and N. S. F. grant BNS79-18554 to C. K.

177.6 GRANULE CELL DEATH DURING POSTNATAL CEREBELLAR DEVELOPMENT OF STAGGERER ↔ WILD-TYPE CHIMERAS. Karl Herrup, Dept. of Human Genetics, Yale Medical School, New Haven, CT 06510.

Staggerer is a mutation of mice that causes the improper development of the cerebellar cortex. Virtually all of the granule cells die after migration to the internal granule cell layer (IGL) and the Purkinje cells (PCs) are morphologically abnormal, ectopic, and reduced in number. In staggerer ↔ wild-type chimeric adults all of the phenotypes of the staggerer PCs are retained and thus are intrinsic properties of cells with that genotype. Based on preliminary observations of staggerer ↔ ichthyosis chimeras the death of staggerer granule cells is an extrinsic event, caused almost certainly by the absence of their postsynaptic target, the PC dendritic spine. In normal development granule cells are produced in approximately the correct numbers as very little cell death is observed in the IGL. In adult staggerer chimeras, the volume of the IGL is intermediate to mutant and wild-type. The question thus arises, are the granule cells in the chimera overproduced during development followed by cell death or is their production adjusted to the intermediate number of other wildtype cells?

Using β-glucuronidase activity as an independent cell marker genotypically staggerer PCs were identified in four 16 to 17 day old chimeras. This identifies these animals as staggerer chimeras in the absence of the ability to progeny test. The volume of the chimeras' IGL varied inversely with the percent of staggerer in the chimera. Further, significant granule cell death was observed in the IGL. The extent of this necrosis increased with the percentage of staggerer in the chimera. The latter finding demonstrates that granule cells in the staggerer chimera are overproduced and then "pruned" back to the number found in the adult. The reason for the overproduction, could be either i) a certain number of granule cells are always generated regardless of the number of other cells present or ii) the staggerer PCs are capable of stimulating granule cell multiplication but, due to the absence of PC dendritic spines, are incapable of supporting them. The results also indicate that there is a limited plasticity to the developmental interaction between the Purkinje and granule cell. If the granule cells could be sustained by many fewer PCs or if the wild-type PCs could sustain many more granule cells, little or no granule cell death would be expected in the young staggerer chimeras.

177.7 CEREBELLAR PURKINJE CELLS ORIGINATE FROM A SMALL NUMBER OF PROGENITORS COMMITTED EARLY IN DEVELOPMENT. Richard Wetts and Karl Herrup, Dept. of Human Genetics, Yale Medical School, New Haven, CT 06510.

During the development of a neuron most cytological differentiation (i.e. the growth processes by which a cell elaborates its characteristic morphology) follows the cycles of cell division that generate the adult number of cells. However, the time at which a neuron (or any other mammalian cell type) undergoes commitment to its adult phenotype is not known. This time of genetic and/or spatial commitment can be any time during or after the cycles of division. Results from our laboratory provide evidence that cerebellar Purkinje cells (PCs) are descended from a small number of progenitor cells which become committed very early in development.

Chimeric mice were produced by the aggregation of lurcher (+/Lc) and wild-type 8-cell embryos. The nervous systems of these chimeras are fine-grained mosaics of mutant and wild-type cells. As previously reported, the lurcher PCs degenerate because of some intrinsic mechanism. Thus all of the PCs remaining in the adult are descended from the wild-type embryo. In one chimera (χ11), the number of remaining PCs (approximately 18,000) is the lowest number observed in a mosaic animal. These cells may represent a single clone; that is all of the PCs of χ11 may have descended from a single progenitor. This argument is supported by the fact that in the other lurcher chimeras the numbers of PCs are roughly integer multiples of the number of PCs in χ11. The number of PCs in wild-type mice is approximately 10 times the number in χ11, suggesting that they are descended from 10 progenitors. If a greater number of progenitors gives rise to PCs, smaller clone sizes would have been seen. We cannot know, however, whether these progenitors also give rise to other cell types.

Because cells increase in number by doubling, 14-15 cell divisions are needed for each progenitor to produce the number of PCs in χ11. Assuming an average doubling time of 7-9 hrs, commitment occurs 4.1-5.6 days before the last cell division. In the mouse, the birthdates of the PCs are E11-E14, and so commitment occurs between E5.4 and E9.9 and most likely between E6.9 and E8.4. At this time in development, the primitive streak has appeared, followed by the formation of the neural plate and, later, the formation of the neural tube. Therefore, approximately 10 progenitors are committed to becoming PCs at the earliest stages of nervous system development.

177.8 ALBINO C57BL/6J-c^{2J} MOUSE OPTIC NERVE: ELECTRON MICROSCOPIC AXON COUNT. J. M. Bolam* and I. S. Westenberg. Institute for the Study of Developmental Disabilities, Chicago, IL 60608.

The mouse is valuable in the neurosciences because of many neurological mutants with appropriate genetic controls. The effects of the albino mutation on retinal ganglion cells can be assessed at the retina or more centrally. Previous estimates placed the number of retinal ganglion cells in the albino C57BL/6J-c^{2J} mouse eye between 27,000 and 39,000. However, it has been hypothesized that these estimates are low. This hypothesis can be tested by counting the number of axons in the optic nerve. The small diameter of the mouse optic nerve allows viewing of a complete cross-section electron microscopically, as required to resolve the smallest axons.

The left optic nerve of an 111-day old albino male C57BL/6J-c^{2J} mouse was processed (aldehyde - osmium - ethanol) and embedded in Epon 812. Serial electron micrographs (scope mag.= 2080X) of an unstained whole nerve cross-section on a filmed slot grid were assembled into a montage. Axons were counted in 27 10 μm X 10 μm sample areas (total mag.= 6650X) evenly distributed across the section. The full cross-sectional area of the nerve was calculated from the montage, and the total axon number was estimated.

The section was ovoid in shape with a long axis of 382 μm, a short axis of 253 μm, and an area of 71,700 μm^2. The total sample area of 2700 μm^2 represented about 4% of the total area. 1800 axons were counted in this small sample. Thus the estimated number of axons for this nerve was 47,800. This estimate is close to other electron microscopic estimates of mouse optic nerve axon number. This confirms the hypothesis that the previous estimates of the number of retinal ganglion cells based on light microscopic studies of the retinae of albino C57BL/6J-c^{2J} mice are low.

177.9 ALTERED THYMIDINE KINASE IN DEVELOPING STAGGERER CEREBELLUM. Anne Messer, Michael Savage*, and Thomas P. Carter*. Div of Laboratories and Research, N.Y. State Dept. of Health, Albany, N.Y. 12201.

The mouse cerebellar mutant staggerer (sg/sg) exhibits a reduced rate of proliferation of cerebellar granule cells and degeneration of the remaining granule cells, as well as a 70-80% loss of Purkinje cells (with the remainder abnormal) prior to the time of granule cell generation. Several lines of evidence, including monolayer cell culture studies, quantitative agglutination, and tests utilizing antibodies, indicate that staggerer cerebellar cells retain embryonic cell surface characteristics. This may be secondary to a lack of interaction with normal Purkinje cells.

The enzyme thymidine kinase (TK) is associated with initiation of DNA synthesis, and shows a sharp increase in activity in the mouse cerebellum at postnatal days 6-8. The present experiments demonstrate that levels do not increase developmentally in the mutant cerebellum at ages when the wild-type level is high. Mixing experiments show that this effect is not due to an endogenous inhibitor of the enzyme. Both the K_m and the susceptibility of the TK to nucleotide inhibitors are unaltered in the mutant animals. It is therefore hypothesized that the enzyme is not induced normally in the mutant.

This finding could offer a mechanistic link between the observations of reduced granule cell proliferation and the mutant cell surface changes. Further experiments to examine the relationship between granule cell surface changes and proliferation, in vivo and in vitro, are in progress.

177.10 MITRAL CELL DEGENERATION IN THE MOUSE MUTANT PCD. Charles A. Greer and Gordon M. Shepherd. Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510

Purkinje Cell Degeneration (pcd) is a mutant gene in mice which, when present in the homozygous recessive condition, has several postnatal effects on the nervous system. These include the rapid loss of cerebellar purkinje cells and slower degenerative losses of photoreceptors, some thalamic nuclei, and mitral cells of the olfactory bulb. Mitral cell degeneration, assessed with Fink-Heimer methods on the lateral olfactory tract, was not pronounced until 10 mo. postnatal. We have studied olfactory bulbs of pcd mice to establish more precisely the timecourse of mitral cell degeneration and the consequent effect upon the functional organization within the bulb.

C57BL/6J mice carrying the pcd gene at one or both loci were obtained from Jackson Laboratories and at either 4 or 8 months postnatal were either sacrificed for routine histological examination or tested for functional organization with the ^{14}C-2-deoxy-D-glucose (2DG) technique. The heterozygous (pcd/++) littermates of affected (pcd/pcd) mice were employed as controls since our early studies demonstrated normal olfactory systems in the heterozygous genotype.

At 4 months postnatal pcd/pcd had only 19% of the number of mitral cells found in pcd/++. By 8 months, only 4% remained. In parallel with the loss of mitral cells the thickness of the external plexiform layer (EPL) decreased. This may reflect the decline in number of mitral cell primary and secondary dendrites. Also, orderly arrangement of the granule cell population into islets appeared in disarray. The olfactory nerve and glomerular layers in pcd/pcd did not exhibit any gross morphological changes. Interestingly, on gross inspection, the population of tufted cells in the EPL does not appear to be subject to the influence of the pcd gene. Examination of the functional organization in the olfactory bulb with the 2DG technique revealed essentially normal spatial density patterns within the glomerular layer of the pcd/pcd mice after stimulation with odor.

These results demonstrate that the degenerative loss of mitral cells in the olfactory bulbs of pcd/pcd mice is occurring earlier than previously suggested. Also the 2DG analyses raise the possibility that the olfactory receptor input is functionally normal despite loss of mitral cells. Consequently this murine mutant would seem to be a promising model for studying the role of the mitral cells in olfactory bulb function, the effect of mitral cell loss on synaptic interactions of remaining elements, and plasticity and reorganization in the olfactory system.

177.11 MORPHOLOGICAL DEFECTS IN MICE HOMOZYGOUS FOR t^{w1}: EFFECTS ON EARLY NEURAL TUBE DEVELOPMENT. Linda C. Chaney. Dept. of Zoology & Neuroscience Program, Michigan State Univ., E. Lansing, MI 48824.

The t mutants (t-haplotypes) identified in mice have been genetically divided into seven complementation groups. In the homozygous state, alleles from each complementation group affect different stages of early embryonic development. The late (from day 14 of gestation to birth) embryonic effects of mutants t^{w1}, t^{w3}, t^{w12}, and t^{w20} from the t^{w1} complementation group have been previously described (D. Bennett, S. Badenhausen & L.C. Dunn, J. Morph., 105: 105, 1959). This study re-examines in greater detail the effects of one mutant, t^{w1}, upon developing embryos at mid-gestation.

Mice heterozygous for t^{w1} were mated and embryos were collected from 9 to 13 days post-coitus (p.c.). Embryos were fixed in Bouins solution, embedded in paraffin, serially sectioned at 8 µm, stained with hematoxylin and eosin, and examined by light microscopy. Embryos homozygous for t^{w1} (t^{w1}/t^{w1}) could not be distinguished from normal littermates ($+/+$, $+/t^{w1}$) on the basis of gross morphology prior to 11 days p.c. From 11 to 13 days p.c., t^{w1}/t^{w1} embryos could be identified by their decreased size, enlarged hearts, and degenerating neural tissues. At the light microscope level, t^{w1}/t^{w1} embryos could be detected as early as day 9 p.c. by the presence of pycnotic cells within the mantle layer of the rostral portion of the rhombencephalon. As mutant embryos continued to develop, the pycnotic cells appeared along the neural axis in a specific pattern. Pycnotic cells were always found first in the ventral region of the rostral portion of the rhombencephalon. With increasing age of the embryos, a wave of pycnosis subsequently appeared along the ventral neural tube in rostral and caudal directions, extended into regions of the dorsal neural tube in the area of the caudal rhombencephalon, and spread along the dorsal neural tube towards the tail. Other neural ectoderm structures did not appear to be affected. In general non-neural structures continued to develop in the presence of the abnormally developing neural tube. By days 12 to 13 p.c. mutant embryos were in the process of being resorbed, the heart was not beating, and neural as well as non-neural structures were pycnotic.

Tail or heart explants taken from t^{w1}/t^{w1} embryos at 9 to 12 days p.c. were cultured in vitro for 2 to 3 months. These studies support the hypothesis that, unlike earlier acting t-haplotypes, the action of the gene t^{w1} is specific for cells within the neural tube and does not affect all cells of the embryo.

177.12 THE USE OF CHIMERAS FOR THE STUDY OF THE MYELIN DEFICIT IN THE CNS OF QUAKING MICE. A. Berarducci*, A. Peterson, A. Aguayo, I. Tretjakoff*. Neurosciences Unit, Montreal General Hospital, Montreal, Quebec, Canada.

The understanding of the mechanisms involved in the pathogenesis of inherited disorders of myelination is hampered by the difficulty in separating the relative role played by neurons and glial cells. To explore this question several in vivo and in vitro techniques have been used in recent years (Bray et al, Ann. Rev. Neurosci. 4:127-162, 1981). The present study utilizes experimental chimeras (Peterson et al, Soc. Neurosci. Symp. 4:258-273, 1979) to investigate the pathogenesis of the myelin disorder in the quaking mouse - an animal counterpart of the human leucodystrophies (Sidman et al, Science 144:309-311, 1964).

Quaking and normal 8-cell embryos were aggregated and allowed to develop into chimeras in which the mutant and normal cell lines coexisted throughout primary development. In mature chimeras highly variable areas of normal and mutant-like myelin are distributed in a highly variegated pattern throughout the central nervous system. Normal and quaking-like myelin were found to share the same axons, suggesting that axons are not responsible for the myelin deficit in the quaking mouse.

If, as indicated, quaking oligodendroglia are intrinsically defective, then identification of quaking and normal myelin in chimeras will permit the study of clonal deployment of these cells in the central nervous system.

177.13 INHERITANCE OF NIGROSTRIATAL TYROSINE HYDROXYLASE ACTIVITY IN THE CXB RECOMBINANT INBRED MOUSE STRAINS. H. Baker, C. Vadasz*, and D. J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll. New York, NY 10021, and Res. Inst. for Neurochem., Wards Island, NY 10035.

The genetic control of tyrosine hydroxylase (TH) activity was studied in the nigrostriatal system in male mice of seven recombinant inbred (RI) strains, their progenitor strains (BALB/cByJ and C57BL/6ByJ), their reciprocal F_1 hybrids and a $CB6F_2$ segregating generation. TH was measured in cell bodies, in substantia nigra (SN) and terminals in corpus striatum (CS). TH activity in the SN fell into 3 subsets: highest in the BALB/cByJ strain; lowest in the CXBI; with intermediate values in the others (3.21 $\pm$ .06, 2.23 $\pm$ .04 and 2.48 $\pm$ .09 to 2.86 $\pm$ .01 nmols DOPA/SN/hr respectively; Duncans multiple range test). The distribution of TH activity in the $CB6F_2$ generation was unimodal with significant genetic as compared to environmental variance. Heritability estimates from both the RI lines (0.48) and the $CB6F_2$ (0.89) generation were high indicating that only a few genes control TH activity in the SN. In the CS a significant source of variance of TH activity ($p<0.01$) was attributable to strain differences but no non overlapping subsets of strains were observed indicating a polygenic mode of inheritance. TH activity was highest in the C57BL/6By strain and lowest in the CXBI/J strain and intermediate in the others (C57BL/6By, 9.37 $\pm$ .09 and CXBI, 6.82 $\pm$ .78 nmols DOPA/mg prot./hr). However, the distribution of striatal TH activities in the $CB6F_2$ generation was bimodal indicating that few genes control TH activity in this brain region. Heritability estimates for striatal TH activity differed for the RI and $CB6F_2$ generations (0.25 and .79 respectivtely). A high and significant ($P < .001$) between-strain correlation ($R = 0.82$) of TH activity in SN and CS suggested the presence of pleitropy or linked genes. The number of midbrain midbrain neurons immunocytochemically labeled with antibodies to TH were counted: in the two strains with the greatest difference in TH activity BALB/cBy mice had more TH-containing neurons than the CXBI strain (9686 $\pm$ 561 vs 8059 $\pm$ 579, respectively). We conclude that: (a) TH activity varies in the cell bodies and terminals in the CXB Recombinant Inbred strains; (b) TH activity in both SN and CS is under the control of relatively few genes; (c) some of the controlling genes for TH activity in CS and SN are shared; (d) the branching of SN nigral neurons may be regulated by additional factor(s); (e) the variations in nigrostriatal TH activity between RI strains may be attributable to differences in the number of midbrain DA neurons.

177.14 ACHE AND BUCHE ACTIVITY IN INBRED RATS. J. A. Edwards and S. Brimijoin. Dept. Pharmacology, Mayo Foundation, Rochester, MN 55905.

We have previously reported wide individual variation in acetylcholinesterase (AChE, EC 3.1.1.7) and butyrylcholinesterase (BuChE, EC 3.1.1.8) activities in adult male Sprague Dawley rats. The regulation of AChE in this outbred strain appeared to be tissue-specific, while BuChE activity was relatively similar in all tissues of a given rat. In order to determine whether the variation of the cholinesterases is genetically influenced, we have examined AChE and BuChE in 15 normal male rats of the inbred Fischer 344 strain and 12 normal male rats of the Wistar-Furth strain, age 5 months (300-350g). Serum, liver, diaphragm, brain, and superior cervical ganglia (SCG) were assayed radiometrically in detergent-containing extracts. AChE activities exhibited at most a 3-fold range (in serum), and varied by about 2-fold in other tissues. BuChE activities also varied about 2-fold in most tissues, although a 5-fold range was seen in serum. These ranges are much smaller than previously noted in the outbred Sprague Dawley rats. In general the coefficients of variation of AChE and BuChE activities in the inbred strains were 40-60% as great as those in corresponding tissues of the outbred rats.

No pair of tissues in the inbred Fischer and Wistar rats showed a significant correlation of AChE activities. This result implies that, as in the Sprague Dawley rats, the regulation of AChE in the inbred strains is tissue-specific. BuChE activities in the diaphragm and liver of the Fischer rats and in the serum and liver of the Wistar rats were correlated at a significant level ($r=0.692$ and 0.643, respectively). However, this result contrasts with the universal correlation of BuChE activities among the tissues of the Sprague Dawley rats. We conclude that body-wide regulation of BuChE is possible, but is not necessarily the rule. To determine if AChE and BuChE were regulated coordinately in the same tissues, correlations between the two enzymes were examined. Most tissues showed little or no correlation between AChE and BuChE activities, as was also found in the Sprague Dawley rats. In contrast, however, a significant correlation between the two enzymes was discovered in SCG in both inbred strains. Further work is required to determine the biochemical mechanisms by which these presumably genetically mediated strain differences in the regulation of cholinesterases arise.

(Supported by the Mayo Foundation and NIH grant NS11855)

178.1 INTERACTIONS BETWEEN CO-CULTURED AMPHIBIAN SENSORY NEURONS AND MECHANOSENSORY TARGET TISSUES. K.M. Mearow, C.A. Nurse*, B. Visheau and J. Diamond. Dept. of Neuroscience, McMaster Univ., Hamilton, Ontario L8N 3Z5.

Previous studies in this laboratory have established that in salamanders the epidermal Merkel cell is the target for sprouting and for regenerating mechanosensory axons. We are now attempting to study these neuron-target interactions under controlled conditions in vitro. We began by co-culturing dissociated salamander DRG neurons and skin tissue. The isolated neurons would survive for some weeks, and were electrically excitable. In general however the (bipolar) neurite outgrowth was sluggish, and electronmicroscopic (E.M.) examination of the skin for the relatively sparse Merkel cells was tedious. We therefore turned to the more embryonic Xenopus tadpole, whose two tentacles appear to be mechanosensory structures containing numerous Merkel cells (Ovalle, Cell Tiss. Res. 204: 233-241, 1979). Explants of tentacle pieces and of trigeminal ganglia (the normal source of innervation) or DRGs from stage 52-57 tadpoles were grown on pre-formed collagen-gel discs either alone or in co-culture, in 70% L-15 medium plus or minus exogenous protein (e.g. serum, insulin and NGF). The fluorescent dye quinacrine (see accompanying Abstract by Nurse et al.) was used as a marker for Merkel cells; positive cultures were further processed for E.M. examination to confirm the presence of these cells.

Little neuritic outgrowth was observed in cultures of sensory ganglia by day 4-5. However when a tentacle piece was present there was a marked enhancement of neurite outgrowth by this time even in the absence of exogenous protein (other than the collagen-matrix). Further, a significant proportion of these neurites were oriented towards the tentacle explant or its epithelial-like outgrowth. In longer term cultures (> 10 days) phase microscopy revealed that many neurites not clearly associated with the target-tissue cells appeared to be degenerating; in contrast, those judged to be most strongly associated with the target tissue looked healthier and persisted longer. Areas of tentacle outgrowth in intimate contact with such neurites often contained quinacrine-fluorescent cells. In the E.M. we have found Merkel cells in the original explant and in the cellular outgrowth; nerve bundles were prominent near basement membranous material. We are now investigating whether morphological neurite-Merkel cell contacts develop in vitro, whether mechanosensory function is established, the characteristics of the target stimulus for neurite outgrowth, and the nature of the recognition of the target by nerve endings.

178.2 OPTIC LOBE EXTRACT STIMULATING NEURITE EXTENSION IN EMBRYONIC RETINAL EXPLANTS *IN VITRO*. N. G. Carri and T. Ebendal*. Department of Zoology, Uppsala University, Box 561, S-751 22 Uppsala, Sweden.

Normal visual function depends on the ordered projection of retinal ganglion cell axons onto the optic centers. During development, the extending optic fibers seem to follow selective orientational cues to establish contact with their appropriate targets. At present, however, little is known about the exact nature of these cues whether acting en route or in the terminal field for the visual projection. We designed a tissue culture procedure to study factors controlling the outgrowth of neurites from embryonic chick retina. Using glass capillary tubes, organotypic explants were punched out from the retina in chick embryos (white Leghorn) of Hamburger-Hamilton stage 28-29 (6 days of incubation). The circular explants (0.5-1.5 mm in diameter) were cultured, vitreal side down, for 4 days on top of medium-containing collagen gels with serum added at 20% (10% fetal calf serum and 10% donor horse serum). At intervals, the length of extending retinal neurites was measured in the dark field and phase contrast microscope. Under the described conditions neurites growing out from the retina were sparse and less than 0.2 mm in length. Retinas were then tested for their response to extracts of the optic lobe, telencephalon, and thigh muscles from 18-day-old chick embryos. These additives increased the neuritic outgrowth considerable. Best results were obtained with optic lobe extract, closely followed by the telencephalon extract; the mean neuritic lengths were 1.2 and 1.0 mm, respectively. Moreover, optic lobe extract distinctly improved the survival of retinal cells in the explants. The stimulative effects of the optic lobe extract were also evident although reduced under serum free conditions. Neuritic outgrowth was not enhanced by either mouse nerve growth factor (NGF), or embryonic chick heart extract, both being stimulators of neuritic extension in peripheral ganglionic neurons. Our data suggest that extractable materials from appropriate target areas may support the growth of retinal axons and possibly present orientational cues needed for setting up the visual projection. It is not yet known whether this control of fiber extension is exerted by "pathway" molecules coating the substratum (e.g. acting to increase growth cone adherence) or by "neuronotrophic" factor(s) active in solution.

(N. G. Carri is a Fellow of CONICET, Argentina).

178.3 TROPHIC INFLUENCE OF THE TECTAL TISSUE ON THE OUTGROWTH OF NEURITES FROM THE CO-CULTURED RETINAL TISSUE, EXPLANTED FROM ADULT GOLDFISH. Myong G. Yoon and Frank A. Baker* Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1.

Trophic interactions between the regenerating neural processes from the retinal tissue and the tectal tissue were studied in vitro under various experimental conditions by co-culturing the retinal and the tectal tissues, explanted from the adult goldfish. The optic nerve was pre-crushed about two weeks before retinal explantation, and 5-15μ Ci of H^3-proline was injected into the eye 24-72 hrs prior to retinal explantation. This procedure allowed us to label the entire length of newly grown neurites from the retinal explant, maintained in culture for 3-4 weeks. If a rectangular piece of the retina was dissected free along the nasotemporal axis near the equator, and implanted on a culture dish, the neurites sprouting out from the retinal explant usually grew in the radial direction towards the phantom optic disc. As they grew out further, these retinal neurites curled up to form clockwise spirals, in the absence of their target tissue. When a piece of the tectal tissue (dissected from the topographically matching area) was introduced, however, the curling retinal neurites tended to straighten, and grew preferentially towards the tectal tissue, and eventually invaded it. The trajectories of the ingrowing retinal neurites within the tectal explant were traced by autoradiographic methods through serial sections. Preliminary result suggests that these retinal neurites tend to grow towards the appropriate layers of their usual passages and terminations within the co-cultured tectal tissue.

178.4 NERVE GROWTH FACTOR ACTION AT THE GROWTH CONE. P.J. Seeley* and L.A. Greene* (SPON: A. Chalazonitis) Dept. Pharmacol., New York Univ. Med. Ctr., New York, NY 10016

The shape and motility of growth cones of PC12 cells and sympathetic neurons were observed to alter rapidly on withdrawal or readdition of nerve growth factor (NGF) to the culture medium. These effects have been documented by time-lapse video recording of light microscope images of living cells. The clonal pheochromocytoma line PC12 has been used for these experiments since it expresses sympathetic neuronal characteristics without being dependent on the factor for its survival. The growth cones of PC12 neurites exposed to NGF are broad, lamellopodial structures which are commonly fringed by filopodia adherent to the substrate. The geometries of both filopodia and lamellopodia are constantly changing on a time scale of minutes. In addition, tentacle-like structures made up of lamellae and microspikes, appearing to originate at the upper surface of the cone, probe the medium above the terminal with rapid gyrations.

Removal of NGF from neurite-bearing cultures of PC12 cells provokes a sequence of changes in the growth cone. Over 1-2h a large proportion of lamellopodia and filopodia are withdrawn, resulting in a neurite tip which is butt-ended. Subsequently a 'bead' forms close to the terminus which is followed by thinning of the neurite and collection of other bead-like structures along its length. Motion of components of the cone gradually decreases and by 4h after initiating removal of NGF, the terminal is almost static. This time-course is partly contemporary with likely slow dissociation of NGF from cell surface receptors. Readdition of NGF to deprived cultures quickly induces (< 5min) rapid motion of filopodia and tentacle-like structures, but spreading of lamellopodia and re-initiation of neurite elongation occur after about 30min. These events induced on readdition of NGF are not blocked by interventions which retard influx of extracellular calcium, nor can they be mimicked by addition of dibutyryl-cAMP. The main features of the growth cone response to NGF withdrawal or readdition occur also for cultures of neurons from rat superior cervical ganglia.

The rapidity of effects observed in the growth cone on re-adding NGF implies a local mechanism for trophic interaction of a growing axon with NGF which is distinct from longer-term, transcription-dependent events elicited by NGF at the cell body (~d). Supported by grants from the March of Dimes and NIH (NS 16036). P.J.S. is a N.A.T.O. Fellow.

178.5 REGENERATION OF NEURITES IN LONG-TERM CULTURES OF SYMPATHETIC NEURONS WITHOUT NERVE GROWTH FACTOR. R.B. Campenot* (SPON: R. Hoy). Sect. of Neurobiology & Behavior, Cornell Univ., Ithaca, NY 14850.

Sympathetic neurons from newborn rats were plated into center compartments of three-compartment dishes. Neurites elongated along a series of parallel collagen channels which served to orient them to the left and right. Neurites readily penetrated silicone grease barriers and entered the separate fluid environments of the left and right side compartments where their progress was monitored by means of a stage micrometer, and their density was evaluated visually (see Campenot, R.B., Methods in Enzymology, 28: 302, 1979). 7S nerve growth factor (NGF) at 1 µg/ml was used. Formulations and general culturing procedures were as described in Hawrot, E. & Patterson, P.H., Methods in Enzymology, 28: 574, 1979), except that side compartments were given medium free of serum and ascorbate.

Neurites readily penetrated barriers when NGF was present in the side compartments, and NGF was removed from the center compartments 4 days after plating (see Campenot, R.B., Proc. Nat'l. Acad. Sci., 74: 4516, 1977). Cultures matured for 20-55 days when neurites were removed from the side compartments by vigorous washing with distilled water. Within 24 hrs, luxurient, regenerating neurites were observed in side compartments given NGF subsequent to washing. They advanced along the channels at about 1 mm/day during at least 4 days of observation. Surprisingly, regeneration also occurred in cultures where neither side compartment was given NGF subsequent to washing. Without NGF the neurites were less dense (but substantial), advanced somewhat more slowly, stopped in about 2 days at distances of 1-2 mm, and held this position for as long as 20 days of observation. Neurite elongation resumed when NGF was subsequently added to previously deprived side compartments, but addition of NGF to center compartments did not augment regeneration into NGF-deprived, side compartments. Also, regeneration was repeatedly observed in cultures subjected to successive washings over periods as long as 20 days without NGF given anywhere, making it very unlikely that residual NGF could have supported the regeneration.

It has been shown that cultured sympathetic neurons from newborn rats die if deprived of NGF during days 10-20 in culture, but that some will survive NGF withdrawal at later times (Chun, L.L.Y. & Patterson, P.H., J. Cell Biol., 75: 705, 1977). The present work strongly suggests that in addition to survival capability, at least some sympathetic neurons develop the capability to regenerate neurites without the trophic support of NGF.

(This work was supported by NIH grant NS15559.)

178.6 LECTIN AFFINITIES OF PNPF, A POLYORNITHINE-BINDING NEURITE-PROMOTING FACTOR. Ruben Adler, Marston Manthorpe and Silvio Varon. Dept. of Biology, Univ. of Calif., San Diego, La Jolla CA 92093.

PNPF is a neurite-promoting factor present in many conditioned media, and particularly concentrated in serum-free medium exposed to the Schwannoma cell line RN22. The RN22 PNPF does not by itself have survival-promoting properties, and its neurite-promoting activities are expressed only after it is bound to polyornithine (PORN) substrata. Dissociated 8-day chick embryo ciliary ganglionic (CG) neurons cultured on PORN with adequate support from the eye-derived trophic factor CNTF survive but fail to grow neurites in the absence of PNPF, and generate a lavish neuritic network in its presence. Neurons from dorsal root and sympathetic ganglia, as well as some neurons from the spinal cord also respond to PNPF. PNPF activity is associated with a heat- and trypsin-sensitive, acidic macromolecule.

We report here current studies on the lectin affinity of PNPF. PNPF binds to agarose-coupled concanavalin A (Con A), wheat germ agglutinin (WGA) and Ricinus commonis agglutinin (RCA), but not to Dolichos Biflorus agglutinin (DBA) or Ulex Europaeus agglutinin (UEA). The activity remains bound to Con A and WGA columns during 1M NaCl elution, but can be eluted from Con A with α-methyl mannoside (αMM), and from WGA with N-acetylglucosamine. Investigations with RCA are impaired by the appearance of toxicity in the eluted fractions. Pretreatment of PORN-bound PNPF with con A prevents neuritic growth from CG neurons, and this inhibition can be removed with αMM. Attempts to block PNPF activity in the CG assay using WGA have so far been unsuccessful.

178.7 FURTHER STUDIES ON THE MECHANISMS OF AXONAL GUIDANCE DURING DEVELOPMENT OF THE CORPUS CALLOSUM. Jerry Silver. Dept. of Anatomy, Case Western Reserve Univ., Sch. of Med., Cleve, OH 44106

During normal ontogeny of the mouse forebrain, and before the arrival of the pioneer fibers of the corpus callosum at the midline (E15), a population of primitive glial cells migrates medially (through the dorsal septum and rostral to the lamina terminalis) from the ependymal zones of each hemisphere. At the midline these cells unite to form a sling-like structure suspended below the interhemispheric fissure (E 16). The first callosal axons grow along the surface of this glial scaffold as they travel towards the contralateral side of the brain (E17). The critical question remains. Does this transient glial tissue actually provide guidance cues to the callosal axons?

I have adopted two courses of study in order to answer this question. Firstly, the developmental stages of a congenitally acallosal mouse mutant (strain BALB/c, supplied by D. Wahlsten) have been analysed to see if malformations occurred in the regular development of the glial "sling" in advance of the first morphological signs of the callosal abnormality. Secondly, the "sling" has been lesioned surgically through the uterine wall in the normal embryo (strain C57Bl/6J at stages E15-16).

In the acallosal mouse mutant the "sling" does not form. Although fusion of the septal midline does occur forward of the lamina terminalis, the glial elements which normally comprise the "sling" do not migrate far enough nor in numbers sufficient enough to form a cohesive structure. Although the would-be callosal axons approach the midline on schedule, they do not cross. Instead, most whorl into a pair of large neuromas adjacent to the interhemispheric fissure. Apparently, some fibers, whose destinations are yet unknown, eventually enter the septum (Ivy and Killackey,'81). Surgical disunion of the glial "sling" in normal embryos (without touching the lamina terminalis) also resulted in acallosal individuals. The anterior and hippocampal commissures were unaltered. It is noteworthy and rather remarkable that the callosal pathology in these affected animals mimicked exactly that of the genetically lesioned mutant.

There are several especially significant aspects of these investigations. Firstly, my observations suggest that the primitive glial "sling" over which the callosal fibers grow is just as important to the guidance of axons as the targets with which they must eventually synapse. Secondly, the highly oriented geometry of this glial structure is apparently organized under genetic control. Thirdly, it appears that the proper development of the corpus callosum has little to do directly with the lamina terminalis, at least in the mouse. Supported by NIH (NS-15731).

178.8 GROWTH CONES EXPAND IN-VITRO BY DEPOLARIZATION UNDER CONDITIONS WHICH PERMIT Ca^{2+} ENTRY. L. Anglister*, A. Shahar*, I.C. Farber* and A. Grinvald. Dept. of Neurobiology, Weizmann Inst. of Sci. and Institute for Biol. Res., Ness-Ziona, Israel.

Calcium action potentials were recently recorded at or near growth cones of regenerating neurites (Meiri et al., Science 211, 709, 1981) and developing neurites (Grinvald & Farber, Science 1981, in press). In order to investigate if Ca^{2+} entry plays a role in neurite growth, we have studied the morphological changes induced by experimental conditions which permit inward calcium currents. Differentiated N1E-115 neuroblastoma cells (4-10 days) were depolarized either by 30mM potassium (for 10-20 min) or by stimulating the soma (for 20-120 min) with an intracellular electrode. Morphological changes in individual cells were followed by time-lapse video recordings and subsequently by scanning electron microscopy. Steady state potassium depolarization or long trains of 0.5 Hz action potentials induced in more than 60% of the experiments pronounced flattening and an increase of 20-120% in the apparent contact area of the growth cone. Statistical comparison of control and potassium depolarized cells (in the presence of 5mM Ca^{2+}), by scanning electron microscopy, indicated that depolarized growth cones had larger contact area with the substrate at least by 25% relative to the control cells. The growth cone membranes were flattened, had a smaller number of micro-spikes, and contained markedly more vesicular protuberances. Similar morphological changes were also observed in restricted zones of expanded membrane area occurring along the neurites of these cells. The same results were obtained when the cells were stimulated in a medium containing 10^{-6}M TTX and 15mM TEA. However such morphological changes could not be observed in the presence of 0.2mM Ca and 1mM Cd^{2+} which block the inward Ca^{2+} currents. Removal of the Cd^{2+}, or elevation of the Ca^{2+} concentration to 5mM, even in the presence of 1mM Cd^{2+}, again led to the changes in these cells. These results indirectly suggest that Ca^{2+} inward current might be the primary trigger of the observed morphological changes. The above changes may play a role in neurite growth.

In some cases we have observed that growth cones of different processes of a single cell responded differently to depolarization e.g., while some growth cones were expanded by 110%, others were not changed at all. One possible explanation might be the regional variations in the distribution of functioning Ca^{2+} channels. This possibility is being examined by local microperfusion combined with focal extracellular recordings and optical recordings from different processes and growth cones of the same cell.

178.9 **CHEMOTAXIS AND REGENERATION OF MAMMALIAN NERVES.**
M.J. Politis, K. Ederle*, and P.S. Spencer. Inst. of Neurotoxicology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

We have continued to reexamine the Weiss/Taylor 1944 rebuttal (1) of Cajal's hypothesis (2) that Schwann cells in distal nerve stumps exert an "attractant" (chemotactic) effect on regenerating axons. Proximal stumps of transected feline peroneal nerves were individually inserted into the single "input" end of hollow, Y-shaped Silastic implants so that regenerating axons grew over a 4-mm distance toward either a tibial (T_{out}) or peroneal (P_{out}) distal stump inserted into the paired output ends of the implant. At 4.5 weeks postoperatively the number of unmyelinated and myelinated axons greater than one micron in diameter in implant forks leading to distal peroneal and tibial nerves were assessed morphologically, and at 6 weeks the number of myelinated axons. At both time points 2-3 times more peroneal axons were found in implant forks leading to "native" P_{out} than to "foreign" T_{out}. Treatment of P_{out} with dry ice and RNA/DNA-synthesis inhibitors to compromise Schwann cells resulted in approximately 10 times more regenerating peroneal axons to T_{out} than to P_{out}. Preliminary data utilizing axonally transported radioactive proteins indicate a preferential growth of both motor and sensory peroneal axons to untreated tibial rather than treated peroneal stumps. Morphological assessment of implant forks revealed a similar though less marked effect when 8-week denervated tibial distal nerve stumps(containing "undifferentiated" Schwann cells, an enhanced density of fibroblasts and little or no myelin debris) were individually inserted adjacent to freshly transected treated distal P_{out}. When Nuclepore filters (0.2-um pore size) were placed between the implant and either treated P_{out} or untreated T_{out}, marked preferential growth to the latter was observed. These results suggest that peripheral nerve regeneration is influenced by diffusible chemotactic factors, possibly of Schwann cell origin.

178.10 AN ELECTRON MICROSCOPIC STUDY OF THE HAMSTER PYRAMIDAL TRACT.
T.A. Reh and K. Kalil. Neurosciences Training Program and Department of Anatomy, University of Wisconsin, Madison, WI 53706

A previous light microscopic study using anterograde tracing techniques demonstrated that the growth of the pyramidal tract of the hamster is primarily postnatal. Thus, the pyramidal tract provides a convenient model system to study the development of fiber pathways in the mammalian central nervous system. We therefore undertook a qualitative and quantitative electron microscopic (EM) study of the development of the pyramidal tract to investigate the mode of growth of the axons, the possibility of fiber degeneration during development, and the process of myelination.

Golden hamsters ranging in age from three to 200 days were perfused intracardially and blocks containing the medullary pyramids were prepared for EM analysis. The total number of fibers in the tract at the level of the inferior olivary nucleus was determined for several postnatal ages by taking the product of axon density and tract area. We found that the pyramidal tract grows through the medulla as a compact bundle containing nearly twice the number of fibers as the mature tract. During the second postnatal week there is a substantial decline in the number of fibers in the tract coincident with the appearance of dark degenerating profiles in the tract. The decline in axon number continues in the third and fourth postnatal weeks at a reduced rate and by 34 days after birth the number of axons reaches the adult value. Myelination in the hamster pyramidal tract begins at seven days and continues at a very slow rate until the third postnatal week, when a dramatic increase in myelin formation occurs. By 34 days after birth the number of myelinated axons is approximately 80% that of the adult. As has been reported for other CNS tracts, there does not seem to be a "critical diameter" of an axon that absolutely determines the presence or absence of myelin. However, all axons above 0.5 in diameter are myelinated at approximately the same rate, while those under this diameter are myelinated much more slowly and even in the adult make up only a small percentage of the total myelinated fibers.

178.11 AXONAL PROJECTIONS OF SUBCORTICAL NEURONS IN CEREBELLAR TISSUE CULTURES.
F. J. Seil and N. K. Blank*. Neurology and Research Services, V.A. Med. Ctr. and Depts. of Neurology and Pathology, Univ. of Oregon Health Sci. Ctr., Portland, OR 97201.

Cerebellar explants derived from newborn mice can be prepared to include or exclude portions of underlying pons. When portions of dorsal pons are included, a clear separation usually becomes evident after maturation in vitro between two subcortical groups of neurons, namely those derived from intracerebellar nuclei and those originating from nuclei of the tegmentum pontis. Large intracerebellar nucleus neurons fall into two major categories when stained with silver and Golgi impregnation methods, including multipolar and spindle-shaped cells. Both forms have aspinous as well as spiney dendritic branches. A variety of neuronal types is evident in dorsal pontine portions of cerebellar explants, ranging from medium size to giant multipolar neurons with predominantly spiney dendritic branches to occasional unipolar mesencephalic V nucleus neurons. Catecholamine positive neurons are infrequent in those portions of tegmentum pontis routinely incorporated with cerebellar explants. The axons of intracerebellar nucleus neurons invariably turn toward cerebellar cortex after a brief ventrad excursion, and multiple branches terminate in dispersed cortical regions. The axons of most pontine tegmental neurons loop back to the explant after initially growing toward or into the ventral outgrowth zone, and their branches terminate in widely separated portions of cortex. A constant exception to this pattern are the peripheral axons of mesencephalic V nucleus neurons, which terminate in far reaches of the outgrowth zone. Mossy fiber terminals are readily evident on ultrastructural examination of cortical regions of cerebellar explants with incorporated segments of dorsal pons, while such terminals are rare in cultures without pontine tegmental neurons. It would thus appear that dorsal pontine neurons, many of which project mossy fibers to the cerebellar cortex in situ, are the source of most mossy fiber terminals in cerebellar explants. Axons of intracerebellar nucleus neurons, deprived of their usual target cells, may universally turn toward cortex in a generally unsuccessful search for central targets, and not because they mimic an in situ nucleocortical projection. (Supported by the Veterans Administration).

178.12 GROWTH OF CORTICOSPINAL AXONS THROUGH LESIONED NEONATAL SPINAL CORD.
D.J. Schreyer and E.G. Jones Department of Anatomy and Neurobiology and McDonnell Center for the Study of Higher Brain Functions, Washington University School of Medicine, St. Louis, Missouri 63110.

The anterograde transport of horseradish perioxidase was used to label the growing axons of corticospinal neurons in neonatal rats that had suffered spinal cord lesions. The appearance of these axons, their length, and the path taken by them were compared to those in unlesioned animals on the ninth day after birth at which time corticospinal axons reach the lumbosacral enlargement. Spinal cord lesions were of two general types: a complete surgical transection, usually involving a limited length of spinal cord, or a thermal lesion produced by brief contact of a heated rod on the dorsal aspect of the vertebral column. The latter type of lesion had a greater rostrocaudal extent, but with varying dorsoventral involvement. All lesions were made at low thoracic levels at different times before the arrival of the first corticospinal axons. The overall growth rate of corticospinal axons was not significantly altered, except in cases where complete transection or massive damage constituted an insurmountable barrier. Corticospinal axons grew toward a lesioned area at the same rate as controls and if they grew through and beyond a lesion, their growth rate was unaffected. The tips of the growing axons appeared normal. The paths taken by growing axons in the vicinity of a lesion were often markedly aberrant. Virtually any remaining neural tissue could provide a substrate for growth through a lesion, but axons never extended outside the CNS. Displaced axons that were successful in passing a lesion sometimes, but not always, returned to their normal position in the dorsal columns distal to the lesion.

Supported by Grants NS15070 and T32NS07071 from the National Institutes of Health, United States Public Health Service.

178.13 IDENTIFICATION OF CULTURED MOTONEURONS BY RETROGRADE TRANSPORT OF HRP. K. W. Tosney* and L. T. Landmesser. Biology Department, Yale University, New Haven, CT. 06511.

Recent work suggests that motoneurons innervating the chick hindlimb are specified early in development, and that their precise and specific responses to environmental cues play a large role in generating specific patterns of innervation. For instance, motoneuron axons sort out into discrete tracts before they reach the limb (Lance-Jones and Landmesser, 1981, Proc. Roy. Soc. Lond. In press). Furthermore, when experimentally displaced from their normal point of entry into the limb, motoneuron axons can still specifically innervate their appropriate targets (Lance-Jones and Landmesser, 1980, J. Physiol. 302:581). In order to analyze further the abilities of motoneurons to fasciculate specifically and to locate their targets, we have developed an in vitro system in which specific populations of motoneurons are identifiable.

Motoneuron pools are labelled in vivo by injecting 5% HRP into specific sites of stage 24-31 chick hindlimbs and allowing retrograde transport for 3 hours (h) in an oxygenated Tyrode bath at 31° C. The ventral quadrant of the lumbosacral cord is then plated either as segment-sized explants or as dissociated cell cultures on tissue culture substrata that have been coated with polyornithine and rinsed with acetic acid-solubilized collagen. The culture medium, containing 10% horse serum and 5% embryo extract, is previously conditioned by confluent monolayers of chick heart ventricle cells. Neurons begin to extend neurites 3 h after plating under these conditions. After fixation, the cultures are processed with diaminobenzidine to allow visualization of label.

One population of neurons is heavily labelled with granular reaction product in dissociated cultures derived from embryos in which all the limb muscles have been injected with HRP. The labelled neurons are 12-15μ in diameter and 80-90% have extended neurites by the time of fixation, 18-24 h after plating. Only a background level of label is present in glial cells or in neurons of other size classes or with dramatically different morphologies. In explants, labelled neurons occur only within the lateral motor column, and are restricted to the appropriate segments when only a single muscle is injected with HRP.

We conclude that specifically labelled populations of motoneurons retain their label in our cultures and actively extend neurites. We are currently using this culture system to examine neurite-neurite and neurite-target interactions which may be important in generating specific patterns of innervation during development.

Supported by NIH grant NS10666 to LTL and MDA fellowship to KWT.

178.14 AN IN VITRO MDOEL OF CEREBELLAR GRANULE CELL MIGRATION. E. Trenkner, N. Segil* and R. Liem* (SPON: U. Drager). Dept. of Pharmacology, New York Univ. Med. Ctr., New York 10016.

It has been suggested that astro glia cell types play a decisive role in the histogenesis of the CNS by serving as guidance for neuron migration (1). We have developed a micro-tissue culture system which allows us to characterize and to manipulate cell migration during cerebellar development (2). We have previously described the process of pattern formation in these cultures. After dissociation, cells reaggregrate and form cables which connect the reaggregates. A population of presumptive granule cells then migrates out of the reaggregates onto the cables. This study was undertaken to confirm the identity of these cells and to further characterize their interaction with glial elements.

At postnatal day 3 (P3), the majority of cells dividing in the cerebellum are external granule cells, a subpopulation of which are destined to begin migrating within 24 hrs. (3). Therefore, we injected ^{3}H thymidine into P3 animals and at various times thereafter prepared cerebellar cultures in order to determine whether this labeled, migrating population of cells appeared as migrating cells in our cultures. 3 days after culture of P4 animals (injected 24 hrs earlier) 30%-40% of the migrating cells were labeled. This % was much lower in cultures prepared 96 hrs (P7) after ^{3}H thymidine injection, indicating that there might be a predetermined length of time during which these cells can migrate. To check this hypothesis, P3 cerebellar cells were labeled and then cultured for various times up to 7 days. The largest % of labeled cells on cables was found after 3 days in vitro. Subsequently, the % of labeled cells on cables declined to near 0, most probably as a result of migration into reaggregrates (2). This study confirms the electron microscopic evidence that the cells migrating on cables are granule cells and suggests that there may be a predetermined length of time for migration to take place.

In an attempt to characterize the cellular composition of the cables, anti-glial filament antibodies were employed immunohistochemically. It was observed that granule cells only migrated onto cables which contained glial elements in addition to the parallel fiber elements previously described (2). However, no direct contact between glial elements and migrating granule cells seemed to be necessary. These observations further substantiate the possible role of glia during granule cell migration.

178.15 GROWTH CONES OF GOLDFISH RETINAL NEURITES GENERATE DC CURRENTS, AND ORIENT IN AN ELECTRIC FIELD. J.A.Freeman, J.M.Weiss, G.J.Snipes, B.Mayes, J.J.Norden. Vanderbilt Medical School, Nashville, TN 37232.

The optic nerves of fish and amphibia are remarkable for their ability to regenerate after injury. Little is known about the mechanisms that control the rate or direction of axonal growth. Some of these mechanisms can be studied to advantage in tissue culture. Goldfish retinal explants were cultured on poly-L-lysine coated petri dishes 10-12 days after optic nerve crush, using a modification of the method of Landreth & Agranoff (Brain Res., 1979). Prolific neuritic outgrowth occurred within 3-5 days. Individual neurites grow at a rate of 15-25μm/hr; the majority of long neurites appear to arise from ganglion cells, and tend to organize themselves into fascicles. The fascicles appear under SEM to be held together by glial cell processes, not by direct contact between neighboring neurites. By contrast, growth cones appear to adhere directly to the substrate. Filopodial processes are often seen extending towards small particles, some of which are negatively charged as shown by their direction of migration in an applied electric field. To further explore the influence of an electric field on neurite growth, a chamber was constructed through which a linear field could be applied at different angles. Fields of 2-3V/cm caused a dramatic orientation of neurites towards the cathode, and increased the rate of growth, as also shown by Jaffe & Poo (J.Expl.Zool., 1979). Applied fields also caused new processes to sprout.

Growth cones themselves generate DC currents of 15-30nA/cm^{2}. These were measured by a platinized microelectrode caused to oscillate in a circle of 15-20μm diameter at 300Hz by a specially constructed driver. A computer was used to average the voltage gradient across the diameter of the electrode's traverse at different angles. Signal averaging and the rapidity of the electrode motion greatly decreased electrode noise, permitting currents of <5nA/cm^{2} to be measured and displayed in polar coordinates. A current appears to flow inwards across the plasma membrane at the tip of the growth cone, and back outwards at the base. Calculations based on these measurements are consistent with the hypothesis that these endogenous currents are produced by the strategic location of a class of ionophores or of pump sites on the tips of the growth cones. These currents might play a role in the molecular assembly and organization of the growth cone, and possibly in controlling the direction of growth, which seems to be quite sensitive to and possibly determined by short-range electric field interactions.

Supported by NIH Grant EY-01117-09.

179.1 ABSENCE OF MORPHOLOGICAL RESPONSES TO INTRACELLULAR INJECTION OF NERVE GROWTH FACTOR INTO CELLS OF THE NEURON-LIKE CLONE PC-12. S. Huttner* and P. O'Lague. Dept. Biology, Univ. of California, Los Angeles, CA 90024.

Nerve growth factor (NGF) triggers the extension of neurite-like processes by clonal pheochromocytoma cells (PC-12). The mechanism (s) of NGF action is not understood but the presence of high affinity binding sites for NGF on both the plasma and nuclear membranes suggests that NGF may have both intracellular and extracellular actions.

The role of cytoplasmic NGF on neurite extension was studied by comparing the effects on PC-12 cells of NGF applied either exogenously or microinjected from a pipette into the cytoplasm or nucleus. Giant multinucleate PC-12 cells, used to facilitate microinjection were produced by chemically induced cell fusion and were grown in cell culture (O'Lague and Huttner, 1980, PNAS 77:1701). Final intracellular NGF concentrations produced by injection were roughly estimated to range between 0.1-5 µg/ml for injection volumes up to 5% of total cell volume. Some control cells were injected with phosphate buffer. Approximately 90% of injected cells (experimental n=150, control n=100) survived the injection for at least 1 week.

Within 2 min many cells exposed to exogenous NGF (1 µg/ml) showed dramatic morphological changes. Individual cells observed with phase contrast optics exhibited an increase in the number of fine microspikes on the cell surface, then by 20 min the lengths of some filopodia increased, and by 24 hrs in many cases neurite-like processes had extended. Cells were also examined in the scanning electron microscope.

NGF-injected cells showed no detectable differences from control cells at any time observed (30 min to 1 week after injection). However the injected cells retained the ability to respond to external NGF, applied in the growth media or ejected from the pipette immediately outside the cell, with the morphological changes seen in uninjected cells exposed to exogenous NGF.

179.2 NGF-DEPENDENT RECOVERY OF FETAL MOUSE DRG AND DORSAL CORD NEURONS AFTER CHRONIC TAXOL EXPOSURE IN ORGANOTYPIC CULTURES. E.R. Peterson and S.M. Crain (SPON: E. Masurovsky). Dept. of Neurosci. Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Taxol induces a striking extensive assembly of "stabilized" microtubules in cultured fibroblasts and Hela cells (Schiff and Horwitz, PNAS, '80) and in neurons and supporting cells in explants of spinal cord and dorsal root ganglia (DRGs) (Peterson et al, & Masurovsky et al, J. Cell Biol.'80). Cross-sections of 14-day fetal mouse spinal cord with attached DRGs were explanted on collagen-substrate coverslips and exposed to 1 µM taxol in a nutrient medium supplemented with NGF (300 B.U./ml). In cultures exposed to 1 µM taxol for 4-6 days without NGF, almost all neurons degenerated, whereas in the presence of NGF survival of DRG neurons was comparable to controls without taxol. The DRGs showed, however, some cytoplasmic aberrations, nuclear distortions, and neuritic outgrowth was essentially blocked. The spinal cord showed rapid necrosis of glial cells and variable patterns of neuronal degeneration that were more clearly evaluated after withdrawal of taxol. In cultures exposed for 4-6 days to taxol + NGF and returned to control media without NGF, only ~ 60 neurons survived per DRG and the spinal cord was almost totally destroyed. (Comparable numbers of DRG neurons survive in control cultures which have never received NGF.) On the other hand, when after 4-day taxol + NGF, the recovery medium was supplemented with NGF (300 B.U./ml), there was not only an almost total survival of DRG neurons (> 90%), but also an unexpected and remarkable survival of dorsal cord tissue -- whereas ventral cord was often reduced to a monolayer. Dorsal cord tissue in the 4-day taxol-treated DRG-cord explants not only showed good morphologic integrity after return to high NGF, but characteristic dorsal-horn network responses could be evoked with DRG stimuli (Crain & Peterson,Br.Res.'74) at 3 wks in vitro. Even after 6 days in taxol + NGF, 30-70% of the DRG neurons recovered in high NGF and small islands of dorsal cord occasionally survived. Abundant swirling bundles of naked neurites were maintained in the outgrowth of these cultures for several weeks, while Schwann cell replication and migration was blocked. Thus, although the presence of high NGF fully prevented degeneration of most DRG neurons during exposure to taxol, additional NGF was required for their recovery after return to normal medium. Furthermore, chronic exposure of cord-DRG explants to taxol appears to alter dorsal cord neurons so that they become unexpectedly dependent for their survival either on the presence of NGF or on trophic influences from NGF-stimulated DRG neurons.

(Supported by NIH research grant NS-14990 to S.M.C.; taxol was provided by Dr. S. Horwitz.)

179.3 LOCAL SPREAD OF NERVE GROWTH FACTOR IN THE SPINAL CORD B.A. Green, T. Khan, R.J. Perez Polo,(SPON: J. Trimble). Dept. of Neurological Surgery, University of Miami Medical School, Miami, Fla. RER&D Center, VA Hospital, Hines, IL. Dept. of Biochemistry UTMB, Galveston, Texas.

This study evaluates the local spread of nerve growth factor (NGF) from the site of infusion in the spinal cord I^{125} labelled β NGF was infused into the experimentally contused spinal cord of rabbits. One hour post injury a dorsal myelotomy was performed and intramedullary infusion of I^{125} NGF was accomplished by inserting a small catheter into the spinal cord through the myelotomy. The other end of the catheter was attached to a small osmotic pump (Alzet). The pump contained 0.2 ml of I^{125}β NGF and a continuous infusion of I^{125} at the rate of 0.3 uc/hour of NGF was accomplished. The duration of infusion was one day and one week post injury. The animals were then anesthetized and perfused through the left ventricle with 4% formaldehyde and 0.5% glutaraldehyde in a phosphate buffer. The spinal cord was removed, dehydrated, embedded in parafin and sectioned. Serial longitudinal frontal sections, 10 microns thick were mounted on gelatinized slides, deparaffinized, dipped in Kodak NTB 2 photographic emulsion and stored for 3 weeks or 6 weeks. At the end of this period slides were developed in DK170 and counterstained with cresyl violet.

Examination of slides infused with I^{125} NGF for one day showed most of the labelled area to be at the site of infusion. Labelling extended circumferentially to 1-2 mm from the edge of the wound. Some cells of dorsal root ganglion (DRG) next to the infusion site were labelled. The sections of spinal cord infused for one week showed some labelling at the site of infusion within the scar tissue. The dorsal root ganglion next to the site and a segment away showed labelling of cells. The labelling of spinal cord, dorsal as well as ventral aspect, away from the lesion area was noted though this labelling seems to be nonspecific.

179.4 POSSIBILITY OF A STABILIZING EFFECT BY NERVE GROWTH FACTOR ON INJURED NEURONS. T. Khan, B.A. Green, J.R. Perez Polo. RER&D Center, VA Hospital, Hines, IL. Dept. of Neurological Surgery, University of Miami Medical School, Miami, Fla. Dept. of Biochemistry, UTMB, Galveston, Texas.

Nerve growth factor (NGF) has been shown to have a positive stabilizing effect on the injured spinal neurons. The effect of NGF was studied on the experimentally contused spinal cord. Since, it was suggested that NGF may not penetrate the blood brain barrier (Freed, W.J., Brain Res. Bull. 1:393-412, 1976), NGF was infused locally in the spinal cord. The lesion was produced by dropping a known weight from known height on surgically exposed spinal cord, sufficient to produce permanent paraplegia. One hour post injury, a myelotomy was performed at the site of the lesion. An implantable silastic osmotic pump reservoir (Alzet) was used for continuous infusion of NGF into the grey matter of spinal cord at myelotomy site. The pump was changed every week and NGF was delivered for 2 weeks, 6 weeks and 12 weeks post trauma. The results were evaluated by histological serial sections stained with the Bodian Protergol method. Our preliminary results showed a beneficial effect of NGF on the central fibers. The dorsal and ventral funiculus showed the same effect. The extent of scar tissue formation and fiber regrowth depends on the duration of infusion of nerve growth factor.

179.5 LOW LEVELS OF IMMUNOLOGICAL CROSSREACTIVITY BETWEEN AFFINITY PREPARED ANTI-MURINE β-NGF AND HUMAN PLACENTAL β-NGF. C. E. Beck*, M. Blum*, K. Turpin*, Claude Jacque* and J. R. Perez-Polo (SPON: R. W. Stach). Dept. of Human Biol. Chem. & Genet., Univ. Tex. Med. Br., Galveston, Texas 77550; Dept. of Med., Univ. of Reims, Reims, France and INSERM, Hopital de la Salpêtrière, Paris, France.

Nerve Growth Factor (NGF) is a multimeric protein that is required for the development and maintenance of the vertebrate sympathetic nervous system. It has been reported that alterations in the levels of NGF, as determined by radioimmunoassays with antisera directed against murine NGF, can be correlated with a number of neuropathies. These attempts to quantitate NGF levels in human serum, body fluids, and tissues using non-species specific antisera have yielded conflicting results. We have used a number of radioimmunological assays in order to determine if there is significant crossreaction between antibodies directed to murine NGF when challenged with human NGF in human biological fluids of interest. The use of a two-site radioimmunoassay (RIA) procedure reduces problems associated with NGF binding proteins found in sera, but results in false values when the total protein concentrations are not comparable in all samples tested. At detectable levels of 500 pg β-NGF per ml of serum, using this RIA technique, we have been unable to reproducibly demonstrate human β-NGF in either normal adult sera or in amniotic fluid samples collected at varying times during pregnancy. We feel that this failure to detect human NGF could be due to the low crossreactivity we have observed between monospecific murine antibodies and human β-NGF isolated from human placenta at term. More recently we have found a high level of crossreactivity between murine α-subunit antisera and an acidic protein associated with NGF activity in human placenta. Contamination of antisera with small amounts of anti-α-subunit may be responsible for the discrepancies in previously reported levels of NGF in human sera and tissues.

179.6 RADIOAUTOGRAPHIC LOCALIZATION OF ^{125}I-NGF IN PC12 CELLS. P. Bernd* and L.A. Greene* (SPON: C.R. Noback). Dept. of Pharmacology, New York Univ. Med. Ctr., New York, NY 10016.

The localization of bound nerve growth factor (NGF) was studied by light and electron microscopic radioautography on a cell line derived from a rat pheochromocytoma (PC12). In response to NGF, PC12 cells cease mitosis and develop neuron-like processes. In all experiments, cells that had not been previously exposed to NGF (naive) were examined, as well as those that were grown with 50 ng/ml of NGF for one week (primed).

Cells were grown on collagen-coated coverslips or directly on collagen-coated plastic dishes at a density of 200,000 cells per 35mm dish in RPMI medium containing 5% fetal bovine serum and 10% heat-inactivated horse serum. ^{125}I-NGF was prepared by the lactoperoxidase method (3.8 x 10^4 cpm/ng). Cells were incubated with 5 ng/ml of ^{125}I-NGF for 15 min, 1 hr, 6 hrs or 24 hrs (control included a 1000-fold excess of nonradioactive NGF). Primed cultures were extensively washed with NGF-free medium prior to exposure to ^{125}I-NGF. The cultures were then washed with iced PBS, fixed (3% glutaraldehyde in 0.1M phosphate buffer containing 3% sucrose, pH 7.5; 1 hr, 25°C), and washed with the above buffer. Coverslips were mounted on slides and allowed to dry; cells in dishes were postfixed in osmium (1% in the above buffer; 1 hr, 4°C), dehydrated and embedded in epon 812. Whole mounts and sections were coated with Ilford L4 emulsion and exposed at 4°C for periods ranging from 1 week to 2 months.

Examination of whole mount radioautographs revealed that all cells were labelled and that the distribution of grains was homogeneous. Primed cells were labelled on neurites and growth cones, as well as cell bodies, and also had a greater density of labelling than naive cells. These patterns were identical for all time points studied. The binding of ^{125}I-NGF was specific, since control cultures showed only background levels of grains. Thick sections (1 μm) were examined to determine if cytosol and/or nucleus were labelled by internalized ^{125}I-NGF. In all cells, the cytosol was heavily labelled while the nucleus was relatively unlabelled; however, in a small percentage of cells (~15%) the nucleus was labelled and the grains often appeared to be concentrated over nucleoli. This apparent nucleolar labelling was observed at all time points studied and was present in both naive and primed cells. Preliminary statistical analysis of electron microscopic radioautographs showed a specific association of grains with lysosomes and a possible association with both heterochromatin (assumed to be nucleolus), the nuclear membrane and the plasma membrane. This study supported by NIH grant # NS 16036, March of Dimes grant # 1-704 and a Pharmaceutical Manufacturers Association Foundation fellowship.

179.7 MOUSE NERVE GROWTH FACTOR-LIKE ACTIVITY (mNGF) IN THE BRAIN OF ADULT MICE: DETECTION BY PC-12 CELL BIOASSAY. S.M. Scott*, R. Tarris*, D. Eveleth*, M.E. Weichsel, Jr., D.A. Fisher*, Perinatal Research Laboratory, Harbor-UCLA Medical Center, Torrance, CA

Previously we reported the detection of NGF in mouse brain by RIA. However, bioassay data from several laboratories have not been in agreement and the presence of NGF in brain remains controversial. Thus we conducted studies of NGF bioactivity in brain tissue using a sensitized PC-12 cell bioassay system (SCBS). PC-12 cells are derived from a rat pheochromocytoma and respond to NGF with neurite outgrowth. The SCBS is sensitive to 100 pg/ml NGF.

Three pools of seven brains each from adult Swiss-Webster mice were homogenized 1:1 wt to volume with PBS and the supernatants collected for bioassay. Prior to bioassay, the supernatants were dialyzed against media used for maintenance of the PC-12 cells except that serum was omitted. The cells were placed in a bioassay plate at time zero at a concentration of 10^4 cells per well in a medium containing 50 ng/ml of mNGF (total volume of 500λ per well); at 48 hrs, the cells were changed to mNGF-free media. At 72 hrs six conditions were established prior to reading the bioassay at 96 hrs. Each condition was duplicated and each brain pool studied on a different day. The pre-immune serum and specific anti-NGF antibody were from the same rabbit: (% outgrowth = % of cells with neurite growth)

Condition	Media	Pre-immune	Brain pool	Antibody	% Outgrowth
1.	500	--	--	--	5%
2.	400	100	--	--	5%
3.	400	--	--	100	5%
4.	400	--	100	--	80-100%
5.	300	100	100	--	80%
6.	300	--	100	100	5%

Results: 3-8% normal PC-12 cells will have neurite extension under control conditions (condition #1). The addition of pre-immune serum and antibody (#2 and #3) show lack of toxicity by these factors. #4 shows the positive response of brain supernatant; #5 shows failure of normal rabbit serum to block this effect. #6 shows the ability of specific anti-mNGF antibody to block the neurite growth promoting effect of brain supernatant. We conclude that the brains of Swiss-Webster adult mice contain an NGF-like substance, probably NGF itself, which promotes neurite outgrowth in PC-12 cells and that this effect is blocked by specific NGF antiserum.

179.8 NERVE GROWTH ACTIVITIES IN RAT PERIPHERAL NERVE. T. Ebendal* and P. M. Richardson, Inst. of Zoology, Uppsala University & Dept. of Neurosurgery, McGill University.

Nerve growth activities in the rat sciatic nerve were assessed by recording the neuritic outgrowth from chick embryo ganglia cultured for two days in collagen gels in close proximity to nerve fragments. Sometimes the normal sciatic nerve was used; sometimes the nerve had been cut at the sciatic notch 2-15 days previously or had been prepared as an autologous graft in the leg two days earlier. Frozen and thawed specimens from normal nerves, like those from several other rat tissues, induced, from both sympathetic and ciliary ganglia, neuritic outgrowth which was not significantly diminished by anti-NGF. Living nerve fragments, on the other hand, released activity resembling NGF in its effect on sympathetic ganglia and almost totally blocked by anti-NGF. Thus, from observations on normal nerves, two agents promoting neuritic extension were deduced to exist although the presence of additional factors has not been excluded. NGF-like activity was not detected in frozen and thawed segments from normal nerves but its level increased markedly in nerve grafts and, to a lesser extent in the distal stump of a nerve transected two days previously. Nerve fragments with strong NGF-like effect on sympathetic ganglia also evoked neuritic outgrowth, partly suppressible with anti-NGF from ciliary ganglia. This phenomenon has not been fully explained but may reflect the actions of a high concentration of one agent similar but not identical to NGF or the combined effect on ciliary neurons of two factors, one recognized by anti-NGF. Two weeks after nerve transection, the distal nerve stump contained little or no nerve growth activity of either kind. However, when then taken to culture, nerve fragments were seen to have retained the capacity to produce NGF-like activity although the course of maximal activity had shifted from the endoneurial to the perineurial region. In summary, cells in the rat peripheral nerve can release soluble agents promoting neurite outgrowth. One factor resembles NGF and its concentration in tissues and site of synthesis are altered by manipulation of the nerve in vivo.

179.9 FURTHER CHARACTERIZATION OF A NEW NEURONAL GROWTH FACTOR AND ITS ANTISERUM. M.D. Coughlin, J.A .Kessler and I.B. Black. Div. of Developmental Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

We recently reported that a new neuronal growth factor (CMF), isolated from mouse heart cell conditioned medium and distinct from nerve growth factor (NGF), stimulates morphological and biochemical development of the embryonic mouse superior cervical ganglion (SCG; Coughlin et al., Develop. Biol. 82:56, 1981). This study further characterizes CMF and describes the effects of an antiserum to the factor which specifically inhibits neurite outgrowth in culture.

All biological activity of the CMF fraction eluted in the void volume of a Biogel P300 column. Use of a larger pore size agarose gel (Biogel A-5M) with or without the dissociating agent sodium lauryl sulfate (SDS) produced similar results. Electrophoresis on standard and SDS polyacrylamide gels gave similar findings: no activity and very little protein entered 3.75% gel. However, both protein and activity migrated through a 0.6% agarose-1.2% acrylamide combination gel. These results suggest that CMF activity is associated with very high molecular weight (>500,000 daltons) material.

Rabbits immunized against CMF developed high titres of antiserum (anti-CMF) with activity specifically directed against CMF. The antiserum inhibited neurite outgrowth in a dose dependent fashion, and the effects were reversed by addition of excess CMF.

Although anti-CMF inhibited NGF-stimulated neurite outgrowth from the neonatal SCG, it did not inhibit the NGF-stimulated increase in tyrosine hydroxylase activity. Moreover, addition of excess NGF did not reverse the effects of anti-CMF. Finally, ganglia incubated for 2 days in the presence of anti-CMF were subsequently capable of producing neurites when washed and cultured in medium free of anti-serum. Thus, in contrast to the effects of anti-NGF in this system, anti-CMF did not cause cell death or irreversible damage.

These findings suggest that CMF activity is associated with very high molecular weight material, and that this factor or antigenically similar material is required for neurite extension in culture.

179.10 THE EFFECT OF A GLIAL CELL RELEASED FACTOR ON SPINAL CORD NEURON GROWTH AND ITS MODULATION BY STEROIDS. B.G.W. Arnason, R.C. Yu, L. Amico* A. Arenander*, J. DeVellis. Dept. of Neurology, University of Chicago, Chicago, Illinois 60637 and Dept. of Anatomy, U.C.L.A., Los Angeles, Calif. 90024

Dissociated embryonic spinal cord neurons (SCNs) survive for only a short period of time in vitro if glial cells are eliminated from the culture, yet SCNs can be maintained in organotypic cultures for several months. This suggests a glial influence on the growth and survival of SCNs in vitro.

We used explant cultures from 14-day-old rat embryonic spinal cord sections to assess the effect of factors released from glial cells on neuronal growth. Fresh serum free F-10 medium was conditioned with rat C_6 Glioma by incubating the medium with semi-confluent C_6 monolayers previously grown in medium supplemented with 10% fetal calf serum. Spinal cord explants were maintained in conditioned medium or in non-conditioned medium as a control. Neuritic outgrowth from explants grown in conditioned medium consistently exceeded that of cultures grown in control medium both in the number as well as in the length of neurites seen. This growth promoting effect was not observed when spinal sensory ganglion cultures were used. Conditioned medium collected from C_6 cultures pre-exposed to medium containing cortisol (1μm) showed neuritic outgrowth which was reduced significantly below control levels. In contrast C_6 conditioned medium from cultures pre-exposed to estrogen (1μm) increased outgrowth beyond that seen with C_6 conditioned medium alone. Extracts from C_6 glioma grown as a solid tumor in young rat brain did not show any growth promoting effect when added to culture medium.

Dissociated SCN from 4-day chick embryos were grown in C_6 conditioned or control medium. SCN in control medium died; in conditioned medium they survived and extended numerous long neuritic processes. Thus the C_6 conditioned medium effect is not species restricted and supports survival and growth of dissociated SCN.

These results lead us to conclude that a glial cell released factor(s) specific to SCNs favors their survival in tissue culture and their capacity to extend processes. The production of this factor by glial cells can be modulated by certain steroids. Growth factors specific for SCN could be relevant to diseases of man, such as amyotrophic lateral sclerosis, in which SCN die.

Supported by a grant from the Amyotrophic Lateral Sclerosis Society of America.

179.11 EFFECTS OF BRAIN EXTRACTS ON THE NUMBER OF ACETYLCHOLINE RECEPTORS IN PRIMARY CULTURES OF RAT MYOTUBES. J. Robert Bostwick* and Stanley H. Appel (SPON: J. Eichberg). Dept. of Neurology, Program in Neuroscience, Baylor College of Medicine, Houston, Texas 77030.

Several laboratories have reported the enhanced effect of peripheral and central nervous system extracts on the synthesis of acetylcholine receptors (AChR) in cultured myotubes. We report here the partial characterization of a soluble factor from rat brain which induced an increase in AChR number in primary cultures of rat myotubes. This effect was not species specific since extracts of embryonic chick (12 days old) or rat (16 days old) brains induced the same response. Daily additions of extract to post-fusion cultures resulted in an optimal 65% increment in AChR number of 8 and 9 day old cultures as compared to non-treated controls. Similar increases were observed in 9 day old cultures which received only a single dose 24 hours previous to assaying for AChR. This response was concentration dependent and saturable. Brains from 16 day old rat embryos appeared to be more enriched in activity on a per milligram protein basis than were brains from new born rats.

The inclusion of protease inhibitors in the culture medium did not affect activity, indicating that the putative humoral factor itself was not susceptible to proteolysis during the incubation period. The trophic substance is probably a protein since its activity was not stable to tryptic digestion or boiling but was stable to lyophilization. When the extract was dialyzed against a 0.1 M phosphate buffer, pH 7.4, containing 0.5mM DTT and 1mM EGTA activity remained in the retentate.

The activity precipitated a 30-55% ammonium sulfate fraction and could be back-extracted in 42% salt for a 3-fold enrichment relative to protein. Gel filtration chromatography of this material on a column of Sephadex G-50 fine yielded two peaks of activity. The first peak eluted in the void volumn with little enrichment; the second peak contained 75% of the activity loaded onto the column and was recovered in an elution volume similar to ribonuclease A (M.W.=13,700). An overall purification of 60-fold from the original extract was obtained. SDS polyacrylamide gel-electrophoresis of the combined fractions indicated a band at 17,000-16,000 daltons which was significantly enriched compared to unfractionated extract.

For Dementia Training Grant supported by the National Institute of Aging #AG-00061 and the Kleberg Tissue Culture Fund and the Kleberg Trophic Factor Foundation.

179.12 NEUROTROPHIC FACTOR INITIATES MYOGENESIS. Heinz Popiela, Daniel L. Taylor*, and Stanley Ellis*. Biomedical Research Division, NASA, Ames Research Center, Moffet Field, California 94035.

NTF was recently purified about 90% from peripheral nerves of adult chickens using a quantitative assay in which the amount of thymidine incorporated into chick muscle cells in vitro was measured (Popiela and Ellis. 1981. Dev. Biol. 83: 266-277).

Primary chick muscle cells are plated in the absence of NTF but presence of horse serum to allow cell attachment to the gelatin substratum; a maximum number of cells attaches 5-8 h after plating but cells do not proliferate in the absence of NTF or do so extremely slowly. Subsequent to a routine attachment period of 6 h, the medium is aspirated and replaced with medium containing 2-20 ug/ml of NTF and 5% horse serum. Upon exposure to NTF, in the obligatory presence of serum but absence of embryo extract, an 8 h lag ensues; then, thymidine is incorporated at NTF dose-dependent rates by growing cell populations but also by single cells. The rates of incorporation into cell populations depends on the initial number of cells plated and the amount of NTF supplied. Thus, populations of growing cells incorporate more thymidine at increasing doses of NTF. Cell counting indicates that dose-dependent proliferation of muscle cells has occurred during the first 48 h of exposure to NTF. Division of incorporated thymidine per dish by the number of cells present per dish reveals NTF dose-dependent increases in the amount of thymidine incorporated per cell. The specific activity of NTF is repeatedly shown to be at least 10-fold greater than unfractionated nerve extract. Shortly after 48 h exposure to NTF, myoblasts characteristically begin to fuse with one another and myogenesis commences. At 72 h of exposure to NTF, dose-dependent myogenesis is visible. Presently, we have no evidence that myogenesis takes place in response to NTF, or that myogenesis occurs automatically due to greater NTF-induced cell densities.

179.13 EMBRYONIC BRAIN EXTRACT STIMULATES COLLAGEN SYNTHESIS BY CULTURED MYOTUBES: POSSIBLE ROLE OF COLLAGEN IN ACETYLCHOLINE RECEPTOR AGGREGATION. C. Kalcheim*, Z. Vogel*, and D. Duksin*. (SPON: M. Schneider). Departments of Neurobiology and Biophysics, The Weizmann Institute of Science, Rehovot, Israel.

Recent studies (1-4) have shown that components of the extracellular matrix are involved in nerve-muscle interaction and in the induction of acetylcholine receptor (AChR) aggregates on the muscle cell surface.

We report here that incubation of cultured rat myotubes with an extract of embryonic rat brain increased the number of receptor aggregates on the myotubes and in addition increased the synthesis and secretion of types I, III and V collagens into the culture medium. A 16 h incubation of myotubes with 0.5 mg/ml of extract of 18 day-old embryonic rat brain produced a seven fold increase in the incorporation of [^{3}H]Proline into collagen in the medium and a three fold increase in the number of AChR aggregates. Extract of adult brain was much less effective in the stimulation of both processes. Ascorbic acid (50 ug/ml) stimulated collagen secretion (2.5 fold) and also promoted a 1.6 fold increase in the number of receptor aggregates formed.

Evidence for the involvement of collagen in receptor aggregation comes from the observation that concentrations of purified bacterial collagenase sufficient to prevent accumulation of extracellular collagen also prevented the brain-extract induced receptor aggregation.

It is an attractive hypothesis that during neuromuscular synapse formation the nerve induces the muscle to synthesize and scerete one or more types of collagen. These collagen molecules either directly or via the interaction with other extracellular matrix components have a role in aggregating the AChR to the junctional areas on the muscle surface.

179.14 MOLECULAR BEHAVIORS OF THE CILIARY NEURONOTROPHIC FACTOR(S). Gilles Barbin, Marston Manthorpe and Silvio Varon. Dept. Biol., Sch. Med., Univ. Calif. San Diego, La Jolla, CA 92093.

Ciliary neuronotrophic factor(s) (CNTF) supports the in vitro survival and growth of dissociated chick embryo ciliary ganglionic (CG) neurons. Intraocular tissues which contain the muscle cells innervated by CG neurons are highly enriched in CNTF activity. During eye development CNTF activity increases sharply during the exact period when CG neurons are forming synapses with their target cells. We have previously reported that eye CNTF could be partially purified (to about 6 x 10^4 Trophic units/mg protein) using microdissection, ion-exchange chromatography and ultrafiltration. In order to evaluate potential steps for further purification we have subjected extracts from selected intraocular tissues, CIPE (choroid, iris-ciliary body and pigment epithelium), to various fractionation protocols.

Fractional precipitation of CIPE extract using ammonium sulfate resulted in recovery of two species of CNTF activity which together contained all of the starting activity. Approximately one-half of the recovered activity and protein precipitated using 50% saturation and could be reconstituted in a small volume. The remaining half of the recovered activity was still soluble above 80% saturation.

When CIPE extract was passed through an immobilized heparin column, only 15-30% of the loaded activity could be recovered using a batchwise elution with 0.35 M NaCl. This same behavior was seen when the recovered salt eluate was diluted and passed over a second heparin column, except that 50% of the loaded activity was recovered.

CNTF activity within CIPE extract did not bind to various immobilized lectin columns (Con A, WGA, DBA, RCA and UEA) indicating that the activity is not associated with bindable carbohydrate moieties. However, when CIPE extract was passed through a Con A column, 70% of the loaded protein (but no CNTF activity) was retained.

Molecular sieving of CNTF activity within the CIPE extract was performed by gel filtration and comparisions were made using separately run molecular weight standards. CNTF activity did not migrate as a single molecular species. At low ionic strength it eluted in regions corresponding to 30-40,000 molecular weight; by increasing the ionic strength (elution in 3 M NaCl) there was a considerable shift of CNTF activity toward the lower molecular weight region, suggesting a dissociation of CNTF from aggregates or complexes.

Further data to be presented include actual protein and activity recoveries, specific activities and gel electrophoretic profiles of selected fractions. Supported by NINCDS grant NS-16349.

179.15 TESTOSTERONE ENHANCES [^{14}C] 2-DEOXYGLUCOSE UPTAKE BY RAT LEVATOR ANI MUSCLES IN VIVO. J. Toop* and S. R. Max (SPON: R. F. Mayer). Dept. of Neurology, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Androgens influence skeletal muscle mass and function. However, mechanisms underlying the anabolic effects of these hormones remain inchoate. To address this problem, we used the 2-deoxy-D [^{14}C] glucose ([^{14}C] 2DG) autoradiographic technique of Sokoloff (J. Neurochem., 28:897, 1977) to detect early metabolic responses of muscle to hormonal stimulation. We chose the levator ani muscle (LAM) of the rat because it has a higher concentration of androgen receptors than ordinary skeletal muscle. This large number of receptors may be linked to the rapid growth of the LAM that occurs when rats are treated with androgens. Growth of the LAM is accompanied by enhanced protein synthesis, which may depend upon increased uptake of glucose as an energy source. In the present study, we used immature male rats, which have low circulatory levels of androgens. We administered testosterone propionate (TP) in DMSO, i.p., at a dose of 2.5 mg/100 g body weight; controls received DMSO. At 1, 3, 10 and 20 hr after hormone injection, paired experimental and control rats were each given 12.5 μCi of [^{14}C] 2DG in 0.2 ml 90% ethanol, i.p. Forty-five minutes later the rats were decapitated, and the LAM was dissected out and rapidly frozen in isopentane cooled in liquid N_2. Frozen sections of LAM were cut in a cryostat and picked up onto pre-cooled slides that had been coated with emulsion. Sections were thawed and dried before exposure at -80°C. Exposed slides were developed, rinsed, fixed, washed and dried. Sections overlying the emulsion were stained with Ehrlich's hematoxylin and eosin. No difference in grain numbers was discernible in muscle from TP-treated rats at 1 hr after injection. A slight increase was seen at 3 hr. By 10 and 20 hr, however, [^{14}C] 2DG uptake was markedly enhanced in muscle fibers in LAM's from TP-treated rats. The LAM is histochemically rather uniform on the basis of myosin ATPase staining, but more variable with NADH-diaphorase. However, [^{14}C] 2DG uptake appeared to be the same in all fibers. The latent period suggests an indirect (genomic) effect of the sex hormones rather than a direct effect. This influence of TP on [^{14}C] 2DG uptake presumably involves androgen receptors. Enhanced glucose utilization, as shown by increased [^{14}C] 2DG uptake, may be a metabolic precursor to the events leading to androgen-induced hypertrophy. These data show the [^{14}C] 2DG technique to be a valuable tool for studying the effects of sex hormones on muscle. [Supported in part by grants from NIH (NS 15766) and NASA (NAG 2-100)].

179.16 ANDROGEN RECEPTOR IN REGENERATING RAT LEVATOR ANI MUSCLE. S. R. Max, S. Mufti* and B. M. Carlson*. Depts. of Neurology and Biochemistry, Univ. of Md. Sch. of Med., Baltimore, MD 21201 and Dept. of Anatomy, Univ. of Michigan, Ann Arbor, MI 48109.

The development of the cytosolic androgen receptor was studied following degeneration and regeneration of the rat levator ani muscle (LAM) after a crush lesion (Gutmann and Carlson, Exp. Neurol. 58:535, 1978). An important feature of muscle regeneration is that it appears to recapitulate myogenesis in many respects. It therefore provides a model tissue available in sufficiently large quantity for investigating the ontogenesis of the androgen receptor. The receptor in the cytosol of the normal levator ani muscle has characteristics similar to those of the cytosolic receptor in other androgen sensitive tissues. Binding isotherms showed that the LAM contains a single class of cytosolic androgen receptor molecules, of limited capacity and high affinity (K_D 0.74 nM; Bmax fmoles/mg protein). Competition studies with a number of steroid hormones (androgens, estrogens, progestins, glucocorticoids) showed the ligand-specificity to be similar to that exhibited by the receptor in "classical" androgen target organs, such as kidney and prostate gland. Also, the steroid-receptor complex binds selectively to DNA-cellulose, as expected for a cytosolic androgen receptor. After crushing the LAM, the receptor number decreased by day 2 to about 50% control. By the 3rd day after crushing the muscle, androgen receptor number further declined to 25% of control values. This decrease was followed by a 4-5 fold increase in receptor number, which attained control values by the 7th day after crush. Receptor number remained stable at the control level through day 30 after crushing. By day 60, however, the number of receptors decreased to 75% control. These results correlated with the morphological development of the regenerating muscle following crushing. It is concluded that there is little, if any, cytosolic androgen receptor present in the early myoblastic stages of regeneration; rather, synthesis of the receptor occurs after the fusion of myoblasts into myotubes and during the differentiation of myotubes into cross-striated muscle fibers. [Supported in part by grants from NIH (NS-15766 and NS-14538) and from NASA (NAG 2-100)].

179.17 PROTEINS OF THE EXTRACELLULAR FLUID IN THE MOUSE BRAIN: CHARACTERIZATION AND MODE OF SECRETION. R. Hofstein* and V.E. Shashoua. Harvard Medical School and Mailman Research Center, McLean Hospital, Belmont, MA 02178.

Recent experiments in our laboratory have demonstrated that increased metabolism of cytoplasmic (CYTO) proteins and their release into the extracellular fluid (ECF) are major steps in a chain of transduction events leading to the processing and storage of newly acquired information. We therefore developed a method for the isolation and characterization of proteins released into the ECF. In brief, balb c mice were ether anesthetized, perfused via the heart with isotonic saline and the brains then dissected out and incubated at 0° in isotonic sucrose solution containing various proteinase inhibitors.

The maximum protein yield obtained was 0.05% of the tissue wet wt. One- and two-dimensional SDS gel electrophoretic patterns of the ECF proteins were obtained and compared to those of the cytoplasmic and serum proteins. Distinct features of the gel patterns characterized ECF fractions as a separate population of brain proteins. That the ECF proteins were not simply due to a nonspecific leakage of cytoplasmic proteins during the period of incubation was established by assays of tyrosine hydroxylase (TH) activity using high pressure liquid chromatography. No TH activity was detected in ECF (<0.01 ng dopa/mg protein/30 min), whereas in CYTO the activity was 100 ng dopa/mg protein/30 min.

The volume of extracellular space as measured by diffusion rate of ^{14}C-inulin into brain tissue at 0° was found to be 20% of tissue wet wt. The protein concentration in ECF was 0.3%, which is considerably higher than the previous values for CSF (0.03%). The extent of ^{14}C-inulin diffusion into mouse brain was confirmed by autoradiographic studies which revealed that the most extensive uptake was into the frontal cerebral cortex posterior to the rhinal fissure.

The pattern of radioactively labeled ECF proteins was determined following i.p. injections of ^{14}C and ^{3}H-valine. Specific protein bands separated by gel electrophoresis were found to be heavily labeled. One of these migrating at 33,000 daltons, P33, was found to increase after the mice were trained in a T-maze. Concurrent studies of cytoplasmic proteins indicated that the observed changes at P33 might be preceded by the labeling of a higher molecular weight cytoplasmic protein which is released into ECF and converted by a series of selective proteolytic steps into P33 protein. These observations suggest that rapidly labeled proteins can be influenced by training and that proteins in ECF might have a functional role as trophic factors in neural plasticity.

179.18 SCIATIN: IMMUNOCYTOCHEMICAL LOCALIZATION OF A MYOTROPHIC PROTEIN IN CHICKEN NEURAL TISSUES. T. H. Oh, C. A. Sofia*, Y. C. Kim*, C. Carroll*, H. H. Kim*, G. J. Markelonis and P. J. Reier. Dept. of Anatomy, Univ. of Maryland Sch. of Medicine, Baltimore, MD 21201.

A myotrophic protein (sciatin) purified from chicken sciatic nerves has "trophic" or "maintenance" effects on cultured muscle. We have elicited a specific antiserum against sciatin in rabbits. Using this antiserum, we investigated the distribution of sciatin in embryonic and adult chicken tissues by an unlabeled peroxidase-antiperoxidase method at the light microscopic level. Adult chicken tissues were fixed in cold 95% ethanol or 4% paraformaldehyde-0.1% glutaraldehyde in 0.1M cacodylate buffer (pH 7.2) and embedded in paraffin. Dissociated embryonic cells were prepared from 12-day old chick embryos and cultured on collagen-coated plastic dishes. The antiserum stained adult chicken neural tissues in situ and cultured embryonic neurons. Staining was intense in the cell bodies of spinal cord neurons and the axoplasm of sciatic nerves. Cerebral cortical neurons were weakly stained by the antiserum. No staining was apparent in Schwann cells, oligodendrocytes or astrocytes. Non-neural tissues such as skeletal, smooth and cardiac muscle, kidney and liver were also unstained by the antiserum. Cultured spinal cord neurons, cerebral cortical neurons and sensory neurons were stained immunocytochemically by the antiserum. There was no reaction product seen in the glial cells which are usually present in neuronal cultures or cultured cells from liver, kidney, skeletal muscle, smooth muscle and cardiac muscle. Our results thus show that the myotrophic protein is localized in neuronal perikarya and their processes.

179.19 SCIATIN INCREASES ACETYLCHOLINE RECEPTORS AND MAINTAINS RECEPTOR CLUSTERS IN CULTURED SKELETAL MUSCLE. G.J. Markelonis, M.E. Eldefrawi*, L. Guth and T.H. Oh. Depts. of Anatomy and Pharmacology & Experimental Therapeutics, Univ. Maryland School of Medicine, Baltimore, Maryland, 21201.

Factors present in neural extracts or in media conditioned by neurons have been shown by others to increase both the number of acetylcholine receptors (AChRs) and the number of receptor clusters in cultures of embryonic skeletal muscle. We have shown that the neuronal glycoprotein, sciatin, has pronounced myotrophic effects on developing muscle in vitro, and we therefore added sciatin to aneural cultures of chick skeletal muscle to ascertain sciatin's effects on AChRs. The effects can be summarized as follows: (1) Sciatin caused significant increases in the number of AChRs/culture dish as measured by binding of ^{125}I-α-bungarotoxin (α-Btx) and in acetylcholinesterase (AChE) activity/culture dish in differentiating muscle cells. The increase in AChRs elicited by sciatin was due solely to increased receptor synthesis and incorporation. The rate of AChR synthesis in sciatin-treated cultures was as much as five times the control rate and was significantly reduced by cycloheximide (10 μM). AChR degradation was unaffected by the trophic protein. (2) Although the number of AChRs/culture dish was increased by sciatin during myogenesis, AChR specific activity, expressed as fmoles ^{125}I-α-Btx bound/mg cell protein was only transiently increased by the trophic protein. This contrasted with AChE specific activity in sciatin-treated cultures which remained elevated throughout differentiation. (3) Autoradiographs of ^{125}I-α-Btx-labeled cultures showed that sciatin caused an increase in the number and size of AChR "hot spots" and maintained the integrity of these AChR clusters in aneural muscle cultures for up to 5 weeks. At this time control cultures had completely degenerated. (4) The mechanism by which sciatin enhanced the synthesis of AChRs appeared to be distinct from that of tetrodotoxin (TTX), an agent which abolishes muscle activity, since the effects of sciatin and TTX on AChR synthesis were additive. The results of this study suggest that sciatin may be identical to the diffusible factor(s) from motor neurons described by others which has trophic effects on AChRs. Furthermore, since sciatin produces only a transient increase in AChR specific activity but promotes the maintenance of AChR "hot spots" for prolonged periods in the absence of innervation, this trophic protein may function in vivo as the initial neuronal regulatory signal for directing the metabolic machinery of the target muscle cell.

179.20 EFFECTS OF NEONATAL 6-HYDROXYDOPAMINE ADMINISTRATION ON CEREBELLAR DEVELOPMENT. KATHRYN L. LOVELL. DEPT. OF PATHOLOGY, MICHIGAN STATE UNIV., E. LANSING, MI 48824.

NOREPINEPHRINE (NE) HAS BEEN PROPOSED TO INFLUENCE CENTRAL NERVOUS SYSTEM DEVELOPMENTAL PROCESSES PRIOR TO AND SEPARATE FROM ITS ACTION AS A NEUROTRANSMITTER. SUCH EFFECTS OF NE ARE LIKELY TO BE EXERTED PRIOR TO DEVELOPMENTAL EVENTS AND POSTNATAL DEPLETION OF NE DOES NOT GENERALLY CAUSE MAJOR DEVELOPMENTAL CHANGES IN THE CEREBRAL HEMISPHERES, WHERE MOST CELL DIFFERENTIATION IS COMPLETED BY THE TIME OF BIRTH. POSTNATALLY DIFFERENTIATING CELL POPULATIONS IN THE CEREBELLUM PROVIDE AN OPPORTUNITY TO EXAMINE EFFECTS OF NEONATAL NE DEPLETION ON NEURONAL PROLIFERATION, DIFFERENTIATION AND MIGRATION. ALTHOUGH THE CEREBELLAR EXTERNAL GERMINAL LAYER (EGL), THE SOURCE OF BASKET, STELLATE AND GRANULE CELLS, IS PRESENT AT BIRTH, MOST OF ITS PROLIFERATIVE ACTIVITY OCCURS DURING THE FIRST 2 POSTNATAL WEEKS. IN ADDITION, A SYSTEM IN WHICH ALL EGL DEVELOPMENT OCCURS POSTNATALLY CAN BE PRODUCED BY METHYLAZOXYMETHANOL (MAM)-INDUCED NEONATAL EGL DESTRUCTION FOLLOWED BY PARTIAL EGL RECONSTITUTION BEGINNING SEVERAL DAYS AFTER BIRTH. THE OBJECTIVE OF THIS STUDY WAS TO CHARACTERIZE ALTERATIONS IN POSTNATAL EGL DEVELOPMENT PRODUCED BY NEONATAL NE DEPLETION IN THE NORMAL MOUSE CEREBELLUM AND THE IN VIVO MODEL SYSTEM PRODUCED BY MAM ADMINISTRATION. REDUCTION IN NE CONTENT WAS ACHIEVED BY INJECTION OF 6-HYDROXYDOPAMINE (6-OHDA; 50 MG/KG, S.C.) ON POSTNATAL DAYS 1, 3 AND 5. THIS DOSE PRODUCED DEPLETION OF CEREBELLAR NE TO 12% OF CONTROL VALUES 8 HR AFTER INJECTION ON DAY 1 AND DEPLETION TO 20-30% OF CONTROL VALUES 24 HR AFTER EACH INJECTION. IN THE FOUR EXPERIMENTAL GROUPS (MAM + 6-OHDA, MAM + VEHICLE, SALINE + 6-OHDA, SALINE + VEHICLE), MORPHOLOGICAL STUDIES WERE CONDUCTED AT 5, 8, 11, 14 AND 21 DAYS OF AGE TO ASSESS CHANGES IN CEREBELLAR SIZE AND FOLIATION PATTERN, IN THE SCHEDULE AND EXTENT OF GERMINAL CELL PROLIFERATION AND IN THE MIGRATION OF BASKET, STELLATE AND GRANULE CELLS. THE CROSS-SECTIONAL AREA OF THE CEREBELLAR VERMIS WAS REDUCED IN THE 6-OHDA + SALINE GROUP COMPARED TO CONTROL ANIMALS, BUT THE REDUCTION IN VERMIS AREA PRODUCED BY MAM WAS NOT ALTERED BY 6-OHDA ADMINISTRATION. IN THE 6-OHDA + SALINE GROUP, NE DEPLETION PRODUCED CHANGES IN THE FOLIATION PATTERN AND ALTERED THE TIME COURSE OF EGL DEVELOPMENT AS MEASURED BY EGL WIDTH IN THE CULMEN AND NODULUS. THE NUMBER OF GRANULE CELL PROFILES IN THE CULMEN WAS REDUCED DUE TO THE 6-OHDA INDUCED DECREASE IN INTERNAL GRANULAR LAYER AREA. THESE STUDIES PROVIDE EVIDENCE TO SUPPORT A ROLE OF NE IN REGULATION OF NEURONAL DEVELOPMENT IN THE CEREBELLUM. (THIS RESEARCH WAS SUPPORTED BY BRSG FUNDING FROM THE COLLEGE OF OSTEOPATHIC MEDICINE, MICH. STATE UNIV.)

179.21 NERVE GROWTH FACTOR (NGF) AND EPIDERMAL GROWTH FACTOR (EGF) ARE BOUND BY THE SAME PC12 PHEOCHROMOCYTOMA CELL: VISUALIZATION BY DOUBLE-ANTIGEN IMMUNOFLUORESCENCE. Leonid Pevzner*, David End*, Stanley Vinores*, and Gordon Guroff. Section on Intermediary Metabolism, Laboratory of Developmental Neurobiology, National Institute of Child Health and Human Development, NIH, Bethesda, MD 20205.

A rat pheochromocytoma cell line, PC12, which has been shown in this laboratory to contain both NGF and EGF receptors was further investigated to determine if both NGF and EGF receptors could be found on the same cell. PC12 cells, growing in tissue culture flasks or on collagen-coated cover slips, were incubated with saturating concentrations (350-500 ng/ml) of NGF and EGF for 45 min at 0°C. After fixation, dilutions of sheep anti-NGF sera and rabbit anti-EGF sera were added and after a 30-40 minute incubation at room temperature, fluorescein-conjugated rabbit anti-sheep $F(ab')_2$ and rhodamine-conjugated sheep anti-rabbit $F(ab')_2$ were added.

Fluorescence microscopy revealed a green fluorescence of PC12 cells due to the NGF binding and a red fluorescence due to the EGF binding. By changing fluorescein and rhodamine filters while observing the same field it was evident that each PC12 cell possessed both kinds of the fluorescence. No background fluorescence was seen with high dilutions of the antisera when the growth factors or specific antisera were omitted.

The double fluorescence observed was similar whether the growth factors and their corresponding antisera were added successively or simultaneously. There was no cross-reaction fluorescence between NGF and anti-EGF sera or between EGF and anti-NGF sera.

The NR11 subclone of PC12 cells, isolated by Bothwell et al., (Cell, 21, 857, 1980), which does not have NGF receptors, was characterized under the same conditions of double-antigen binding experiment by a red EGF-binding fluorescence alone. No green fluorescence was observed. Absence of the NGF binding to these cells was confirmed by the more sensitive peroxidase-antiperoxidase method of Sternberger (L.A. Steinberger, Immunocytochemistry, 2nd edition, John Wiley, New York, 1979).

Red fluorescence due to the EGF binding to the PC12 cells was substantially reduced when an agent blocking the EGF receptors, TPA (200 ng/ml), was added simultaneously with EGF. Red fluorescence was also markedly reduced when cells were grown for 72 hours in a medium containing NGF (50 ng/ml), a condition shown in this laboratory to result in a profound decrease in EGF receptors.

180.1 INTRAMUSCULAR "COMPARTMENTALIZATION" OF THE CAT BICEPS FEMORIS AND SEMITENDINOSUS MUSCLES: ANATOMY AND EMG PATTERNS. A.W.English and W.D. Letbetter, Emory University, Atlanta, GA.

The anatomy and innervation patterns of cat biceps femoris (BF) and semitendinosus (ST) muscles were examined to see if they were organized about the same principles of compartmentalization found in the calf muscles. On the basis of gross fiber architecture and nerve supply, a distinct posterior head of BF (BFp) can be identified while the remainder of the muscle appears to be divided into an anterior (BFa) and a middle component (BFm). Glycogen depletion, through stimulation of primary muscle nerve branches, confirmed this compartmentalization scheme for BF, although the organization of BFm may be somewhat more complex than that of BFa and BFp. BFa and BFm insert into an aponeurosis attached at the femur. BFp inserts into an aponeurosis attaching laterally to the leg and forming a crural fascial hood which extends as far distad as the ankle. ST consists of two heads arranged in-series about a tendonous inscription. Each head is supplied by a separate branch of the ST muscle nerve. By glycogen depletion techniques, each of the proximal (STp) and distal (STd) heads was shown to contain distinct populations of muscle fibers. STd's aponeurosis of insertion is attached to the tibia, but mainly forms the medial part of the crural fascial hood. To examine the possible functional roles of these compartments, EMG recordings were made from surgically implanted electrodes and synchronized with stepping movements using high speed (200fps) cinematography. Although all EMG records showed substantial variability in onset, duration and intensity of activity (i.e., relative to individual step cycles), some patterns can be recognized. BFa tended to be active during the stance phase, sometimes early (during E^2 or the E^1-E^2 boundary) but most often late (E^3). BFp activity occurred mainly during the mid to late swing phase (F-E^1 boundary) but activity was also recorded during the early stance phase (E^2), or at both times. BFm was generally active in phase with BFa, although late swing phase activity was sometimes also present. STd's activity was similar to BFp's, but more strongly biphasic. STp showed only weak activity, in phase with STd, except at high speeds of stepping. It is concluded that the differences in patterns of EMG activity in the in-parallel components of BF may reflect mechanical differences in their roles as hip extensors, knee flexors or crural fascial tensors. The intramuscular localization of monosynaptic group I inputs to motor neurons supplying these compartments (Botterman et al., Neurosci. Lett. in press) may thus serve to reinforce these separate mechanical linkages. The differences in EMG patterns for STp and STd may reflect its peculiar, in-series linkage and its role (along with BFp) in tensing the crural fascia. (Supported by AM19916 and NS15452 from the USPHS).

180.2 THE RELATIONSHIP BETWEEN PERIPHERAL INTRAMUSCULAR "COMPARTMENTS" AND SPATIAL ARRANGEMENT OF BICEPS FEMORIS AND SEMITENDINOSUS MOTOR NUCLEI IN THE CAT LUMBAR SPINAL CORD. William D. Letbetter and Arthur W. English, Department of Anatomy, Emory University, Atlanta, GA 30322.

Retrograde transport of horseradish peroxidase (HRP) was used to label motoneurons belonging to the biceps femoris (BF) and the semitendinosus (ST) motor nuclei in cats. One of the whole muscle nerves was soaked in a 10% HRP-1.6 mg% hyaluronidase solution in the ipsilateral hindlimb while one of the distinct intramuscular nerve branches supplying either the anterior (BFa), middle (BFm), or posterior (BFp) head of BF muscle, or the proximal (STp) or distal (STd) head of ST muscle, was soaked in the contralateral limb. After a 3-day survival period, spinal cord segments L6-S1 were serially sectioned at 20 μm so that a detailed analysis of the spatial organization of labeled motor nuclei could be made from 3-dimensional serial reconstructions.

BF motoneurons were distributed over longitudinal distances of 12-14 mm within spinal segments S1, L7, and L6. Those supplying BFp were located in the caudal 65% of the BF distribution range (95% of which were restricted to the caudal 50% of the BF range), while those supplying BFa were located in the rostral 85% of the BF distribution range (but 95% of which were restricted to the rostral 70% of the BF range). BFm cells were located in the 55% of BF's distribution range beginning 15% of the way from the caudal end and ending 30% of the way from the rostral end. Thus, a very prominent topographical relationship exists between the central location of motoneuronal cell bodies and the intramuscular compartments of BF to which these cells supply axons. The 1100 BF motoneurons are distributed as follows: approximately 50% to BFa, 20% to BFm, and 30% to BFp. The STp portion of ST muscle is supplied by neurons in the rostral 85% of the 12 mm of spinal cord segments S1 and L7 giving rise to ST motoneurons, leaving the distal portion (STd) of ST muscle to be supplied by the remainder. However, each of these two subpopulations of motoneurons is approximately symmetrically distributed rostrocaudally so that there is extensive overlap among the motor cells supplying this hamstring synergist.

Thus, with regard to motor nucleus organizational principles, it would appear that there is an anatomical correlate which could underlie at least the topographical (or "location") portion of the argument pertaining to intramuscular reflex organization of the monosynaptic reflex (Botterman et al., Neurosci. Let. in press).

180.3 REFLEX PARTITIONING IN THE MOTOR NUCLEUS SUPPLYING THE CAT BICEPS FEMORIS MUSCLE. T.M. Hamm, B.R. Botterman, R.M. Reinking* and D.G. Stuart. Dept. of Physiology, Univ. of Arizona, Coll. of Med., Tucson, AZ 85724

This report describes physiological experiments which demonstrate the existence of an intramuscular localization of monosynaptic Ia reflex effects in a cat hindlimb muscle.

Intracellular recordings from biceps femoris (BF) motoneurons were made in anesthetized low spinal cats during periods of electrical stimulation of the nerve branches supplying the anterior (AB), middle (MB) and posterior (PB) portions of the BF muscle. Recordings were also made during stimulation of nerves to semimembranosus (SM) and semitendinosus (ST) in order to provide a means of categorizing MB cells as "extensors" (MBe; i.e., like AB cells) or as "flexors" (MBf; like PB). Measurements of intrahomonymous (i.e., from AB, MB or PB) composite monosynaptic Ia-EPSPs revealed that in three of four comparisons (AB nerve onto AB and MBe cells, MB onto MBf and PB, PB onto MBf and PB) the AB, MB and PB nerve branches contributed larger EPSPs to their "own" motoneurons than to motoneurons supplying other "compartments" of the muscle. In the fourth case, MB input appeared to have similar effects onto AB and MBe cells. A normalization was performed to eliminate the possibility that the differences in EPSP sizes were due to differences in cell type within the four cell groupings (i.e., differences in the number of cells supplying FF, FI, FR and S muscle units). This normalization confirmed the presence of localization in the first three comparisons and, in addition, suggested that MB may indeed have greater effects on MBe than AB cells. In addition to the asymmetrical effects of AB and MB nerves onto AB and MBe motoneurons, it was shown that while ST and PB contributed larger EPSPs to MBf than to MBe cells, the AB and SM nerves contributed equally to the two MB groups. By analysis of cell location in the spinal cord, pair-wise testing of neighboring motoneurons of different category, and rostro-caudal differences in group I volley sizes and Ia afferent distributions, it is argued that somatotopic factors contribute importantly to the observed localization. However, neuronal recognition factors were also evident.

Supported by U.S.P.H.S. grants NS 07888, HL 07249, RR 94575, NS 05871 and NS 06462. Present address of B.R. Botterman: Dept. of Cell Biology, Univ. of Texas Health Sciences Center, Dallas, TX 75235.

180.4 INTRAMUSCULAR REFLEX LOCALIZATION IN RELATION TO MUSCLE DESIGN AND ACTION. B.R. Botterman, T.M. Hamm, R.M. Reinking* and D.G. Stuart. Dept. of Physiology, Univ. of Arizona College of Medicine, Tucson, AZ 85724.

By measurement of composite Ia-EPSPs, it has been shown that there is an intramuscular localization of monosynaptic Ia reflex effects in the unifunctional (hip extensor and knee flexor) components of the cat biceps femoris (BF) muscle (Botterman et al., Neuroscience Letters, In Press) but, as measured by single Ia-fiber EPSPs, not in the fellow hamstring muscle, semitendinosus (ST) (Nelson and Mendell, J. Neurophysiol. 41: 778-787, 1978). This report summarizes a composite Ia-EPSP study (152 motoneurons/12 experiments) that confirms the ST result. In addition, the atypical gross architecture (at least for a hindlimb muscle) of ST, with a proximal compartment (STp) in series with a distal compartment (STd), is emphasized by showing that spindles are unloaded by twitch of their "own" compartment but loaded by twitch of the in-series compartment. Conversely, tendon organs are loaded by twitch of both their own and the in-series compartment. It is argued that intramuscular reflex localization within ST would be mechanically unsound; in contrast to that in BF, whose fibers more typically extend largely in parallel from aponeurosis of origin to insertion. An important similarity between BF and ST is that the fibers of the anterior (AB) portion of BF and of STp are more proximally situated than the fibers of the middle (MB) and posterior (PB) portion of BF and of STd, respectively. An organization corresponding to this peripheral somatotopicity is present in the spinal motor nucleus of BF but not that of ST. As based on locations of cells identified antidromically during intracellular recording, the AB, MB and PB cells all overlap to some extent but the AB and PB population are concentrated in the rostral and caudal ends of the spinal motor nucleus, respectively, while the MB cells are concentrated toward the middle. In sharp contrast, the ST cells supplying STp and STd are co-extensive in the spinal cord.

These results suggest that somatotopic factors contribute to the localized Ia effects observed in BF and that the lack of such factors is a neuronal specialization that helps prevent the appearance of similar localization in ST.

Supported by USPHS grants NS 07888, HL 07249, RR 05675, NS 05871 and NS 06462. Present address of B.R. Botterman: Dept. of Cell Biology, Univ. of Texas Health Sciences Center, Dallas, TX 75235.

180.5 LACK OF SYNCHRONY BETWEEN MUSCLE RECEPTOR AFFERENT SPIKE TRAINS IN THE PASSIVE MUSCLE AT FIXED LENGTH: SIGNIFICANCE FOR INTERPRETATION OF SPIKE-TRIGGERED AVERAGING EXPERIMENTS. R.M. Reinking*, D.D. Roscoe, T.M. Hamm, B.R. Botterman, W.E. Cameron and D.G. Stuart. (SPON: W.A. Sibley). Dept. of Physiology, Univ. of Arizona, Coll. of Medicine, Tucson, AZ 85724.

Spike-triggered averaging (STA) experiments with the test muscle passive and at fixed length have revealed a monosynaptic excitatory spindle group II connection with homonymous and heteronymous motoneurons. This report describes a method which tests for the possibility that such an averaged EPSP is attributable to the impulses of a Ia afferent fiber, firing in synchrony with a reference spindle group II spike.

Spindle afferent discharge was analyzed in nine deeply anesthetized cats. In six cats, the nerve to medial gastrocnemius (MG) was intact (whole nerve experiments). In the remaining three cats, only a single intramuscular nerve branch (Letbetter, Anat. Rec. 178: p402, 1974) was left in-continuity with the spinal cord (nerve branch experiments). Simultaneous recordings for a 60-120 sec epoch were made of the discharge of 1-4 muscle receptor afferents and of the neurogram signal from the MG nerve or one of its branches. The MG muscle was de-efferented and held at fixed length under moderate (100g) tension. In two cats, the muscle was subjected to brief stretches that evoked a synchronous volley of Ia afferent discharge. A quantitative synchronization index (SI) of synchrony between each recorded afferent and other afferent signals in the neurogram was computed by comparing averages of rectified and unrectified versions of the neurogram (Roscoe, Ph.D. thesis, 1980). The SI and PPSTH tests revealed synchronized muscle receptor discharge during brief stretches of particularly small amplitude (20μm). In contrast there was no evidence of any synchronization between spindle group II and other afferents in the passive muscle at fixed length even when the recording epochs were extended well beyond those used in previous STA studies to establish the monosynaptic spindle group II connection. The results confirm the validity of this connection with homonymous and synergistic motoneurons, at least in experiments that featured use of closely comparable test muscle conditions (e.g., Stauffer et al., 1976; Lüscher et al., 1979; Munson et al., 1980; Sypert et al., 1980).

Supported by U.S.P.H.S. grants NS 07888, HL 07249, RR 05675, NS 05871 and NS 06462. Present addresses: D.D. Roscoe, Dept. of Orthopedics-REC, Cleveland Metro General Hospital, Cleveland, OH 44109; B.R. Botterman, Dept. of Cell Biology, Univ. of Texas Health Sciences Center, Dallas, TX 75235; W.E. Cameron, Dept. of Physiology and Biophysics, Univ. of Washington School of Medicine, Seattle, WA 98195.

180.6 "SENSORY PARTITIONING" OF CAT TRICEPS SURAE MUSCLES BY TENDON ORGANS. D.G. Stuart, T.M. Hamm, D.D. Roscoe, B.R. Botterman, and R.M. Reinking*. Dept. of Physiology, Univ. of Arizona, College of Medicine, Tucson, AZ 85724.

This report summarizes data on Ib afferent behavior in both "passive" and "active" muscles with an emphasis on the detailed description of Ib firing patterns during spontaneous motor activity in the unanesthetized decerebrate cat. For passive muscles, data from MG (Cameron, Ph.D. thesis, 1979) and SOL (Stauffer, Ph.D. thesis, 1974) reveal that force sensitivity values (pps/g) progressively increase when based on responses to contraction of the whole muscle, an intramuscular compartment, and single motor units. This finding offers compelling indirect evidence that tendon organs respond to intramuscular forces directly coupled to them rather than to whole muscle force recorded at the tendon. Similarly, we have found Ib firing patterns in active muscles that are: 1) a discontinuous function of whole muscle force (Fig. 1); and, 2) not synchronized to the discharge of other afferents. However, such firing patterns give a reasonably representative picture of total muscle force as if to suggest that localized intramuscular forces and single Ib spike trains are a relatively but not fully representative version of the muscle's total force output.

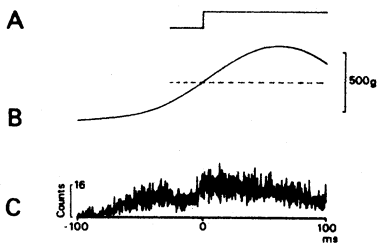

Fig. 1. Pre- and post-"stimulus" time histogram of a Ib afferent's discharge (PPSTH) during rhythmic MG activity (Roscoe, Ph.D. thesis, 1980). The Ib spike train was recorded while MG was undergoing spontaneously rhythmic (approx. 2/sec) contractions (>500g). A shows a force gate pulse enabled when the force signal exceeded 430 g (broken horizontal line). B shows averaged force profile (2048 sweeps) of MG triggered by A. C shows a PPSTH (200μ sec bin width, 1000 samples) of Ib discharge again with A as the reference event.

Supported by USPHS grants NS 07888, HL 07249, RR 05675, NS 05871 and NS 06462. Present addresses: D.D. Roscoe, Dept. of Orthopedics-REC, Cleveland Metro General Hospital, Cleveland, OH 44109; B.R. Botterman, Dept. of Cell Biology, Univ. of Texas Health Sciences Center, Dallas, TX 75235.

180.7 IDENTIFICATION OF THE HUMAN ANKLE STIFFNESS TRANSFER FUNCTION. R.E. Kearney and I.W. Hunter, Biomedical Engineering Unit, McGill University, Montreal, Quebec, Canada H3G 1Y6.

The dynamic relationship between joint position and torque (stiffness) or its inverse (compliance) is an important constraint on the motor control system since it will ultimately limit the performance that can be attained. The objective of the present study was to identify the stiffness transfer function of the human ankle using the techniques of engineering systems analysis.

A high-performance, servo-controlled, electro-hydraulic actuator was used to drive ankle position according to a computer-generated, repeated, stochastic pattern. Ankle position and the associated torque were sampled at 200 Hz for periods of up to 90 s. The resulting position input was found to have significant power in the range 0-50 Hz. Subjects were instructed not to oppose the displacement but were required to maintain a tonic contraction of either tibialis anterior or triceps surae at a level ranging from 0 to 20% of the maximum voluntary contraction.

Position and torque records were first ensemble averaged over 10-15 stimulus repetitions to reduce noise. Subsequently, the portion of the torque record due to the actuator dynamics was subtracted to leave only the component generated by the subject's ankle. The dynamic relationship between ankle position and ankle torque was then studied using both frequency and time domain analysis techniques.

The coherence between ankle position and torque was found to be greater than 0.9 over the range 0.2 to 50 Hz indicating that the dynamic relationship between the two variables is nearly linear. The stiffness gain curves were relatively flat from DC to about 20 Hz and thereafter rose at 40 db/decade. However, at intermediate frequencies (5-15 Hz) there were systematic, significant departures from the behaviour expected of a second-order system. Consequently, a more complex model is required to describe the observed behaviour. It is possible that this complexity arises from the interaction between torque generated by passive joint properties and that due to reflex activity. If so, the reflex contribution could serve to extend the range of frequencies over which ankle stiffness remains approximately constant thus simplifying the control task faced by more central motor structures.

180.8 COMPARISON OF EMG RESPONSES TO JOINT DISPLACEMENT IN HUMAN ANKLE FLEXORS AND EXTENSORS. C.W.Y. Chan and R.E. Kearney, School of Physical & Occupational Therapy, Biomedical Engineering & Aviation Medical Research Units, McGill University, Montreal, Quebec, Canada, H3G 1Y5

Evidence that reflex mechanisms are organized differently in forelimb flexors than in extensors (Lenz, et al., Canad. Physiol., 11 (1980): 98) motivated us to carry out a comparative study of reflex responses to joint displacement of human ankle flexors and extensors.

Subjects lay supine with their left foot attached to the pedal of an electro-hydraulic actuator. They were instructed not to oppose perturbations of ankle positions but were required to maintain a tonic contraction of either the ankle flexors (tibialis anterior, TA) or extensors (triceps surae, TS). Ramp displacements of various amplitude and velocity were applied in random order while the joint position and smoothed, rectified surface EMGs from the ankle muscles were recorded. The data were subsequently sorted and ensemble averaged prior to analysis.

The results revealed 5 principal differences in the behaviour of ankle flexor and extensor muscles as detailed below:

1. The pattern of the TS response was typically a short synchronous burst of activity starting at about 40 ms and lasting no more than 30 ms. In contrast, the TA response (at similar latency) lasted much longer and frequently could be resolved into two distinct components.
2. The threshold of the TA response was much higher than that of TS.
3. Increasing displacement velocity increased the magnitude of the response in TS as well as the early component of the response in TA but decreased the late TA component.
4. Increasing the level of tonic activity augmented the magnitude of the TS response initially, but saturation soon occurred. In contrast, both components of the TA response increased with increasing tonic TA activity.
5. Finally, shortening of the tonically active TS evoked no consistent response, whereas shortening of the active TA evoked a significant pause in its activity.

The contrasting behaviour of the ankle flexors and extensors appears to indicate that there are significant differences in their reflex organizations. These findings are consistent with the hypothesis that muscle spindles in the flexor muscles are subject to a greater static fusimotor drive than are their counterparts in the extensors.

180.9 TREMOR ASSOCIATED WITH RELAXATION-BREATHING PROCEDURE. R. S. Pozos, L. E. Wittmers*, and N. Nathan*. Dept. of Physiol., Sch. of Med., Univ. of Minnesota, Duluth, MN 55812.

Overt physiologic tremors are usually associated with fatigue induced states or cold exposure--shiver. Presently a system for relaxing subjects using a modified breathing maneuver has been used to cause an overt tremor in normal subjects. It became of interest to investigate if the tremor seen during the relaxing maneuver was similar in frequency to that reported for tremor induced by fatigue and shiver.

Subjects laid on their back and surface electrodes were placed on the following muscles: adductor longus, extensor digitorum, and the frontalis. To follow the respiratory function, the following parameters were monitored: 1) expired O_2, 2) expired CO_2, 3) minute ventilation, and 4) chest movement.

The surface EMGs were initially full wave rectified and demodulated and analyzed using traditional autocorrelation and power spectral techniques. During initial breathing, there was the presence of demodulated EMGs seen in the thighs. Eventually as the process continued there was tremor in the thighs, forearms, and forehead. This occurred early on in the experiment, usually within 5 minutes. The frequency for the thigh tremor was in the 5-7 Hz range and the forehead tremor was in the 7-8 Hz range. During the relaxing maneuver, there is an increase in minute ventilation paralleled by a decrease in end expiratory CO_2 and an increase in end expiratory O_2. The minute ventilation increased early on and returned to normal value during the relaxing procedure. The onset of the overt tremor seems to occur at the maximal increase in minute ventilation; however, this tremor continues even when minute ventilation returns toward normal levels. Interestingly, this tremor pattern of thigh, arm, and forehead seems somewhat different than that observed during shiver.

180.10 RECIPROCAL EXCITATION: OBSERVATIONS IN NORMAL ADULTS, INFANTS, AND CEREBRAL PALSY PATIENTS. Barbara M. Myklebust, Gerald L. Gottlieb, Gyan C. Agarwal, Bernice Kaufman*, James Poyezdala*, Laura Baldwin*, Dennis Vaccaro*, Richard Penn. Dept. Neurosurg. and Physiol., Rush Med. Coll., Chicago, IL 60612.

In an earlier paper [1], we contrasted the amount of simultaneous EMG activity that could be evoked in muscle antagonists by stretch stimuli in normal and CNS injured patients. Such activity we have called "reciprocal excitation" [2]. Reciprocal excitation is caused by an abnormality of the segmental neuronal circuitry. Its presence may be a sign of abnormal growth of synaptic connections in the presence of supraspinal pathology or it may be sign of maturational failure.

Surface EMG activity from tibialis anterior and gastrocnemius-soleus muscles was assessed with tibial nerve stimulation (H-reflexes), quick stretches applied to dorsiflex the ankle, and tendon taps applied to the soleus tendon in normal subjects, from infancy to adulthood, and patients with spasticity.

Preliminary data shows a quantitative difference in the amount of simultaneous reciprocal activity evoked in soleus and tibialis anterior muscles following these stimuli between different classes of subjects. According to these measures, it may be possible to differentiate between normal infants, normal adults and patients (aged greater than 7 years) with cerebral palsy.

180.11 TORQUE-ANGLE RELATIONSHIPS AT THE HUMAN THUMB INTERPHALANGEAL JOINT. PATRICK E. CRAGO AND KEN SUTIN* Rehabilitation Engineering Center, Case Western Reserve University, Cleveland, Ohio 44106.

Joint rotation in response to a torque disturbance is determined by the mechanical properties of the muscle fibers recruited prior to the disturbance and the reflexively induced change in muscle activation. Both are affected by other fixed parameters such as the initial torque and angle, and the disturbance time course and amplitude. We are cataloging these dependencies in order to provide a basis for quantitative evaluation of normal and abnormal motor function.

Torque-angle relationships were measured at the interphalangeal joint of the thumb of normal human subjects. The subjects established the initial torque and angle conditions by flexing their thumb against a load provided by a torque servo motor. Torque and angle at the interphalangeal joint, and EMG of the flexor pollicus longus were measured continuously before, during and after step increases or decreases in torque. Subjects were instructed not to intervene voluntarily to correct for changes in position caused by the disturbance (Crago, Houk, and Hasan, 1976, J. Neurophysiol.,39, 925-935). Any response with an obvious voluntary component was excluded from this analysis.

The change in angle elicited by a step change in torque was also steplike, with the majority of change taking place before any reflex response could be detected in the EMG. There were small position variations in the period between 50 and 250 ms, after which both the EMG and angle remained steady.

For fixed values of initial torque and angle, the magnitude of the steady-state angular change increased more than proportionally with the magnitude of the torque disturbance. Thus, the incremental stiffness (defined as the amplitude of the disturbance divided by the change in angle) decreases as the amplitude of the disturbance increased. The greatest effects were seen with angular changes less than one degree.

Steady-state stiffness was measured as initial torque was varied with a constant amplitude disturbance. For torques less than approximately 15 N-CM, stiffness was nearly proportional to initial torque. For larger torques, stiffness increased less than proportionally.

A data base including the experiments described above is being established to assess the normal range of responses to load change. This data base will allow the evaluation of motor-servo theories such as stiffness regulation and evaluation of stretch reflex function in patients with movement disorders.

180.12 A COMPARISON BETWEEN LOAD COMPENSATING REACTIONS AT THE WRIST AND ANKLE IN HUMANS. G.C. Agarwal, G.L. Gottlieb, and R.J. Jaeger. Dept. of Physiology, Rush Medical College, Chicago IL 60612, and Bioengineering Program, Univ. of Ill., Chicago IL 60680.

The large data base concerning load compensating responses from many muscles and paradigms has made it difficult to formulate a general classification scheme for these responses. Most classification schemes are based on latency alone. We have performed nearly identical studies at the wrist and the ankle in the same group of subjects.

Step torque perturbations, randomized in amplitude, were applied to flex and extend the wrists and ankles of normal human subjects. The effects of various instructions, torque directions, and resting muscle tensions (bias) were investigated. Subjects were asked to: 1) restore the joint to its starting position, 2) overcome and reverse the torque with a maximal response, 3) assist the torque, and 4) do not react. Subjects knew the direction of torque would be the same (simple) or unpredictable (choice).

The EMG activity was divided into four intervals: myotatic, late myotatic, postmyotatic, and stabilizing response. Our myotatic and late myotatic responses are equivalent to the M1 and M2-M3 respectively of Lee and Tatton (Can. J. Neurol. Sci. 2:285, 1975). Responses showed similar patterns in wrist flexor and extensors and the ankle flexor (tibialis anterior). The ankle extensor (soleus) lacked the late myotatic response. The myotatic and late myotatic responses were more dependent on bias than on instruction; the reverse was true for the postmyotatic and stabilizing responses. The postmyotatic response did not exhibit a latency difference between simple and choice situations and exhibited a proportional response when a maximal response was requested.

Each interval appears to have its own set of functional properties, and these may be more suitable classification criteria than latency alone. In a companion abstract, evidence is presented that each of these load compensating responses may depend on different afferent information.

180.13 THE EFFECT OF CORTICAL LESIONS ON REFLEX REPONSES TO TORQUE PERTURBATIONS IN THE SQUIRREL MONKEY FORELIMB. Lenz, F.A.,* Tasker, R.R.,* Tatton, W.G., (Spon: H.C. Kwan). Playfair Neuroscience Unit, University of Toronto, Toronto, Canada.

Previous work has demonstrated that in the relaxed limb the EMG response of Flexor Digitorum Profundus (FDP) to imposed joint displacement consists of a medium latencey (M2) component without a short latencey (M1) component equivalent to that seen in Flexor Carpi Ulnaris (FCU) and Short Head of Biceps (SHB) (Lenz et al, The Pysiologist 22:23, 1980). The purpose of this study was to examine the effect of motor cortical lesions on reflex activity in these different muscles.

Forelimb motor cortex was delineated by: 1) surface anodal stimulation at less than 400 uA under combined light halothane/ N02 general and local anesthetic 2) comparison with cytoarchitectonic maps for this species. This area was ablated by subpial aspiration. Postoperatively, animals had pronounced weakness of the forelimb contralateral to the ablation. The weakness resolved within one month but the animals had not regained normal manipulative ability in the hand over a period of up to four months. Graded torque loads were applied about the metacarpo-phalangeal, wrist and elbow joints of these animals. The resulting EMG response in FDP, FCU, and SHB was digitized, rectified, sorted by baseline EMG level and initial velocity of displacement and finally averaged. After some trials the animals were sedated with Ketamine and the M response to supramaximal nerve stimulation determined for the EMG electrode location used in the individual reflex study. In these cases, the M2 response (normalized to our measure of maximal motoneuron output, the M response) was plotted against initial velocity as an indication of reflex "gain". These results were compared with normals and the contralateral limb.

M2 responses contralateral to the lesion were decreased or absent in FDP of all animals studied. Reflex "gain" was decreased and threshold was increased at a series of increasing baseline EMG levels. These responses did not reach normal levels even at the highest baseline EMG levels examined. No consistent difference from normals was found in FCU or SHB.

The results in finger flexors can be most easily explained either by the interruption of a reflex pathway traversing forelimb motor cortex or by the loss of descending modulation of segmental reflex activity. In any case, the results indicate that the central and/or peripheral mechanism generating the M2 response in the FDP differs from those in FCU and SHB in terms of cortical dependency.

180.14 RELATION OF VOLUNTARY LIMB ACCELERATION TO INCREASES IN LONG LATENCY STRETCH RESPONSES PRIOR TO MOVEMENT. James A. Mortimer & Thomas G. Dukich* Geriat.Res.Educ.Clin.Ctr., V.A. Med. Ctr., Minneapolis, MN 55417 & Dept. Neurol., Univ. MN, Minneapolis, MN.

Prior to the initiation of voluntary EMG associated with rapid flexion movements of the forearm, there is a large, transient increase in the amplitude of long latency (50-100 ms) stretch responses of the agonist muscle (Mortimer et al., Soc. Neurosci. Abstr., 1979). One function that such an increase may serve is to provide enhanced facilitation to α-motoneurons during the initial phase of movement when limb inertia must be overcome. To examine this possibility, the relationship between the increase in gain of long latency pathways and the peak velocity and acceleration of the subsequent movement was investigated in 18 normal subjects.

The experimental technique has been described previously (see above ref.). Briefly, subjects were asked to respond to a tone by flexing their forearm at maximum velocity from an initial position of 90° flexion. Two Nm torque pulses of 500 ms duration stretching the biceps were presented at 8 different time intervals relative to tone onset. For each interval 20 torque pulses were given, and the tone was presented without torque perturbation on 20 trials. Biceps and triceps EMG responses corresponding to the 9 modes of stimulus presentation were sorted and computer-averaged with torque and position. The average EMG response to the tone in the absence of torque pulses was subtracted from the average EMG response for each time interval to obtain the response to the torque pulse at that delay. Motor response indices were calculated from integrals of the rectified EMG waveforms from 50 to 75 ms (M2) and 50 to 100 ms (M2-M3) following the onset of the torque pulse. Velocity and acceleration were obtained by computer differentiation of position.

For the 18 subjects, the mean interval between the initiation of voluntary motor activity and the time of peak acceleration was 140 ms, which allows sufficient time for fusimotor-induced discharge of spindle afferents to be conducted through long latency pathways and influence motor discharge prior to peak acceleration. To assess the association between the gain of long latency pathways and movement parameters, the peak values of the motor response indices prior to the time of maximum acceleration were divided by the values of these indices before tone onset. The ratios obtained in this manner were found to be significantly correlated with both peak velocity and peak acceleration.

The results of this study are consistent with the transient increase in long latency stretch responses before rapid movements providing increased excitatory input to α-motoneurons at a time when a rapid increase in EMG is needed to overcome inertia.

180.15 LONG-TERM STABILITY AND SHORT-TERM VARIABILITY OF THE PRIMATE M1 RESPONSE. V. A. Kieffer*, J. R. Wolpaw, D. J. Braitman and M. G. Sanders* (SPON: D. R. Livengood). Dept Physiol, Armed Forces Radiobiology Res Inst, Bethesda MD 20014; Div Labs Res, NYS Dept Health, Albany NY 12201.

In a study to determine if monkeys can control the amplitude of the largely monosynaptic M1 component of the muscle stretch reflex (Wolpaw et al., this vol), we measured M1 amplitude for continued periods of up to 5 mos. Rhesus monkeys were trained to maintain elbow angle at 90° (±1.5°) against steady extension force. If correct angle was held for a randomly selected 1-2s period, and if the average absolute value of biceps EMG (from chronic intramuscular electrodes) for the final 0.5s was 1.0-1.5 X a preset value, a 20ms pulse of additional extension force occurred. This stimulus extended the elbow 3-4°. M1 amplitude was the average absolute value of biceps EMG 12.5-21.5ms after stimulus onset minus pre-stimulus EMG amplitude. Under the Control condition, reward occurred 70ms after stimulus onset. Under the M1↑ or M1↓ condition, reward occurred only if M1 was greater (M1↑) or less (M1↓) than a criterion value. Each monkey normally completed 2500-6000 trials daily. Electrodes, pre-stimulus EMG, steady extension force, stimulus amplitude, and stimulus-induced movement were stable throughout.

Control condition data were obtained from six animals over 1-7 wks. For all six, average M1 amplitudes over the control periods were 120-150% of the pre-stimulus EMG amplitudes. No steady increases or decreases in M1 amplitude occurred during the control periods. For a given monkey, the standard deviation of daily M1 amplitudes was 10-15% of the average M1 amplitude for the entire control period.

When a monkey increased M1 amplitude under the impetus of the M1↑ condition, a marked diurnal variation of up to 50% in M1 amplitude often became apparent. M1 was typically greatest around midnight and least around noon, even though monkeys worked in constant light. This 24-hr rhythm was superimposed on the steady rise in M1 amplitude that occurred over 1-2 weeks.

The results indicate that in awake monkeys with constant muscle length and constant alpha motorneuron tone as measured by pre-stimulus EMG amplitude: (1) M1 amplitude remains stable over months under the Control condition, although day-to-day variations do occur, and (2) under the M1↑ condition, a marked 24-hr rhythmic change in M1 amplitude may be superimposed on the long-term progressive increase in M1 amplitude. Possible causes of the observed changes in M1 amplitude include change in gamma motorneuron tone, humoral effects on muscle spindle sensitivity, change in alpha motorneuron recruitment, and change in Ia synaptic function.

180.16 MODULATION OF STRETCH REFLEXES DURING LOCOMOTION IN THE DECEREBRATE CAT. J.W. Aldridge, R.B. Stein, K. Akazawa* and J.D. Steeves. Dept. of Physiology, Univ. of Alta., Edmonton, Alberta, Canada. T6G 2H7.

Environmental inputs that result in a stretch reflex could either assist or disturb locomotion, depending on the phase of the step cycle. Thus, the central pattern generator for locomotion may also control reflex pathways to provide adaptive control. This possibility was studied using the premamillary decerebrate cat. The left hindlimb of the cat was denervated, except for the nerves to the soleus muscle, and rigidly fixed. Locomotion was induced by stimulating the mesencephalic locomotor region with a constant current (50-200 μA) at 30 Hz and 0.5 ms duration. Brief stretches (10-100 ms) of about 1 mm were applied to the muscle at all phases of the step cycle. Isometric tension, soleus EMG and soleus nerve activity were recorded. In most experiments H-reflexes elicited by shocks to the sciatic nerve were also studied. Stimulation levels were monitored by using the EMG and nerve recordings. The levels used produced a constant afferent volley below that which produced M-waves. In a later computer analysis each step was divided into 14 periods equivalent in time and phase. The responses were averaged over several steps with the time at which the stimulus occurred determining in which of the 14 periods the response was placed. Generally there was about one stimulus per step and usually 100 to 500 steps were analysed. The reflex contribution to the total tension or EMG was calculated by subtracting the mean tension or EMG in each of the 14 time periods.

The results demonstrated a marked modulation of reflex responses as a function of the step cycle phase. The greatest EMG reflex response occurred at the time of the peak EMG produced as a result of locomotion. The reflex output diminished to zero during the time at which the soleus EMG due to walking was low (i.e., flexion phase). Between these extremes there was a gradation of reflex responses correlated to the step cycle. The results for tension paralleled the EMG responses. Thus, the central pattern generator for locomotion influences the response of stretch reflex pathways. Furthermore, the control it exerts is such that the reflex system is utilized to assist the behavioral goal.

Supported by MRC and MDAC. J.W.A. is a postdoctoral fellow of MDAC. Permanent address for K.A.: Dept. of Electrical Engineering, Osaka Univ., Osaka, Japan, and for J.D.S.: Dept. of Zoology, Univ. of British Columbia, Vancouver, Canada.

180.17 TOPOGRAPHIC WEIGHTING OF HOMONYMOUS GROUP IA AFFERENT INPUT TO CAT MEDIAL GASTROCNEMIUS MOTONEURONS. Sylvia M. Lucas and Marc D. Binder. Dept. of Physiol. & Biophys., Univ. of Washington Sch. of Med., Seattle, WA 98195.

The nerve innervating the cat medial gastrocnemius (MG) muscle generally divides into four to seven intramuscular branches. The muscle fibers innervated by a branch occupy a relatively distinct volume or "compartment" within the muscle and the Ia afferent fibers innervating spindles within such a compartment are contained in the same nerve branch (Farina and Letbetter, J.S.C. Med. Assoc., 73: 15, 1977). It has recently been shown that muscle receptors in MG are more responsive to contractions of their "own" intramuscular compartment than to those of neighboring and more distant compartments (Cameron et al., J. Neurophysiol., in press). These findings invite the question as to whether the topographic organization of the MG muscle is preserved in the pattern of its muscle afferent-motoneuronal connectivity (Binder and Stuart, Prog. Clin. Neurophysiol., 8: 72, 1980). The present series of experiments were specifically designed to determine if the homonymous Ia input to a motoneuron is "topographically weighted", reflecting a disproportionate contribution from spindles located within its muscle unit's territory. The MG nerves of anesthetized cats were cut away from the muscle after dividing into their natural branches. Each of three branches was placed on a separate stimulating electrode and a fourth electrode was placed proximally on the whole muscle nerve. MG motoneurons were impaled with glass microelectrodes while the muscle nerve and the individual branches were stimulated sequentially at 2 X threshold. Dorsal root volleys were recorded continuously. In most cases, it was necessary to hyperpolarize the motoneuron to prevent antidromic invasion consequent to stimulation of either the muscle nerve or the branch containing the motor axon. For each motoneuron studied, the relative contribution of each of the branches to the maximal (whole muscle) group I EPSP was calculated. This method permits a direct comparison of the synaptic input from a given branch to its "own" motoneurons (branch containing motor axon) versus that to other motoneurons within the MG pool. Moreover, this analysis obviates problems associated with variations in branch "size" and in maximal group I EPSP amplitude in different motoneurons. Thus far, in 11 of 12 successful experiments (81 motoneurons) we have found that the fraction of the maximal EPSP produced by a branch in its own motoneurons is significantly greater than that produced by the same branch in other motoneurons. These results are consistent with the hypothesis that homonymous Ia input to motoneurons is topographically weighted.

180.18 ANALYSIS OF HETERONYMOUS GROUP IB SYNPATIC INPUT TO THE CAT MEDIAL GASTROCNEMIUS MOTONEURON POOL. Randall K. Powers* and Marc D. Binder. Dept. of Physiol. and Biophys., Univ. of Washington Sch. of Med., Seattle, WA 98195.

Previous work on cat medial gastrocnemius (MG) motoneurons has shown that the amplitudes of homonymous and heteronymous Ia EPSPs as well as those of disynaptic Ia IPSPs are largest in type S, smaller in type FR and smallest in type FF motoneurons (Burke et al., J. Neurophysiol. 31:447, 1976). Although Eccles et al. (J. Physiol. 138:227, 1957) found that Ib IPSPs were larger in soleus than in MG motoneurons, there has been no report of the relative amplitude of Ib input to different unit types within the MG motoneuron pool. The present study was designed to examine Ib input to different MG motoneurons, as well as to compare the synaptic potentials from a variety of other peripheral inputs onto the same cells. Intracellular recording and current injection were used to determine the input resistance, rheobase current (I_{Rh}), axonal conduction velocity (CV) and duration of afterhyperpolarization (AHP) of MG motoneurons in low spinal, chloralose-anaesthetized cats. In the same cells, heteronymous Ia EPSPs, sural PSPs (1.1, 1.5, 2 and 5 x threshold), flexor digitorum longus Ib PSPs and quadriceps Ib PSPs were evoked by stimulation of the respective peripheral nerves. MG motoneurons were divided into two groups on the basis of the pattern of synaptic input from the sural nerve (5 x T) (Burke et al., J. Physiol. 207:709, 1970). Thus far we have found that motoneurons with predominantly excitatory sural nerve input have significantly higher I_{Rh}s and CVs, shorter AHPs and smaller Ia EPSPs than motoneurons with mixed or predominantly inhibitory sural nerve PSPs. These results suggest that the former group is probably composed of type FF units while the latter group is probably composed of type FR and S units (Munson et al., Neurosci. Abstr. 6:714, 1980). The amplitude of Ib IPSPs is significantly smaller ($p<.01$) in these presumed type FF units than in the presumed FR and S units, and thus Ib inputs appear to show the same general pattern of relative efficacy that has been observed for group Ia input.

180.19 Convergence from Golgi tendon organs and Mechanoreceptors in Muscle onto Force Sensitive Interneurons in the Spinal Cord of the Cat

Corey L. Cleland, W. Zev Rymer, Stephen E. Grill*, Neuroscience Program and Depts. of Physiology and Neurology, Northwestern University Medical School, Chicago, Ill., 60611.

Convergence from different sensory receptors in muscle onto spinal interneurons has been traditionally investigated by electrically stimulating muscle afferents and recording from interneurons and motoneurons. This approach, however, does not directly address how interneurons respond to natural patterns of sensory stimulation. In order to investigate the natural response of interneurons to muscle receptor input, we have used physiologically relevant stimulation of muscle receptors to evaluate modal and spatial convergence onto spinal interneurons.

The activity of interneurons in the intermediate nucleus was extracellularly recorded in decerebrated/spinalized (T12) or chloralose anaesthetized cats. Interneurons were driven by stimulation of muscle receptors in the triceps surae and plantaris muscles. Static and dynamic changes in muscle force, produced by stimulation of the ventral roots or peripheral nerve at 5-30 Hz, were used to identify force sensitive interneurons. Convergence from primary spindle afferents was demonstrated if the interneuron was excited by longitudinal vibration (160 Hz, 90 um amplitude). Golgi tendon organ convergence if the interneuron was excited by electrical stimulation of the peripheral nerve at group I strength but not excited by vibration. Secondary spindle afferent convergence if the interneuron was excited by stretch at short muscle lengths. Mechanoreceptor input if the interneuron was excited by mechanical probing, especially light stroking, of the muscle. Interneurons were distinguished from tract neurons by tract stimulation at T12.

Many force sensitive interneurons in both decerebrated/spinalized and chloralose anaesthetized cats received input from Golgi tendon organs and mechanoreceptors but not from primary or seconday spindle afferents. Their discharge paralleled static changes in force, showed dynamic sensitivity at the onset of stimulation, and a prolonged afterdischarge at the cessation of stimulation. Unexpectedly, most responded vigorously to light stroking of the muscle and tendon surfaces. Discharge rates often equalled their maximum response to increases in muscle force. Although Golgi tendon organs are linear force transducers, the potency of mechanoreceptor input, which bears an uncertain relation to force, suggests that these interneurons may not always provide accurate information about muscle force.

180.20 REFLEX ACTIVITY OF THE RAT SPINAL CORD FOLLOWING SEGMENTAL APPLICATION OF PENICILLIN.
(SPON: M.H. BENITEZ)

K. Schwerdtfeger[x] and A.C. Nacimiento Research Laboratory, Department of Neurosurgery, Saarland University School of Medicine, 6650 Homburg/Saar, FRG

Mono- and polysynaptic discharges evoked by peripheral nerve stimulation (tibial and peroneal nerves) were recorded in decerebrate and spinal transected rats (at 10) following local application of Na-Penicillin G (PNC) to exposed lumbar segments. The tip of a glass micropipette (diameter about 20 μ) filled with a penicillin solution (5.10^5 I.U./ml) was placed upon the lateral aspect of the spinal cord between L5 and L6. By means of a microsyringe 4 μl of the solution were delivered. Reflex discharges into the ventral root of L5 and L6, as well as cord dorsum potentials were analyzed. A few minutes following drug application both mono- and polysynaptic discharges increased. Polysynaptic reflex facilitation was clearly dominant. Also after discharges appeared, triggered at latencies of 20 - 80 ms. Input-output curves for the monosynaptic reflex showed increased temporal summation. Posttetanic potentiation was decreased and shortened as penicillin effects set in. Recurrent inhibition was reduced by about 20%. Excitability changes in the monosynaptic reflex pathway tested with paired stimulus. Analyses at varying intervals displayed the following sequence: at the shorter intervals (up to about 20 msec) there was a decrease of the strong inhibition usually seen in control measurements; at longer intervals (up to 100 msec) a prolonged depression was observed. These results suggest that topically applied penicillin a) brings about clear cut qualitative and quantitative changes in the reflex activity of the rat spinal cord and b) in particular, influences inhibitory processes in a complex way.

181.1 ANTICIPATORY NEURONAL ACTIVITY IN THE MONKEY CORTEX DURING REACTION TIME FOREPERIOD. J.C. Lecas*, L. Mistler* and J. Requin. Inst. of Neurophysiol. and Psychophysiol., CNRS, Marseilles, France.

A number of single-cell recordings in monkeys trained to perform sensorimotor tasks have shown that neurons in precentral motor areas and prefrontal associative areas are activated prior to movement. The purpose of this study was to systematically investigate these anticipatory neuronal discharges using a paradigm in which the level of preparation for response was controlled.

Four monkeys (Macaca fascicularis) were trained to perform a between-hand, choice-reaction time (RT) task initiated by a warning signal (WS), in which the animal was required to point at a target. The probability of each hand performing this movement was varied within each session in blocks of trials. An inverse relationship between RT and response probability was found, while movement duration remained constant. A double chamber was then attached to the skull, allowing simultaneous microelectrode recording in both the precentral cortex and either the posterior parietal or prefrontal cortex.

Preliminary results were based on an extensive analysis of 20 cells which were activated during the pointing movement. They show that a small number of neurons, especially in the precentral areas, have discharges which are modified during the foreperiod, in correlation with the decrease in RT produced by an increase in response probability. That some of these changes appeared prior to ipsilateral movement - but without correlation with RT - could be further evidence for selective presetting processes triggered by the WS.

181.2 SINGLE UNIT ACTIVITY IN CAT PRECRUCIATE CORTEX DURING ALTERNATING MOVEMENTS. M. E. Melnick* and M. W. Rogers* (SPON: N. J. Pantazis). Graduate Programs in Physical Therapy, Univ. of Iowa, Iowa City, IA 52242.

Alterations in the pattern and rate of unit activity have been demonstrated in the cat motor cortex prior to the onset of movement and prior to the onset of EMG activity. A study by Neafsey et al. (Electroenceph. Clin. Neurophysiol. 44: 706, 1978) showed that the changes in unit activity of neurons in the medial precruciate cortex (projecting to axial and proximal musculature) occurred prior to changes in the lateral precruciate cortex (projecting to distal limb musculature). The present study is directed towards examining further functional differences in regions of the motor cortex.

Cats were trained to release one of two levers in an alternating sequence. Between trials, the animal was required to depress both levers for a minimum of 3 sec. After training, the cats were prepared for single unit recording in both precruciate cortices and for EMG recording from the triceps, brachialis, varying proximal muscles and the paraspinal muscles. The cat precruciate cortex was divided into three divisions: a medial region corresponding to area 6; an intermediate region corresponding to that portion of area 4 projecting to the proximal and axial muscles; and a lateral region corresponding to that portion of area 4 projecting to the distal limb muscles (Hassler and Muhs-Clement, J. Hirnforsch. 6: 377, 1964). Neural unit activity in all areas were classified as: 1) related to contralateral paw movement only, 2) ipsilateral paw movement only or 3) bilaterally related. Units were also classified as "early" or "late". "Early" units exhibited neuronal activity changes more than ½ sec preceding movement; "late" units, less than ½ sec before the movement. The results showed that 75% of the movement related units in the medial region, 47% of the units in the intermediate region and 14% of the units in the lateral region were "early" units. Over half of the units in area 6 were bilaterally related whereas only one-third of the units in both parts of area 4 were bilateral. The bilateral units in area 6 often had initial changes in activity which were in the same direction prior to movement of the contralateral and ipsilateral paw. Bilateral units in area 4 usually showed reciprocal changes. There were no consistent early EMG activity changes even in the axial muscles which could be correlated with the early neuronal activity changes.

These data are consistent with the hypothesis that the medial-intermediate regions of the motor cortex are preferentially involved in the preparatory adjustments for movement. They also suggest further functional differences between these two regions.

181.3 CODING OF TARGET AND RESPONSE VARIABLES IN CAT MOTOR CORTEX. J. Martin*, H. Yumiya*, and C. Ghez. Ctr. for Neurobiology and Behavior, Columbia P&S, New York, N.Y.

The arm area of cat motor cortex includes two functional subdivisions. Neurons in caudal (MCc) and rostral (MCr) regions differ in their receptive field properties and in the timing of their activity during tracking performance (Neurosci. Abstr.6:125, 1980). Task related activity in MCc lags force production. In MCr activity may lead but is better timed to target shifts than to motor behavior. This study further characterizes the coding of target and response variables in task related neurons.

The activity of single neurons in MCc and MCr was recorded in cats performing extensor or flexor adjustments in force applied to a lever with their forearm to match shifts in a target. The animals were provided with a compensatory display of their force error that moved to the right or left. To dissociate the coding of target and response variables in correlated unit activity, the animals were trained to respond appropriately when the display polarity was inverted or its gain altered. Additionally, the effects of display shifts not eliciting responses, receptive fields, antidromic activation from the cerebral peduncles and microstimulation from recording sites were routenely checked.

Three classes of task related units were identified. One showed reciprocal changes in activity according to response direction which were better timed to response onset but with a lag. Such neurons were located in MCc and had receptive fields on the responding limb. They could contribute either to tonic force production via feedback mechanisms or to other late response events. A second class showed a consistent relation to a given direction and to the time of occurence of display shift rather than to the response. Such neurons appeared to code target variables contingent on the occurence of a response in either direction. The third and major class showed reciprocal and contingent changes in activity with the direction of force production while bearing a more consistent relation to the time of occurence of the target shift than to the response. Thus, a neuron active with a given direction of force could be driven (or suppressed) at short latency by display shifts either to the right or the left according to the polarity of displayed error. These neurons could contribute to response initiation since their acitivity preceded and correlated with the direction of force production. The latter two classes of neurons were intermingled in areas of MCr where microstimulation produced contraction of arm muscles.

It is concluded that gating mechanisms operating presynatic to neurons in MCr enable the efficient transfer of behaviorally relevent target information leading to the short latency learned motor responses in our tracking task. (Supported by NS 52750)

181.4 TOPOGRAPHY OF DIFFERENTIAL PROJECTIONS TO ROSTRAL AND CAUDAL CAT MOTOR CORTEX. H. Yumiya* and C. Ghez (SPON: F. Salazar) Center for Neurobiology and Behavior, P&S, Columbia University, New York, NY, 10032.

Physiological data suggest that neurons in rostral and caudal portions of the arm area of cat motor cortex play predominant roles respectively in the initiation and control of ongoing motor responses. This study examines the differences in topographic organization of thalamocortical and corticocortical projections to the cat motor cortex. Single small injections were made intracortically in area 4γ of ten cats and the distribution of retrogradely labeled neurons was examined following processing with TMB.

In the thalamus, labeled cells were found in VL nucleus, VL-VB border zone and in CL nucleus. Within VL, clusters of labeled neurons formed lamellae with a lateral curvature in roughly parasagittal planes extending rostrocaudally. There were clear topographic relations between the location of the cortical injection site and the lamella of labeled VL neurons. Thus, the medial part of VL projected to medial precruciate area 4γ, lateral part of VL to medial postcruciate and intermediate regions projected to portions of pericruciate cortex in between. Postcruciate injections labeled neuron clusters in the VL-VB border zone in areas which were roughly co-planar but separate from those in VL proper. In contrast, precruciate injection sites yielded significantly fewer labeled neurons in VL-VB border zone. No specific topographic arrangement was observed in CL nucleus.

Clear differences between pre- and postcruciate injections were also found in the locations of labeled neurons within ipsilateral cortices (layers III and II). Following postcruciate injections, labeled neurons were abundant in areas 3a, 2, 5 and 2pri with a topographic arrangement compatible with known somatotopic representations of arm and leg in these areas. Additionally labeled neurons were present in separate portions of area 4γ remote from the injection sites and in other areas (especially medial part of area 5b and bank of anterior suprasylvian sulcus). In contrast, precruciate injections labeled many neurons in remote portions of area 4γ but only rare and scattered neurons in areas 2, 5, and 2pri. A few neurons in the banks of orbital and cingulate sulci, areas 6, 4δ, 4fu, 4sfu, 3b and 7 were labeled after some injections. These observations suggest that differences in the sources of afferent input to rostral and caudal area 4γ may give rise to the observed differences in physiological properties of neurons in these two areas.

181.5 CORTICAL MECHANISMS OF TWO-DIMENSIONAL AIMED ARM MOVEMENTS. III. RELATIONS OF PARIETAL (AREAS 5 AND 2) NEURONAL ACTIVITY TO DIRECTION OF MOVEMENT AND CHANGE IN TARGET LOCATION.
J.F. Kalaska*, R. Caminiti and A.P. Georgopoulos (SPON: A.Sastre) Dept. of Physiology, The Johns Hopkins Un. School of Medicine, Baltimore, Maryland 21205.

We hypothesize that frontal (4 and 6) and parietal (5 and 2) areas cooperate closely in the control of arm movements aimed at targets in space. An important spatial attribute of aimed movements is their direction. We showed previously (Soc. Neurosci. Abstr. 6:156,1980) that the activity of precentral motor cortical cells is related to the direction of movement in an orderly but non-exclusive manner, so that movement of a given direction engages the activity of neurons with overlapping directional preferences. We studied similarly the effects of the direction of movement on the activity of 164 single neurons electrically isolated in 39 microelectrode penetrations in areas 5 and 2 of two rhesus monkeys. A two-dimensional tracking apparatus was used in which animals were trained to move a manipulandum over a plane surface and capture with it lighted targets in a reaction task, as described before (Fed. Proc. 39:601,1980). This experimental arrangement provides 8 directions of movements which cover the whole circle with a resolution of 45^{o}. The cells studied in the task discharged with spontaneous arm movements, and most responded to passive manipulations of the arm, mainly to rotations at joints and/or palpation of deep tissues; for some cells the activation during movement was more intense than during passive manipulations. We found that the direction of movement affected the magnitude, latency, sign and time course of the cell response. These response characteristics varied in an orderly fashion with the direction of the movement. In another task the target changed during the reaction or movement time: the cell activity also changed in a systematic way, in that the pattern of activity related to the movement towards the first target was promptly interrupted and replaced by that appropriate to the movement towards the second target.

These results show that cell activity in parietal areas 5 and 2 is intimately related to the direction of movement and its changes that ensue following change in target location. Although the neuronal changes in the parietal areas generally occurred later than in frontal areas, the quantitative relations to the direction of aimed movements were similar in both of these cortical areas. This and the similar responses observed during change of target location strengthen the hypothesis of close cooperation of these frontal and parietal areas in the control of aimed arm movements. (Supported by USPHS Grants 5-RO1-EY03167-02 and NS-07226-11.)

181.6 CORTICAL MECHANISMS OF TWO-DIMENSIONAL AIMED ARM MOVEMENTS. IV. EFFECTS OF ARM POSITION IN SPACE.
R. Caminiti, J.F. Kalaska* and A.P. Georgopoulos. Dept. of Physiology, The Johns Hopkins Un. School of Medicine, Baltimore, Maryland 21205.

The direction of aimed movements is a major factor to which cell activity in precentral and parietal (5 and 2) areas is related (Soc. Neurosci. Abstr. 6:156,1980; and this Meeting). We identified another important factor that influences neuronal activity in these areas; namely, the position of the arm in space. Monkeys were trained to hold steadily a manipulandum at different points in a two-dimensional space. The desired position was indicated by a lighted target which the animal had to capture with the freely moving manipulandum and hold there for a variable period of time. The apparatus has been described before (Fed. Proc. 39:601,1980). We studied under these conditions the activity of 134 precentral and 53 parietal (areas 5 and 2) single neurons electrically isolated in 52 penetrations in two rhesus monkeys. These cells discharged during spontaneous arm movements; most parietal and some frontal neurons also responded to passive manipulations of the arm, mainly to rotations at joints and/or palpations of deep tissues. The activity of 72% precentral and 77% parietal cells was influenced by the active maintainance of the arm at different positions in space. Cells discharged at higher rates when the manipulandum was held within certain parts of the two-dimensional space; the discharge decreased as positions at increasing distances from this part were occupied. Maxima and minima of activity occurred at different parts of space for different cells.

These results show that position of the arm in space is an important determinant of cell discharge in both frontal and parietal areas studied. This underscores the participation of these areas in the control of aimed movements since a basic spatial attribute of these movements concerns the position of the arm in space, in addition to the direction of movement. Different mechanisms may account for the effects observed in frontal and parietal areas: a relation to motor commands in the first and a peripheral input in the second, but a peripheral input to precentral cells and a corollary motor output to parietal cells may also contribute. We propose that the similarity of the relations of frontal and parietal neuronal activity to arm position in space and the direction of movement indicates the use by these cortical areas of a common "language" in processing information for the spatial control of aimed movements. The nature of this common system of reference remains to be elucidated.

181.7 CORTICAL MECHANISMS OF TWO-DIMENSIONAL AIMED ARM MOVEMENTS. V. INTERACTIONS BETWEEN DIRECTION OF MOVEMENT AND ARM POSITION IN SPACE.
A.P. Georgopoulos, J.F. Kalaska* , R. Caminiti and J.T. Massey. Dept. of Physiology, The Johns Hopkins Un. School of Medicine, Baltimore, Maryland 21205.

The spatial characteristics of aimed movements comprise the direction of the movement and the arm position in space (which defines the trajectory of the movement). Both of these factors influence the neuronal activity in precentral and parietal cortical areas (Soc. Neurosci. Abstr. 6:156,1980; and this Meeting). It is important to know whether these factors influence the same or separate populations of cells, and if the latter is true, how they interact at the single cell level. We investigated this problem by training monkeys to make equal amplitude (8 cm) movements that were either (a) of opposite directions but made between the same points (e.g., from 12 o'clock to center, and vice versa), or (b) of the same direction but made between different points in space (e.g., from 12 o'clock to center, and from center to 6 o'clock). A two-dimensional tracking apparatus was used (Fed. Proc. 39:601,1980). Starting and final target positions were varied in a randomized block design. We studied the activity of 117 precentral and 53 parietal (areas 5 and 2) arm-related single neurons in 2 rhesus monkeys. 1) The activity of 70% frontal and 74% parietal cells was related to both the direction of the movement and the actively maintained arm position in space; smaller percentages were related to direction only (23%, 21%), arm position only (1%, 4%), or to neither (6%, 1%) in frontal and parietal areas respectively. 2) The directional and positional effects were additive in some cases but not so in others. Generally, the response for a preferred direction of movement was stronger if its trajectory lay within a part of space for which the cell discharged at higher rates during steady holding. 3) Movements of opposite directions made between the same points elicited responses that differed strongly when one of the two directions was the most preferred for a given cell; for other pairs of directions differences were less pronounced.

These results show that the spatial characteristics of aimed movements are not handled in these areas by separate "directional" or "positional" populations; instead, information concerning both of these spatial attributes is processed to a large extent by the same single neurons. The exact use of this information at the single cell level remains to be elucidated. We believe that more detailed investigation of the interactions between direction of movement and arm position in space may contribute to this elucidation, as well as lead to a better understanding of the specific contribution of each area and of the nature of their cooperation in the spatial control of aimed movements.

181.8 CORTICAL MECHANISMS OF TWO-DIMENSIONAL AIMED ARM MOVEMENTS. VI. ELECTROMYOGRAPHIC ANALYSIS.
J.T. Massey, R. Caminiti, J.F. Kalaska* and A.P. Georgopoulos. Dept. of Physiology, The Johns Hopkins Un. Sch. Medicine, Baltimore, Maryland 21205.

The direction of aimed arm movements and the arm position in space are two important factors to which neuronal activity in precentral and parietal cortical areas is related (Soc. Neurosci. Abstr. 6:156,1980; and this Meeting). We investigated how these movements are performed by muscles acting on joints of the arm, and particularly how each muscle is related to the factors mentioned above. EMG activity of 21 muscles acting on shoulder, elbow and wrist joints, and of paraspinal musculature, was recorded intramuscularly in 3 rhesus monkeys while they made movements of various directions in a two-dimensional tracking task (Fed. Proc. 39:601,1980), and also when they were actively maintaining different arm positions in space. These tasks were accomplished by muscles acting on the upper arm (teres major, anterior and posterior deltoid, pectoralis, latissimus dorsi, and caudal part of trapezius); other muscles were generally inactive. The earliest onset of EMG activity preceded constantly the beginning of movement (as judged from the velocity record) by at most 150 ms; decrease of activity in antagonists occurred earlier, at most 170 ms before the onset of movement. Reaction times were 250-300 ms. For the muscles that were active in the task, the magnitude, latency, sign, and time course of the EMG response varied with the direction of movement in an orderly manner. However, the directional specificity of any single muscle was rather low, with excitatory sector widths (A.P. Georgopoulos et al., Soc. Neurosci. Abstr. 6:156,1980) of at least $170\text{-}180^{o}$. (By comparison, about 75% of precentral motor cortical neurons studied in the same animals with the same task had sectors below 180^{o}.) Muscles that were active with movements were also differentially activated during active maintainance of arm position in space. These effects were spatially congruent, so that, for example, a muscle that was phasically activated when moving from the center to an outer target (e.g. at 12 o'clock) was also tonically active when holding steadily at that target position. These results show that any two-dimensional movement performed by action of muscles at the shoulder joint is accomplished by a patterned activation of these muscles; this pattern varies in an orderly fashion with the direction of movement. We conjecture that precentral neurons, under certain circumstances, may indeed relate to the pattern rather than (or in addition) to individual muscles alone. (Supported by USPHS Grants 5-RO1-EY03167-02 and NS-07226-11.)

181.9 INPUT-OUTPUT RELATIONSHIPS IN AREA PREINSULARIS (2PRI) OF THE SECOND SOMATIC SENSORY CORTEX. A Mori*, R. S. Waters, H. Asanuma. The Rockefeller University, New York, N.Y. 10021.

Efferent projections from area preinsularis (2 pri) of the second somatic sensory cortex to limb and trunk muscles were examined in unanesthetized or lightly sedated (ketamine,1-2mg/kg) cats using the same microelectrode for intracortical microstimulation (ICMS) and recording cellular activities. In addition, connections from area 2 pri to area 4γ were examined using the electrophysiological technique. Under halothane anesthesia, areas 4γ and 2 pri were exposed and a double barreled chamber was installed over the skull. Through the anterior chamber, 8 tungsten in glass microelectrodes were inserted into area 4γ and they were positioned at depth of 1.2mm below the surface of the cortex. Receptive fields of neurons around the electrodes and muscle responses to ICMS through each electrode were examined. Through the posterior chamber, an electrode used for both ICMS and recording was inserted into area 2 pri. The motor effects were examined either by recording EMG or observing movements. The receptive fields of neurons were examined by using natural somesthetic stimulation. The spikes were monitored on the oscilloscope and also fed into a speaker through a window discriminator.

ICMS through the 2 pri electrode could elicit flexion of fingers, flexion of elbow, extension of elbow, flexion of hindlimb joints, movement of shoulder and abdomen on the contralateral side of the body. The minimum threshold current for movement was 2μa and the maximum current used was 30μa. The low threshold sites for a particular movement were confined to a small area of the cortex and constituted a columnar shape with a diameter of 200-1000μm. Neurons in the effective area received afferent input from receptors in the skin or deep structures in the region of the body which was related to the movement. To examine whether the pyramidal tract mediates the motor effects, a recording electrode was inserted into the lateral cervical cord (C_5) and large synchronized volleys were recorded in the pyramidal tract following ICMS delivered to area 2 pri.

Neurons of area 2 pri which were activated antidromically by ICMS in area 4γ had receptive fields which were similar to those of neurons around the responsible area 4γ stimulating electrode. It is concluded that neurons of areas 2 pri and 4γ are closely interconnected, but area 2 pri also has motor function which is independent of the motor cortex.

181.10 SUSTAINED EXCITATORY SYNAPTIC INPUTS TO MOTOR CORTEX NEURONS IN AWAKE ANIMALS; A COMPARATIVE STUDY OF MEMBRANE POTENTIAL IN ANESTHETIZED AND UNANESTHETIZED STATE. M. Matsumura (SPON: E. E. Fetz). Department of Physiology and Biophysics, and Regional Primate Research Center, University of Washington, Seattle, WA 98195.

A considerable difference has been noted in membrane potentials of cortical neurons observed in awake and anesthetized animals. In awake animals investigators tend to observe smaller (more depolarized) membrane potentials (-50 to -60mV) (Woody, C. D. et al., Brain Res. 158: 343, 1978, Matsumura, M. Brain Res. 163: 33, 1979) than those observed in anesthetized animals (typically -70mV; Phillips, C. G. Quart. J. exp. Physiol. 41: 58, 1956). This difference indicates that the level of depolarization of cortical neurons may depend on the anesthetic state of the animal.

However, measurements of membrane potential could also be affected by recording conditions, such as electrode parameters or by experimental criteria of "good" intracellular recording. These factors might skew the sample. To minimize these factors and clarify the effect of anesthesia, identical recording techniques and selection criteria were applied in recording the membrane potentials of cortical neurons in the same animals, under awake and anesthetized conditions.

Chronic intracellular recordings (Woody, C. D. et al., J. Neurophysiol. 36: 1104, 1973) were obtained from motor cortex neurons of cats. Microelectrodes were beveled to a tip diameter of about 1μ to reduce the probability of dendritic penetration. After several hours of recording from the awake cat (restrained by a blanket), sodium pentbarbital (35mg/kg) was administered intraperitoneally, and the same recording procedures were repeated at the same cortical site. Approximately 1 week later the contralateral side of the motor cortex was similarly investigated.

To date, 50 neurons from pre- and postcruciate gyrus have been recorded intracellularly. The average membrane potential of the neurons was -62±7(S.D.)mV (n=30) in the anesthetized state and -54±7mV (n=20) in the awake state. The difference between these two groups was significant (t-test, $p<0.001$). Results were similar across animals for the same anesthetic state. Action potential amplitude was also significantly different between these two groups. Spikes recorded in the anesthetized state exhibited a greater overshoot (+5.4mV) than those in the awake state (+1.2mV). This observation suggests a difference in membrane conductance of cortical neurons in awake vs anesthetized preparations. (supported by NIH Grants NS12542 and RR00166).

181.11 EFFECTS OF SINGLE INTRACORTICAL MICROSTIMULI ON ACTIVITY OF INDIVIDUAL FORELIMB MOTOR UNITS IN BEHAVING MONKEYS. S. Sawyer and E. E. Fetz, Dept. of Physiol. and Biophysics and Regional Primate Research Center, University of Washington, Seattle, WA 98195.

The effects of single intracortical microstimuli on the firing probability of isolated forelimb motor units (MU) were investigated in monkeys generating isometric ramp-and-hold torque responses about the wrist. One objective was to determine whether the output effects elicited from a given cortical site were similar on all MUs of a muscle, or whether particular MUs were preferentially affected. Widespread effects would be expected if corticomotoneuronal (CM) cells terminate ubiquitously on all motoneurons of a pool, similar to Ia afferent fibers (1); selective effects would be consistent with the observation that CM-EPSPs were evoked from different cortical sites for different motoneurons of the same hindlimb muscle (2).

As previously described (3), effective output sites in precentral cortex were first identified by the appearance of post-stimulus facilitation (PStF) in stimulus-triggered averages of rectified multiunit EMG activity, recorded via electrode pairs in 5-6 identified synergist muscles. During active muscle contraction single intracortical microstimuli of 5-10 μa were subthreshold for evoking overt EMG responses; stimulus pulses were delivered slowly enough to preclude temporal summation (15/s). After identifying an effective output site, single MUs in the facilitated muscle(s) were recorded with tripolar tungsten microelectrodes, positioned in the muscle with a remotely controlled microdrive. Motor units were identified by the characteristic size and shape of their waveform in MU-triggered averages of multiunit EMG activity.

The majority of MUs identified as belonging to a particular muscle were individually facilitated from the same cortical site. Stimulus-triggered averages of rectified action potentials of single MUs showed briefer peaks than averages of multiple MUs. The post-stimulus time histogram of MU spikes exhibited peaks with half-widths in the range of .25-1.75ms, indicating that the variance in the latency of MU firing could not account for the duration of PStF of multiunit EMG. These results suggest that the cortical output effects evoked from single cortical sites may affect most, if not all, the motoneurons of a muscle.

181.12 INTRACORTICAL MICROSTIMULATION AND SINGLE NEURONE RECORDING DATA RELATED TO FACE, JAW AND TONGUE REPRESENTATIONS IN SENSORIMOTOR CORTEX OF MACACA FASCICULARIS. M. Sirisko* and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Toronto, Canada M5G 1G6.

Since little information is available of the organization in the cerebral cortex of face, jaw and tongue sensorimotor representations, the present study was designed to delineate the "excitable" cortex related to orofacial movements with the use of intracortical microstimulation and, in the same animals, to determine the presence of cortical neurones that receive cutaneous or muscle afferent inputs and/or project to the vicinity of the cranial nerve motor nuclei. The motor representation of the face jaw and tongue was determined in six unanaesthetized monkeys by examining the twitch movements and EMG responses evoked by microstimulation in a series of microelectrode tracks made 1 mm. or less apart in the sensorimotor cortex; intracortical sites were stimulated (<30 μA) every 250 μ or less over vertical depths of 3-5 mm. Each animal was then anaesthetized with barbiturate, and stimulating electrodes were placed on the facial skin, oral mucosa, and the temporalis (V), facial (VII) and hypoglossal (XII) muscle nerves to produce short-latency (4-20 msec) orthodromic activation of cortical neurones; corticobulbar neurones were identified by their antidromic response evoked from stimulating electrodes located in the V, VII or XII motor nuclei. Lesions were placed in selected cortical tracks, and histologica reconstruction of the tracks was subsequently carried out.

The motor representation in the precentral cortex was characterized as a central core of tongue (and sometimes jaw) movement surrounded on its anterior, medial and posterior sides by a horseshoe-shaped area that predominantly represented facial movements. Field potential and single neurone recording data indicated that antidromically identified corticobulbar neurones were largely confined to this "excitable" cortex. Some corticobulbar neurones could be activated by stimulation of low-threshold muscle afferents in V, VII or XII nerves, but the predominant focus of muscle afferent input occurred more posteriorly, in the depths of the central sulcus. This region especially involved area 3a, although some neurones further up the posterior bank of the sulcus also appeared to receive this input. Convergence of cutaneous and muscle afferent inputs was not uncommon, since about 25% of neurones excited by muscle afferent electrical stimulation and muscle stretching could also be activated by electrical or tactile stimulation of afferents supplying facial skin or oral mucosal sites. The present findings have provided fundamental information on input-output features related to orofacial movements that will be utilized in studies of these features in chronic recordings made from monkey cortex.

181.13 MOVEMENTS EVOKED BY INTRACORTICAL MICROSTIMULATION IN THE SUPPLEMENTARY MOTOR AREA (SMA). J. M. Macpherson, C. Marangoz*, T.S. Miles* and M. Wiesendanger (SPON: J.S.McIntosh). Institut de Physiologie, Univ. de Fribourg, CH-1700 Fribourg, Switzerland.

In this study, the supplementary motor area (SMA) in the mesial cortex of area 6 was investigated using intracortical microstimulation. Each of three monkeys (Macaca fascicularis) was implanted with a cylinder over the exposed SMA using standard techniques. Perpendicular electrode penetrations were made into the SMA on a 1 mm grid and stimulation (12 pulses at 300 Hz, 0.2 mm duration) was applied every 250 um to a depth of 10 mm. After completion of mapping, horseradish peroxidase (HRP) was injected into the spinal cord at cervical or lumbo-sacral levels.

Discrete movements of the contralateral forelimb and hindlimb were evoked by SMA stimulation at currents less than 30 uA. The thresholds were, however, higher than those in the hindlimb area of the primary motor cortex. Movements of the forelimb, at both proximal and distal joints, were evoked from a small patch of mesial cortex anterior to the precentral hindlimb and tail area. Some hindlimb responsive points were found in area 6 ventral and posterior to this forelimb region. No hindlimb representation was found in the dorsal bank of the cingulate sulcus ventral to area 4. Movements could not be evoked in muscles of the face and head.

HRP-filled cells were found in the SMA mesial cortex and the dorsal and ventral banks of the cingulate sulcus. The zone of labelled cells in the SMA corresponded very well to the microexcitable region. Following the lumbar injection, the area of filled cells in mesial area 6 was surprisingly large, extending well anterior to the end of the giant Betz cell zone.

In conclusion, the SMA is microexcitable, suggesting a relatively tight coupling between this cortical area and spinal motor nuclei. Proximal muscles and, to a lesser degree, distal muscles appear to be controlled by the SMA.

182.1 A NEURAL BASIS FOR AGE DEPENDENT RESISTANCE TO HERPES SIMPLEX VIRUS INFECTION. Robert R. McKendall* (Spon: J.R.Baringer). Dept. Neurology, University of California and VA Medical Center, San Francisco, CA 94121.

Following birth, mice develop increasing resistance to neurologic disease from herpes simplex virus type 1 (HSV-1). This resistance has been attributed to maturation of cellular immune mechanisms, particularly macrophage ability to restrict virus replication. Previous studies have shown that 7-week old mice require a higher dose of virus in the footpad to cause neurologic disease than 4-week old mice (McKendall, RR, J. Med. Virology 5:25-32, 1980). The dose of virus required correlated with the dose necessary to cause viral spread along sciatic nerve.

To determine whether neural factors or immunologic factors were involved, viral tissue titers and viral spread was studied following footpad inoculation of $10^{5.5}$ pfu HSV-1 in young (4-week) and old (22-week) Balb/c mice. Viral titers in footpad were the same in both groups and remained elevated for several days after infection. Appearance of virus in sciatic nerve and spinal cord was rapid (48 hours post infection) in young mice and delayed in old mice (day 5). This delay was confirmed using a very sensitive technique for virus recovery from spinal ganglia explants. Spinal ganglia explants from 12/12 (100%) young mice contained virus by 24-48 hours after infection, while none of 12 (0%) old mice were positive through 62 hours post infection ($P < 0.01$). Thus, virus spread along nerves to spinal ganglia and spinal cord was greatly delayed in 22-week old mice despite equivalent levels of virus present in footpad. The latter finding is incompatible with an immunologic basis of resistance and suggests that neural development after birth has a major impact on virus spread and neurovirulence.

182.2 ULTRASTRUCTURAL RECOVERY IN NON-MYELINATED NEURONS DAMAGED BY ENERGY DEPRIVATION. N.A. Dahl, J.K. Marling*, G.A. Looney*. Univ. of Kansas, Lawrence, KS 66045

The reversibility of ultrastructural changes seen in nerve axons following oxygen-glucose deprivation was examined. Rabbit vagus nerves were pulled into a multicompartment perfusion chamber, stimulated 5/sec and deprived of energy by substituting nitrogen and deoxyglucose for oxygen and glucose in the Locke's perfusate. At the end of two hours or four hours of insult, the chamber was reperfused with oxygen-glucose Locke's to allow two hours of recovery. At the end of the recovery period nerves were prepared for electron microscopy. Cross sectional areas were measured for 100 randomly selected C fiber axons per nerve. Control neurons had a mean area of .85 μm^2 (S.D. $\pm$ .47). As previously reported (Dahl, Looney, Black, The Physiologist, 22: 25, 1979), two hours of energy deprivation causes significant shrinking. When this insult is followed by two hours of control Locke's, there is structural recovery, with the size and physical appearance not significantly different from controls. All C fibers are contained within normal looking Schwann cells. Four hours of energy deprivation causes startling changes, both extreme shrinking and swelling, and it is the most shrunken axons that are interrupted by huge ballooned regions. When this disruption is followed by two hours of energy substrates, this trend is not significantly reversed and the distribution of the axonal cross sectional areas is still bimodal. The smallest axons have no microtubules but are packed with neurofilaments. The huge axons are also devoid of microtubules, but contain dispersed neurofilaments and flocculant material, and have disrupted membranes. Thus, it appears that the initial shrinking of axons seen after two hours of oxygen-glucose deprivation is reversible when followed by control conditions but the extreme shrinking and swelling seen at four hours is too disrupting to allow structural recovery. (Supported by Biomedial Sciences Support Grant #RR07037).

182.3 DYSTROPHY OF CEREBELLAR AXONS OCCURS IN THREE STRAINS OF MYELIN DEFICIENT MICE. Jeffrey Rosenfeld and Victor Friedrich, Jr. Lab. of Neuromorphology, Dept. of Biobehavioral Sciences, University of Connecticut, Storrs, CT 06268.

In addition to the widespread deficit of myelin, quaking and shiverer mice exhibit neuronal abnormalities in the cerebellum. We now report that jimpy, another myelin deficient mutant strain, exhibits pathological axonal and synaptic changes similar to those in quaking and shiverer.

In Golgi impregnations of jimpy mice, twelve Purkinje cells were found with the minimal criteria that the cell body and at least 40 μm of axon were impregnated. The axons of four of these cells exhibited smooth focal elongate swellings, from 1.5-4 μm in diameter and 2-6 μm long. In three cases the swellings occurred 35-40 μm distal to the cell body; in one instance multiple swellings were seen on several recurrent collaterals branching away from the primary axon.

The swellings are of varied fine structure. Some examples contain increased amounts of endoplasmic reticulum, distributed mainly as narrow flattened cisternae, and numerous membrane vesicles, some as small as synaptic vesicles. Microtubules and neurofilaments are present but disoriented in these swellings. Other examples of the swellings are largely depleted of endoplasmic reticulum, mitochondria, microtubules and neurofilaments and contain a prominent, coarsely flocculent ground substance. It is not clear at this time whether this heterogeneity in the fine structure of the axonal swellings reflects different stages of dystrophy, or the involvement of other neuron types.

Striking abnormalities occur in the Purkinje cell terminals in the cerebellar nuclei, including enlargement of the terminals, increased occurrence of large multivesicular bodies, membrane whorls and irregular endoplasmic reticulum. In addition to these dystrophic changes, some of the Purkinje cell synaptic terminals in jimpy mice contain unusual clusters of very tightly packed small vesicles. These clusters appear identical to those in quaking and shiverer (Brain Res. 192:209).

Focal axonal swellings and abnormal synaptic fine structure have now been demonstrated in three disparate myelin disorders. This coincidence suggests that the axonal and synaptic dystrophy are related directly or indirectly to dysmyelination.

182.5 ULTRASTRUCTURAL CYTOPATHOLOGY AND CYTOCHEMISTRY OF TRIMETHYLTIN NEURONAL TOXICITY. T.W. Bouldin*, N.D. Goines*, C.R. Bagnell* and M.R. Krigman. Dept. of Pathology, Univ. of North Carolina, Chapel Hill, North Carolina 27514.

The organotin compounds, trimethyltin (TMT) and triethyltin (TET) produce very different types of cellular injury. Whereas TET produces widespread intramyelinic edema in the CNS, TMT produces neuronal necrosis that preferentially involves the hippocampal formation and pyriform cortex. To define the ultrastructural basis and evolution of the cell injury that occurs in TMT neuronal toxicity, we acutely intoxicated adult rats with single daily doses of TMT (5 mg/kg). After perfusion-fixation, hippocampus and pyriform cortex were examined by electron microscopy. The first signs of cell injury, which occurred 24 hours after 2 daily doses, were multifocal collections of dense-cored vesicles and tubules and membrane-delimited vacuoles in the neuronal perikaryon and proximal dendrite. Ultrastructural cytochemistry revealed that the dense-cored vesicles and tubules had acid phosphatase (AcPase) activity analagous to GERL; the membrane-delimited vacuoles occasionally had thiamine pyrophosphatase activity analagous to the trans aspect of the Golgi complex. Many of the collections of GERL-like smooth membranes appeared to have no spatial relationship to the Golgi apparatus. By 24 hours after the appearance of dense-cored vesicles and tubules, numerous autophagic vacuoles and polymorphic dense bodies accumulated in the perikaryon. Some dense bodies appeared to arise directly from the dense-cored tubules. The dense bodies also demonstrated AcPase activity. Neuronal necrosis was frequently present 24 hours after 4 daily doses of TMT and was much more prevalent in granule cells of the fascia dentata than in pyramidal neurons of the cornu ammonis. Necrotic neurons had electron dense cytoplasm, usually numerous cytoplasmic dense bodies, and large, electron-dense intranuclear masses. A similar series of subcellular pathological changes was observed in chronically intoxicated adult rats (1 mg/kg/day for 14-16 days) and neonatal rats (1 mg/kg/alternate day from the 3rd to the 29th day of life). Early ultrastructural alterations were NOT found in neuronal mitochondria or other neuronal organelles.

The multifocal cytoplasmic accumulations of GERL-like smooth membranes that characterize the early neuronal injury in TMT toxicity are unique. The frequent association of autophagic vacuoles and dense bodies with the GERL-like membranes suggests that the initial hypertrophy of GERL-like membranes may be a reactive change in the neuron to the TMT-induced increase in autophagy and lysosome formation. (Supported by U.S.P.H.S. Grants ES02083 and ES01104).

182.6 REDUCED ACTIVITY OF METHIONINE ADENOSYLTRANSFERASE IN ERYTHROCYTES OF EARLY ONSET SCHIZOPHRENICS. J. R. Kelsoe, Jr.*, L. C. Tolbert, E. L. Crews* and J. R. Smythies. Neurosciences Program & Department of Psychiatry, University of Alabama in Birmingham, Birmingham, Al. 35294.

Abnormalities of methylation have been repeatedly implicated in schizophrenia particularly because of the exacerbation of symptoms associated with methionine loading in some schizophrenics. Methionine adenosyltransferase (MAT), because of its key role in methylation, has been studied in erythrocytes from schizophrenic patients with differing results. One group found no significant differences in the activity of this enzyme between erythrocytes from normals and schizophrenics using low methionine concentrations. However, another group did find a difference using higher methionine concentrations in the assay.

The present study examined kinetic parameters of MAT activity in erythrocytes from normal and schizophrenic patients (diagnosed by Feighner) using methionine concentrations from 0.6 to 100 μM in an effort to examine this discrepancy. The results demonstrate differences in the enzyme from schizophrenics compared with normals. Vmax was significantly decreased in the samples from the early onset schizophrenics (1.71 pmoles/mg protein/hour) as compared with controls (2.65 pmoles) ($p < 0.025$, Mann-Whitney U Test). A significant difference in Km between schizophrenics (2.94 μm) and controls (3.95 μm) was also observed ($p < 0.05$, Mann-Whitney U Test). There was a significant difference between the ages of the schizophrenic patients and controls but no significant correlation was obtained between age of the patient and MAT activity. No correlation was observed between the sex of the subject and MAT activity. Although all the schizophrenic patients were receiving medication, most commonly dopamine blockers of various types, the patients with the lowest Vmax values were receiving only lithium carbonate and reserpine, which suggests that neuroleptic therapy may not have a significant effect on MAT activity.

The lower Km, supportive of a higher affinity, and a lower Vmax enzyme in schizophrenics could explain the discrepancy in previous investigation. This study lends support to the hypothesis that decreased methylation may be an important component in some schizophrenic diseases.

182.7 SCANNING ELECTRON MICROSCOPIC STUDIES OF COVERSLIP IMPLANTS IN THE RAT CEREBRAL CORTEX. C.H. Phelps, J.R. Norris* and J.C. Pearson*. Department of Anatomy, Wright State University School of Medicine, Dayton, Ohio 45435.

To examine and compare the migration of various types of inflammatory cells into wounds in the brain and skin after injury, small pieces of plastic or glass coverslips ($3mm^2$) were implanted in the parietal cortex and under the skin of adult Sprague-Dawley rats. At selected time intervals from 1 to 10 days following implantation the coverslip fragments were removed, fixed in 2% glutaraldehyde, stained with either toluidine blue or Giemsa stain, and examined with the light microscope (LM). After classification and enumeration of cell types, typical cells were photographed and the coverslip fragments were then dehydrated in ethanol, critical point dried, coated with gold and examined with the scanning electron microscope (SEM). Using these procedures it was possible to confirm the identification of the cells seen with SEM by using the nuclear and cytoplasmic characteristics demonstrated with LM. Coverslip fragments removed during the first three days after implantation contained many monocytes and young macrophages, but very few polymorphonuclear cells in either the brain or skin wounds. With SEM the monocytes appeared to have few surface specializations except for a single central enlargement containing the cell nucleus. The young macrophages were larger and had many more surface irregularities including blebs and pits. The thinner margins of the cells exhibited lamellipodia and filopodia. By the fourth day many mature macrophages characterized by large surface pits were prominent and the formation of multinucleated giant cells by fusion of macrophages were noted in both skin and brain. In early stages of fusion adjacent macrophages contacted each other by numerous cell projections and the cells then appeared to gradually merge. With time more cells were added until polykaryons containing up to 100 nuclei were observed. These cells resembled "foreign-body-type" giant cells. Spindle shaped cells were occasionally observed in the brain implants but positive identification of these cells awaits further clarification.

182.8 STAINING OF ALZHEIMER'S NEUROFIBRILLARY TANGLES WITH ANTISERUM AGAINST THE 200,000 MOLECULAR WEIGHT COMPONENT OF NEUROFILAMENT. Y. Ihara*. (SPONS: A. Pope).

To clarify the nature of the paired helical filaments (PHF) which accumulate in selected neurons in senile dementia of the Alzheimer type (SDAT), we employed an immunocytochemical approach using an antiserum against the 200K component of neurofilaments and an antitubulin antiserum. Paraffin sections of hippocampus from a brain with SDAT were processed for immunocytochemical staining (PAP method). After staining with diaminobenzidine, sections were counterstained with hematoxylin. Neurofilaments were purified from rat spinal cords with a modification of the method of Schlaepfer and Freeman (1978). Antisera were raised against each gel purified component of the neurofilament triplet. Purified tubulin was obtained from in vitro reconstituted rat microtubules by phosphocellulose column chromatography. Antiserum raised against tubulin was further purified by affinity chromatography.

Alzheimer's neurofibrillary tangles were clearly and intensely stained with the anti-200K protein antiserum by the PAP method. Some neurons contained immunolabeled granules scattered in the perikaryon which may correspond to granulovacuolar degeneration. Clusters of small dark granules, presumably representing degenerating neurites, were also clearly visible in the periphery of senile plaques. No tangles and senile plaques were immunostained with normal rabbit serum or with anti-200K serum preabsorbed with purified neurofilaments.

With antitubulin antibody, dendrites of pyramidal cells were intensely stained and normal neuronal perikarya were diffusely and lightly stained, but tangles and senile plaques were not immunolabeled. These observations strongly suggest that PHF present in Alzheimer's disease originate from neurofilaments, not from microtubules. Staining with antisera against 68K or 160K protein is now underway in our laboratory.

182.9 ULTRASOUND INDUCED LOCALIZED HYPERTHERMIA IN THE CENTRAL NERVOUS SYSTEM: THERMAL DOSIMETRY AND DAMAGE THRESHOLD STUDIES. B.E. Lyons*, R.H. Britt and D.W. Pounds* (SPON: L.H. Ostrach). Div. Neurosurg. R155., Stanford Med. School, Stanford, CA 94305.

The application of ultrasound (US) for induction of localized hyperthermia in normal brain tissue was investigated. In 9 cats lesion size as generated by US was studied by correlating thermal dosimetry data with neuropathological findings. Proper system design for localized heating in the CNS is necessitated by the lethal effects of whole brain temperatures elevated above 42.2°C. Evaluation of ultrasonic energy in penetrated tissue as offset by thermal conduction and perfusion was examined to determine damage threshold levels in normal brain tissue.

In 9 pentobarbital anesthetized cats the overlying scalp and muscle tissue were retracted and a large craniotomy was performed to allow proper transducer alignment. Temperature within the US field was continuously monitored by multiple thermocouples embedded in 26 gauge needles (Bailey Instr.). Electrical energy was converted to US by a piezoelectric Lithium Niobate crystal transducer, operating at 2.060 MHz, driven by a function generator operating in the sinewave mode. The operating frequency was monitored by an electronic frequency counter. The transducer housing provided a water-path coupling ("cuff") of US energy between the crystal and the intact dura membrane. Transmission gel was used as a contact medium for US impedance matching. Tissues were irradiated at a distance of 0.4cm from the cortical surface-transducer interface. Incident power was varied as a function of treatment duration to achieve desired temperatures.

Although threshold values defining thermal properties in the cat's brain have not been obtained to date, the authors have histologically quantitated discrete spherical thermal lesions (0.5cm in diameter) in highly perfused normal gray matter when heated to 47.0°C for 2 hrs. The spatial uniformity of the thermal lesion correlates precisely with the temperature profile recorded during US treatment. These studies suggest that the irradiated field corresponding to the lesion size caused by the thermal effects of US at this source-target distance is directly dependent on the acoustical intensity as a function of tissue temperature and the duration of treatment.

The correlation of temperature gradients with cellular viability in the CNS of the cat demands an aggressive investigation evaluating the thermal response of tumor cells in the brain. The potential role of US hyperthermia as a treatment modality by itself or as an adjunct to conventional modalities for malignant intracranial neoplasms is currently being analyzed using experimental models. 182.10 CLINICAL SIGNIFICANCE OF CHANGES IN SUPPRESSOR T-CELL (S-CELL) FUNCTION IN CHRONIC PROGRESSIVE MULTIPLE SCLEROSIS (CPMS) DURING PLASMAPHERESIS (PP) AND IMMUNOSUPPRESSIVE DRUG THERAPY. B. Khairi*, S. Koethe*, K. Mezra*, and M. McQuillen. Depts. of Neurology and Pathology, Med. Coll. of Wis., Milwaukee, WI 53226.

Alterations in S-cell function in 24 consecutive patients with CPMS correlate with clinical improvement, as measured by a modified Kurtzke disability status scale (DSS) and functional systems scale (FSS) (Neurology 15:654, 1965), during weekly PP given in conjunction with cyclophosphamide (1-1.5 mg/kg/day) and prednisone (1 mg/kg/alternate day). The patients segregated into two groups, depending upon the degree of their clinical improvement. Group I (n=8) showed the greatest improvement (in DSS by >3 steps; on FSS by >6). Group II was subdivided according to the pattern of improvement -- Group IIA (n=4) showing steady improvement commencing with the first PP; and Group IIB (n=12) following a pattern of slight improvement during the first 5 PP, followed by a clinical "plateau" (accompanied by depression and increasing bladder problems), and then gradual but sustained improvement thereafter.

Concanavalin A (Con A; 10µg/ml) was used to induce S-cells, with their activity expressed in a mitogen response assay using Con A for further stimulation. The Mann-Whitney test for significance of non-parametric data was used to compare S-cell activity pre- and post-PP, and with 19 normal controls. Significance is at the $p<0.01$ level.

Patients with significantly low S-cell function pre-PP showed steady and sustained clinical improvement commencing with the first PP; the S-cell functional assay did not distinguish patients showing marked improvement (Group I) from those experiencing only modest clinical change (Group IIA). Patients with S-cell function indistinguishable from normal controls pre-PP (Group IIB) showed similar though modest improvement, but only after S-cell function dropped to significantly low values (generally after 5 PP). S-cell function in all patients approached normal values after their final PP.

182.11 THE EFFECTS OF INCREASING EXTRACELLULAR Ca^{++} CONCENTRATION UPON NEURONAL EXCITABILITY AND LONG-TERM POTENTIATION IN HIPPOCAMPAL SLICES FROM ALUMINUM ENCEPHALOPATHIC RABBITS. B.J. Farnell*, U. De Boni* and D.R. Crapper McLachlan, Dept. of Physiology, Univ. of Toronto, Toronto, Canada. M5S 1A8.

We previously reported a progressive decline in the CA1 population spike evoked in slices from rabbits with an aluminum induced encephalopathy (Soc. Neurosci. Abstr. #248.10 1980). This occurs in the absence of changes in the evoked population epsp and antidromic population spike and suggests an aluminum induced uncoupling between epsp input and spike output. The effects of increasing extracellular $[Ca^{++}]$ upon these phenomena are now reported. Four week old rabbits received either 5 µmoles aluminum lactate or 15 µmoles sodium lactate into each lateral ventricle. Slices were prepared from the dorsal hippocampus at 5, 10, 15 and 20 days post injection. A standard medium was used containing 2.4 mM $CaCl_2$. Using a perfusion chamber the total bath volume was exchanged in less than one minute with a medium containing 4.8 mM $CaCl_2$. Input - output curves relating stimulation strength, population epsp and population spike were analysed. Following a conditioning stimulus of 100 Hz. for 1 sec. to the stratum radiatum, long-term potentiation (LTP) was assessed in CA1. The criteria was an increase in the population spike of at least 25% above the baseline.

In contrast to control slices, after increasing the extracellular $[Ca^{++}]$ the magnitude of the evoked population spike is increased dramatically ($p < .001$) in slices from 15 and 20 day post aluminum animals in response to both apical and basilar inputs. This relationship remains when population spike amplitude is plotted against epsp amplitude, which isolates the epsp - spike coupling relationship from $[Ca^{++}]$ induced changes in the stimulation - population epsp relationship. The augmentation of orthodromic excitability is fully developed within 15 minutes after total bath exchange and is stable for at least 45 minutes. The effect is reversible. Elevated Ca^{++} increases both the percentage of slices developing LTP and the average magnitude of the potentiation ($p < .01$) in 10, 15 and 20 day post aluminum treated animals. The increase in $[Ca^{++}]$ must be present during and immediately following the tetanus in order to produce the LTP enhancement. This enhancement remains when the $[Ca^{++}]$ is returned to 2.4 mM in the 5 to 10 min post tetanus period. There appear to be at least two calcium dependant processes altered in the aluminum encephalopathy.

182.12 PATHOPHYSIOLOGY OF EXPERIMENTAL ARTERIAL STENOSIS. P.A. Grady and O.R. Blaumanis* Dept. of Neurology, University of Maryland Sch. of Med., Baltimore, MD 21201

Hydrodynamic theory and experiments with models of arterial stenoses have suggested that abnormal flow patterns may play a role in the pathogenesis of several vascular lesions such as mural thrombus, atherosclerosis, poststenotic dilation and aneurysm. We have examined the consequences of disturbed flow patterns in experimental animals (dog, cat and rabbit). Arterial stenoses were created in the aorta and common carotid, vertebral and renal arteries by partial ligation (40-90% area reduction). Blood vessels supplying the brain were of primary interest because of the high incidence of stenosis in these vessels and the effect on perfusion. Segments of arteries consisting of several centimeters proximal and distal to the stenosis were examined with the scanning electron microscope from one hour to one year after ligation.

A number of morphological changes were seen involving endothelial cells lining blood vessels. These changes extended from nuclear disruption of endothelial cells to restructuring of luminal surfaces of vessels. Short term effects included infiltration of monocytes followed by platelet and red blood cell thrombi. Long term effects included restructuring of endothelial surfaces.

Regardless of the degree or duration of the stenosis there was invariable disruption of the endothelium, platelet aggregation and in many instances mural thrombosis. The location of endothelial disruption and thrombosis found in this study corresponds to the predictions of hydrodynamic theory and the studies of flow patterns in glass models. The lesions did not heal with time and were not atherosclerotic in nature. These experimental results confirm the theoretical and model studies and suggest that even a mild arterial stenosis has a thrombogenic potential.

182.13 EFFECTS OF PENTOBARBITAL ON ION FLUX AFTER CEREBRAL MICROEMBOLISM IN THE RAT. J.P. Hansen* and W.J. Giardina. Department of Pharmacology, Abbott Laboratories, North Chicago, IL 60064

Cerebral ischemia can be induced by intra-arterial microsphere injections (Kogure, et al., Brain, 97:103-114, 1974; Siegel, et al., Arch. Neurol., 26:73-77, 1972). The protective effects of pentobarbital against cerebral ischemia in animals have been widely reported (Michenfelder, et al., Arch. Neurol., 33:345, 1976; Moseley, et al., Neurol., 25:870, 1975). To study the effects of pentobarbital on ischemia following microembolization, cerebral ischemia was produced in male, Sprague-Dawley rats, weighing 180-240 gms. The rats were anesthetized with sodium pentobarbital (40 mg/kg i.v.). The left external carotid artery was ligated. The left common carotid artery was cannulated rostrally with a 20 gauge cannula. Approximately 50,000 microspheres (3-M, 25±5 μ average diameter) suspended in normal saline (0.2 cc) were injected over 30 seconds. The cannula was removed and the artery ligated. Animals were sacrificed at 2 or 24 hours after injection of the microspheres to evaluate the effects of pentobarbital on early and late brain ischemia. The brains were removed, halved and wet weights were recorded. The brains were dried for 72 hours at 100 C. Dry weights were recorded. Dried brains were analyzed for sodium (Na) and potassium (K) content by flame photometry. Na, K and water content of microembolised (E) hemispheres was compared to that of nonembolised hemispheres.

In saline treated animals sacrificed at 2 and 24 hours, K content of E hemispheres was significantly decreased and Na and water contents of E hemispheres were significantly increased. In animals sacrificed at 24 hours, pentobarbital (40 mg/kg i.p.) (P) administered 30, 120 and 180 minutes after microembolization prevented significant changes in Na and K concentrations. P administered at 60 and 120 minutes also prevented significant changes in water content. In rats sacrificed at 2 hours, P administered at 45 minutes after microembolization did not prevent significant changes in Na concentration and water content of E hemispheres, but P prevented the significant decrease in K concentration of E hemispheres. Compared with saline treated rats K content was significantly increased in both hemispheres.

The K ion changes observed 2 hours after microembolization reflect cytotoxic events in the brain resulting from ischemia. The mechanism for increase in cellular K may be a stabilizing effect of pentobarbital on cell membranes (Astrup, et al., Acta Neurol. Scand. 64:148, 1977).

182.14 ANALYSIS OF THE E-C COUPLING: GENOTYPE RELATIONSHIP IN MOSAIC (MUSCULAR DYSGENIC, mdg ↔ NORMAL, +) MYOTUBES. Alan Peterson[1], David Cross[1]*, Rohan Bhup[2]*, and Sergio Pena[2]*. [1]Neuroscience Unit, Montreal General Hospital and [2]Montreal Neurological Institute, McGill University, Montreal, P.Q. Canada.

Mice affected by the recessive muscular dysgenesis, mdg mutant express a dramatic failure of in vivo myogenesis with skeletal muscle typically achieving only an abnormal and immature myotube stage by birth (Cluecksohn-Waelsch, S., Sci. 142:1269-1276, 1973). Newborns demonstrate no spontaneous movements and die presumably of respiratory failure. In vitro, mdg/mdg myoblasts proliferate well and form extensive myotubular plexes. However, these myotubes do not contract to ACh stimulation and a failure in normal excitation-contraction coupling mechanisms has been proposed (Powell, J. and Fambrough, D., J. Cell Physiol. 82:21-38, 1973). The contractile response and genotype of mosaic myotubes containing +/+ and mdg/mdg myonuclei was investigated to determine: (1) if such myotubes would contract either spontaneously or in response to ACh; and (2) if contraction was expressed, what proportion of +/+ myonuclei would be required.

Potentially, mosaic myotubes were derived by simultaneously plating +/+ and mdg/mdg myoblasts in the same culture plates with the expectation that both would enter common myotubes during in vitro maturation. In addition to their +−,mdg difference these myoblasts differed also in an inherited electrophoretic variant of the enzyme glucosephosphate isomerase (GPI). After assessing the spontaneous or evoked contractile phenotype of individual myotubes, they were dissected from the culture plate and the ratio of GPI types expressed in each was determined by microelectrophoretic techniques (Peterson, A., Frair, P. and Wong, G., Biochem. Genet. 16:681-690, 1978) to provide an estimate of +/+ and mdg/mdg myonuclear proportions.

Mosaic mdg/mdg ↔ +/+ myotubes do form in vitro. They contract spontaneously or in response to ACh and the apparent proportion of +/+ myonuclei necessary to confer this in vitro activity is approximately 1%. This result limits the number of theoretically possible defects underlying the mdg disease and further, demonstrates a strategy of genotype assessment applicable to mosaic myotubes derived from a wide range of species. (Supported by MDAC).

183.1 A NEUROPHARMACOLOGICAL EXAMINATION OF THE EFFECTS OF NOREPINEPHRINE ON HYPOTHALAMIC NEURONS. W.-H. Tsai, F. C. Barone, M. J. Wayner and R. Guevara-Aguilar. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210 and Depto de Fisiologia, Facultad de Medicine, U.N.A.M., Mexico.

Seven barrel electrodes were utilized to record simultaneously from and apply chemicals to single neurons located in the lateral hypothalamus (LH) of urethane anesthesized rats. The center barrel, used for electrical recording, and one of the outer barrels, used for current balancing, were filled with 2 M NaCl. Two other outer barrels were filled 0.5 M L-Norepinephrine bitartrate and 2 M L-Glutamic acid. The other three barrels were filled with 0.01 M Yohimbine HCl, 0.01 M Propranolol, 0.05 M Sotalol HCl or 0.05 M L-Phenylephrine HCl. When a stable baseline discharge frequency was established for single LH neurons, chemicals were administered microiontophoretically. Appropriate control procedures were utilized to eliminate current and pH effects and dose effect relations were determined. In addition, various regions known to contain noradrenergic neurons which project to the LH such as the nucleus of the solitary tract, locus coeruleus, and the medial mesencephalic reticular formation (Barone et al., Brain Res. Bull. 7, in press; Takagi et al., Brain Res. 193: 315-338, 1980) were stimulated with small concentric bipolar electrodes, 0-500 μA of 0.5 msec single pulses, in conjunction with neuropharmacological testing. As described previously (Barone et al., Brain Res. Bull. 5: 325-332, 1980), the microiontophoretic ejection of glutamate increases neuronal discharge frequency while norepinephrine usually decreases it in this part of the brain. All other chemicals tested significantly decreased the discharge frequency of LH neurons. Yohimbine was the most effective and decreased neuronal firing at the lowest ejection currents. In some cases, if antagonists were applied for long periods (1-4 min) using low ejection currents, the blocking effects of these substances could be demonstrated. Under these conditions phentolamine and sotalol were able to attenuate norepinephrine induced decreases in neural activity. Results indicate that the effects of norepinephrine on LH neurons are probably mediated by α and β postsynaptic receptors which receive noradrenergic inputs from brain stem structures. However, since neurons were most sensitive to yohimbine, presynaptic noradrenergic mechanisms might also be significant. (Supported by NIH Grant NINCDS USPHS No. 13543.)

183.2 NORADRENERGIC SYSTEM IN CULTURE: AN ELECTROPHYSIOLOGICAL STUDY. R.Y.K.PUN, K.C.MARSHALL†, S.FITZGERALD*, P.B.GUTHRIE, P.G.NELSON. Lab. Devel. Neurobiol., NICHD, NIH, Bethesda, MD 20205; † Dept. of Physiol., Univ. of Ottawa, Ottawa, Ontario, K1N 9A9, Canada

We previously reported the development of an in-vitro system in which dissociated mouse spinal cord cells were co-cultured with locus coeruleus (LC) region of the brain stem (Marshall et al., Canada Physiol., 11: 103, 1980). Noradrenaline (NA) was suggested to mediate the slow depolarising responses evoked by the stimulation of the explant. We present evidence here to further support this hypothesis. Our data further suggest that the frequency of occurence of the depolarising responses is enhanced by the innervation by the LC neurones.

The depolarising responses evoked by stimulation of the explant and by exogenously applied NA were accompanied by a small increase (<20%) or no change in input resistance of the membrane. The membrane time constant, determined with hyperpolarising pulses, was increased at the peak of the evoked responses.

Both the neurally evoked response and the response to NA were antagonised by the α-adrenoceptor antagonists piperoxan (7 cells, 5 and 50 μM), phentolamine (2 cells, 1 μM) and phenoxybenzamine (3 cells, 1 μM). However, the antagonism of the latter compounds was more rapid and effective for the response to NA than for the neurally evoked response. The β-adrenoceptor antagonist propranolol did not antagonise the responses at the concentration tested (4 cells, 2.5 μM).

Neurones responding to the stimulation of the explant showed a high incidence of depolarising response to applied NA (69%). In contrast, spinal cord neurones not innervated by LC neurones had a very low incidence of depolarising response to applied NA (14% in cultures without explant, 11% in cultures with explants but in cells not responding to stimulation of the explant). It remains to be determined whether the presence of noradrenergic terminals 1) induces an increase in sensitivity of spinal neurones to NA or 2) promotes the survival of spinal neurones that are sensitive to NA.

183.3 ACTIVATION OF LOCUS COERULEUS NEURONS IN CLONIDINE WITHDRAWAL DUE TO REDUCED RESPONSIVENESS OF α_2-RECEPTORS. T.H. Svensson, G. Engberg* and M. Elam*. Dept of Pharmacology, University of Göteborg, S-400 33 Göteborg, Sweden.

Sudden withdrawal of chronic treatment with the centrally active, antihypertensive α_2-adrenoceptor agonist clonidine has been associated with a rebound syndrome, including a hypertensive reaction, tachycardia and mental symptoms such as anxiety, restlessness and insomnia. It is also accompanied by increased peripheral catecholamine (CA) secretion.

Recent evidence indicates increased sensitivity of centrally located postsynaptic adrenergic receptors in clonidine withdrawal presumably due to functional denervation, since clonidine causes inhibition of central noradrenergic neuronal activity (Svensson et al., Brain Res. 92, 291, 1975). We have also shown biochemical evidence for increased activity in central noradrenaline (NA) pathways in the withdrawal phase (Svensson & Strömbom, Naunyn-Schmiedeberg's Arch. Pharmacol. 299, 83, 1977). Here we have used single cell recording techniques and microiontophoresis to characterize the function of brain NA neurons in locus coeruleus (LC) of rats after discontinuation of a chronic clonidine regimen (100-200 μg/kg/day for 14 days).

During treatment the average firing rate of LC neurons remained significantly reduced, whereas after withdrawal of the drug it was largely increased above base-line (maximum 60 per cent, 25--35 h after discontinuation). In withdrawal phase, the LC neurons showed a significantly reduced responsiveness to the inhibitory effect of systemically or microiontophoretically applied clonidine, as reflected in the larger charge (C_{50}) required to obtain a 50 per cent decrease in the rate of spontaneous firing. In contrast, the inhibitory response of the LC neurons to morphine in analogous experiments was unchanged.

The degree of reduced responsiveness of the neurons to the α_2--receptor agonist was directly correlated to their degree of activation above base-line. Thus, the LC activation in clonidine withdrawal is related to, and probably caused by, the specifically reduced responsiveness of the α_2-receptors on these cells, which seem to mediate the inhibitory influence on the LC of noradrenergic axon collaterals.

Since electrical stimulation of LC has been found associated with restlessness and increased blood pressure, the activation of central NA neurons such as those in the LC may in clonidine withdrawal, analogously to the situation in morphine abstinence, be important for the mediation of the withdrawal syndrome. (Supported by the Swedish Medical Research Council, project no. 4747).

183.4 RELATIVE POTENCIES OF ANTAGONISTS AT α_2-ADRENOCEPTORS OF THE LOCUS COERULEUS AND α_1-ADRENOCEPTORS OF THE LATERAL GENICULATE NUCLEUS. Jwaharlal Marwaha and George K. Aghajanian, Depts. of Psychiat. and Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508.

Previous studies (Cedarbaum and Aghajanian, Brain Res., 112, 413, 1976 and Rogawski and Aghajanian, Brain Res., 182, 345, 1980) have shown that the adrenoceptors of the locus coeruleus (LC) are of the α_2-type and those of the dorsal lateral geniculate (dLGN) of the α_1-type. In vitro studies in the periphery (Starke and Docherty, J. Cardiovas. Pharmacol., 2, S269, 1980) show the following order of potency for antagonists at α_1-adrenoceptors: prazosin ≥ WB-4101 > corynanthine >> piperoxane >>> yohimbine > rauwolscine; the reverse order applies to α_2-adrenoceptors. In the present study, the potencies of the above antagonists to reverse the inhibitory effects of the α_2-agonist, clonidine (i.v. and iontophoretic) in the LC or the activation of dLGN neurons by iontophoretic application of the α_1-agonist, phenylephrine were examined by single-cell recording in chloral hydrate anesthetized rats.

Clonidine (20 μg/kg, i.v.) totally suppressed LC neuronal firing for at least 20 minutes. Antagonists administered intravenously 3 minutes after clonidine inhibition of LC firing restored neuronal firing with the following order of potency: rauwolscine = yohimbine > piperoxane >>> WB-4101 ≥ corynanthine = prazosin. Rauwolscine, yohimbine, and piperoxane were able to completely reverse the effect of clonidine, but WB-4101, corynanthine and prazosin were often inactive at cumulative doses of up to 3-4 mg/kg. Similar results were obtained when clonidine was administered iontophoretically.

Phenylephrine applied iontophoretically to dLGN neurons produced a brisk activation of firing which could be maintained without attenuation for 15-20 minutes. Alpha-antagonists reversed this activation in the following order: prazosin = corynanthine = WB-4101 >> piperoxane = yohimbine = rauwolscine. The ED_{50} for WB-4101 was 20 μg/kg while that for piperoxane and yohimbine 300 μg/kg and 350 μg/kg respectively. ED_{50} values for piperoxane and yohimbine in the LC were 600 μg/kg and 350 μg/kg respectively.

Our results suggest that the order but not the magnitude of potencies for α-antagonists observed in vitro in the periphery is largely valid for the adrenoceptors of the LC and dLGN. The above antagonists of α_1-receptors are highly selective in that they have very weak activity at α_2-receptors. In contrast, piperoxane and yohimbine which have hitherto been considered selective α_2-antagonists block α_1-receptors at a similar dose as that required to block α_2-receptors.

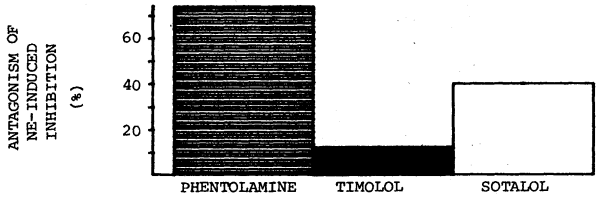
183.5 NORADRENERGIC RESPONSES IN RAT HIPPOCAMPUS: EVIDENCE FOR THE PARTICIPATION OF α AND β COMPONENTS IN VIVO. Alan L. Mueller*, Michael R. Palmer, Barry J. Hoffer*, and Thomas V. Dunwiddie. Dept. of Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262.

Utilizing the in vitro rat hippocampal slice preparation, we have previously demonstrated that noradrenergic responses can be pharmacologically separated into distinct α- and β-receptor-mediated components (Mueller, Hoffer and Dunwiddie, Soc. for Neurosci. Abstracts 6: 607, 1980; Mueller, Hoffer and Dunwiddie, Brain Research, in press). Activation of α-receptors and β-receptors leads to a decrease and an increase, respectively, in hippocampal pyramidal neuron population spike size. In this study, the effect of locally applied norepinephrine (NE) on single action potentials of identified pyramidal (P) cells in region CA1 of the in vivo rat hippocampus was examined. Pressure ejection of NE from one barrel of a multibarreled pipette generally produced depressions of P cell single unit activity. These NE-induced inhibitions were effectively antagonized by the concurrent pressure ejection of the α-receptor antagonist phentolamine. In contrast, the β-receptor antagonist timolol was without effect. Another β-receptor antagonist, sotalol, was found to occasionally elicit a partial but inconsistent antagonism of the NE-induced inhibition. In approximately 25% of the cases, micropressure ejection of NE resulted in an increase in P cell single unit discharge. These NE-induced excitations were effectively antagonized by timolol and sotalol and were largely unaffected by phentolamine. Finally, local application of the β-receptor agonist isoproterenol and the α-receptor agonist clonidine, by micropressure ejection, usually resulted in increases and decreases, respectively, in P cell activity. Taken together, these results provide additional support for the hypothesis that exogenous NE is able to interact with both α- and β-adrenergic receptors to decrease and increase, respectively, pyramidal cell excitability. (This work was supported by DA-02702 to T.V.D.)



183.6 METHYLXANTHINE EFFECTS ON NE NEURONAL ACTVITY ASSOCIATED WITH THE QUASI-MORPHINE WITHDRAWAL SYNDROME. S.J. GRANT, D.E. REDMOND, Jr. Dept. of Psychiatry, Yale School of Medicine, New Haven, CT 06510.

The reversal by clonidine of increases in noradrenergic (NE) neuronal function and of the clinical manifestations of the opiate withdrawal syndrome have been demonstrated. These studies were undertaken because of the observation that increased NE function in monkeys was similar to opiate withdrawal. Since certain non-opiate compounds, primarily methylxanthines, precipitate withdrawal-like syndromes which are potentiated by naloxone and blocked by opiates, it has been suggested that a common mechanism underlies true morphine withdrawal and the "quasi-morphine withdrawal syndrome" (QMWS) produced by methylxanthines. The present study was designed to test whether brain NE systems may, in fact, represent such a common mediator. If so, methylxanthines should increase noradrenergic function, as is observed during opiate withdrawal, and clonidine should reverse such an increase. In addition, the behavioral signs associated with the QMWS should be attenuated by the alpha-2 adrenergic agonist clonidine.

Single unit activity was recorded from the principal brain NE nucleus, the locus coeruleus (LC) using conventional extracellular recording techniques in chloral hydrate anesthetized rats. Isobutylmethylxanthine (IBMX) (1-10 mg/kg I.V.) markedly increased unit activity in the locus coeruleus. Clonidine (5-15 microgram/kg I.V.) restored unit activity to baseline or below. Clonidine also reduced the behavioral effects of IBMX in a pilot behavioral study. The QMWS was precipitated in drug naive rats by a combination of IBMX (10-15 mg/kg I.P.) and naloxone (1 mg/kg I.P.). The subjects were pretreated with either clonidine (50 microgram/kg I.P.) or saline. Seventeen withdrawal symptoms were rated by one or two observers blind to the drug treatment. Clonidine pre-treated rats exhibited significantly less diarrhea, ptosis, salivation, rhinorrhea, lacrimation, jumping, rearing, wet dog shakes, grooming and restlessness compared with saline treated animals. However, squeaking on touch was increased after clonidine pre-treatment.

These results are consistent with the hypothesis that brain noradrenergic neurons may mediate the QMWS induced by methylxanthines, as well as some aspects of true opiate withdrawal. This possibility is supported by other biochemical evidence of interactions of methylxanthines with NE function based on changes in cyclic adenosine monophosphate or on effects at adenosine receptors, both of which may alter NE function.

183.7 ACTIVATION OF LATERAL GENICULATE NEURONS BY NORADRENERGIC PATHWAY STIMULATION: SELECTIVE BLOCKADE BY THE α_1-ADRENOCEPTOR ANTAGONIST PRAZOSIN. Michael A. Rogawski and George K. Aghajanian. Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

Previously we reported that electrical stimulation in the region of the locus coeruleus (LC) facilitates the firing of single dorsal lateral geniculate nucleus (LGN) neurons (Nature 287: 731-734, 1980). Iontophoretic norepinephrine (NE) mimics this effect (Brain Res. 182: 345-359, 1980) and both the responses to stimulation and to locally applied NE are blocked by the α_1-antagonist WB-4101. These observations suggested that LC stimulation activates LGN neurons via the release of NE from coeruleo-geniculate fibers, although inadvertant activation of other pathways could account for the data as well. There are two extraretinal brainstem inputs to the LGN in addition to the LC projection: (1) a serotonergic pathway from the raphe nuclei and (2) a cholinergic pathway from the dorsal midbrain tegmentum (Hoover and Jacobowitz, Brain Res. 170: 113-122, 1979). Serotonin suppresses the activity of LGN neurons whereas acetylcholine (ACh) and the non-hydrolyzable cholinergic agonist carbachol (CCh) are facilitatory. The present study provides evidence against the participation of ACh in the effects of LC stimulation.

Extracellular recordings were carried out in the LGN of rats lightly anesthetized with chloral hydrate. Pulse trains (1 ms, 10 Hz, 0.3-0.8 mA) applied in the vicinity of the LC produced a marked acceleration in the spontaneous firing of LGN neurons; activations were unassociated with the individual stimuli and often were delayed in onset and persistent beyond the termination of the train. Similar effects were obtained with stimulation of the LC axons in the dorsal NE bundle (DB) except that lower currents were effective (0.1-0.3 mA). Intravenous or iontophoretic WB-4101 antagonized the effects of LC stimulation. However, WB-4101 also diminished the response to iontophoretic ACh indicating that it had cholinergic blocking activity and would not discriminate between a NE and ACh pathway. The antihypertensive α_1-antagonist prazosin selectively blocks NE but not CCh in the LGN (Menkes, Baraban & Aghajanian, submitted). In contrast to WB-4101, prazosin (120 μg/kg, i.v.) blocked the response to LC or DB stimulation (up to 30 min) without affecting responses to iontophoretic CCh. In addition to confirming that LC stimulation activates LGN neurons via a NE pathway, these experiments demonstrate that systemically administered prazosin can influence central α-adrenergic transmission in clinically relevant doses.

183.8 EFFECT OF YOHIMBINE ON RAT SERUM PROLACTIN LEVELS, H. Y. Meltzer*, M. Simonovic and R. So. Department of Psychiatry, University of Chicago Pritzker School of Medicine, Chicago, IL. 60637.

Pharmacologic and binding studies have established that yohimbine (Y), a naturally occuring alkaloid, is a selective antagonist of adrenergic alpha$_2$ receptors. In addition, Y has been reported to increase dopamine (DA) turnover in the brain suggesting that it may also be a DA receptor blocker. At least two types of DA receptors are believed to exist in the brain: D_1 which is coupled with adenylate cyclase and D_2 which is not linked to adenylate cyclase. It has recently been proposed that Y blocks D_2 receptors (Scatton et al., J.Pharmacol. Exp. Ther. 215:494,1980).

Rat prolactin (PRL) secretion is under tonic dopaminergic inhibitory control. Thus, blockade of pituitary DA receptors results in a prompt rise in circulating PRL levels. The DA receptors involved in the regulation of PRL secretion are believed to be of the D_2 type. In order to test the postulated ability of Y to block D_2 receptors, we have examined its effect on rat PRL secretion and its ability to displace ^{3}H-spiroperidol from bovine anterior pituitary membrane preparations. The ability of neuroleptic drugs to stimulate rat PRL secretion in vivo is correlated with these ability to displace ^{3}H-spiroperidol from rat pituitary. Y(1, 5 or 10 mg/kg,ip) was administered to male rats 30 min before decapitation. The two higher doses produced marked increases in serum PRL levels. The rise in serum PRL levels due to Y (5 mg/kg,ip) lasted for more than two hours, and was completely blocked by apomorphine (3 mg/kg,sc). The ability of Y to stimulate rat PRL secretion is not due to its alpha$_2$ antagonist properties since another selective alpha$_2$ antagonist, piperoxane (1 10 or 20 mg/kg) had no effect on serum PRL levels. Clonidine (0.1 mg/kg,ip), which can effectively antagonize the presynaptic effects of Y, had no effect on Y-induced increase in serum PRL levels. Thus, stimulation of PRL secretion by Y is not due to the blockade of presynaptic alpha$_2$ receptors. Y does not effectively compete with ^{3}H-spiroperidol for binding sites on membrane preparations from anterior pituitary membranes. This could mean that Y exerts its effect on PRL secretion by binding to a separate population of DA receptors on pituitary lactotrophs not labeled by ^{3}H-spiroperidol. It is also possible that Y stimulates PRL secretion through a non-dopaminergic mechanism. This research was supported by USPHS MH 30,938 and MH 29,206.

183.9 EVIDENCE FOR A NEW TYPE OF ALPHA-ADRENERGIC RECEPTOR IN THE CEREBRAL (PIAL) MICROCIRCULATION. S. Lassoff* and B.M. Altura. Dept. of Physiol., SUNY Downstate Med. Ctr., Brooklyn, NY 11203.

Recent biochemical studies on isolated brain preparations suggest the presence on cerebral microvessels of binding sites for alpha-and beta-adrenergic stimulants. However, no quantitative in vivo functional studies exist. With this in mind, we undertook quantitative in situ studies on pial terminal arterioles (PTA) in the anesthetized rat in order to determine the structure-activity relationships (SAR) of alpha-adrenergic stimuli. Animals of both sexes, weighing 150-350g, were subjected to craniotomy and removal of the dural membrane. High-resolution closed-circuit television microscopy (at magnifications up to 3000x) allowed measurement of pial vessel diameter down to 0.02 μm. The animals remained normocapnic (PCO_2 = 29-34 mm Hg) and normotensive (systolic average pressure = 115-120 mm Hg) throughout testing. Neither epinepherine (E), α-methylnorepinepherine, nor isoproterenol (up to 10^{-1} mg), when applied perivascularly, elicited any constrictor or dilator responses in PTA, either in the absence or presence of phentolamine (PH) and propranolol (PR). Phenylephrine (PE), however, produced potent concentration-dependent constriction of PTA (7-30%, 10^{-8}-10^{-2} mg) while norepinephrine (NE) and dopamine (D) elicited equi-potent constrictions (5-20%, 10^{-6} to 10^{-1} mg); these were less potent then those elicited by PE. PH (5-10 pg), but not PR, shifted the concentration-response curves for PE, NE, and D rightward in a parallel manner. Intracarotid infusion of all adrenergic agents (10^{-8} mg to 10^{-1} mg) produced no significant change in PTA size. Although α-adrenergic receptors exist in PTA, the SAR (i.e., where PE $>$ NE $\cong$ D $\gg$ E) is atypical of that found in other microvasculatures and on peripheral arteries and veins. (Supported in part by PHS Grants HL-18015, DA-02339 and T32 NS 07117-02).

183.10 (Na^+,K^+)-ATPase, OUABAIN BINDING, AND NORADRENERGIC ACTIVITY. A.C. Swann, S.E. Hattox, S.J. Grant, J.W. Maas. Dept. of Psychiatry, Univ. of Texas Med. Sch., Houston, TX 77025, and Yale Univ. Sch. Med., New Haven, CT 06510.

The molecular mechanism of the hyperpolarization produced by norepinephrine (NE)$_+$ has not been established. NE has been shown to stimulate (Na^+,K^+)-Adenosine triphosphatase (ATPase) in vitro; this is consistent with neurophysiologic effects of NE, but may result from nonspecific properties of NE rather than receptor binding. We have shown, however, that acute NE stimulation in vivo increases ATPase activity (Life Sci 28, 251). If ATPase mediates any NE effects, its adaptation to chronic or repeated changes in NE activity may be important in NE regulation. The experiments reported here examine 1) the effects of acute NE stimulation and inhibition on ATPase activity and on NE impulse flow as indicated by the NE metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) and 2) the effects of long term NE changes, produced by denervation, hyperinnervation, and repeated stimulation, on ATPase activity and on the binding of ouabain to the cardiac glycoside receptor associated with ATPase.

Acute NE inhibition by clonidine (50 μg/kg) or debrisoquin (10 mg/kg) decreased ATPase activity. NE stimulation with piperoxane (5 mg/kg) increased enzyme activity. Cerebral cortex MHPG and ATPase activity were strongly correlated ($r=0.85$; $P<.005$).

Denervation and hyperinnervation were examined by comparing ipsilateral and contralateral cerebral cortex and cerebellum, respectively, after unilateral 6-hydroxydopamine lesions of the dorsal NE bundle. Denervation decreased, and hyperinnervation increased, ATPase activity and ouabain binding. Daily injections of piperoxane also increased ATPase activity and ouabain binding 24 hours after the last dose.

Inhibition by Erythrosin B (Silbergeld, Neuropharmacol. 20,87) showed that the effects of denervation and hyperinnervation were accounted for entirely by changes in the nerve-specific form of ATPase (Sweadner, J. Biol. Chem. 254, 6060).

These results demonstrate parallel changes in NE impulse flow and ATPase activity. Chronic NE changes produced persistent effects on the binding of ouabain to its receptor associated with brain ATPase. The ouabain receptor has been shown to have endogenous ligands (Lichtstein and Samuelov, Biochem. Biophys. Res. Commun. 96, 1518; Gruber et al., Nature 287, 743). Changes in this receptor may be involved in long term NE effects.

183.11 TRANSMITTER ACTIVATION OF REGIONAL BRAIN ATPases E.Undesser and D.H.Ross Division of Molecular Pharmacology Univ. Texas Health Sci. Center, San Antonio, TX 78284

Membrane ATPases regulate ionic flow in excitable cells. Recently Na-K ATPase has been shown to be stimulated by various putative neurotransmitters including norepinephrine (NE) and dopamine (DM). These transmitter activated ATPases have been suggested to play a role in transmitter release although a mechanism is not yet established. Sincetransmitters regulating ion flux may alter the release of other transmitters or neurohormones, we have investigated the interaction of two transmitters NE and DM with two membrane ATPases, Na-K, and Ca-Mg ATPase in different regions of rat brain. Regional brain tissue was prepared from male Sprague-Dawley rats(100-150gm) and crude P_2 fractions isolated by conventional techniques. P_2 fractions were lysed with TRIS-DTE buffer washed twice and resuspended to protein concentrations of 1mg/ml. ATPase activity was measured colorimetrically. Ca concentrations were regulated by EGTA buffers to 5 uM. Mg and ATP were added to final concentration of 250 uM in a HEPES buffer pH 7.4. Reactions containing 100 ug of membrane protein were started by addition of ATP and terminated 5 min later with TCA. NE (10^{-4}) had no effect on Mg ATPase. NE stimulated Na-K ATPase in the hippocampus, cerebellum, and brainstem ($P<.05$) but had no significant effect on Ca-Mg ATPase. DM showed no effects on Na-K ATPase but significantlly stimulated Ca ATPase in the cortex, striatum and hypoththalamus. These studies suggest that neurotrans mitters may differentially regulate the flow of ions in different brain regions. The ability to regulate calcium flux presynaptically may provide a mechanism for transmitters to regulate their own release as well as that of other neuromodulators.

183.12 EVIDENCE FOR A ROLE FOR CATECHOLAMINES IN THE HEMISPHERIC CHANGES IN THE ACTIVITY OF A BRAIN ENZYME FOLLOWING A LOCAL CORTICAL INJURY. W.G. Dail, M.G. Boyeson, D.M. Feeney and H.M. Murray. Departments of Anatomy and Psychology, University of New Mexico School of Medicine, Albuquerque, NM 87131.

We have previously reported that a focal injury to the cortex of the rat results in a widespread depression or loss in histochemical staining for the enzyme alpha glycerophosphate dehydrogenase (α-GPDH) in the ipsilateral hemisphere (Dail et al., Brain Res. 211: 79, 1981). Reduction of enzyme staining, which was most evident in cortical layers II and III throughout the hemisphere, appeared as early as 36 hours after focal cortical ablation, laceration or contusion injuries. The staining pattern returned to normal by 9 days. We have investigated a possible role for catecholamines in the loss of enzyme staining since (1) amphetamine has been shown to speed behavioral recovery in injured animals (Feeney et al., Neurosci. Absts. 6: 802, 1980) and (2) small infarcts in the cortex lead to widespread reductions in brain catecholamine levels (Robinson et al., Nature 255: 332, 1979). In the present study, a single injection of d-amphetamine (2mg/kg i.p.) prevented the loss of enzyme staining which is normally seen at 4 days after an undercut laceration of the cortex. Moreover, d-amphetamine was effective only when administered 24 hours following the laceration and not when given at 18, 30, 36 and 72 hours post injury. This latter observation suggests that once the metabolic alterations are set in motion throughout the hemisphere, amphetamine cannot reverse the process. To determine if the staining pattern of the lesioned cortex would be changed in the catecholamine depleted brain, rats were studied following a unilateral radiofrequency lesion of the locus ceruleus (LC). A lesion of the locus ceruleus alone had no affect on α-GPDH staining, however, when a lesion of the locus ceruleus was followed in two weeks with a focal cortical injury, the well-defined loss of enzyme staining occurred at 12 hours, much earlier than with motor cortex injury alone. This result indicates that depletion of noradrenergic innervation to the cortex shortens the time to onset of the metabolic disturbance. The mechanisms underlying the effects of amphetamine and LC lesions on α-GPDH activity are currently not understood, although catecholamines, in particular norepinephrine, have been implicated in disturbances of oxidative metabolism (LaManna et al., Brain Res. 204: 87, 1981). Our pharmacological and LC lesion alterations of enzyme staining after cortical injury suggest an important role for noradrenergic systems in the cortical response to trauma. (Supported by NIH #NS-13684-03.)

184.1 NEUROTENSIN SELECTIVELY ACTIVATES DOPAMINERGIC NEURONS OF THE SUBSTANTIA NIGRA. Rodrigo Andrade and George K. Aghajanian. Depts. of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

Neurotensin is a tridecapeptide originally isolated from bovine hypothalami by Caraway and Leeman (1). Subsequent studies have shown it to be located in nerve cell bodies and terminals (3). Neurotensin is released by K+ depolarization through a Ca^{2}+ dependent mechanism (2) and has an heterogeneous distribution in the mammalian CNS (3). In the midbrain the highest density of neurotensin receptors is present in the zona compacta of the substantia nigra (4). By immunohistochemistry, neurotensin-like immunoreactivity has been detected over the zona compacta but not over the zona reticulata (3). In the present study we have examined by single-cell recording and microiontophoresis the effects of neurotensin on dopaminergic and non-dopaminergic neurons in substantia nigra and compared its effects to that of substance P, an undecapeptide present in high concentrations in the substantia nigra.

Sprague-Dawley rats anesthetized with chloral hydrate were used in these experiments. Extracellular single-unit recordings were obtained through the center barrel of a 5 barrel micropipette. The remaining 4 barrels were used for current balancing and peptide microiontophoresis. Low currents of neurotensin (1-20 nA; 3 mM in 20 mM sodium acetate, pH 4.5) consistently excited dopaminergic neurons of the zona compacta. In contrast, non-dopaminergic neurons of the zona reticulata showed no response to similar currents of neurotensin. Unlike neurotensin, substance P (1-15 nA; 5 mM in 50 mM sodium acetate, pH 4.5) had no effect on dopaminergic neurons and excited only a small proportion of non-dopaminergic zona reticulata neurons.

These results support a neurotransmitter or neuromodulator role for neurotensin and suggest the existence of an excitatory neurotensin input to substantia nigra which could selectively activate the dopaminergic neurons in this region.

184.2 POSSIBLE ELECTROTONIC COUPLING BETWEEN SETS OF RAT NIGRAL DOPAMINERGIC NEURONS. A. A. Grace and B. S. Bunney. Depts. Pharmacology and Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510

The activity of dopaminergic (DA) neurons in the mammalian substantia nigra is known to be affected by several inherent properties, including inhibitory autoreceptors for their own neurotransmitter. We report here data which suggests that an excitatory interaction, mediated by electrical synapses between two or more DA neurons, may also be present.

In vivo intracellular recordings were obtained from DA neurons in the substantia nigra zona compacta of albino male rats. In order to identify these cells as DA neurons, one of tnree compounds was injected intracellularly to increase the catecholamine fluorescence of the DA neurons studied. The compounds were: (1) L-DOPA (to load cell with DA precursor); (2) enzyme cofactor (to activate tyrosine hydroxylase) or (3) colchicine (to cause DA accumulation). Antidromic activation from the striatum further confirmed their identity as nigral DA neurons.

Presumptive anatomical evidence of coupling was obtained by intracellular injection of the dye Lucifer Yellow, which is known to cross gap junctions. Out of a total of 20 DA neurons injected with Lucifer Yellow, 6 neurons demonstrated coupling to one neighboring DA cell, and 2 neurons demonstrated 3-way coupling. However, as this dye has been observed to be taken up by damaged fibers when injected extracellularly in vivo, intracellular recording was necessary to confirm an electrotonic interaction.

Spontaneously occurring small (3-15 mV) potentials have been described in intracellular recordings obtained from DA neurons (Grace and Bunney, Science 210: 654-656, 1980). As these potentials exhibit a rate and firing pattern (1-8 Hz, irregular with occasional burst firing) similar to that seen extracellularly in DA neurons, the possibility that they arise from electrical coupling was investigated. These potentials could be activated antidromically from the caudate nucleus at a constant latency, follow high frequency antidromic stimulation, and collide with spontaneous small potentials but not reliably with somatic spikes. Depolarizing and hyperpolarizing current injection resulted in an increase and decrease, respectively, in their rate of spontaneous occurrence. The activity of these potentials also could be inhibited by i.v. apomorphine and excited by i.v. haloperidol.

This fast excitatory interaction between DA cells may be important in controlling synchrony between functionally related cells and may be related to their frequently observed burst firing. (Supported by USPHS Grants MH-28849, MH-25642 and the State of Connecticut.)

184.3 PROJECTION FROM AMYGDALA TO GLOBUS PALLIDUS VIA NUCLEUS ACCUMBENS: ELECTROPHYSIOLOGICAL STUDIES. C.Y. Yim* and G.J. Mogenson. Dept. of Physiology, University of Western Ontario, London, Canada N6A 5C1.

Anatomical studies have shown that the nucleus accumbens (NA) receives projections from the amygdala (AMY) and in turn projects to the globus pallidus (GP). Previous electrophysiological studies demonstrated that stimulation of the AMY produced short latency excitations in NA frequently followed by prolonged inhibition; stimulation of NA produced short latency inhibitions in GP that seemed to be GABA-mediated. The present study investigates whether output from the AMY is relayed to the GP via the NA and whether this relay is modulated by activity of the mesolimbic dopamine (DA) projection.

Extracellular single unit recordings were obtained from neurons in GP of urethane anesthetized rats using glass micropipettes filled with 0.5 M sodium acetate. The effect of electrical stimulation of AMY on neurons in the ventral part of the GP known to receive heavy projections from NA was investigated.

GP neurons had discharge rates of 10-30 spikes/sec. In 12% (10/82) of the neurons electrical stimulation of the AMY elicited inhibitory responses having a mean latency of 17 ms. The inhibitory response was followed in 6 cases by a prolonged period of excitation. Stimulation of the ventral tegmental area (VTA) with a train of 10 pulses (600μA, 0.15 ms delivered at 10 Hz) 1.1 sec before stimulation of the AMY attenuated the inhibitory response in 4 cases and in each case, the excitatory response that followed was not affected. Procaine hydrochloride (20% solution) injected into NA (0.3 μl) attenuated both the inhibitory response and the excitatory response that followed.

The response of GP neurons to AMY stimulation appears to be the reciprocal of the response of NA neurons. This is consistent with the hypothesis that output from the AMY may synapse directly on an inhibitory GABAergic neuron projecting to the GP. Results of microinjection of procaine HCl into NA support the hypothesis as well. It has previously been shown that stimulation of the VTA with a train of pulses attenuates the excitatory response of NA neurons to AMY stimulation but not the inhibitory response. The present study shows that responses of GP neurons to AMY stimulation can be affected in a similar way indicating that activity of the mesolimbic DA pathway was altering the response of output neurons from NA. NA has been considered as a possible interface between the limbic and motor systems. Results of the current study support the hypothesis, but the precise functional role of this pathway requires further investigation.

184.4 STUDIES OF DOPAMINE AS A NEUROTRANSMITTER IN THE TURTLE OLFACTORY BULB. Martha C. Nowycky, Norbert Halász* and Gordon M. Shepherd. Sec. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, Ct. 06510.

Several recent studies have indicated that dopamine (DA) is present in part of the periglomerular cell population in the rat olfactory bulb, and may serve a neurotransmitter or neuromodulatory function (Hökfelt et al, Neurosci. Letters 1: 85, 1975; Halász et al. Brain Res. 154: 253, 1978; Priestley et al, Brain Res. 165: 149, 1979). In the course of physiological studies of the isolated turtle olfactory bulb, we have carried out preliminary studies of the possible role of dopamine in this structure.

Single volleys in the lateral olfactory tract (LOT) or olfactory nerves (ON) generate large field potential responses in the olfactory bulb (Nowycky et al., Soc. for Neurosci. Abstrs. 4: 583, 1978; Waldow et al. Brain Res. in press). Dopamine was added to the Ringer solution in the bath in concentrations of 10^{-6}M to 10^{-3}M. In the presence of DA, there was an increase in latency, and a slight decrease in peak amplitude, over most of the concentration range, with a steep fall in amplitude at the highest concentrations. The conduction velocity of the ON was not affected by DA. Using paired volleys, there was a profound and prolonged depression of responses to the test volley, over periods of several seconds, as previously reported. In the presence of DA there was less depression of the test response. The dopamine agonist apomorphine (10^{-5}M) caused similar effects as DA. The dopamine antagonist fluphenazine (10^{-3}M) in contrast was associated with a decreased latency and an increase in amplitude of single responses; with paired volleys, there was increased suppression of test responses, especially with LOT stimulation.

The uptake of ^{3}H-dopamine in the isolated turtle olfactory bulb has been studied with autoradiography. At the light microscopic level, the greatest amount of labelling was seen in the glomerular layer, within the glomerular neuropil and also in cell bodies surrounding the glomeruli. Heavy labeling was also seen over terminals in the granule layer. These results are similar to those previously reported in the rat. Additional labelling was found in cells of the periventricular region of the turtle. The labelled structures showing affinity for catecholamines may modulate the inhibitory responses as revealed in the physiological studies.

184.5 DOPAMINE MODULATES GLOBUS PALLIDUS RESPONSES TO IONTOPHORETICALLY APPLIED GABA. J.R. Walters and D.A. Bergstrom. NIH, NINCDS, Bethesda, MD 20205.

Previous studies in our laboratory have demonstrated that systemically administered apomorphine (APO) or d-amphetamine markedly enhances the activity of spontaneously active neurons in the rat globus pallidus (GP). To determine whether stimulation of dopamine (DA) receptors located on GP neurons plays a role in mediating these effects, pallidal responses to direct application of DA were analyzed. We also examined whether DA, applied iontophoretically, modulates pallidal responsiveness to GABA's inhibitory actions.

Extracellular single unit responses of GP neurons were recorded in gallamine-paralyzed, locally anesthetized and artificially respired rats. Drugs were iontophoretically applied to spontaneously active cells via 5-barrel micropipettes: DA HCl, 0.2M, pH4; l-norepinephrine bitartrate (NE), 0.2M, pH4; acetylcholine HCl (ACH), 0.2M, pH4; GABA, 0.001M in 0.2M NaCl, pH4.

Direct application of DA increased baseline firing rates of 7 of 22 cells tested by an average of 23±2%, decreased the rates of 4 cells by 25±2%, and had no significant rate effect on 11.

Responses to iontophoretic pulses of GABA (30 sec duration at 30 sec intervals) were examined before and during ejection of DA (10nA, 3-5 min). Currents of GABA (0-10nA) were selected which, when administered alone, depressed neuronal firing by approximately 80%. When DA was simultaneously iontophoresed with GABA, GABA was approximately half as effective at inhibiting pallidal activity; DA significantly attenuated the inhibitory effects of GABA by 47±5% (n=22). DA antagonized GABA's effects on 3 cells by more than 75%. Similar reductions of GABA's ability to inhibit pallidal firing were observed when APO (80 µg/kg) was given i.v. and GABA applied directly. APO markedly reduced GABA's effects on 5 of 7 cells by an average of 48±9%. Subsequent administration of haloperidol (0.2 mg/kg, i.v.) reversed APO's effects.

To investigate the specificity of this DA-GABA interaction, effects of NE and ACH on GABA-inhibition were assessed. NE (10nA) exerted no consistent effects on GABA-induced decreases in pallidal activity: NE attenuated GABA's effects on 4 cells by an average of 22±8%, potentiated GABA's effects on 1 cell by 18.5% and had no marked rate effects on the remaining 4 cells. Moreover, ACH (10nA, n=6; 15nA, n=2) had no significant effect on GABA's ability to inhibit pallidal activity.

These results suggest that pallidal DA receptor stimulation plays a role in mediating APO-induced excitation of pallidal activity. Further, in addition to their other actions in the basal ganglia, DA agonists and, to the extent that DA fibers innervate the GP, DA itself may affect basal ganglia function by modulating GABAergic transmission in the globus pallidus.

184.6 APOMORPHINE INCREASES THE ACTIVITY OF RAT GLOBUS PALLIDUS NEURONS; EVIDENCE THAT THE SCHEDULE OF ADMINISTRATION DETERMINES THE MAGNITUDE OF EXCITATION. D.A. Bergstrom, S.D. Bromley* and J.R. Walters. NIH, NINCDS, Bethesda, MD 20205.

Dopaminergic agents may interact with several dopamine (DA) receptor types in the basal ganglia and substantia nigra to affect the neuronal activity of these nuclei. How the actions of DA agonists at different DA receptor subtypes and at different anatomical regions summate to affect information processing in the basal ganglia is not clear. In this study we hoped to gain some insight into the net effects of these agonists in the basal ganglia by investigating the effects of systemic administration of apomorphine (APO) on the tonic activity of the globus pallidus (GP). Low doses of APO which appear to preferentially stimulate DA presynaptic receptors and higher doses which stimulate DA postsynaptic receptors were studied.

Extracellular single unit responses were recorded from spontaneously active cells in the GP of rats paralyzed with gallamine, locally anesthetized and artificially respired; one cell was monitored per rat. All drug injections were given i.v. In general, nonsignificant rate increases were noted after 5 µg/kg (n=15) and 20 µg/kg (n=10) APO; only 1 cell showed a decrease in activity after 20 µg/kg APO. Significant increases in pallidal activity were observed with 80 µg/kg, 160 µg/kg, 320 µg/kg and 1 mg/kg (32±13%, 71±17%, 111±12%, 115±16%, respectively, n=7-18). APO-induced excitations were blocked by pretreatment with haloperidol (HAL) (0.4 mg/kg, n=5) or reversed by subsequent administration of HAL. The ergot derivatives, lisuride and pergolide (1µmol/kg, a dose equivalent to 320 µg/kg APO), also caused marked increases in activity (113±25%, 127±25%, respectively, n=5,5).

To determine whether different schedules of APO administration affect the magnitude and/or direction of neuronal firing changes in the GP, 3 different schedules of i.v. APO administration were compared. A single 320 µg/kg dose increased GP activity by 111±12% (n=18). Significantly attenuated responses to APO were observed when this dose (320 µg/kg) was administered in divided doses (5, 35, 280 µg/kg) 3-5 min apart or when a non-excitatory dose (20 µg/kg) of APO preceded the excitatory dose (320 µg/kg). Average increases of 39±19% (n=15) and 35±17% (n=9) were observed for these 2 dose schedules, respectively.

These data indicate that APO, 0.08-1.0 mg/kg, administered systemically, markedly enhances firing of spontaneously active GP neurons. Low doses (5, 20 µg/kg), which preferentially stimulate presynaptic DA receptors, did not cause (24/25 cells) effects opposite to those observed with higher doses. Moreover, the results suggest that the expression and magnitude of APO-induced excitation are influenced by the schedule of APO administration.

184.7 DOPAMINE EFFECTS ON STRIATAL NEURON ACTIVITY: A PUSH-PULL PERFUSION STUDY. E.P. Schoener and D.P. Elkins*. Department of Pharmacology, Wayne State Univ., Sch. Med., Detroit, MI 48201.

Effects of discretely perfused dopamine (DA) were studied on extracellular single unit activity in the rat striatum. Male Sprague-Dawley rats (250-300 gm) anesthetized with urethane (1 gm/kg, I.P.) were cannulated in order to monitor heart rate and blood pressure on a Grass 7C polygraph. The animal's head was fixed in a DKI stereotaxic apparatus and a 3 x 8 mm burr-hole was made in the skull at coordinates .5 - 3.5mm lateral of the midline and 1mm posterior - 7.0mm anterior to bregma (A Stereotaxic Atlas of the Rat Brain, Pellegrino, L.J. and A.J. Cushman, Meredith Pub., N.Y., 1967). A push-pull cannula (0.8mm O.D.) was stereotaxically placed in the caudate nucleus (CN) at a 20° angle and the region of perfusion was probed with a glass coated Pt-Ir electrode. Perfusion of mock CSF (Merlis, J. Physiol., 13(2):231, 1940) was established and maintained at 50 µl/min by means of a pressure-damped peristaltic pump circuit (Harvard, model 1203). While varied concentrations of DA were added to the perfusion fluid, the neuronal firing rate was recorded on a Bell and Howell CPR 4010 FM recorder. A continuous count-rate analysis of neuron activity was performed on-line.

When DA was administered by single trial (3 min exposure) to naive units at 10^{-9}M (10), 10^{-8}M (9) and 10^{-7}M (12) there was an initial increase in the firing rate (10% above control) at 10^{-7}M and a significant dose-dependent decrease over the range of test concentrations (avg. = 58, 72 and 76% decrease, respectively). Neuronal effects were noted within 0.1 - 9.0 min of discrete drug application depending upon drug concentration and the cannula to electrode distance. The average duration of depression was 8 min at 10^{-9}M, 22 min at 10^{-8}M and 13 min at 10^{-7}M. Progressive loss of sensitivity was observed with repeated administration of DA at 10-20 min intervals. The initial increase in firing rate did not occur with a second application of 10^{-7}M DA, but decreases were observed at 10^{-8}M and 10^{-7}M (33 and 21%, respectively). The average duration of response was 8 min at 10^{-8}M and 7 min at 10^{-7}M. A third application of 10^{-8}M DA produced a 13% decrease of firing rate (duration = 8 min) but no response was seen following a third application of 10^{-7}M DA. Administration of the DA antagonist Sulpiride (Ravizza, Milan, Italy) was followed by a prolonged polyphasic change in firing rate with applications as low as 10^{-10}M.

184.8 The action of dopamine on rat cortical neurons recorded intracellularly.
E. Cherubini, P. Stanzione, M.G. Marciani, N. Mercuri and G. Bernardi (Spon: C.D. Hull)
2a Clinica delle Malattie Nervose a Mentali - Universita di Roma - Italy.

Previous results have shown that dopamine (DA) has a complex action on mammalian striatal neurons. This catecholamine induces a slow depolarization of the membrane potential, inhibits the "spontaneous" and evoked action potentials without evident changes of the membrane conductance. Since there is anatomical evidence for a mesencephalic dopaminergic projection to rat cerebral cortex, the purpose of this study was to investigate the effects of dopamine on rat cortical neurons.

63 cortical neurons were recorded intracellularly ; only 3 out of 24 cells that responded to DA application were monosynaptically activated by stimulation of the SN or ventral tegmental area with a latency of 5-7 msec. In 21 neurons, DA, applied iontophoretically (50-200nA) slowly depolarized the membrane potential and decreased the "spontaneous" and evoked action potentials. The amplitude of the EPSP-IPSP sequences evoked by SN or ventral tegmental area stimulation decreased. No clear change of the membrane conductance was detected. The block of the firing rate was not due to the Na+ inactivation, since the shape of the action potential was not changed during DA application and Glutamate applied during the plateau phase of DA could restore the firing.

In 3 neurons DA induced an hyperpolarization of the membrane potential and decreased the firing rate. Sometimes the initial hyperpolarization in these neurons was followed by a slow depolarization. DA action on rat cortical neurons overlaps the effect of this catecholamine on rat and cat striatal neurons (Bernardi et al. 1978 ; Herrling and Hull, 1980), in which high frequency stimulation of the SN elicit similar effects. In conclusion this work support evidence for on inhibitory role of DA on rat cortical neurons.

184.9 DIFFERENTIAL SUBSENSITIVITY OF PRE- AND POSTSYNAPTIC DOPAMINE RECEPTORS FOLLOWING LONG-TERM TREATMENT WITH APOMORPHINE. George V. Rebec and Eunjee H. Lee. Dept. Psychol., Indiana Univ. Bloomington, IN 47405.

Dopamine (DA) autoreceptors in the substantia nigra pars compacta (SNC), which participate in dendrodendritic synapses on DA neurons, appear to be more sensitive to DA agonists than postsynaptic DA receptors in the neostriatum (Skirboll et al., Science, 1979, 206:80). To determine if these receptors change their sensitivity with repeated stimulation, we examined the response of neurons in the SNC and neostriatum to apomorphine, a direct acting DA agonist, following its long-term administration. Adult, male rats received subcutaneous injections of saline, 0.05, 0.5 or 2.0 mg/kg apomorphine twice daily for 5 consecutive days. Approximately 12 hours after the last injection, single unit activity was recorded by conventional means after the animals had been immobilized and locally anesthetized. Recordings were obtained from neurons in the SNC whose firing characteristics resembled those previously described for DA neurons and from spontaneously active units in the neostriatum. Apomorphine was administered via a previously implanted jugular catheter in increasing incremental doses.

Consistent with a growing body of evidence, neurons in the SNC of saline pretreated animals were more sensitive to apomorphine than neostriatal neurons. Thus, apomorphine inhibited SNC activity at doses as low as 0.01 mg/kg, but neurons in the neostriatum typically required doses of 0.32 mg/kg to elicit the same response. Following chronic treatment, there was a progressive dose-dependent decrease in the sensitivity of DA neurons to this drug. Pretreatment with 0.5 mg/kg, for example, raised the mean effective dose of apomorphine-induced inhibition in the SNC to 0.32 mg/kg. A similar, though less dramatic, shift in sensitivity occurred following chronic administration of 0.05 mg/kg. In the neostriatum, however, repeated administration of 0.05 or 0.5 mg/kg apomorphine did not significantly alter the response to challenge injections compared to saline controls. Only long-term treatment with 2.0 mg/kg decreased the sensitivity of neostriatal neurons to apomorphine. The results of these experiments indicate that in comparison with postsynaptic DA receptors, DA autoreceptors are not only more sensitive to apomorphine but they are also more likely to develop subsensitivity following repeated administration of this drug.

This research was supported by USPHS Grant DA-02451-03 from the National Institute on Drug Abuse.

184.10 DOPAMINE(DA), NOREPINEPHRINE(NE) AND SEROTONIN(5HT) INCREASE THE EFFICACY OF EVOKED EPSPs IN CAT HIPPOCAMPAL PYRAMIDAL CELLS. Paul L. Herrling* (SPON.: B.H. Gähwiler). Pharmaceutical Division, Preclinical Resarch, Sandoz LTD., CH-4002, Basle, Switzerland.

Intracellular recordings were made in halothane anaesthetised cats with K^+-citrate filled electrodes while the fornix was stimulated (0.2 to 0.5 mA, 100 μs, 0.5 Hz) to produce an EPSP-IPSP sequence. With stimulation intensity adjusted just below threshold for the generation of action potentials on the evoked EPSPs, iontophoretically applied DA, NE or 5HT (≈100 nA) reversibly increased the amplitude of the EPSP and evoked an AP in 9 of 13 cells, the membrane was hyperpolarized by 3 to 12 mV and the rate of spontaneous or carbachol-induced firing was markedly reduced. Intracellular current pulses (-0.1 to-0.3 nA, 100 ms) applied at the time of the evoked EPSP did not induce APs. With stimulus intensity above threshold, NE, DA or 5HT had neither no effect or increased the amplitude of the AP in 9 of 10 cells. In contrast, GABA applied to the same cells shunted the evoked AP for at least 5s and caused membrane hyperpolarizations of 5 to 10 mV in 10 of 11 cells.

The observed effects of DA, NE and 5HT on the EPSP and AP might be due either to the increase of the membrane resistance (Herrling, P.L., Brain Res., in press) and the hyperpolarization and/or to additional pre- or postsynaptic effects.

The present results are in partial agreement with findings reported since the early '70s and recently reviewed by Woodward et al. (Fed.Proc. 38: 2109-2116, 1979) from which it was conjectured that one important role of NE in the brain is to decrease background firing activity while enhancing synaptic signals.

184.11 THE EFFECT OF BUSPIRONE, A NOVEL ANXIOLYTIC DRUG, ON RAT BRAIN DOPAMINERGIC NEUROTRANSMISSION. B.A. McMillen, M.K. Sanghera, R.T. Matthews and D.C. German. Depts. Pharmacology, Physiology and Psychiatry, U. Texas Health Science Ctr. Dallas, TX. 75235.

Stanton et al. (1981) reported that buspirone is a weak inhibitor of apomorphine (APO) stereotopy and conditioned avoidance responding, but does not cause catalepsy. Buspirone lacks clinical efficacy for treatment of schizophrenia in doses over 2.0 g/day, but buspirone is equi-potent to diazepam for relief of anxiety in clinical trials. These authors tested buspirone in a battery of radioligand receptor assays and found significant displacement only of N-n-propylnorapomorphine and spiperone (20 and 290 nM, respectively). Because of the higher affinity for APO binding, they suggested buspirone may be a presynaptic dopamine (DA) agonist. However, we have found that buspirone does not inhibit tyrosine hydroxylase (Tyr-OH) activity in striatal synaptosomes and does not reverse the 'in vivo' activation of Tyr-OH (determined by 30 min accumulation of L-DOPA after inhibition of DOPA-decarboxylase) caused by γ-butyrolactone (GBL). These results with functional receptor systems indicate that buspirone is not a DA autoreceptor agonist. Buspirone shifts the APO inhibition curve for synaptosomal Tyr-OH activity to the right with a calculated K_B=2.1 μM and reverses 'in vivo' APO inhibition of GBL-induced Tyr-OH activation, similar to classical anti-psychotic drugs. Buspirone, from 0.03 to 3.0 mg/kg s.c., causes a dose related increase of DA metabolism (30% to 400%) and 'in vivo' Tyr-OH (determined by L-DOPA accumulation). During extracellular recording from single DA cells in the substantia nigra pars compacta, systemic buspirone (0.01-0.05 mg/kg I.V.) reverses APO or d-amphetamine induced inhibition of impulse flow. Systemic and iontophoretically-applied buspirone inhibits the reduction in DA neuronal impulse flow caused by iontophoresis of DA onto nigral DA cells. These data demonstrate that buspirone is not a presynaptic agonist, but rather an inhibitor of presynaptic DA autoreceptors. Buspirone at 3.0 or 10 mg/kg causes neither catalepsy nor inhibition of APO-induced turning in rats with unilateral nigral lesions, which indicates a low affinity for the classical postsynaptic DA receptor. A further observation is that buspirone, unlike diazepam, does not decrease noradrenergic impulse flow determined by single cell recordings from the locus coeruleus. Whether these effects are related directly or indirectly to the anxiolytic properties of buspirone is unclear. (Supported by USPHS grants MH-30546 and MH-33513)

184.12 ACTIONS OF ZOXAZOLAMINE AND RELATED CENTRALLY ACTING SKELETAL MUSCLE RELAXANTS ON NIGROSTRIATAL DOPAMINE NEURONS. M.K. Sanghera, P. Shepard*, H.S. Jarrah*, D.C. German and P.A. Shore. Depts. of Physiology, Psychiatry and Pharmacology. Univ. of Texas Health Science Center, Dallas, TX 75235.

Zoxazolamine (ZOX) and related centrally acting skeletal muscle relaxants, chlorzoxazone and mephenesin, in doses producing loss of righting reflex (100-120 mg/kg) greatly lowered striatal dihydroxyphenylacetic acid (DOPAC) concentrations in the rat with less effect on homovanillic acid (HVA). Diazepam (5-20 mg/kg) produced no significant lowering. ZOX inhibited the haloperidol-induced elevation of DOPAC and, again to a lesser degree, HVA. ZOX, in combination with haloperidol, tended to raise dopamine (DA) levels compared to haloperidol alone, and ZOX inhibited the DA lowering seen after the combination of haloperidol and the tyrosine hydroxylase inhibitor, α-methyltyrosine. The DA lowering and marked DOPAC elevation seen after the combination of haloperidol and amfonelic acid, a DA uptake inhibitor, was greatly lessened by ZOX, while HVA elevations were less affected. In this system as well, diazepam had little effect. The effects of ZOX are not due to MAO blockade since ZOX did not block DA lowering by the tetrabenazine analog, Ro-4-1284, whereas pargyline did so. ZOX did not significantly affect normal tyrosine hydroxylase activity in vivo (dopa accumulation method), but lessened the enhanced enzyme activity seen after haloperidol. ZOX did not alter spontaneous or K^+-induced DA efflux from striatal synaptosomes. Unlike other agents which lower DA metabolism in vivo by decreasing DA neuronal activity (e.g. apomorphine), electrophysiological experiments showed little or no effect of systemic ZOX on the firing rates of nigrostriatal DA cells.

Thus ZOX and related agents have a unique effect on DA neurons in vivo. The drugs appear to influence DA metabolism by altering the normal intraneuronal flux of DA such that the main DA storage pool is stabilized. This results in lessened availability of stored DA for release and intraneuronal DA metabolism. These effects occur in the absence of significant changes in DA neuronal impulse flow.
(Supported by USPHS Grants MH 05831, 30546 and 33513.)

185.1 MECHANISM OF INHIBITION OF FIRING BY OPIATES OF NEURONS IN RAT LOCUS COERULEUS. J.T. Williams*, T.M. Egan* and R.A. North (SPON: R.D. Wurster). Neurophysiology Laboratory, Department of Pharmacology, Loyola University Stritch School of Medicine, Maywood, Illinois 60153.

Intracellular recordings were made from locus coeruleus neurons contained in slices cut from rat pons. Membrane potentials ranged from -45 to -60 mV and all cells showed spontaneous overshooting action potentials (frequency 1-10 Hz) throughout recording periods of up to 5 hours. Normorphine and D-Ala^2-D-Leu^5-enkephalin were applied by perfusion in concentrations from 10 nM - 3 μM. These opioids caused a concentration-dependent inhibition of firing in almost all neurons. This inhibition was accompanied by a membrane hyperpolarization and conductance increase in only about one-third of neurons. Action potentials induced by passing repeated depolarizing currents (10-25 Hz for 100-1000 ms) were followed by a hyperpolarization of up to 10 mV which lasted 0.5 to 5 s. This post-tetanic hyperpolarization (PTH) was associated with an increase in membrane conductance and was greatly reduced or abolished in calcium-free or cobalt containing solutions. The opioids prolonged the duration of the PTH 1.5 to 10 fold in the majority of neurons, including many in which they had no effect on resting membrane potential. The results indicate that the inhibition of firing of locus coeruleus neurons may be due not only to an increase in the resting membrane potential but also to an enhancement of the calcium-dependent hyperpolarization which follows the action potential.

185.2 DO OPIATES PLAY A ROLE IN POTENTIATION OF HIPPOCAMPAL FIELD POTENTIALS? M. A. Linseman and W. A. Corrigall. Neurobiology Section, Addiction Research Foundation, Toronto, Canada, M5S 2S1.

We have previously shown, both in vitro and in vivo, that opiates have an excitatory effect on hippocampal field potentials recorded in the CA1 pyramidal cell layer following stimulation of the stratum radiatum. This is manifest as an increase in size of the primary spike, including a reduction of threshold, and by the appearance of additional population spikes in the field potential response. It has also been shown that the size of hippocampal field potentials may be similarly enhanced, more or less permanently, by the application of one or more short bursts of high frequency stimulation, a process referred to as potentiation.

In behavioral experiments, morphine has been shown to be readily self-administered (i.e. acts as a reinforcer) as well as to enhance learning, both in appetitive and aversive conditioning paradigms, when administered immediately post-trial, an effect generally interpreted to reflect an enhancement of the consolidation process. Potentiation is believed by many to be a possible neurophysiological model of the process of learning. It was of interest therefore to determine if the administration of opiates or their antagonists might affect the process of potentiation within the hippocampus.

Rats were implanted with chronic stimulating and recording electrodes in the stratum radiatum and CA1 areas respectively. The experiment took place following a one-week recovery period. Initially, to study low frequency potentiation, changes in responses were measured during trains of 2 and 10 Hz separated by a 2 min interval. The 10 Hz train was then considered the first in a series of 6 trains from 10-100 Hz (100 pulses/train) intended to induce long term potentiation (LTP). Potentiating current in both cases was chosen so as to produce a spike that was 50% of maximum. LTP was measured at 3 equally spaced stimulus intensities along the input/output curve from just above threshold to maximum for the spike, 10 min following each train in the series and 24 hours later.

In the first experiment, 5 mg/kg naloxone s.c. was administered 10 min prior to the start of the session in one half of the animals, saline in the other half. There were no differences on any of the measures of potentiation between the 2 groups, suggesting that endogenous opiates are not involved in potentiation within the hippocampus. To assess whether exogenously administered opiates might nevertheless affect the process, an experiment in which potentiation is measured similarly following 10 mg/kg i.v. morphine is currently in progress, and these results will also be presented.

185.3 ENKEPHALINS RELEASE INTRINSIC BURST GENERATION IN HIPPOCAMPAL CELLS THROUGH DISINHIBITION. L.M. Masukawa and D.A. Prince. Dept. Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Enkephalin-induced excitation in the hippocampus has been attributed to augmentation of EPSPs and blockade of IPSPs by different investigators. CA1 and CA3 pyramidal cells of guinea pig hippocampal slices maintained in vitro were examined electrophysiologically to determine contributions of intrinsic membrane currents and synaptic transmission to the increase in excitability produced by enkephalins. Five-100 μM D-alanine^2-D-Leucine^5-enkephalin (DADL), an analogue of leucine-enkephalin, or leucine^5-enkephalin dissolved in physiological solution was applied to slices by pressure ejection or leakage from a micropipette, or by superfusion. Enkephalins increased the number of field potential population spikes from 1-2 to 5 in the CA1 and CA3 pyramidal layer in response to stimulation of stratum radiatum. These effects were seen at concentrations as low as 5 μM DADL and were reversed by 10 μM naloxone.

Enkephalins hyperpolarized the resting membrane potential by 1.5 ± 1.8 mV (n = 23). However, they did not significantly affect anomalous inward rectification exhibited by these cells. The Ca^{2+}-dependent afterhyperpolarization was unaffected by 100 μM DADL. These results suggest that changes in intrinsic conductances do not underlie increases in the number of population spikes seen with enkephalins.

The effects of enkephalins on EPSP-IPSP sequences evoked in CA1 and CA3 pyramidal neurons by stratum radiatum stimulation were studied. Following application of 10-100 μM enkephalin, IPSPs were decreased or blocked, leading to a prolongation of the decay phase of the EPSP and often to development of a burst of spikes. IPSPs evoked by alvear stimuli were also blocked. Recovery occurred within minutes when leucine^5-enkephalin was applied by pipette. Hyperpolarizing responses with a reversal potential of -75 to -80 mV were evoked by pressure application of 50 μM GABA in physiological solution. 100 μM DADL, which blocked IPSPs, had no effect on nonsaturating GABA responses. Therefore, enkephalin is not acting as a GABA antagonist. Effects of enkephalins on EPSPs were tested during superfusion with 5 μM bicuculline, which completely blocked alveus-evoked IPSPs. Under these conditions, EPSPs did not increase in amplitude or duration after application of 100 μM DADL.

The increase in excitability of hippocampal pyramidal neurons in the presence of enkephalin is consistent with a presynaptic block of inhibitory interneurons in both the CA1 and CA3 areas of the hippocampus, and is apparently not related to direct effects on EPSPs on voltage-dependent conductances.

185.4 METHOD FOR QUANTITATING OPIOID EFFECTS ON SYNAPTIC TRANSMISSION IN THE RAT HIPPOCAMPAL SLICE. Rita J. Valentino* and Raymond Dingledine, Dept. Pharmacol., Univ. N. Carolina, Chapel Hill, NC 27514.

Extracellular recordings were made with separate microelectrodes of the evoked field EPSP and population spike in the CA1 region of the hippocampal slice preparation. The sigmoidal relationship between the slope of the EPSP and spike amplitude (input-output curve) was plotted before and 30 min after perfusion of the slice with 300 nM morphine. Morphine shifted the input-output curve to the left, and this effect was only partially reversed by subsequent perfusion with 1 μM naloxone. The input-output curves were normalized by expressing the population spike as a percent of its maximum amplitude, and the EPSP as a ratio to that value producing a half-maximal population spike in control conditions. Drug effects were expressed as the change in the normalized EPSP required to produce a standard population spike that is 50% of its maximum amplitude. This procedure allows the pooling of data from different experiments since the drug effect measured is relatively independent of the orthodromic response characteristics of individual slices. Using this method we determined that 300 nM morphine decreased the EPSP required to produce a standard population spike to 60 ± 11% of the control value, and in 1 μM naloxone the EPSP recovered to only 73 ± 10% of its control value (n = 5 slices). We are using this method to construct dose-response curves to various opioid agonists and antagonists.

This technique was also used to study opioid pharmacology in slices prepared from morphine-dependent rats and bathed continuously in 300 nM morphine. The addition of 1 μM naloxone to these slices produced a small but significant increase in the normalized EPSP (110 ± 2%, n = 9 slices). The magnitude of this naloxone shift was similar to that produced by naloxone in slices prepared from narcotic - naive animals following a 30 min exposure to 300 nM morphine. Thus, in contrast to the guinea pig ileum, we have not been able to demonstrate a narcotic abstinence sign in the hippocampal slice from rats chronically treated with morphine. Supported by DA02360, NS07166, and a Sloan Research Fellowship to RD.

185.5 ENKEPHALIN EFFECT ON CALCIUM SPIKES, N-METHYL-ASPARTATE RESPONSES AND SYNAPTIC INHIBITION IN THE RAT HIPPOCAMPAL SLICE, Raymond Dingledine, (SPON: Dr. J.E. Wilson), Dept. of Pharmacol., Univ. of North Carolina, Chapel Hill, NC 27514.

Previous studies suggest that the epileptiform effect of opioid peptides in the hippocampus may be due either to a reduction in non-somatic inhibition onto pyramidal cells or to a post-synaptic facilitation of excitatory synaptic transmission onto pyramidal cell dendrites. These possibilities are being tested. Intracellular recordings were made from neurons in the CA1 pyramidal cell layer in the presence of tetrodotoxin (0.5-1 μM) to suppress Na-spikes. In TTX transmembrane depolarizing current pulses triggered high-threshold, broad, slowly rising spikes; the spike risetime was further slowed by cobalt (10 mM) and verapamil (3 mM) applied in a small droplet (<1 nl) to the surface of the slice. Neither the threshold nor amplitude of these probable Ca-spikes appeared altered in [D-ala, D-leu]-enkephalin (DADL) applied by droplet in high concentration (10 μM). N-Me-Aspartate (NMA) iontophoresed into st. radiatum evoked complex depolarizations, including Ca-spikes arising from several discrete voltage thresholds and large Ca-spike after-hyperpolarizations. NMA depolarizations that were subthreshold for a frank Ca-spike were regularly associated with an apparent increase in membrane input resistance, and were reduced in magnitude as the cell was hyperpolarized by injected current. In 16 tests on 12 neurons, DADL had no consistent effect on NMA responses. These results lend no support to the hypothesis that DADL acts on pyramidal cell dendrites to enhance the coupling of dendritic potentials to the soma membrane.

With low-frequency (<0.1 Hz) stimulation in st. radiatum two forms of apparently non-somatic synaptic inhibition can be revealed by pairing orthodromic stimuli through separate stimulating electrodes. The first form of inhibition is a reduction in the extracellularly recorded field EPSP by a prior orthodromic stimulus. The second is a long-lasting inhibition of the intracellularly recorded EPSP when the amplitudes of "control" and "conditioned" dendritic field potentials are matched. Both forms of synaptic inhibition show fatigue at stimulus frequencies above ~0.5 Hz; both are obliterated by short tetanic trains and recover slowly. Both appear to be reversibly blocked by a droplet of DADL (10 μM). In other experiments it was shown that the potentiating effect of DADL on orthodromic EPSPs is voltage-sensitive, the opioid effect being reduced as the cell is hyperpolarized. The data taken together suggest that part of the epileptiform activity of DADL in the hippocampal slice may be due to blockade of synaptic inhibitions that are distinct from classical recurrent inhibition. Supported by DA02360 and FR05406.

185.6 MODULATION OF NIGROSTRIATAL DOPAMINE ACTIVITY BY OPIATES. D. Hommer*, D. P. van Kammen and A. Pert. Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

There is considerable evidence to suggest that opiates exert an important influence on the nigrostriatal dopamine system. In our studies as well as in studies by Iwamato et al. (J. Pharmacol. Exp. Ther. 197:503-516, 1976), rats lesioned unilaterally in the substantia nigra (SN) with 6-OHDA rotated ipsilateral to the lesion following systemic injections of morphine. We have found this rotational behavior to increase in intensity with repetitive administration. Direct unilateral microinjections of opiates into the SN induce rotational behavior contralateral to the injection. This rotational behavior can be blocked by injections of haloperidol into the ipsilateral caudate nucleus. Unilateral injections of opiates into the SN also induce a significant elevation in homovanillic acid in the ipsilateral caudate.

Single-unit recording techniques were also used to study the effects of systemically administered morphine on the activity of rat SN dopamine (SN-DA) neurons and a specific sub-population of SN zona reticulata (SN-ZR) neurons. It has been reported that i.v. morphine increases the firing rate of SN-DA neurons but decreases the firing rate of unidentified SN-ZR neurons. Our results confirm and extend these findings. SN-DA neurons increase their firing rate an average of 70% above baseline following administration of 4.0 mg/kg i.v. morphine. This increase is completely reversed by 0.01 mg/kg of i.v. naloxone. The class of SN-ZR neurons we examined have an inhibitory influence on SN-DA neurons and were identified using previously established criteria (Grace and Bunney, Eur. J. Pharmacol. 59:218, 1979). These SN-ZR neurons were more sensitive to morphine than SN-DA neurons and decreased their firing rate an average of 26% below baseline following 1.0 mg/kg i.v. morphine. Naloxone 0.01 mg/kg i.v. led to a consistent rebound increase in firing rate of these SN-ZR neurons to 29% above baseline. No such rebound was seen in SN-DA neurons following naloxone. Data related to the effects of iontophoretically applied opiates on the basal activity of identified SN-DA and SN-ZR cells will also be described.

185.7 A COMPARATIVE MICROIONTOPHORETIC STUDY ON THE EFFECTS OF METHIONINE-ENKEPHALIN AND MORPHINE ON SINGLE UNIT ACTIVITY IN THE RAT GLOBUS PALLIDUS. J. M. Frey* and R. D. Huffman. Department of Pharmacology, Division of Neuropharmacology, The University of Texas Health Science Center at San Antonio, San Antonio, TX 78284

While the globus pallidus of the rat brain has been shown to have only moderate to diffuse opiate receptor density, it has been shown to contain the highest content of met-enkephalin found within the rat brain. In addition, it has recently been demonstrated that striatal enkephalinergic neurons send projections to globus pallidus. It has been previously demonstrated in this laboratory (Huffman, R.D. and Felpel, L.P., Neurosci. Lett., 22: 195, 1981) that the microiontophoretic application of morphine depressed the spontaneous firing of single globus pallidus neurons in morphine-naive rats. The present study was conducted in order to compare the effects of microiontophoretically applied met-enkephalin and morphine on spontaneous single unit activity within the globus pallidus of paralyzed, locally anesthetized rats. Male Sprague-Dawley rats (170-250g) were initially anesthetized with Halothane for the purpose of tracheotomy and placement of an indwelling catheter into the external jugular vein. While under anesthesia, a left craniectomy was performed to expose the cortex dorsal to the globus pallidus. The animals were then paralyzed with gallamine triethiodide and maintained on a respirator for the remainder of the experiment. Pressure points and surgically manipulated areas were anesthetized by the infusion of a local anesthetic. Drugs were applied by microiontophoresis from 5-barrel glass micropipettes with tip diameters of 10-14μm. Drug concentrations utilized were as follows: (met-enkephalin, 70mM in 70mM NaCl, pH 4.5 (Sigma); morphine hydrochloride, 100mM, pH 4.0-5.0 (MacFarlan Smith Ltd.); naloxone hydrochloride, 50mM in 50mM NaCl, pH 4.0-5.0 (Endo); NaCl, 4M for recording; NaCl, 1M for current control. The electrodes were filled by centrifugation and utilized within a short time thereafter. Preliminary results have revealed depression of spontaneous neuronal firing by both met-enkephalin and morphine on all globus pallidus neurons tested. At the injection currents used in this study (70nA met-enkephalin and 100nA morphine), the mean reductions in unit activity of 36.2% ± 2.6 (SEM) and 38.7% ± 3.8, respectively, were statistically significant. The specificity of drug effects was demonstrated by naloxone reversal. (Supported in part by Morrison Trust Foundation and NSF grant BNS-24774.)

185.8 ELECTROPHYSIOLOGICAL EVIDENCE IN FAVOR OF DIFFERENT OPIATE RECEPTOR POPULATIONS IN THE CAUDATE AND THE CENTRAL GRAY OF THE RAT. A.Schurr, B.M.Rigor and N.Dafny. Dept. Neurobiology and Anatomy and Dept. Anesthesiology, Univ. Texas Med. Sch. Houston, TX 77025.

The aim of the present study was to compare the direct actions of morphine on two brain areas which are known to be rich in their content of opiate binding sites,namely, the caudate nucleus and the central gray. Electrophysiological recordings of spontaneously active single units and morphine injections by microiontophoresis were made through a multi-barreled glass micropipettes.

Four different patterns of neuronal response to increasing currents of morphine could be followed in both brain sites. However, differences in the response to morphine were detected between the two brain areas in morphine-dependent rats. While the caudate neurons of morphine-dependent rats exhibited super-sensitivity to morphine,the neurons of the central gray of these animals displayed tolerance to the drug and in some, morphine dependence was evident when naloxone iontophoresis was used.

The distribution of spontaneously active neurons within these two brain areas was found to be generally corresponds to the known distribution of the opiate binding sites in the striatum and the periaqueductal gray matter.

The electrophysiological findings of this study support the notion that the two tested brain areas contain different sets of opiate receptors.

185.9 TOLERANCE TO MORPHINE IN THE C-FIBER REFLEX (CFR) OF THE ACUTE DECEREBRATE SPINAL CAT. James A. Bell* (Spon: Wallace B. Pickworth). NIDA Addiction Research Center, Lexington, KY 40583.

Cats were treated for 30 days with morphine (15 mg/day, i.p.). They were given morphine (10 mg/kg, i.p.) immediately before preparation for electrophysiological recording of the CFR. CFR's were recorded from an L_7 ventral root after stimulation of the ipsilateral superficial peroneal nerve with a stimulus intensity sufficient to activate C-fibers. The magnitude of the CFR recorded from the chronic morphine preparations averaged 240% larger than the CFR recorded from cats not treated with morphine. This demonstrates tolerance to morphine because morphine (10 mg/kg, i.p.) completely abolished the CFR if administered before the experimental procedure in untreated cats. Tolerance to i.v. injections of morphine was also demonstrated. To significantly depress the CFR in the morphine-treated cat (67% of control) an i.v. dose of 10 mg/kg was required, whereas the minimal i.v. dose required to depress the CFR in the untreated cat (66% of control) was 0.15 mg/kg. The 10 mg/kg i.v. dose completely abolished the CFR in the untreated cat. We conclude from these studies that morphine tolerance of a C-fiber-activated spinal reflex arc can be produced by chronic treatment of the cat with morphine. Furthermore, these morphine tolerant CFRs can serve as a model system in which to study the neuronal mechanisms which produce morphine tolerance.

185.10 MORPHINE ANTAGONIZES GAMMA AMINOBUTYRIC ACID-INDUCED INHIBITION IN RAT CEREBELLUM. Hylan C. Moises, Hermes H. Yeh and Donald J. Woodward. Dept. Cell Biology, Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235.

To determine whether opiates may exert some of their central effects by altering gamma aminobutyric acid (GABA)-mediated synaptic transmission, we examined the effect of morphine on GABA-mediated inhibition in cerebellum, a well-defined neuronal system. Direct GABAergic inputs to the Purkinje cell were activated by local stimulation (LOC) of the cerebellar surface, and pure 'off-beam' inhibitory responses of single units were recorded extracellularly in halothane-anesthetized rats. Poststimulus time histograms were used to quantitate inhibitory responses to LOC stimulation applied before, during and after iontophoretic or intravenous administration of morphine. Inhibitory responses to microiontophoretic pulses (10 sec duration at 45 sec intervals) of GABA, glycine and norepinephrine (NE) were also examined before, during and after morphine iontophoresis.

Microiontophoretic application of morphine 50 mM (10-120 sec, 5-30 nA) reversibly depressed the spontaneous discharge of 32 of 68 (47%) neurons tested and accelerated firing rate in 19 cells (28%). Antagonism by naloxone and opiate receptor stereospecificity, however; could only be demonstrated for the depressant action of morphine on Purkinje cell activity. In 8 of 12 neurons, iontophoresis of morphine reduced the 'off-beam' inhibitory response to LOC stimulation. This attenuation of synaptically-induced inhibition often occurred independent of opiate effects on Purkinje cell background activity and was observed in 3 of 5 cells following systemic injections of morphine (0.2-0.6 mg/kg, i.v.). Inhibitions produced by the direct application of GABA were reversibly antagonized during iontophoresis of morphine in 15 of 18 cells. Glycine-induced inhibitions were also blocked in 5 of 6 cells from the same population, whereas NE-induced inhibitions were not altered by morphine (8 of 8 cells). Prior administration of naloxone prevented morphine blockade of GABA-induced inhibition in 3 of 8 cells. However, levorphanol was found to be no more effective in blocking GABA responses (0 of 6 cells) than was dextrorphan, its inactive stereoisomer (0 of 4). Down-regulation by morphine of the previously described tonic noradrenergic bias on GABA action (Woodward et al., Fed. Proc. 38, 1979) was unlikely to account for the present findings, because responses to GABA were also blocked by morphine in 8 of 12 neurons from 6-hydroxydopamine pretreated animals.

In summary, these data suggest that morphine at analgesic dose levels may have non-specific effects on membrane mechanisms which result in a decreased postsynaptic efficacy of GABA action.

185.11 ENKEPHALINS AND TRANSMISSION IN MAMMALIAN SYMPATHETIC GANGLION CELLS. M. A. Simmons, Z. G. Jiang* and N. J. Dun. Dept. of Pharmacol., Loyola Univ., Maywood, IL 60153.

The effects of met- and leu-enkephalin (met- and leu-Enk) on guinea pig inferior mesenteric ganglion cells and on ganglionic transmission were studied by means of intracellular recording techniques. Bath application of Enk (0.05-5 μM) to sympathetic neurons caused no consistent membrane potential change. A portion of the neurons showed a hyperpolarization of 1-5 mV which was associated, in some neurons, with a fall in input resistance. A depolarization (2-5 mV) was observed in a few neurons that was not accompanied by any clear change in input resistance; however, the membrane potential and resistance in the majority of neurons tested were not appreciably affected by Enk. The most consistent effect of Enk was a reversible depression of the amplitude of the fast epsp. The depressant effect of Enk was concentration-dependent and prevented by pretreatment with naloxone (1 μM) or naltrexone (1 μM). In a low Ca (0.5 mM)/ high Mg (5.5 mM) solution the quantal content was significantly reduced by Enk whereas the quantal size was not appreciably affected. While depressing the amplitude of the fast epsp, Enk caused no significant change of the amplitude of the acetylcholine (ACh) potential induced by iontophoretic application of ACh to the same ganglion cells. Increasing the extracellular Ca concentration to 5 and 10 mM partially antagonized the depressant effect of Enk on the amplitude of the fast epsp. The non-cholinergic excitatory potential, the transmitter of which may be substance P, induced by repetitive nerve stimulation was also depressed by Enk in a number of cells tested whereas the depolarization induced by bath application of substance P was not reduced by Enk. Naloxone or naltrexone potentiated the response of the non-cholinergic excitatory potential in a portion of the neurons studied. Our results suggest that the primary action of Enk in sympathetic ganglia is to regulate transmitter output, probably by affecting Ca influx into the preganglionic nerve terminals. 185.12 OPIATE ALKALOID EFFECTS ON GLYCINE- AND GABA- MEDIATED POSTSYNAPTIC INHIBITION: CORRELATION WITH PAROXYSMAL ACTIVITY. M.A. Werz, K. Baum*, A.B. Young, and R.L. Macdonald. Neurosciences Program and Dept. of Neurology, The University of Michigan, Ann Arbor, MI 48109.

We have investigated opiate actions on GABA, glycine (GLY), and glutamate (GLU) postsynaptic responses using intracellular recording techniques applied to murine spinal cord neurons in primary dissociated cell culture and on amino acid receptor binding to rat spinal cord homogenates.

Morphine antagonized GLY and GABA but not GLU postsynaptic responses. GLY and GABA response amplitudes were reduced to half of control (IC_{50}) at morphine concentrations of 33 μM and 475 μM, respectively. The opioid peptide, [D-ala^2]-met-enkephalinamide, did not affect GLY, GABA, or GLU responses. Opiate alkaloid interaction with GLY was weakly stereospecific with levorphanol three times as potent as dextrorphan while GABA responses were reduced equipotently by the enantiomers. Naloxone did not reverse opiate depression of GLY responses. These data suggested that opiate effects on postsynaptic inhibitory amino acid responses were not mediated by opiate receptors since these effects were not naloxone reversible, only weakly stereospecific, and not produced by the opioid peptide.

To determine if opiate effects on inhibitory amino acid responses were due to opiate alkaloid interaction with GLY and GABA receptors, receptor binding assays were performed. Morphine displaced ^{3}H-strychnine from GLY receptors and ^{3}H-muscimol from GABA receptors with IC_{50}s of 113 ± 17 μM and 315 ± 78 μM, respectively. Levorphanol (IC_{50} = 70 ± 10 μM) was three times more potent than dextrorphan (IC_{50} = 195 ± 18 μM) in displacing ^{3}H-strychnine. In contrast, the opiate enantiomers were equipotent in displacing ^{3}H-muscimol with IC_{50}s of 322 ± 21 μM and 313 ± 11 μM for levorphanol and dextrorphan respectively. Naloxone inhibited ^{3}H-muscimol binding equipotently with morphine (IC_{50} = 273 ± 88 μM) but was much weaker than morphine in displacing bound ^{3}H-strychnine (IC_{50} = 2.5 ± 0.6 mM).

These data support an opiate alkaloid action to depress inhibitory amino acid responses by interacting with GLY and GABA receptors rather than opiate receptors. Antagonism of inhibitory amino acid transmission may underlie the convulsant action of high concentrations of the opiate alkaloids. Indeed, we found opiate antagonism of GLY responses to be correlated with induction of paroxysmal depolarizations in cultured spinal cord neurons.

185.13 EFFECTS OF OPIATES ON IDENTIFIED SEROTONERGIC AND NON-SEROTONERGIC NEURONS IN THE RAPHE MAGNUS (RM) M.W. Wessendorf, E.G. Anderson, and H.K. Proudfit, Dept. Pharmacology, Univ. of Illinois Medical Center, Chicago, IL 60612.

It has been suggested that excitation of neurons in the RM is essential for the expression of the analgesic effects of opiates. This hypothesis was tested using single unit recording of identified serotonergic and non-serotonergic neurons. Rats were anesthetized with urethane, curarized, ventilated, and single units were recorded from the RM using single barrel glass microelectrodes pulled to a tip diameter of about 0.75 µm. Conduction velocities of raphespinal units were determined by antidromic activation and serotonergic neurons were identified by their conduction velocities of <6.0 m/sec. Fentanyl (50 µg/kg) was administered i.v., and the effect on neuronal firing rate recorded.

A total of 48 units were recorded. Twenty four were non-serotonergic, and of these 29% were excited by fentanyl, 46% inhibited, and 25% showed no change. Another 24 units were serotonergic, and of these only 13% were excited, while 54% were inhibited and 33% showed no change.

It is concluded that excitation of either serotonergic or non-serotonergic units in the RM is probably not necessary for systemic opiate analgesia. On the other hand, spinal perfusion studies have shown increased serotonin release after microinjection of morphine into the periaqueductal gray. Since tissue concentrations of drugs are unknown in microinjection studies, it is possible that very high local tissue levels are attained. Thus it was decided to test the effects of very high systemic doses of morphine on serotonergic units.

Morphine was administered i.v. in cumulative doses of 3,5,10, 20,40 and 80 mg/kg, and the firing of serotonergic units was observed for 15 minutes after each dose. Only 6 units survived the entire regimen. Of these, 2/3 (4 units) showed a surprising result: higher doses of morphine would produce the opposite of the response (either inhibitory or excitatory) established at the 3-5 mg/kg dose. Naloxone 0.2 mg/kg was given in 2 cases, and in one it suceeded in reversing 80 mg/kg morphine. These effects did not appear to correlate consistantly with blood pressure changes.

It is tentatively concluded that high doses of opiates may have effects different from, or opposite to, those seen at low doses, and that this may have relevance to the interpretation of microinjection studies.

185.14 ANTICONVULSANT EFFECTS OF ELECTROCONVULSIVE SHOCK (ECS) ON SUBSEQUENT KINDLED SEIZURES IN RATS. Y. Shavit, S. Caldecott-Hazard and J. C. Liebeskind. Department of Psychology, UCLA, Los Angeles, CA 90024.

Because naloxone shortened and morphine prolonged the post-ictal behavioral depression normally seen after a kindled seizure, it was suggested that opioid peptides are released during ictus and reduce the severity of subsequent seizures (Frenk et al., 1979). We later found that morphine (50 mg/kg, but not 20 mg/kg) and an enkephalin analogue (6 mg/kg) significantly decreased the number of behavioral seizures in kindled rats (Caldecott-Hazard et al., 1980). Since ECS is reported to cause opioid peptide release (Hong et al., 1979), we sought to determine if ECS would also inhibit kindled seizures.

Rats were kindled with electrical stimulation to the amygdala until 3 generalized seizures were produced. After a week of rest, all rats were stimulated 7 times (spaced at 2 min intervals) in the amygdala. The severity of each behavioral seizure was rated for each rat and the mean provided a baseline seizure index. A week later, half the rats were given naloxone (2 injections of 10 mg/kg, 15 min apart) and half saline. ECS was then induced through a pair of cortical electrodes. Two min after ECS, amygdala stimulation was applied as before and the seizure index recalculated. A week later, this procedure was repeated with reversed drug treatments. Another group of kindled rats was made tolerant to morphine, and then tested for baseline seizure index and the effect of ECS, as described above.

ECS significantly decreased the seizure index, and fewer behavioral seizures were seen. When generalized seizures did occur, they were seen only towards the end of the series of 7 stimulations. The inhibitory effect of ECS on kindled seizures was greater than what we previously observed with 50 mg/kg morphine. Naloxone partially reversed the inhibitory effect of ECS. The baseline seizure index of morphine tolerant rats was not different from that of controls, but the effect of ECS was reduced to the same extent as that following naloxone, providing evidence for cross-tolerance between morphine and the effect of ECS.

The present results support the hypothesis that opioid peptides released by ECS serve to reduce the severity of subsequent kindled seizures. Because the effects of naloxone and cross-tolerance were only partial, ECS appears to exert its anticonvulsant action by nonopioid as well as by opioid mechanisms. (Supported by NIH grant #NS07628 and fellowship #NS06289.)

185.15 THE EFFECTS OF INTRA-AMYGDALOID NALOXONE INFUSION ON KINDLED CONVULSIONS. A. Mansour, B. Himmelstein* & E.S. Valenstein; Depts. Psych. & Neurosci. Lab., Univ. Michigan, Ann Arbor, Mich. 48109.

Previous research in our laboratory has shown that kindling, the progressive development of behavioral convulsions of increasing severity in response to a regimen of brain stimulation, produces long-lasting changes in morphine sensitivity. These changes in morphine responsiveness may reflect some change in the endogenous opiate systems of the animal. To test this hypothesis, we examined the effects of naloxone, a specific opiate receptor blocker, on kindled convulsions. Thirteen DBA/2J mice were stereotaxically implanted with chemtrodes in the right amygdala. The chemtrodes consisted of a combined 23 gauge cannula and a teflon coated twisted wire electrode. Following recovery from surgery, all the animals were stimulated once daily with one second of 50 u AMP., 60 Hz electrical current until they reached a criterion of 5 consecutive generalized (Stage 5) convulsions. The animals were then divided into two groups: One group (N=7) was infused with naloxone (2.5 ug/0.5 ul, over a 2 minute period using a Harvard infusion pump), while the second group (N=6) was similarly infused with an equal volume of saline. Five minutes after the completion of the infusion procedure, both groups were stimulated with the kindling current. Naloxone significantly blocked the appearance of generalized kindled convulsions (chi square = 5.28 $p < .05$). Most of the kindled animals showed minor, nongeneralized (Stage 1 or 2) convulsions and greatly attenuated electrographic afterdischarges, while the saline treated animals showed generalized convulsions. These results implicate opiates in kindled convulsive activity. Infusion of naloxone prior to electrical stimulation on subsequent days did not block the kindled convulsions and may, in fact, have had a facilitory effect. These results parallel the finding that naloxone pretreatment inhibits morphine induced convulsions in rats with the first administration, but fails to do so with subsequent pretreatment.

185.16 THE EPILEPTIFORM DISCHARGES PRODUCED BY ENKEPHALIN AND THE EFFECT OF BODY TEMPERATURE. Rabi Simantov, Elias Motles and Zeev Elazar. Department of Genetics, Weizmann Institute of Science, Rehovot and Department of Physiology and Pharmacology, Sackler School of Medicine, Tel-Aviv University, Israel.

The influence of different body temperatures on the epileptiform discharges induced in hippocampus by local microinjections of leu-enkephalin was studied in rats.

The animals were divided into four groups according to rectal temperatures during the experiment: 25-26°C; 29-30°C; 37-38°C; and 39-40°C. Rectal temperature and hippocampal EEG were monitored continuously during cooling or heating the body. Once a required temperature was reached, it was maintained during the rest of the experiment.

In the absence of enkephalin, epileptiform discharges were induced by either cooling or heating the body while the rectal temperature changed. After temperature stabilization these discharges disappeared and the hippocampogram looked normal for long periods of time.

Leucine-enkephalin (30 µg in 1.5 µl saline) was infused into the dorsal hippocampus at a speed of 0.01 µl/sec. Prolonged seizure-like discharges were recorded from the microinjection area at normal rectal temperature (38°C). These discharges could be prevented by local microinjections of naloxone given ten minutes before enkephalin. At below normal temperatures (25-26°C and 29-30°C) the epileptiform episode induced by enkephalin was of longer duration. At above normal rectal temperatures (39-40°C) the epileptiform episode was less intense and of shorter duration.

An in vitro study of the effect of temperature on the degradation of leu-enkephalin by brain tissue was conducted. One nmole of leu-enkephalin was incubated for 5 minutes at four different temperatures with rat brain tissue homogenate. The enkephalin was then re-extracted and assayed by the opiate radioreceptor assay. The amount of enkephalin recovered after incubation at different temperatures was quantified. A progressive reduction in the enkephalin activity recovered with the increase in temperature between 0 and 40°C was found. This finding is in remarkable agreement with our findings in the in vivo experiments.

It is proposed that changes in the temperature of the hippocampus as a result of cooling or heating of the body, by affecting the enzymatic activity involved in the breakdown of enkephalin, played the main role in determining the strength of enkephalin's epileptogenic effect. This indicates that in conditions of hyperthermia the activity of the enkephalinergic system in the brain is reduced.

186.1 EFFECTS OF TRANYLCYPROMINE AND PHENELZINE ON RAT BRAIN 5-HYDROXYTRYPTAMINE/TRYPTAMINE RATIOS. D.F. LeGatt*, G.B. Baker, H.R. McKim*, J.L. Hay*, W.G. Dewhurst* and R.T. Coutts*. Neurochemical Research Unit, University of Alberta, Edmonton, Canada.

The trace amine tryptamine (T) and the neurotransmitter 5-hydroxytryptamine (5-HT) are derived from the amino acid tryptophan via independent metabolic pathways. T and 5-HT have been implicated in the etiology of various psychiatric disorders.

The ratios of 5-HT/T in rat whole brain were calculated for animals undergoing treatment with the monoamine oxidase inhibitors (MAOIs) phenelzine (PLZ) and tranylcypromine (TCP) for varying time periods, to monitor the effect of the antidepressants on relative amounts of T and 5-HT. Separate groups of rats were administered the drugs i.p. once daily (10 mg/kg for TCP and 15 mg/kg for PLZ) for 1, 2, 8, and 19 days. Rats were sacrificed 6 h after the final dose. Some animals which received TCP or PLZ for one day were administered tryptophan i.p. (100 mg/kg) 1 h prior to sacrifice. Analyses of T and 5-HT were based on a procedure utilizing electron-capture gas chromatography with a capillary column (Calverley et al., Can. J. Neurol. Sci. 7:237, 1980).

The control 5-HT/T ratio was > 550/1. For TCP, the ratio was 79/1 on Day 1, and varied from 77/1 to 128/1 through to Day 19. For PLZ, the 5-HT/T ratio was > 550/1 on Day 1, but a gradual decline to 380/1 occurred by Day 19. The 5-HT/T ratios after PLZ remained several times higher as compared to TCP for all time periods. A much higher increase in T was demonstrated with TCP than with PLZ, and 5-HT levels did not vary markedly between the two drugs. Supplementation of TCP (10 mg/kg) and PLZ (50 mg/kg) with tryptophan on Day 1 resulted in 5-HT/T ratios of 19/1 and 84/1 respectively. The reason for higher levels of T with TCP than with PLZ is unclear at this time, but it has been reported that TCP does cause a significant increase in brain concentrations of tryptophan, the precursor of T, over control values. This investigation demonstrates differing effects of the two MAOIs and the influence of tryptophan on 5-HT/T ratios in rat brain.

186.2 METHYSERGIDE ANTAGONISM OF FACILITATORY BUT NOT INHIBITORY EFFECTS OF 5-HYDROXYTRYPTAMINE ON LUMBAR MOTONEURON EXCITABILITY. S.R. White and R.S. Neuman. Faculty of Medicine, Memorial Univ. of Newfoundland, St. John's, Newfoundland, A1B 3V6.

5-Hydroxytryptamine (5-HT) has recently been shown to produce a long lasting facilitation of glutamate-evoked firing of lumbar spinal motoneurons (White & Neuman, Brain Res., 188 (1980) 119). While this facilitatory effect of 5-HT is always observed, it is often preceded by a period of brief inhibition. Engberg, Flatman & Kadzielawa (Acta Physiol. Scand., 1976, 96, 137-139) reported that iontophoretic application of 5-HT, NE and a variety of other amines produced a nonspecific hyperpolarization of α-motoneurons. In the present experiment, we examined the specificity of the facilitatory and initial inhibitory effects of 5-HT on glutamate-evoked motoneuron activity using the 5-HT antagonist, methysergide. Rats were anesthetized with urethane (1.3-1.5 g/kg). The lumbar spinal cord and cauda equina were exposed and lumbar motoneurons were identified by responses to antidromic stimulation of L_4 and L_5 ventral roots. Extracellular unit recordings were made from the center NaCl barrel of a 7 barrel glass micropipette. Other barrels contained glutamate, NaCl for current balance, 5-HT, methysergide and norepinephrine (NE). Motoneurons were found which responded to application of 5-HT (15-25 nA, 30-60 sec) with a brief inhibition followed by a prolonged facilitation of glutamate-elicited firing. NE (15-30 nA, 30-60 sec), like 5-HT, also facilitated glutamate-evoked motoneuron activity and the facilitation was often preceded by brief inhibition. Methysergide (10 nA, 2 min.) antagonized only the facilitatory effect of 5-HT, sparing the inhibitory effect of 5-HT as well as both the excitatory and inhibitory effects of NE. The selective antagonism by methysergide of only the 5-HT facilitatory effect on motoneurons supports the conclusion by Engberg, et al. that the inhibition of motoneurons produced by iontophoretic application of 5-HT is a nonspecific action.

186.3 IDENTIFICATION AND QUANTITATION OF N-ACETYLSEROTONIN IN RAT BRAIN REGIONS BY GCMS. G. M. Brown, A. Porietis and N. Narasimhachari . Dept. of Neurosciences, McMaster University, Hamilton, Ontario, Canada. L8N 3Z5 and Dept. of Psychiatry, Medical College of Virginia, Richmond, Virginia.

N-Acetylserotonin (NAS) has previously been identified in the pineal and has been quantitated by GCMS using N-acetyltryptamine as internal standard (A.R. Green, S.H. Koslow and E. Costa, Brain Res. 51, 371, 1973). In previous studies we have identified NAS specific immunoreactivity in areas outside the pineal, including cerebellum, hippocampus, brain stem and retina, however, absolute identification and quantitation has not been reported in those areas. We have now identified NAS in rat hippocampus and cerebellum by GCMS. The tissue was homogenized in 5 vols of phosphate buffer (0.1 m pH 7.4) centrifuged at 2500 rpm and the supernatant separated. d_4-N-Acetylserotonin which was prepared from d_4 - serotonin by selective-acetylation was added to the supernatant as internal standard, pH adjusted to 4.5 with a few drops of 1N hydrochloric acid and extracted twice with 10 ml of ethyl acetate. The pooled ethyl acetate extract was evaporated to dryness under nitrogen, the residue heated with trifluoracetic anhydride for 15 minutes at 80°C (K. Blan, G.S. King and M. Sandler, Biomed. Mass Spect. 4, 232, 1977). The identity of this compound was established by obtaining the total mass spectrum by GCMS and comparing it with the spectrum of standard N-Acetylserotonin-TFA under identical conditions. The gc retention time and the mass spectra obtained from the brain tissue and the standard were identical. N-Acetylserotonin in the hippocampus was quantitated by selected ion monitoring in the electron impact mode using the molecular ion m/z 392 and m/z 396 for $d_4$internal standard. In another set of experiments the pentafluoropropionyl derivative was prepared, where ions m/z 492 and 496 were monitored for the sample and internal standard respectively. A standard calibration curve was obtained using 10 to 100 ng of N-Acetylserotonin and 250 ng of internal standard.

Using this technique we have quantitated NAS in rat hippocampus and examined the effect of tryptophan hydroxylase inhibition with parachlorophenylalanine (PCPA). Male Wistar rats of about 200 g were treated with PCPA (Sigma) 350 mg/kg/day or saline for three days and sacrificed 12h after the last treatment. Hippocampal NAS concentration in controls was 496 ng/g, S.E. 168, n = 4 and following PCPA was 79 ± 65, n = 4 ($p < 0.05$).

We conclude that NAS is present in rat hippocampus and that the enzyme tryptophan hydroxylase is essential in its synthesis.

186.4 EFFECTS OF PHENCYCLIDINE (PCP) ON SEROTONERGIC AND GABAERGIC SYSTEMS IN THE RAT BRAIN. M. A. Peat* and J. W. Gibb, Dept. of Biochem. Pharmacol. and Toxicol., Univ. of Utah, S.L.C., UT 84112

Behavioral and biochemical studies have indicated that PCP, like amphetamine, may act as an indirect dopamine agonist. Tyrosine hydroxylase activity was decreased after both acute and chronic treatment with PCP (10 mg/kg) (Doherty et al., Eur. J. Pharmacol. 65:139, 1980; Smith et al., J. Neural. Trans. 48:289, 1980). Doherty et al. postulated that PCP may also act by blocking transmitter uptake. PCP has been reported to have differing effects on whole brain concentrations of 5-HT and 5-HIAA; no studies of its effect on tryptophan hydroxylase have been reported. Methamphetamine and cocaine have been shown to alter the activity of this enzyme. A single dose of PCP (10 mg/kg) decreased whole brain concentrations of GABA, although it has not been reported to inhibit glutamic acid decarboxylase (GAD) activity in vivo.

In this study we investigated the effects of PCP on the concentrations of 5-HT, 5-HIAA and tryptophan (TRP) and on GAD activity in various brain regions. Rats were administered PCP (10 mg/kg i.p.) either acutely or chronically and sacrificed by decapitation; neostriatum and cerebellum were dissected. Acute administration consisted of one single injection of PCP; groups of rats were sacrificed at 10, 15, 20, 30, 60 and 120 min after injection. Chronic administration consisted of 30 daily injections; rats were sacrificed 15 min and 24 hr after the last injection. GAD activity was measured by a modified $^{14}CO_2$ trapping procedure (Hotchkiss et al., Life Sci. 25:1373, 1979) and indoleamine concentrations by an HPLC-fluorescence method.

GAD activities (expressed as % of control values) in the cerebellum after acute dosing were as follows: 10 min 104%, 15 min 98%, 20 min 104%, 30 min 96%, 60 min 108% and 120 min 110%. The increase in activity seen after 120 min is significantly different from control. The corresponding activities after chronic dosing were: 15 min 109% and 24 hr 80%. Four injections of PCP (2.5, 5 and 10 mg/kg, given at 3 hr intervals) decreased cerebellar GAD activity. The results of acute and chronic PCP treatment on striatal indoleamine levels (expressed as % of control values) are tabulated below:

	Time after injection (minutes)							
	Acute						Chronic	
	10	15	20	30	60	120	15	1440
5-HT	79	115	86	132	105	98	110	114
5-HIAA	97	151	86	151	115	85	104	91
TRP	100	-	99	113	89	92	121	106

These preliminary data indicate that PCP has an effect on the serotonergic and GABAergic systems in the rat brain regions examined. (Supported by USPHS Grant DA 00869)

186.5

WITHDRAWN

186.6 MORPHOLOGY OF DORSAL RAPHE NEURONS INTRACELLULARLY INJECTED WITH HRP. LIGHT MICROSCOPIC FINDINGS. H. Imai*,M.R. Park and S.T. Kitai (SPON: J. Thornburg). Dept. of Anatomy, Michigan State Univ., East Lansing, MI 48824.

Neurons of the dorsal raphe nucleus of the rat were intracellularly recorded and filled with horseradish peroxidase. The neurons subsequently identified resided within 300μm of the midline in the rostral part of the nucleus, dorsal to the medial longitudinal fasciculus. Classification according to axonal trajectory yielded a minimum of two neuron types: 1) neurons whose axons were ventrally projecting as they left the nucleus and 2) neurons with either dorsally or laterally directed axons which were not seen to leave the nucleus. Considering this latter class of neurons, the following soma-dendritic features were noted: Somata ranged in size from 110μm^2 to 380μm^2 in cross-sectional area. The smallest cells (110-200μm^2) had round somata and were completly spine-free. Larger cells had fusiform or polygonal somata, sparse dendritic spines and, occasionally, somatic spines. Neurons of the first type, those with ventrally projecting axons, had fusiform or polygonal somata ranging in size from 250 to 430 μm^2. These cells possessed dendritic spines and occasionally somatic spines as well. There was no obvious correlation between the pattern of dendritic arborization and axon trajectory so that the following observations apply to both neuronal classes: Neurons gave off 3 to 7 primary dendrites which branched within 10-20μm of the soma. The two daughter dendrites then continued in a relatively straight course with little or no further branching except at their extreme tips. Here, they often ended in a terminal tuft of 3-10 branches. The dendritic arbors had a preferential rostro-caudal orientation with a dendritic extent of up to 1.2mm in that plane but having a lateral extent of no more than 700μm. The averaged length of all dendrites from any neuron ranged from 250-500μm. The longest dendrites observed were 750μm in length and were directed in the rostro-caudal plane, Dendrites remained within the dorsal raphe nucleus in the medio-lateral axis. Rostrally, some dendrites extended as far as the rostral border of the principal occulomotor nucleus. Dorsally, dendritic processes could extend to the IVth ventricle and ventrally, some dendrites were seen to penetrate the medial longitudinal fasciculus. For both cell types, axons most frequently originated from a primary dendrite and less often arose directly from the soma. Axons first described a bend or loop within the dendritic field of the parent cell before becoming directed in their eventual course, be it ventral, dorsal, or lateral. The axons of both neuron types gave off a few axon collaterals which arborized within dorsal raphe. Axonal varicosities along these intrinsic collaterals suggest a synaptic interconnection among raphe neurons. (USPHS Grant NS 14866)

186.7 EVIDENCE FOR SEROTONIN CONTAINING NEURONS IN RAT RETINA. J.W. Zemp, T.N. Thomas and L.D. Middaugh. Depts. of Biochemistry and Psychiatry, Medical Univ. of S.C., Charleston, S.C. 29425.

The evidence for a 5-hydroxytryptamine (5-HT, serotonin) containing neuronal system in rat retina was studied. By high performance liquid chromatography rat retina was found to contain appreciable amounts of the precursor tryptophan, 5-HT, and its major metabolite 5-hydroxyindole-3-acetic acid (5-HIAA). In vitro incubation studies showed that homogenates of rat retina accumulates ^{3}H-5-HT by a process with properties similar to an active uptake system: it was sodium and temperature dependent, ouabain-sensitive and saturable. Inhibitors of 5-HT uptake such as chlorimipramine, desimipramine and fluoxetine were potent inhibitors of ^{3}H-5-HT uptake in rat retina whereas dopamine uptake was more sensitive to inhibition by drugs such as benztropine and d-amphetamine, thus demonstrating the accumulation of 5-HT and dopamine by distinct populations of nerve terminals. Kinetic analysis of the 5-HT uptake data demonstrates a high affinity transport system with an apparent Km of 3.95 x 10^{-7} M, which presumably inactivates 5-HT following synaptic release. The 5-HT is presumably stored in storage vesicles as the uptake was extremely sensitive to reserpine. Intravitreal injection of 5,7-dihydroxytryptamine, which produces degeneration of serotonergic terminals, produced significant reduction in 5-HT uptake by rat retina. Fractionation studies demonstrated that the 5-HT accumulating terminals are localized to elements in the inner plexiform layer, i.e. bipolar or amacrine cells. The results are consistent with the suggestion that 5-HT is a transmitter candidate in rat retina (supported by P.H.S. Grant EY03098 (T.N.T.)).

186.8 SEROTONIN-POSITIVE NEURONS IN MONKEY SPINAL CORD. C. C. LaMotte, N. C. de Lanerolle, and D. Johns*. Sections of Neuroanatomy and Neurosurgery. Yale Univ. Sch. of Med., New Haven, CT. 06510.

The possibility that serotonergic interneurons are present within the spinal cord has occasionally been suggested from physiological and pharmacological studies which indicate 5-HT does not completely disappear following transection to interrupt descending 5HT axons from the brain stem raphe (Shibuya & Anderson 1968; Anderson, 1972; Jones and Wright, 1980).

We have identified a total of 150 neurons in samples of 3 monkey (M. fascicularis and M. arctoides) spinal cords which are positive for serotonin, using a 5-HT antibody (courtesy R. Elde) with the Sternberger peroxidase-anti-peroxidase method. Most of these neurons were located in a small, sparsely-populated column of cells in lamina X, ventral to the central canal. They were either in the ventral commissural grey or lying on the midline ventral grey-white border. The cells were usually very small, 5-10 microns in diameter. EM examination revealed cytoplasmic and nuclear morphology typical of neurons and they could be readily distinguished from glia. Processes of some cells extended toward the ventral motor horn; in others, processes reached to the central canal or wrapped around large blood vessels situated in lamina X. Cells were most frequent in the cervical cord (approx 6-7/mm length of cord) and less frequent in thoracic (1.5/mm), lumbar (3/mm), and sacral (2/mm) cord. In the sacral cord only, a second set of small cells was found consistently in the medial marginal zone, approximately 2/mm length of sacral cord. Their processes could not be traced beyond the marginal and gelatinosal regions.

Immunohistochemical controls confirm the specificity of the immunoreaction used for staining these neurons. In addition, the Falck-Hillarp histofluorescence technique was applied to the lumbosacral cord from one of the 3 monkeys; results confirmed the presence of cells in lamina X with characteristic yellow color and rapid fading typical for serotonergic cells.

It is possible these cells contribute to the innervation of spinal neurons, spinal vessels, or in some cases may secrete into the CSF or may be receptors for CSF composition. Transection experiments in progress may clarify the functions of these cells. (Supported by NIH grant NS13335)

186.9 CENTRAL SEROTONERGIC NEURONS CLEARLY VISUALIZED USING COLCHICINE PRETREATMENT AND A RAPID GLYOXYLIC ACID TECHNIQUE. S. A. Rasmussen* and B. S. Bunney (SPON: J. S. Ebersole). Depts. of Psychiatry & Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510

The application of the Falck Hillarp fluorescence technique to visualize monoamine systems in mammalian brain ushered in a new era in neuroscience. However, the technique is not without problems. It is time consuming, special equipment is required, and axons and terminals are visualized only in neurons with relatively high concentrations of monoamines. The development of a rapid and more sensitive technique using glyoxylic acid resolved most of these problems but added some of its own. One of these difficulties was the fact that serotonergic neurons could not be adequately visualized in rat brain.

Colchicine, a substance which inhibits axoplasmic transport, concentrates enzymes and transmitters in cell bodies. It has been used effectively in combination with immunocytochemistry to visualize peptidergic neurons with low peptide content. We have found that intraventricular colchicine (20 ul, 0.015 M; 24 hrs before death), combined with the modified glyoxylic acid (SPG) method of de la Torre and Surgeon[1], greatly improved the visualization of rat CNS monoaminergic neurons including serotonergic cell bodies.

There are three major advantages to the use of colchicine pretreatment with the SPG method. First, we have been able to consistently visualize serotonergic neurons. The cells emit a bright yellow light with UV illumination. The intensity of their fluorescence is comparable to that obtained with the Falck Hillarp technique. In addition, although the intensity does diminish, it does so quite slowly in a manner similar to that of neighboring catecholamine neurons. Sections can be examined and photographed on multiple occasions over a four to six week period without the rapid fading of fluorescence seen in Falck Hillarp preparations. Second, visualization of the dendritic fields of catecholaminergic neurons is vastly improved. Processes can often be followed for several hundred microns. Resolution is comparable to that seen with tyrosine hydroxylase immunocytochemistry. Finally, catecholaminergic cells with low amine content, such as those found in the arcuate and periventricular nuclei, are readily visualized. The intensity of fluorescence in these cells is comparable to that seen with immunocytochemical techniques. Thus, intraventricular colchicine has been found to extend the usefulness of the SPG technique to the serotonergic system and to catecholaminergic perikarya with low amine content. (Supported by USPHS grants MH-28849, MH-25642 and the State of Connecticut.)

186.10 INFLUENCE OF NEUROLEPTICS ON SEROTONIN- AND DOPAMINE-METABOLISM IN MESOLIMBIC AND STRIATAL AREAS OF THE RAT BRAIN. H. Gerhards*, H. Dilsky*, and A. Hullmann* (SPON: S. FIELDING). HOECHST AG, 6230 Frankfurt/M., Germany.

Levels of 5-hydroxytryptamine (5-HT), 5-hydroxyindole-acetic acid (5-HIAA), dopamine (DA), dihydroxyindole-acetic acid (DOPAC) and homovanillic acid (HVA) in rat striatum and mesolimbic areas (N. accumbens, Tub. olfact.) were determined using High Performance Liquid Chromatography (HPLC) with electrochemical detection.

The method consists of an extraction/homogenization step with formic acid/acetone (twice), a wash of the extract with heptane/chloroform, drying of the aqueous portion under a stream of nitrogen and resuspension in the HPLC-buffer (0.1 M citrate-disodiumphosphate, pH 3.5, containing 0.004 % sodium octylsulfate and 11 % methanol) and is a modification of the method described by C.C. LOULLIS et al.; Pharmacol. Biochem. & Behavior 11, (1979) 89-93. The HPLC-system utilized a C-18 reverse phase column (WATERS Ass. INC, Milford, Mass.) coupled with a glassy carbon detector (Bioanalytical Systems INC., West Lafayette, IN.) set at a potential of + 0.8 V versus the reference electrode. Different chemical classes of neuroleptics, Chlorpromazine (CPZ) and Clozapine (CLOZ) in the phenothiazine resp. dibenzazepines group, Haloperidol (HAL) and Pimozide (PIM) in the butyrophenone group and Sulpiride (SUL) in the benzamide group were given in acute (2 h) and subacute (10 days) experiments to male Wistar rats and levels of 5-HT, 5-HIAA, DA, DOPAC and HVA were determined in striatum and mesolimbic areas of the rat brain.

When compared with untreated controls, all neuroleptic drugs tested increased DOPAC and HVA-levels in both areas in the acute study, whereas only CPZ and CLOZ induced an increase of 5-HIAA-levels. Tolerance developed to both effect after 10 days of treatment.

While the increase in DA-metabolism after neuroleptics is well known and probably a result of the DA-receptor antagonism of those drugs, their effect on 5-HT-metabolism is not well understood. The possible relationship between sedative and muscle relaxant effects of neuroleptics and their effect on 5-HT-metabolism will be discussed.

186.11 METABOLITES OF DOPAMINE AND 5-HYDROXYTRYPTAMINE IN CEREBROVENTRICULAR PERFUSATES OF RATS PRETREATED WITH INTRACEREBROVENTRICULAR INJECTIONS OF 6-HYDROXYDOPAMINE OR 5,7-DIHYDROXYTRYPTAMINE. J.A. Nielsen* and K.E. Moore. Dept. of Pharmacol./Toxicol., Michigan State University, East Lansing, MI 48824.

The present study was initiated to evaluate an in vivo cerebroventricular perfusing technique for estimating the activity of dopamine (DA)- and 5-hydroxytryptamine (5HT)-containing neurons in the central nervous system (CNS) of unanesthetized freely-moving rats. Male rats were implanted with permanent push-pull cannula such that the tips were located in a lateral cerebral ventricle (Tilson and Sparber, J. Pharmacol. Exp. Ther. 181: 387, 1972). Following recovery the cerebroventricular system of each rat was perfused with artificial cerebrospinal fluid (CSF) at a rate of 20 µl/min, and perfusate samples were collected in a high performance liquid chromatography (HPLC) mobile phase (0.1 M citrate-phosphate buffer, pH 3.0, containing 8% methanol and 0.036% sodium octyl sulfate) every 15 min for up to 105 min each day. The concentrations of DA metabolites, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), and of the 5HT metabolite, 5-hydroxyindoleacetic acid (5HIAA), were analyzed by HPLC using a C_{18} µBondapak column coupled to an electrochemical detector. The administration of haloperidol (1 mg/kg, s.c.) increased the efflux of DOPAC and HVA but not 5HIAA, while the administration of L-tryptophan (100 mg/kg, i.p.) increased the efflux of 5HIAA but not DOPAC or HVA. Seven days after the intracerebroventricular (icv) injection of 6-hydroxydopamine (6OHDA; 200 µg) the basal and haloperidol-induced release of DOPAC and HVA were markedly reduced, while the basal release of 5HIAA was unaltered. Seven days after a second dose of 6OHDA there was a further reduction in the basal and haloperidol-induced efflux of DOPAC and HVA, while the basal efflux of 5HIAA was still unaltered. On the other hand, 10 days after icv 5,7-dihydroxytryptamine (200 µg) the basal and L-tryptophan-induced release of 5HIAA were markedly reduced while the basal release of DA metabolites were unaltered. These results reveal that the metabolites of DA and 5HT appearing in CSF perfusates originate from DA and 5HT neurons in the CNS, respectively, and suggest that this technique can be employed to monitor the activity of DA and 5HT neurons in conscious, unrestrained rats. (Supported by USPHS grant NS 15911.)

186.12 REGIONAL DIFFERENCES IN THE RESPONSE OF NEOSTRIATAL NEURONS TO SYSTEMIC AMPHETAMINE ADMINISTRATION: APPARENT INVOLVEMENT OF A SEROTONERGIC PROJECTION FROM THE DORSAL RAPHE NUCLEUS. Stephen D. Curtis and George V. Rebec, Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

We have previously reported that a direct infusion of d-amphetamine into the dorsal raphe nucleus (DRN) inhibits unit activity in this site but produces a concomitant mirror-image increase in firing rate in the lateral, but not medial, neostriatum (Rebec et al., Soc. Neurosci. Abstr., 1980, 6: 233). These results are consistent with evidence that serotonergic afferents from the DRN are confined to the lateral neostriatum (e.g., Azmitia & Segal, J. Comp. Neurol., 1978, 179: 641) and that they exert an inhibitory influence on neostriatal activity (e.g., Miller et al. Brain Res., 1975, 97: 133). The present study further examined the DRN-neostriatal interaction following systemic amphetamine administration in immobilized, locally anesthetized rats. Unit activity was recorded simultaneously in the DRN and in the medial or lateral anterior neostriatum. d-Amphetamine was administered via an indwelling intraperitoneal catheter.

An injection of 1.0 mg/kg d-amphetamine inhibited the activity of single neurons in the DRN but produced a simultaneous increase in the firing rate of neurons in the lateral neostriatum. Consistent with previous reports, unit activity in the medial neostriatum was typically inhibited by this low dose of the drug. In some animals, electrolytic lesions of the DRN produced a dramatic acceleration of neostriatal activity but only if this activity was recorded in the lateral neostriatum. The results of these experiments suggest that the response of neurons in the neostriatum to amphetamine is not homogenous and that serotonin may mediate regional differences in the response to this drug.

This research was supported by USPHS Grant DA-02451-03 from the National Institute on Drug Abuse.

186.13 EFFECTS OF THE SEROTONIN AGONIST, QUIPAZINE, ON SPINAL REFLEXES IN THE RAT. Barry D. Goldstein and Edmund G. Anderson. Dept. of Pharmacology, Univ. of Illinois Coll. of Med. Chicago, IL 60612.

We have used quipazine, a serotonin (5-HT) receptor agonist, to study the role of 5-HT in modulating dorsal and ventral root reflexes in the rat spinal cord.

Male Sprague-Dawley rats were anesthetized with halothane and the spinal cord transection at C1. Following laminectomy the L4-S1, dorsal roots were bilaterally sectioned. The monosynaptic reflex (MSR), dorsal root potential (DRP), and dorsal root reflex (DRR) were recorded. The spontaneous ventral root discharge (VRD) and spontaneous antidromic dorsal root discharge (DRD) were simultaneously recorded from the L6 ventral and L5 dorsal roots.

Quipazine (1.0 mg/kg, i.v.) increased the MSR and VRD to 210 and 330 percent above control values, respectively. Conversely, quipazine depressed the DRP, DRR and DRD to 70, 55 and 50 percent of control. The maximal effect on the ventral root responses (MSR and VRD) appeared about one minute after injection. These effects remained maximal throughout the experiment. On the other hand, the depression of the dorsal root responses was delayed, requiring about 30 minutes for the maximal effect.

Cinanserin (4 mg/kg, i.v.), a 5-HT antagonist with high affinity for the 5-HT_2 receptors, was only effective in reversing the quipazine-induced excitation on the ventral root. It had no effect on the quipazine-induced depression of the DRP, DRR, and DRD. The 5-HT antagonist metergoline (0.5 mg/kg, i.p.) was tried because it has a high affinity for both 5-HT, and 5-HT_2 receptors. Metergoline had little effect on reversing the excitation of the ventral root responses, or the depression of the DRP. It did, however, reverse the depressant effect of quipapzine on the DRR, increasing it to 225 percent above control. However when metergoline alone was given it increased the DRR to 260 percent above control without affecting the MSR or VRD. The increase in the DRR by metergoline was antagonized by cinansein, suggesting metergoline may have some 5-HT agonist actions. Low doses of quipazine (0.1 mg/kg) were investigated to clarify the actions on the DRR. Low doses of quipazine, like the high dose, increased the MSR and VRD. However, unlike the high dose, this dose increased the DRR and DRD. Again, the onset of the dorsal root effects was slow.

In conclusion, quipazine appears to facilitate motoneuronal discharge, an action reversed by 5-HT antagonists with high affinity for 5-HT_2 receptors. Low doses of quipazine facilitate and high doses depress the DRR. These actions are not blocked by 5-HT_2 receptor antagonists. Metergoline also increase the DRR. The effects on the DRR may be mediated by a 5-HT_2 receptor system. (Supported by USPHS Grant PHS NS 14985)

186.14 SPINAL SEROTONIN MEDIATES A SUPRASPINAL COMPONENT OF ANALGESIA PRODUCED BY VAGINAL STIMULATION IN RATS. J.L. Steinman* and B.R. Komisaruk.

Previous studies have shown that perispinal (intrathecal) administration of phentolamine significantly attenuates vaginal stimulation-produced analgesia (VS-PA) on both tail flick and vocalization to shock tests. On the other hand, intrathecal methysergide antagonized VS-PA on the vocalization measure only. To further elucidate the role of spinal serotonin in the mediation of VS-PA, we administered 5,7-dihydroxytryptamine (DHT) intrathecally to the lumbar cord to destroy serotonergic terminals in the spinal cord.

DHT was injected through PE-10 catheters passed to the lumbar level of the spinal cord via an incision in the cisterna magna according to the method of Yaksh and Rudy (1976). VS(200g force) was applied via a calibrated glass probe assembly (modified 1cc syringe plunger). Analgesia was assessed by the latency (in sec) to withdraw the tail from radiant heat and the threshold (in mA) to vocalize in response to tail shock.

Three separate groups of ovariectomized rats received 4ug or 10ug of DHT or vehicle control in 10ul saline (with .2mg ascorbic acid/ml). Data reported were taken three days after perispinal drug administration. No significant differences were observed among groups on the tail flick measure; VS significantly increased the tail flick latency in all groups (preprobe latencies: 4ug-2.2; 10ug-2.15; Saline-2.49; after 5sec VS: 4ug-5.08; 10ug-5.42; Saline-5.31). In contrast, using the vocalization measure, both 4ug and 10ug DHT significantly depressed the effects of VS (correlated t test; *:$p<.05$). Vocalization threshold is expressed as percent increase from preprobe baseline 4ug-135% ns; 10ug-106% ns; Saline-181%*.

The present findings demonstrate that destruction of serotonergic terminals in the spinal cord with 5,7-DHT attenuates the effects of VS-PA as measured by vocalization, but not tail flick tests. Vocalization threshold was used as an indicator of a supraspinal nociceptive process and tail flick as an indicator of a spinal mechanism, since the latter is blocked by VS even in spinal transected rats. These findings indicate that a descending spinal serotonergic mechanism which is activated by VS differentially suppresses a supraspinal but not a spinal nociceptive response. These results support our earlier findings that intrathecal serotonin receptor blockers inhibit the effects of VS on vocalization tests only.

186.15 CHARACTERIZATION OF THE ACUTE EFFECTS OF METHAMPHETAMINE ON SEROTONERGIC AND DOPAMINERGIC ACTIVITY IN SELECTED REGIONS OF THE RAT BRAIN. C. Bakhit*, M. A. Peat* and J. W. Gibb (SPON: W. Stevens). Dept. of Biochem. Pharmacol. and Toxicol., Univ. of Utah, Salt Lake City, Utah 84112.

Acute administration of methamphetamine (METH) to rats results in a dose-dependent depression of brain tryptophan hydroxylase (TPH) activity. In this study, we measured TPH activity, tyrosine hydroxylase activity (TH) and the levels of dopamine (DA), 5-hydroxytryptamine (5-HT), 5-hydroxyindoleacetic acid (5-HIAA) and tryptophan (TRP) in the cerebral cortex and neostriatum of the rat brain at 15, 30, 60 and 180 min following a single injection of METH (2.5 or 10 mg/kg, s.c.). TH and TPH activities were measured as described previously (Hotchkiss et al., Life Sci. 25, 1373, 1979). DA, 5-HT, 5-HIAA and TRP were measured concurrently by an HPLC-fluorescence method. In both the neostriatum and cerebral cortex, TPH activity was depressed at lower doses of METH and at earlier times than 5-HT and 5-HIAA. The depression of TPH was then followed at a later time by a decrease in levels of 5-HT and its metabolite. For the cerebral cortex, METH (2.5 mg/kg) produced a significant decrease in TPH activity at all time points, no change in 5-HT levels, a transient increase in 5-HIAA at 30 min and a significant rise in TRP levels at 60 and 180 min. When 10 mg/kg of METH was given, the depression of TPH was more pronounced, compared to the depression observed with the 2.5 mg/kg dose of METH, and a profound depression of 5-HT and 5-HIAA was observed at the later time points in both regions. TRP was increased at an earlier time at this dose of METH. In contrast, no change was found in TH activity at the times and doses of METH selected. Preliminary results show an increase in DA levels with the lower dose of METH. The results indicate that the primary effect of METH on the serotonergic system is on TPH activity and that the serotonergic system is more sensitive than the dopaminergic system to the effects of METH. (Supported by USPHS Grant DA 00869)

186.16 RECORDING OF RAPHE UNIT ACTIVITY IN VITRO IN MOUSE BRAIN SLICES. Gailyn A. Howell, J. W. Brandstetter*, Mary H. Frederickson, Christopher J. Frederickson and Michael E. Trulson. Dept. Psychol. Univ. of Texas at Dallas, P.O. Box 688, Richardson, TX 75080.

Serotonin-containing raphe neurons display a characteristic slow and rhythmic discharge rate (0.5-3.0 spikes/sec) in chloral hydrate anesthetized rats. However, the significance of this discharge pattern and the factors which generate it are completely unknown. Interestingly, these neurons maintain this characteristic slow and rhythmic discharge pattern when recorded from rat brain slices in vitro (Mosko and Jacobs, Neurosci. Lett. 2: 195-200, 1976). This suggested that it may be possible to develop an in vitro preparation for studying the synaptic pharmacology of raphe neurons. In the present study we explored this possibility by recording the activity of raphe neurons from mouse brain slices in vitro with and without high concentrations of magnesium in the incubation medium. Adult mice were decapitated, the brains rapidly removed, and the brainstem was sectioned into 400 u coronal slices using a Sorvall tissue slicer. The slices were incubated in standard oxygenated Yamamoto's solution at 34°C under an atmosphere of moist 95% O_2 - 5% CO_2. A glass micropipette (tip dia 1-2 u) filled with 2 M NaCl was lowered into the dorsal raphe nucleus with the aid of a dissecting microscope, and extracellular unit activity was recorded and analyzed. Raphe neurons recorded in mouse brain slices in vitro discharged spontaneously with a slow and regular rhythm (3.2 ± 0.4 spikes/sec) very similar to that observed in rat brain in vivo or in vitro. Consistent with the findings of Mosko and Jacobs (1976), a few cells with a rhythmic discharge pattern but much higher rate (8-13 spikes/sec) were found within the dorsal raphe nucleus. When magnesium ion (as the sulfate salt) was added to increase the media concentration to 20 mM, for the purpose of inhibiting all synaptic transmission (e.g., Barker and Nicoll, J. Physiol. 228: 259-277, 1973) raphe neurons continued to display the same discharge pattern and rate (3.0 ± 0.5 spikes/sec). These latter cells were recorded between 10 - 120 min post-magnesium, and several were recorded through the transition of pre- to post-magnesium. The fact that raphe neurons continue to discharge in the characteristic regular fashion in the apparent absence of any synaptic input suggests that they have an endogenous rhythm and may function as pacemaker cells in the CNS. Moreover, the fact that these cells can be identified by their characteristic firing pattern in high magnesium media makes it possible to investigate the action of drugs which are believed to act directly on raphe neurons (e.g., LSD, DMT, psilocin), i.e., independent of confounding presynaptic effects.

187.1 EFFECTS OF PERINATAL HYPOXIA ON KINDLED CONVULSIONS IN YOUNG RATS. B. J. Albala, S. L. Moshe' * and I. Katz.* Dept. of Psychiatry and Dept. of Neurology, Albert Einstein College of Medicine, Bronx, New York 10461.

Early childhood seizures are often attributed to perinatal oxygen deprivation. To evaluate this relationship of perinatal hypoxia to seizure development we exposed newborn rats to hypoxia and measured their susceptibility to electrically kindled seizures.

Two litters of Sprague-Dawley rats, bred in these labs., were randomly divided into three groups. Within the first 24 hours after birth two of the groups were removed from their mothers and placed into one of two glass bell jars equipped with a water mattress which was maintained at 34-36 C. Humidified room air or 6% oxygen in nitrogen was passed through the sealed chamber at the rate of 2-3 L/min. The levels of oxygen, CO_2, temperature and the behavior of the animals were monitored during the 4 hour experimental period. The parameters of hypoxia used have previously been reported to produce long lasting neurochemical and behavioral alterations which persist for at least 4 weeks after a single exposure (Hedner, T., *Acta Physiol. Scand., suppl.460:1,* 1978). Both groups were returned to their home cage with their mother and the undisturbed third group of rat pups and were allowed to grow until they were stereotaxically implanted at 27 days of age with a bipolar electrode in the left amygdala. After two days of recuperation each animal was given a 50 *uA*, 60 Hz 1 sec sinusoidal stimulation which was then increased by 50 *uA* every hour until an afterdischarge (AD) was elicited; this current was designated as the AD threshold. The animals were subsequently given a suprathreshold (400 *uA*, peak to peak) stimulation every hour until a generalized motor convulsion was elicited or the fortieth stimulation was completed; this procedure was conducted over four days.

During the 4 hour period of hypoxia the newborn pups became markedly cyanotic in contrast to their littermates in air. No seizures or deaths occurred. There were no statistically significant differences in body weight at 27 days of age among the three groups. Analysis of the kindling data did not reveal any significant differences in the AD thresholds, AD duration at threshold, AD duration during the first generalized convulsion and in the number of stimulations required to elicit a generalized convulsion.

These preliminary results indicate that this degree of hypoxia during the first day of life does not facilitate the development of kindling later in life. The data also suggest that neither early nutritional deprivation nor maternal separation for a period of 4 hours significantly alters later weight or any of the epileptogenic variables that were measured in the present study.

187.2 PHOSPHORYLATION OF SYNAPTIC PROTEINS IN AMYGDALOID-KINDLED RATS. Elizabeth I. Tietz* and Robert F. Berman (SPON:Joyce A. Benjamins) Dept. of Psychology, Wayne State University, Detroit, MI 48202.

Converging lines of evidence suggest that alterations in phosphoprotein metabolism may be involved in the initial formation or maintenance of a seizure focus. The kindling model of epilepsy was used to investigate possible changes in phosphoprotein metabolism occuring during the development of an amygdaloid-kindled seizure focus.

Bipolar electrodes were stereotaxically implanted in the amygdala of adult male hooded rats. Afterdischarge thresholds were determined and animals were stimulated once daily at threshold (100 Hz, biphasic, square wave, 0.1 msec pulse duration) for 1 sec until Stage 5 kindled seizures were elicited on 3 of 5 days. After reaching criterion, kindled rats were sacrificed by decapitation immediately after (n=6), or without (n=5) an elicited seizure. Non-implanted matched controls were sacrificed with each kindled animal for comparison. Brains were removed and the amygdala-entorhinal cortex, hippocampus, and frontal cortex of each animal were dissected within 1 min and homogenized at 4 C. The homogenate was centrifuged to yield a crude P_2 pellet which was resuspended for 30 min in ice-cold dH_2O and recentrifuged. The resultant pellet was resuspended and the protein concentrations were adjusted to 3-4 mg/ml. The samples were phosphorylated in vitro by incubation with 5 uM (^{32}P)-ATP for 2 min. The phosphorylated samples were subjected to SDS-polyacrylamide gel electrophoresis, stained with Coomassie Blue, and densitometrically scanned for protein concentration. Dried gels were placed in contact with No-Screen X-ray film for 3-5 days and the resultant autoradiograms were scanned to determine the amount of ^{32}P incorporation into protein.

Decreases in ^{32}P incorporation were seen in synaptic proteins isolated immediately after a kindled seizure from amygdaloid-kindled rats, compared to non-kindled controls. Specific decreases were most prominent in bands 55K and 80K daltons in membranes derived from the amygdaloid region. Less prominent decreases in ^{32}P incorporation were also observed in hippocampal-derived membranes, but not in samples from cortex. In contrast, an increase in ^{32}P incorporation was observed in amygdala-derived membrane fractions obtained from kindled rats sacrificed without seizure, with the most pronounced change occuring at 80K daltons.

These results support the possible involvement of synaptic phosphoproteins in the development and maintenance of an amygdaloid-kindled seizure focus. (Supported by NIMH Grant MH35078-01)

187.3 LONGLASTING ALTERATIONS IN INHIBITORY PROCESSES IN KINDLED RATS. L.P. Tuff, R. Racine and R. Mishra. (SPON: H. Weingarten). Dept. of Psychology, McMaster Univ., Hamilton, Ont. L8S 4K1.

Repeated intermittent electrical stimulation of many brain structures, particularly in the limbic system, eventually produces increasingly long and widespread afterdischarges and culminates in the production of major motor seizures. This phenomenon has been termed 'kindling' and is essentially permanent. As a model of epilepsy it provides a unique opportunity to examine the longlasting effects of epileptogenesis uncontaminated by the immediate sequelae of the ictal event.

Inhibitory systems, and in particular those mediated by GABA, have for sometime now been associated with seizure phenomena. We have measured GABA and benzodiazepine receptor binding in thirteen different brain areas in kindled and control rats two weeks after their last stimulation. ^{3}H-flunitrazepam binding was significantly increased ($p<.01$, n=10) in both the stimulated and contralateral amygdalae of kindled animals by 15% compared to controls. In addition, significant decreases were seen in striatal tissue on both sides of the brain which were of similar magnitude. Subsequent Scatchard analyses indicated that the number of binding sites and not their affinity was the source of the changes. ^{3}H-GABA binding in TX-100 treated tissue was unaltered in kindled animals, but in tissue that was washed without detergent ^{3}H-muscimol binding was significantly increased in the ipsilateral hippocampi of kindled rats.

In a parallel experiment, the effects of kindling on paired pulse depression of potentials evoked in the dentate by stimulation of the perforant path were examined. This phenomenon is thought to be indicative of granule cell recurrent inhibition. Kindling produced a dramatic increase in the depression effect that was not seen in unkindled control animals.

Taken together, these experiments suggest that following kindling, GABA mediated inhibition is increased in several brain areas. It would appear then, that if inhibitory failure plays a role in the established kindled response, it is probably not due to a tonic deficit.

187.4 IN VIVO AND IN VITRO INVESTIGATIONS OF KINDLING-INDUCED EPILEPTOGENESIS. E.W. Kairiss*, R.J. Racine and G.K. Smith. Dept. of Psychology, McMaster University, Hamilton, Ontario, Canada L8S 4K1.

The experiments reported here use the kindling model of epilepsy to determine which brain areas develop spontaneously discharging epileptic foci most readily.

Five experimental groups of male Long-Evans rats were prepared. Bipolar stimulating electrodes were stereotactically implanted in region CA3 of hippocampus (HPC), lateral amygdala (AMY), lateral olfactory tract (LOT), perforant path (PP) and fornix (FX). EEG and evoked potentials were recorded with monopolar electrodes from hippocampus, pyriform cortex, caudate nucleus, thalamus and brainstem reticular formation. Daily kindling stimulations were applied until five class V seizures (Racine, R.J., EEG Journal, 32:281, 1972) had been elicited. Spontaneous and evoked ictal and inter-ictal spikes were recorded before, during and after seizure induction, and spike latency and and amplitude were compared. Finally, the animals were sacrificed and in vitro slices of hippocampus were prepared (Dingledine, R. et al., J. Neuroscience Meth, 2:323, 1980). Stimulus evoked population responses were recorded from sub-regions of dentate gyrus and hippocampus during exposure to 3, 6 and 9 mM concentrations of extracellular K^+, and in response to single, double and repetitive (60 Hz) stimulation of afferents.

Our in vivo observations may be summarized as follows: 1) Spontaneous and evoked post-ictal spikes were most readily elicited in the AMY and LOT animals; 2) dominant (in terms of latency and amplitude) spikes (spontaneous and evoked) were most often seen in the amygdala and pyriform cortex, irrespective of stimulation site; 3) the hippocampus tended not to be a dominant site in any of these groups, including HPC.

In vitro, there was little evidence for alteration of hippocampal excitability as measured by the K^+-sensitivity of the evoked responses. There was, however, an increased tendency to generate double-spiked field potentials in 3 mM $[K^+]$.

We conclude that a) of the sites studied, the amygdala and pyriform cortex demonstrate the greatest susceptibility to kindled epileptiform activity, and b) in spite of the low threshold of the hippocampus for evoked epileptiform activity, it appears relatively immune to the long term, spontaneous focal epilepsy generated via kindling stimulation.

187.5 MECHANISMS OF EPILEPTOGENESIS IN KINDLING-PRONE VS KINDLING-RESISTANT RATS. M. Oshima* and R.J. Racine. (SPON: W. Heron). Dept. of Psychology, McMaster Univ., Hamilton, Ont. L8S 4K1.

The kindling phenomenon is one of several that have proved useful in the study of the mechanisms of epileptogenesis. The epileptiform response, in the kindling preparation, is triggered by electrical brain stimulation, and the strength of the response is increased by repeated activation of stimulated sites. Many studies (e.g. neurochemical analyses) involve the comparison of kindled vs non-kindled animals. One problem with these studies is that observed differences may be produced by, but not be necessary for, kindling.

As another approach to the question of kindling mechanisms, we have begun to consider some of the differences, present prior to kindling, that could account for fast vs slow kindling rates. To do this, we have outbred kindling-prone (KP) and kindling resistant (KR) rat strains (based on amygdala kindling rates). KP rats typically reach the first generalized convulsion within about 7 stimulations with an epileptiform afterdischarge (AD) threshold of about 50 μA, whereas KR rats usually require over 21 stimulations with a threshold of about 100 μA.

KP rats were not different from KR rats in the extent or duration of post-tetanic potentiation or long-term potentiation. They were different, however, in paired pulse effects. There appeared to be a greater paired pulse depression effect in KR vs KP rats. This possibly reflects a stronger recurrent inhibition effect in KR rats (Lømo, T., Exp. Brain Res., 12:46, 1971).

The KP rats also showed increased susceptibility to convulsant drugs that act by suppressing the GABA system (bicuculline, picrotoxin, and isoniazid), but were not different in their response to strychnine (a putative glycine blocker), or in the frequency of occurrence of audiogenic seizures. Higher doses of diazepam were required to prevent seizure responses in previously kindled KP rats. There were no differences, however, in benzodiazepine or muscimol binding in these strains.

We hypothesize that KP rats have lower AD thresholds and faster kindling rates due to a weaker background recurrent inhibition in the affected sites. These inhibitory systems may also be more prone to failure in KP rats.

187.6 EFFECTS OF GABA AGONISTS AND ANTAGONISTS ON WELL-ESTABLISHED AMYGDALA-KINDLED SEIZURES. W.M. Burnham, M.W. Kalichman and K.E. Livingston. Dept. of Pharmacology, University of Toronto, Toronto, Ontario M5S 1A8.

Seven GABA-related drugs were tested against well-established amygdala-kindled seizures. Adult, male Royal Victoria hooded rats served as subjects, each subject being implanted with a single bipolar amygdaloid electrode and "kindled" on a daily schedule to a criterion of 20 (minimum) stage 4-5 seizures. Drugs were administered via the i.p. route in a standard volume of 1 ml/kg body weight. Tests followed at appropriate post-injection intervals. Dose levels ranged from subtherapeutic to toxic.

It was found that 3-Mercaptopropionic acid, bicuculline, and picrotoxin decreased motor seizure latency, but did not otherwise exacerbate kindled seizures. Pentobarbital and gamma-vinyl-GABA both antagonized the generalized component of the seizures, but gamma-vinyl-GABA was active only at high doses which caused severe toxicity. Imidazole acetic acid and the GABA agonist SL 76-002 had no measurable effect.

The results indicate that (except at the ionophore level) manipulation of the GABA system has little effect on kindled seizures. These data, in combination with other results relating to GABA effects on the development of kindled seizures, suggest that kindling is not a GABA-related phenomenon.

187.7 ANATAGONISM OF MOTOR SEIZURE GENERALIZATION BETWEEN CONCURRENTLY DEVELOPING KINDLED SEIZURE FOCI. J.L. Burchfiel, K. Serpa*, F.H. Duffy. Children's Hospital, Boston MA 02115

The "transfer" effect of kindling is usually thought of in positive terms: kindling of one site accelerates the rate of kindling from other, secondary sites. However, McIntyre & Goddard (EEG Clin. Neurophysiol., 35:533-543, 1973) and Burnham (Can. J. Neurol. Sci., 2:417-428, 1975) have also demonstrated a "negative transfer" effect in which transfer kindling of a secondary site transiently interfered with the kindling of the original, primary site. Recently, we investigated negative transfer effects in more detail (Duchowny & Burchfiel, EEG Clin. Neurophysiol., in press). We attempted to concurrently kindle septum and ipsilateral entorhinal cortex (EC) by stimulating them in alternation. The dominant outcome of this paradigm was antagonism of motor seizure generalization from one of the sites.Only one site kindled; kindling from the other site was suppressed.

The present study extends this investigation by trying concurrent kindling of new pairs of sites in the limbic system of the rat: septum and contralateral EC, amygdala and ipsilateral EC, bilateral amygdalae, and bilateral EC. Each pair was stimulated in alternation on a trial-by-trial basis. Antagonism of motor seizure development was the consistent finding. For all pairs except bilateral amygdalae, one site became dominant and progressed to generalized seizures, while kindling from the other site was suppressed. For pairs of sites with equal rates of primary kindling (e.g., septum and EC), which site became dominant was random. For pairs with unequal kindling rates (e.g., amygdala & EC), the one with the higher rate was always dominant. Kindling antagonism was comparable whether the two sites were in the same or different hemispheres. Concurrent kindling of bilateral amygdalae resulted in mutual antagonism. For most trials, both sites elicited only partial motor seizures; fully generalized convulsions were rare. In all cases, antagonism of kindling was expressed as suppression of motor seizure generalization. The suppressed site consistently elicited ADs, accompanied by arrest of ongoing behavior, automatisms and occasional partial motor seizure activity, but the usual progression to generalized convulsions did not occur.

187.8 LASTING INFLUENCE OF AMYGDALOID KINDLING ON CHOLINERGIC NEUROTRANSMISSION. Noda, Y.*, Uemura, S.*, McGeer, E.G., and Wada, J.A.* Division of Neurological Sciences, University of British Columbia, Vancouver, B.C. Canada V6T 2A1

Eighteen male hooded rats of the Royal Victoria Hospital strain weighing 300-500 g were implanted with nichrome wire electrodes in left amygdala. Nine animals were stimulated once a day with 60 Hz at afterdischarge threshold (100-200 μA) for one second and the other nine animals were handled daily without stimulation and used as control. The animals reached Stage 5 with 11-18 daily stimulations. Stage 5 seizures were induced for additional 18-25 days. Fifteen days following the last stimulation, the animals were killed and various brain areas were dissected from 500 μm thick coronally sectioned brain slices. Choline acetyl transferase (CAT) activity and muscarinic receptor binding were measured with radio chemical assays using acetyl[1-^{14}C] coA and ^{3}HQNB respectively. CAT activities were decreased in whole brain areas examined in kindled animals. Significant changes were detected bilaterally in frontal cortices ($p < 0.05$), hippocampi (same) and amygdalae, right ($p < 0.01$): left, ($p < 0.05$). While no consistent change was found in muscarinic cholinergic receptor binding among various brain areas tested, in the stimulated hemisphere, muscarinic cholinergic binding was decreased in the frontal cortex ($p < 0.01$)., but the amygdala and pyriform cortex showed an increase ($p < 0.01$).

Participation of the muscarinic cholinergic system in the amygdaloid kindling seizure has been suggested by biochemical and pharmacological studies. Furthermore, anatomical study has indicated that the cholinergic projections from the basal nuclei to neocortex and amygdala. Although the possible role of muscarinic cholinergic mechanism in the kindling model of epilepsy has been discussed (Dasheiff, R.M. et al., Brain Research 206: 233-238, 1981), recent study seems to suggest that the change observed shortly after the completion of kindling may not reflect the processes involved in the kindled 'permanent' change. (Peterson et al., Experimental Neurology 71:144-153, 1981). Our results show that the influence of kindling on the cholinergic system is till obvious fifteen days following the last stimulation.

187.9 FACILITATION OF HIPPOCAMPAL KINDLING WITH AMYGDALA LESIONS. D. C. McIntyre* and K. A. Stokes* (SPON: J. Metuzals). Physiological Psychology Lab., Carleton University, Ottawa, Ontario, Canada.

Kindling appears to involve the progressive breakdown of inhibitory influences in the brain (eg., McIntyre, 1980). Noradrenergic systems seem to play an important role in this inhibition, for depletions of forebrain norepinephrine facilitates amygdala kindling (McIntyre, Saari and Pappas, 1979). This effect has also been demonstrated with discrete depletion of norepinephrine in the amygdala (McIntyre, 1980). Thus, it was postulated that the amygdala interacts with the kindling process of other structures of the limbic system. Lesion of the amygdala might have an influence on the kindling rate of the relatively slow-kindling dorsal hippocampus. Electrodes were implanted into the right dorsal hippocampus of Sprague-Dawley rats, and either ipsilateral, contralateral, bilateral or sham direct current lesions (2 mA., 40 seconds) were performed on the amygdala. After a three-week rest period, hippocampal kindling was begun (60 Hz, 100 μA, sine wave, 5 second duration, one stimulation per day). Results indicated that animals with bilateral or ipsilateral lesions of the amygdala demonstrated significantly facilitated hippocampal kindling, as compared to sham and operated controls. Contralateral lesions produced no facilitatory effect on kindling rate. An interesting negative correlation was found between kindling rate and latency to onset of the behavioural seizure. The data support three issues in kindling: 1) kindling involves a breakdown of inhibitory processes; 2) the amygdala influences seizure development of other limbic structures, being inhibitory as far as the dorsal hippocampus is concerned, and 3) the changes involved in kindling are primarily ipsilateral in nature.

187.10 RELATIVE CHANGES IN FOCAL SITE OXYGEN AVAILABILITY MEASURED BY POLAROGRAPHIC MICROELECTRODE IN THE KINDLED EPILEPTIC RAT. T.J. Lynch* and W.J. Jackson* (SPON: G. Doetsch). Dept. of Physiol., Medical College of Georgia, Augusta, Ga. 30912

Following kindling stimuli of 150uA (60 Hz, 3 sec train) applied to the left amygdala of male, Sprague-Dawley rats, focal oxygen availability, aO_2, has been observed to increase to an extent at least 8 times greater than its normal, rhythmic oscillation. A combination aO_2/EEG/stimulation electrode was fabricated, the aO_2 segment of which was a platinum-iridium rod of 120 micron diameter, insulated but for 800 microns at its tip. This working surface was coated with Rhoplex and positioned between the two poles of the electrode's EEG/stimulation aspect, the inter-pole separation of which was 1.5mm. The rest of the aO_2 circuit consisted of a Ag-AgCl reference electrode applying +.6V, and an op. amp. current to voltage converter driving an x-y plotter. The representative trace shown below was made at 100 sec./inch and shows 8.5 min. of pre- to postictal aO_2, the early spike in which is stimulus artifact. Increases in ictal aO_2 are observed in most cases from the first day of stimulation and increase in extent and duration as the afterdischarges take on motor involvement. The increment in aO_2 ranges between 20 and 50% above the pre-ictal aO_2. The downward turn of the ictal aO_2 record toward baseline correlates with the termination of the high frequency-high amplitude segment of the ictal EEG. The postictal aO_2 generally shows a 5 to 10 min. period during which the amplitude of its normal, rhythmic variation is decreased.

187.11 FACILITATION OF KINDLED SEIZURES IN RATS FED CHOLINE-SUPPLEMENTED DIETS. K.J. McCann*, D.P. Cain and D.J. Philbrick* (SPON. J.J. Seguin), Departments of Psychology and Physiology, University of Western Ontario, LONDON, Ontario, CANADA. N6A 5C2.

Repeated electrical or chemical stimulation of the brain at initially subconvulsive levels gradually leads to the development of seizures -- the "kindling" effect. Recent studies have indicated that activation of ACh- containing neurons can facilitate kindling.

In order to study the possible influence of dietary choline on the rate of kindled seizure development, male hooded rats were fed either a choline- deprived diet (ICN Pharmaceuticals choline-deficient diet with 0.8% L-cystine added) or a choline-supplemented diet 556 mg choline/kg diet) beginning at age 40 days. Amygdaloid electrodes were implanted at age 70 days and after-discharge threshold (ADT's) were determined after two weeks The rats were then stimulated at their individual ADT with a 1-second train of biphasic pulses once daily until a generalized seizure developed.

Rats fed the choline-deprived diet had significantly higher ADT's and required significantly more AD's to develop generalized seizures than the choline- supplemented rats (133μA vs 70 μA and 12.4 vs 8.6 AD's respectively). However, the results of the choline-deprived rats are quite comparable to those observed in normal control rats, indicating that the choline-supplemented rats kindled faster than normal. This result is consistent with the finding that dietary choline deprivation does not reduce the level of ACh in the brain, presumably because compensatory mechanisms act to maintain normal levels (Haubrich et al., J. Neurochem. 27: 1305, 1976). It is also consistent with the finding that increased dietary choline intake can affect brain ACh metabolism (Cohen and Wurtman, Science, 191: 561, 1976), and supports the view that cholinergic circuits are important in the development of amygdaloid kindled seizures. Based on these preliminary results, studies are planned to establish a possible dose-response relationship, and to measure brain levels of ACh in the different groups.

Supported by a grant from the Natural Sciences and Engineering Research Council of Canada to D.P.C.

187.12 PENTYLENETETRAZOL SENSITIZATION FACILITATES SUBSEQUENT AMYGDALOID KINDLING IN THE RAT. D.P. Cain. Department of Psychology, Univ. of Western Ontario, London, Ontario, CANADA, N6A 5C2.

The repeated administration of a variety of convulsant agents in initially subconvulsant amounts results in the gradual development of seizures--the kindling effect. We and others have demonstrated that subjects kindled using one convulsant agent can be rendered thereby more susceptible to a second such agent, but the mechanism by which this transfer facilitation occurs is not well understood. In particular, it is not clear whether subconvulsive behavioral sensitization to the initial kindling agent is sufficient for transfer facilitation, or whether full-blown behavioral convulsions also must be evoked. The approach that was taken in the present study was to compare the degree of transfer facilitation that occurred in two intact groups of rats that differed only in terms of their sensitization or seizure history.

Adult male hooded rats were implanted with bipolar electrodes in the amygdala and were randomly placed into sensitized, convulsed, or control groups. The sensitized subjects received 30 bidaily injections (i.p.) of pentylenetetrazol (PTZ) at 20 mg/kg, which resulted in the gradual development of behavioral sensitization (twitching, myoclonic jerks) in all subjects. The convulsed subjects received 25 similar injections, plus a mean of 5.8 injections of PTZ at gradually increased doses until either 2 or 3 generalized seizures had occurred. The control subjects received 30 injections of saline. When the subjects were subsequently electrically kindled through the amygdaloid electrode the sensitized subjects required a mean of 9.5 afterdischarges (ADs), the convulsed subjects required 7.6 ADs, and the control subjects required 13.2 ADs to kindle. Both PTZ-injected groups kindled significantly faster than the control group ($p<.02$ and $p<.01$), but did not differ significantly from each other in their rate of kindling. These results indicate that substantial transfer facilitation of electrical kindling of the amygdala occurs whether sensitization alone or sensitization together with convulsions are induced by prior repeated injection of PTZ. These results, taken together with results obtained earlier in our laboratory, also indicate that transfer facilitation occurs bidirectionally when injection of PTZ and electrical stimulation of the amygdala are the two convulsant agents administered in the rat.

Supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

187.13 ELECTROCONVULSIVE SHOCK INHIBITS AMYGDALA KINDLING

Robert M. Post, M.D., Frank W. Putnam, M.D.,* & Nancy R. Contel*
National Institute of Mental Health, Bethesda, MD 20205

Amygdala-kindled seizures are associated with the development of long-term alterations in convulsive and behavioral responsivity. In an attempt to alter the development of amygdala kindling, we administered electroconvulsive shock (ECS) either six hours before or immediately after amygdala stimulation in order to distinguish direct and retrograde effects.

Male Sprague-Dawley rats were implanted with 0.25 mm diameter platinum iridium electrodes in the left amygdala. Animals were randomly assigned to three groups to receive either a sham ECS or ECS (120-130 volts for 0.5 seconds) six hours prior to once-daily amygdala kindling. A third group received ECS immediately following termination of the amygdala-kindled after-discharge. Rats were kindled with once-daily stimulation (500-1000 μamps at 50 Hz for 1.0 second). Stimulation current was delivered above each animal's after-discharge threshold or at a maximum current of 1000 μamps. After-discharge duration, seizure stage and duration, and presence of wet shakes were analyzed.

Animals receiving ECS six hours prior to amygdala kindling had markedly inhibited development of major motor seizures in comparison to sham ECS animals ($p < .001$) or those receiving ECS immediately following amygdala kindling ($p < .001$). Only 1 of 9 ECS pretreated rats displayed stage 4 major motor seizures, compared to 7 of 7 sham ECS or 3 of 9 receiving ECS after kindling. The rate of development of after-discharges was also suppressed by ECS six hours prior to amygdala kindling as compared to the other two groups ($p < .001$).

These data demonstrate marked anticonvulsant effects of ECS administered prior to amygdala kindling. ECS also inhibited the rate of growth of amygdala-kindled after-discharges. The findings are of interest in relation to recent reports that anticonvulsants such as carbamazepine (which inhibit amygdala kindling) are useful in the treatment of manic and depressive illness (Ballenger and Post, Am. J. Psychiatry 137: 782-790, 1980). The mechanisms underlying the therapeutic effects of ECS in affective illness are unknown, but the current study raises the possibility that limbic anticonvulsant effects of ECS could contribute to its efficacy.

187.14 ONTOGENY OF ELECTROSHOCK SEIZURE AND RELATED BEHAVIORS IN THE RAT.

L. Zimmer,* S. Overmann,* and D. Woolley* (SPON: E. Carstens). Dept. of Animal Physiol., Univ. of Calif., Davis, CA 95616.

The developmental pattern of electroshock induced seizures was described from birth to 60 days of age over a wide range of shock intensities. Two independent groups were tested. Group 1 was administered electroshock on days 1, 3, 5, and 7, then daily from 8 to 20 days of age and on days 30 and 60. Group 2 was tested only on days 10, 20 and 30 to determine the effects of repeated shock. Electroshocks via scalp electrodes consisted of a 0.2 sec, 60 Hz alternating current at 5, 10, 15, 20, 25, 35, 50, 100, 250 and 500 mA. Animals were randomly assigned a shock intensity each test day. The occurrence of seizure and related behaviors were recorded on a checklist and timed. The thresholds for clonic and tonic seizures were determined from 1 to 60 days of age. The number of pups was 171 in Group 1 and 138 in Group 2. Pup body weights did not differ at any age between Groups 1 and 2. The threshold for clonic seizures, which included an infantile form of seizure behavior and adult-like clonic behaviors, increased to day 5 and then declined on days 10 through 20. The threshold for tonic seizures increased to a maximum on day 7 and then declined to a minimum on day 20. Clonic but not tonic thresholds for Group 1 were increased relative to thresholds for the less frequently shocked Group 2 at 30 days but not at 10 and 20 days of age. On days 13 through 18 and at electroshock intensities from 35 to 250 mA death was often observed following tonic seizures and were not observed at younger or older ages. The behaviors following a seizure-inducing stimulus showed a striking developmental pattern. Locomotion often preceeded clonus up to 20 days of age and typified the locomotor capability of the pup at its developmental stage. Locomotion began at birth with paddling, then circling, and finally to a walk or run. During the first week, subtonic seizure behaviors consisted of paddling with loss of righting or limb clonus and progressed to adult-like clonic behaviors by the second week. In the youngest animals maximum stimulus intensities evoked only forelimb flexion. By two weeks of age maximal tonic responses included the complete adult pattern of fore and hindlimb extension. Opioid-related behaviors were observed during post-seizure depression. Wet-dog-shakes followed clonic convulsions and grooming movements followed tonic seizures. These behaviors were optimally evoked during the second week and were not observed after weaning. These data provide a thorough description of behaviors induced by electroshock during ontogeny of the rat and a basis for assessment of the effects of perinatal toxin or drug exposure on development of the CNS. (Supported by ES-01503 and ES-05145.)

188.1 HIPPOCAMPAL PYRAMIDAL CELL SPINE DENSITY IN SEIZURING AND NON-SEIZURING GERBILS AT SEVERAL AGES. L.A. Paul*, P.T. Duong*, A.B. Forsythe*, A.B. Scheibel. (SPON: R.L. Katz). Depts. of Anatomy and Biomathematics, School of Medicine, UCLA, Los Angeles, CA 90024.

Continuing our investigations of neuronal structural correlates of seizure behavior in an animal model of epilepsy, we have performed analyses on dendrite spine densities of hippocampal CA3 pyramidal cells in gerbils of several ages under two test conditions. Brains of seizing (SS) and nonseizing (SR) gerbils aged 30, 50, 90 and 180 days, following a history of repeated (T) or minimal (NT) seizure testing were stained with a rapid Golgi variant. Dendrite segments from both apical and basilar regions were selected and the spines enumerated according to the procedure previously reported (Science, in press). A maximum likelihood mixed model analysis of variance was used for this nonorthogonal design.

As reported, adult (180 day) SS gerbils had fewer spines per apical dendrite segment than did SR. However, SS animals from the earliest ages sampled (30 and 50 days) showed the opposite pattern: SS had more spines per apical segment than did SR's. In fact, the mean spine density for SS gerbils at age 50 days was higher than that of any other group in the study. Spine counts at ages 50 and 90 days did not differ between the two strains.

The changes in spine density during development in the two strains were also of interest. The seizing gerbil experiences a constant reduction in spine density from the age of 50 days onward. The nonseizing animal, on the other hand, shows no significant decline in spine density with age. Scores for apical and basilar dendrites within each strain during development are approximately parallel. Finally, T-NT effects were noted in the older animals. These effects were more prominent in basilar dendritic systems.

The impact of a group of experimental variables including strain, test condition, and age upon the spine density along two distinct (apical and basilar) dendrite systems deserves interpretation in the light of the unique presynaptic ensembles involved. We speculate that epileptic behavior might be interpreted as the result of a complex interaction among many factors rather than as a single function of dendrite spine density.

188.2 DISTRIBUTION AND IMMUNOHISTOCHEMICAL LOCALIZATION OF CALCIUM-BINDING PROTEIN IN THE CEREBELLUM AND HIPPOCAMPAL FORMATION OF THE RAT BRAIN. K.G. Baimbridge* and J.J. Miller (SPON: B.R. Sastry). Dept. of Physiology, Univ. British Columbia, Vancouver, Canada. V6T 1W5

The distribution and immunohistochemical localization of calcium-binding protein (CaBP) in the rat brain was examined by radioimmunoassay (RIA), immunoperoxidase and immunofluorescence techniques. RIA indicated a high concentration of CaBP in the cerebellum (15 µg/mg total soluble protein - TSP) with lesser, but significant amounts in many other regions of the brain, including the hippocampus (0.96 µg/mg TSP). Microdissection of the hippocampal formation followed by RIA further indicated a marked differential distribution of CaBP within this structure, notably a concentration in the dentate gyrus of 1.71 µg/mg TSP with lesser amounts in the CA1 and CA3 regions (0.55 and 0.33 µg/mg TSP respectively).

The immunohistochemical localization, using antibodies purified by affinity chromatography, demonstrated that within the cerebellum only the dendrites, somata and axons of Purkinje cells were stained; no other neuronal or neuroglial population was labelled. In the hippocampal formation immunoreactive staining was observed in the perikarya of dentate granule and CA1 pyramidal cells. In both of these regions extensive labelling was also present in the apical dendritic layers. A dense plexus of immunoreactive fibers, corresponding to the mossy fibre system, was observed coursing from the granule cell layer through the hilar zone and terminating in the CA3 molecular layer. The CA3 pyramidal cell bodies and processes were not stained. Both the distribution and relative density of staining observed by these histochemical techniques closely agree with the distribution of CaBP determined by RIA.

We have previously suggested that the function of this protein may be that of an intraneuronal, free cytoplasmic buffering system. In this respect the localization of CaBP within specific neurones, and its absence in others, suggests that the capacity to buffer an influx of calcium may vary from one neurone type to another. The presence of CaBP may therefore have a pronounced effect upon the excitability of neurones which contain it.

188.3 LONG TERM ALTERATIONS IN HIPPOCAMPAL CALCIUM-BINDING PROTEIN FOLLOWING KINDLING-INDUCED EPILEPSY. J.J. Miller & K.G. Baimbridge*. Dept. of Physiology, Univ. of British Columbia, Vancouver, Canada V6T 1W5.

Repeated subconvulsive electrical stimulation of various subcortical structures results in progressive changes in neuronal activity eventually culminating in generalized seizure. The physiological and biochemical events which underly this form of kindling-induced epilepsy, and which result in permanent changes in neuronal excitability, remain unclear. Recent studies have suggested that calcium, calmodulin and calcium-binding protein (CaBP) may play a significant role in long-term alterations of synaptic efficacy in the hippocampal formation. The following experiments were undertaken to determine whether alterations of these proteins may be associated with kindling-induced seizure activity.

Rats were chronically implanted with stimulating electrodes in the midline commissural pathway and kindled with once daily stimulation (60 Hz, 100 µA, 1 sec) until at least five consecutive full motor seizures (stage V) were evoked. Animals were sacrificed either 24 h or 7 days following the last seizure response and the hippocampus, cerebellum and frontal cortex dissected free and prepared for the determination of CaBP (using a specific mammalian brain CaBP radioimmunoassay-RIA), calmodulin (using a phosphodiesterase activation method), and total soluble protein (TSP).

In a series of experiments the concentration of CaBP in the hippocampus was consistently reduced for both the 24 h post-seizure group (597±27 ng CaBP/mg TSP) and 7 day post-seizure group (611±63) when compared to weight-matched controls (816±18) and implanted controls (874±47). Calmodulin and TSP remained constant in all groups. Additionally no changes were detected in the CaBP content of other brain regions (cerebellum and frontal cortex) as a result of kindling.

These data indicate that a specific and permanent reduction in the intracellular content of CaBP in the hippocampal formation accompanies kindling-induced epilepsy. In view of the differential distribution of CaBP within hippocampal neuronal elements and its postulated role as a cytosolic buffer for intracellular calcium, any permanent reduction in this buffering capacity may lead to increased excitability and epileptiform discharge.

188.4 KAINIC ACID INCREASES EXCITABILITY AND PROMOTES BURSTING IN HIPPOCAMPAL PYRAMIDAL CELLS Westbrook, G.* and Lothman E., Wash. Univ., Dept. Neurol., St. Louis, MO 63110.

Previously we described the use of kainic acid (KA) in a model of temporal lobe epilepsy that allows comparative in vitro and in vivo studies. We now report the effect of KA on hippocampal monosynaptic excitatory synapses and the cellular correlates of KA-induced interictal spikes.

Slices of rat hippocampus (400 µM) were prepared and maintained according to standard techniques at 37°C in a medium with an ionic content resembling brain extracellular fluid. Recording microelectrodes were positioned in the cell body and apical dendrite layers of CA_1 and semimicroelectrodes placed for Schaffer collateral stimulation. KA (.03-.3 µM) markedly increased the amplitude and number of population spikes without altering the presynaptic volley or population epsp amplitude. Spontaneous paroxysms characterized by a 50-200 msec positive wave with superimposed negative transients over the cell bodies and opposite polarities over the dendrites were seen in 0.1 µM KA. These interictal spikes were triggered in an all-or-none fashion with low intensity stimuli. Rinsing with control media returned responses to normal. In control media intra- and extracellular recordings of CA_3 pyramidal cells showed spontaneous bursts without accompanying field potentials; CA_1 pyramidal cells displayed single action potentials spontaneously or in response to low intensity, low frequency stimuli. With tetanization or high voltage stimuli, afterdepolarizations and/or double action potentials were seen. In KA both CA_1 and CA_3 cells exhibited bursts, either spontaneously or in response to low intensity, low frequency stimuli, which were synchronized with field interictal spikes.

Like others, we conclude that all hippocampal pyramidal cells are intrinsically capable at bursting, but that those in CA_1 only do so under special conditions. The behavior of pyramidal cells made epileptic with KA is like that produced with penicillin. Since penicillin blocks inhibition and KA is believed to be a potent activator of excitatory amino acid receptors, it appears that different mechanisms can lead to bursting of hippocampal neurons. The data indicate that a change in post synaptic "excitability" rather than augmentation of synaptic potentials is a primary mechanism for the convulsant action of KA.

188.5 SEIZURES AND NEURONAL DEGENERATION: RELATIONSHIPS INVESTIGATED BY INTRAHIPPOCAMPAL KAINIC AND IBOTENIC ACID. Caterina Aldinio*, Edward D. French and Robert Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD. 21228.

Both kainic (KA; 2µg) and ibotenic (IBO; 10µg) acid have been shown to cause extensive axon-sparing lesions upon intrahippocampal injection (Schwarcz et.al., Exp.Brain Res. 37:199, 1979). KA and IBO were now employed to examine the question if neuropathological changes may be causally related to preceding seizure activity. The two amino acids were infused into the right hippocampus (HPC) of chronically cannulated unanaesthetized rats and EEG measurements were performed simultaneously in injected and contralateral HPC and bilaterally in the cortices. 4-10 days after injection, the animals were perfused and the brains analyzed histologically by brightfield microscopy.

Application of as little as 500pg KA caused behavioral and concomitant EEG changes. The behavioral syndrome, which became increasingly pronounced at higher doses, included sniffing, enhanced locomotor activity, rearing, grooming, scratching, mouth movements, wet-dog shakes, and, at the highest dose, ipsiversive rotation. No generalized motor seizures were observed in our dose range (up to 250ng KA). EEG changes ranged from a highly rhythmic fast activity (25Hz) and spikes at lower doses to repeated high frequency spiking with increased doses. In quantitative terms 50% of all animals (N=4-6 at each of 7 doses) infused with 5ng KA and every rat treated with>20ng KA developed seizure activity. Latency of onset of the first seizure, which was reliably preceded by EEG irregularities in the ipsilateral HPC, was 10-20 min. Total duration of seizure activity was (in a roughly dose-dependent fashion) 1-3 hr. Notably, after the last seizure, fast electrical activity persisted in the injected HPC for an additional 1-3 hr. Upon morphological examination, only the highest dose employed in this study (250ng KA) could be demonstrated to result in loss of HPC neurons (CA_{3+4} pyramids).

The pattern of EEG changes after IBO was clearly different. Only doses in excess of 15µg reliably resulted in seizure activity. However, seizures were much fewer in number, composed of lower frequencies and characteristic spiking activity was replaced by sustained (2-3 hr) slow wave EEG activity in all leads within 30 min of injection. Behavioral changes, consisting of increased locomotor activity, ataxia, loss of righting reflex, and onset of sleep paralleled EEG changes.

These results show that low doses of KA can elicit seizure activity that is not accompanied by morphological damage. However, excessive neuronal discharge produced by high doses of KA does result in neuropathological changes. Since IBO-induced seizures are markedly less severe than those seen with low doses of KA, it is difficult to relate IBO neurotoxicity to its epileptogenic effects.

188.6 LIMBIC SEIZURES DOWN REGULATE MUSCARINIC CHOLINERGIC RECEPTORS IN HIPPOCAMPAL FORMATION. J. O. McNamara and R. M. Dasheiff. Departments of Medicine (Neurology) and Pharmacology, Duke University; and Epilepsy Center, VA Medical Center; Durham, NC 27705

We have previously reported declines of muscarinic cholinergic receptors (MCR) in the hippocampal formation (HPF) following amygdala kindled seizures. This decline of MCR could be related to the kindling process itself or be a consequence of kindled seizures. The time course of the MCR alterations favor the latter possibility. To test this hypothesis directly, limbic seizures were induced in male Sprague-Dawley rats by making a unilateral, right-sided entorhinal cortex (EC) lesion (see abstract this volume). Controls were sham operated. MCR were measured with a radioligand binding assay using [^{3}H] QNB. Membranes prepared from microdissected HPF showed a bilateral and symmetric decline in MCR number without change in affinity at 3 days post lesion; data is pmol/mg expressed as % control: Dentate Gyrus, Right 69%, Left 66%; Regio Superior, R 85%, L 80%; Regio Inferior, R 84%, L 79%, all statistically significant. The epileptic activity induced by this lesion remits within ten days. The MCR declines parallel this activity, returning towards control values by 10 days and equalling controls by 30 days. Further, if rats are pretreated with phenobarbital 2 days prior and 3 days following the lesion, the MCR declines found at 3 days are reversed in a dose dependent manner, in parallel with blocking of the epileptic activity. The symmetry of the receptor alterations is in striking contrast to the predominantly ipsilateral projections from the EC to HPF. The declines were not increased with bilateral lesions. Together with their time course and reversal with phenobarbital, the data support seizures as the mechanism down regulating MCR in EC lesioned animals. This observation lends credence to the hypothesis that seizures are responsible for the same type of receptor regulation in kindling. We suspect that this biochemical alteration is an endogenous inhibitory response to seizures and the accompanying neuronal depolarization.

188.7 BENZODIAZEPINE RECEPTOR INCREASES FOLLOWING REPEATED SEIZURES: EVIDENCE FOR LOCALIZATION TO DENTATE GRANULE CELLS F. Valdes*, R. M. Dasheiff, F. Birmingham*, K. Crutcher, and J. O. McNamara (SPON: R. Fanelli). Departments of Medicine (Neurology) and Pharmacology, Duke University; and Epilepsy Center, VA Medical Center; Durham, NC 27705

Repeated seizures, whether induced by kindling or electroshock, result in increased numbers of benzodiazepine receptors in hippocampal formation (HPF) membranes (Proc. Natl. Acad. Sci. U.S.A. 77, 3029-3032, 1980). We sought to determine which cells in HPF contain the receptor increases. Kindled seizures were induced by daily administration of low levels of electrical current through electrodes stereotaxically implanted in the right amygdala. Control animals underwent electrode implantation but received no stimulation. Animals were killed 24 hours after the last seizure. In vitro [^{3}H] flunitrazepam binding (mean of fmol/mg protein ± SEM) was performed on membranes prepared from microdissected samples of HPF. Significant increases of benzodiazepine receptors were restricted to the fascia dentata (control 408 ± 24, experimental 576 ± 35, $p < .001$ students' t-test). No significant changes in binding were observed in the adjacent hippocampal gyrus. Scatchard plots of [^{3}H] flunitrazepam binding isotherms indicated the increase to be due to increased numbers of binding sites without alteration in affinity. [^{3}H] flunitrazepam autoradiographs demonstrated significant increases of silver grain density over the granule cell and molecular layers of fascia dentata in seizure treated animals, but not in other regions of hippocampal formation. The discrete lamination of the increased grain density throughout the granule cell and molecular layers is most consistent with a localization to the somata and dendrites of the granule cells. Destruction of granule cells in normal rats by colchicine or neonatal X-irradiation was associated with marked decline of benzodiazepine receptor binding. Together these results provide strong evidence for localization of the receptor increases to the somata and dendritic tree of the granule cells. We suggest that this cellular localization may provide a clue to the network of altered neural circuitry underlying amygdala kindling.

188.8 INTRACELLULAR AND FIELD POTENTIAL RECORDINGS OF EPILEPTIFORM ACTIVITY FROM IMMATURE RAT HIPPOCAMPAL SLICES. John W. Swann. Lab. of Developmental Neurophysiology, Birth Defects Institute, Div. Labs and Research, N.Y.S. Dept. Health, Albany, NY 12201

Hippocampal slices were prepared following methods described previously (Andersen, P., et al., J. Physiol., 302:463, 1980). Slices were taken from immature (1-2 weeks old: 10-40 grams) and mature rats (7-8 weeks old: 200-250 grams). Slices from an immature and a mature rat were placed together in the experimental chamber and comparisons were made between them under identical experimental conditions. After recording from slices in control bathing medium, penicillin (1.7 mM final concentration) was added to the perfusate. Intracellular and field potential recordings were made from the CA3 pyramidal cell body layer. Orthodromic activation was achieved through electrical stimulation of stratum radiatum.

In control bathing media, field potential recordings in both immature and mature slices revealed only isolated spontaneous single unit activity. In both slices, orthodromic activation of the CA3 pyramidal cells resulted in a population spike. Upon exposure to penicillin the mature slices exhibited spontaneous epileptiform bursts of population spikes, which could also be evoked by orthodromic stimulation (Schwartzkroin, P.A. and Prince, D.A., Ann. Neurol., 1:463, 1977). Slices taken from immature rats (9-19 days) generated similar spontaneous epileptiform discharges. However, these discharges were less frequent and often longer in duration. Orthodromic stimulation evoked identical discharges in an all or none fashion. In contrast, these bursts were invariably followed by a large (1-5 mv), slow negative field potential. Riding on the envelop of this slow potential was an afterdischarge often of 15-30 sec duration. Slices from 7 and 8 day old rats did not generate large epileptiform bursts, slow negative field potentials or afterdischarges. The epileptogenic properties of slices from 24 and 25 day old rats appeared similar to those of the mature rat slices.

In control bathing media, orthodromic stimulation resulted intracellularly in an epsp, a resultant action potential, and a subsequent ipsp in both the mature and immature slices . In penicillin the CA3 pyramidal cells from mature slices generated large depolarization shifts (DS's) associated with high frequency bursts of action potentials. The DS's occurred both spontaneously and in response to orthodromic stimulation. Neurons in the immature slices underwent similar DS's which often were longer in duration. The DS's were followed by slow depolarizing afterpotentials and afterdischarges. The afterdischarges consisted of multiple large (20-40 mv) slow (50-100 msec) depolarizing potentials which resulted in one or more action potentials in the neuron.

188.9 ULTRASTRUCTURAL COMPARISON OF HIPPOCAMPAL DAMAGE PRODUCED BY ELECTRICAL STIMULATION OF THE PERFORANT PATH AND THAT INDUCED BY KAINIC ACID, FOLIC ACID OR DIPIPERIDINOETHANE. T. deGubareff*, J. W. Olney and R. S. Sloviter (SPON: E. Robins). Washington Univ., St. Louis, MO and Pennsylvania State Univ., Hershey, PA.

A distinctive laminar pattern of hippocampal damage selectively involving neural elements innervated by putative glutamergic fibers has been described in rats as a consequence of sustained limbic seizures induced by kainic acid (KA), folic acid (FA) or dipiperidinoethane (DPE). Sloviter and Damiano (Fed. Proc. 40, 309, 1981) recently found that sustained intermittent electrical stimulation (x 24h) of the perforant path (PP), the major excitatory input to the hippocampus, duplicates specific electrophysiological effects of KA (decreased recurrent inhibition and increased granule cell activity) while also causing hippocampal damage which, by light microscopy, appears very similar to that induced by KA, FA or DPE. The present study documents, by electron microscopy, that the acute hippocampal pathology resulting from PP stimulation is identical in every essential detail to that induced by KA, FA or DPE. The neuronal changes consist of acute edematous swelling of specific dendritic elements and either swelling or dark cell degeneration of neuronal somata (primarily hilar interneurons and CA4, 3 and 1 pyramids). Massive swelling of specific glia that lie in close proximity to the affected neurons is a conspicuous feature of the acute reaction. Tentatively, we interpret this as a reversible response of glia to high extracellular K^+ concentrations produced by repetitive neuronal depolarization. It is noteworthy that both FA (which is structurally related to KA) and DPE (which is not) reproduce the KA type of sustained limbic seizure activity. The observation that sustained PP stimulation and treatment with KA, FA or DPE result in an identical pattern of hippocampal damage supports the hypothesis that sustained discharge activity *per se* is an important common denominator of this type of neuropathology. Moreover, a cardinal feature of the changes observed (massive dilatation of postsynaptic dendrites with sparing of their presynaptic axonal contacts) is the "excitotoxic" type of reaction that glutamate (Glu) and aspartate (Asp) are known to produce. Since both PP stimulation and KA treatment cause disinhibited excitatory firing of specific hippocampal inputs that putatively use Glu or Asp as transmitter, excessive release of these endogenous excitotoxins at hippocampal synapses may be responsible for the postsynaptic degeneration observed. That a similar mechanism might underlie neuronal degeneration in certain types of human epilepsy warrants consideration. Supported by USPHS grants NS-09156, DA-00259 and RSA MH-38894 (JWO).

188.10 SIMULATIONS OF THE CA3 HIPPOCAMPAL REGION: SINGLE CELLS, ELECTROTONIC INTERACTIONS, SYNCHRONIZATION, SEIZURES. R.D. Traub and R.K.S. Wong. IBM Watson Res. Ctr., Yorktown Heights, NY 10598.

We have developed a detailed model of the CA3 hippocampal pyramidal cell which is capable of generating bursts in either soma or apical dendrites. A burst consists of a series of spikes with growing calcium-mediated afterpotentials terminating in a calcium spike, and depends in part for its generation on a voltage-dependent inactivation of gK. This model is capable of repetitive bursting. Simulations of a pair of cells joined by an electrotonic junction demonstrate spread of bursting with a latency of tens of ms. We have abstracted the essential features of this model to construct a network of 100 pyramidal cells together with a small number of inhibitory interneurons, and have used this network to gain insight into penicillin-induced epileptiform behavior. Synaptic connectivity of the network is consistent with known data: excitatory interconnection of one pyramidal cell to another occurs with probability about 5%. In the penicillin case, recurrent inhibition is assumed severely reduced compared with the non-penicillin case. A shock to a small group of cells leads to a synchronous population burst with latency (experimental and in the model) of about 100 ms. Electrotonic coupling is not required for synchronization, but such coupling may play a modulatory role. With a small tonic drive to some of the cells, the network reproduces periodic synchronous population discharges, mimicking periodic interictal spikes. As excitatory coupling is increased, clonic and tonic seizures develop. Factors influencing the period of the population discharge relative to the period of individual cells are analyzed, as are factors contributing to development of seizures.

188.11 EVIDENCE THAT PENICILLIN-INDUCED SYNCHRONY IN GUINEA PIG HIPPOCAMPAL SLICES IS NOT ACCOMPANIED BY INCREASED ELECTROTONIC COUPLING. J. H. Schneiderman* and P. A. Schwartzkroin (SPON: A. R. Wyler), Department of Neurological Surgery, University of Washington, Seattle, Washington 98195.

Electrotonic coupling of neurons has been proposed as a mechanism for synchronization and spread of epileptiform discharges in mammalian central nervous system (Gutnick, M. J. et al., Science 211:67, 1981; MacVicar, B. A. et al., Brain Res. 196:494, 1980). We present evidence that the synchrony produced by penicillin in the CA3 region of guinea pig hippocampal slices is not associated with an increase in electrotonic coupling.

The field potentials evoked by stimulation of the stratum radiatum were recorded in the CA3 somatic region of guinea pig hippocampal slices *in vitro*. The stimulus intensity was maintained well below that necessary to produce a maximal antidromically-evoked CA3 population spike.

The amplitude of the antidromically-evoked CA3 population spike did not increase after perfusion of the tissue with 3.4 mM sodium penicillin G even though a population burst, riding on a depolarizing envelope, followed the antidromic population spike. If penicillin increased electrotonic coupling, the antidromically-evoked population spike should have increased in amplitude.

188.12 AFTERPOTENTIALS FOLLOWING BURST DISCHARGES IN NEOCORTICAL NEURONS. R.N. Friedman* and D.A. Prince. Dept. Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305

Epileptogenic burst discharges are followed by slow afterpotentials in neocortical neurons in vivo. We used standard intracellular recording techniques (K-acetate and K-sulfate electrodes) to investigate afterhypolarizations (AHPs) and afterdepolarizations (ADPs) which followed orthodromically evoked depolarization shifts (DSs) and associated spike bursts in neurons of guinea pig neocortical slices treated with penicillin (3.4-10mM) or bicuculline (10^{-5}M). Single neurons usually generated either AHPs or ADPs. Only in rare instances were AHPs replaced by ADPs in a given cell that had a stable resting potential. AHPs and ADPs could be recorded from neighboring neurons in the same slice under identical experimental conditions. Burst afterpotentials were observed in neurons impaled at depths of 160-2000 μm below the pial surface. AHP amplitudes and durations ranging to 8mV and 4 sec were dependent on size of burst, resting potential, $[K^+]_o$, and frequency of triggering. ADPs had durations up to 5 sec and, unlike AHPs, persisted in cases in which spike bursts on the DS failed. AHPs and ADPs were accompanied by conductance increases of 36.9±7.8% (n=8) and 38.2 ± 5.8% (n=7), respectively. AHPs and most ADPs could be reversed by the application of intracellular current. The AHP reversal potential (E_{AHP}) determined with $[K^+]_o$ = 4, 5, and 8 mM was -92.4 ± 6.6 (n=7), -78.3 ± 6.7 (n=6) and -81.0 ± 7.8 (n=6) (mV.±7.8 (n=6) (mV.±S.D.), respectively. The positive shift of the E_{AHP} with increasing $[K^+]_o$ suggests that a K^+ conductance has a significant role in the AHP. Microelectrode impalements of single cells were maintained through changes of perfusing solutions which differed in $[K^+]$ (K^+ substituted for Na^+). Data collected after at least 10 minutes' equilibration in each solution showed that increasing $[K^+]_o$ decreased the E_{AHP} (n=7). E_{ADP} (measured in $[K^+]_o$ = 5mM) was -48.0 ± 13.9 mV (N=10). The amplitude and duration of AHPs and the ADP duration were dependent on the frequency of DS triggering. Rates ≥ 1Hz totally depressed AHPs and markedly decreased ADP duration. AHPs were stable at DS frequencies of ≤.33 Hz. The ADP required as long as 20 sec for complete recovery. AHPs could be recorded in neurons after intracellular application of K-EGTA (.1 - .2M). 14 of 27 EGTA injected cells generated spontaneous or directly evoked bursts suggesting that some neocortical neurons have latent, intrinsic mechanisms for burst generation. The results of these experiments suggest that the AHP is mediated, in large part, by an increase in K^+ conductance. However, the mechanisms for ADP generation are distinctly different, perhaps involving superimposed conductances for Na^+ and $Ca^{++}$and/or contributions of excitatory synaptic events. (Supported by NINCDS Grant NS 06477)

188.13 POWER SPECTRAL ANALYSIS OF SLEEP EEG RESPONSE TO ANTICONVULSANT COMPOUNDS OF DIFFERING THERAPEUTIC EFFECTS IN THE MONKEY. M. B. Sterman and R. A. Kovalesky*. Neuropsychology Lab., VA Medical Center, Sepulveda, CA 91343 and Depts. of Anatomy and Psychiatry, UCLA School of Medicine, Los Angeles, CA 90024.

Four rhesus monkeys were prepared surgically for monitoring of cortical EEG patterns during sleep and for determination of the effects of specific chemical compounds on normal sleep EEG characteristics. Data were quantified using an established application of power spectral analysis which provided standard sleep EEG spectral density profiles during baseline conditions and following the administration of five anticonvulsant drugs, including: pyridoxine, diazepam, phenobarbital, carbamazepine and sodium valproate. Following the completion of these studies, animals were challenged with a convulsant drug, monomethylhydrazine (MMH) and the protective characteristics of these anticonvulsants compared with their effects on sleep EEG spectra.

After recovery from surgery all animals were adapted to sustained chair restraint and EEG polygraphic data collected on paper and analog tape during five consecutive baseline nights. Ten minute samples of continuous nonREM sleep were selected approximately two hours into this period and subjected to power spectral analysis using established techniques. The animals were then administered therapeutic doses of the anticonvulsant drug series in counterbalanced order at two-week intervals. Each drug was administered just prior to the start of recording and data collected as before. Additionally, however, after two hours of recording blood samples were drawn from the femoral vein and evaluated for determination of corresponding blood levels of the compound. On MMH challenge trials these drugs were administered as before but were followed after 10 min. by the convulsant (15mg/kg).

Power spectral profile data based on mean values from the four animals showed significant change following drug administration. Blood levels obtained for these compounds confirmed therapeutic ranges. Normative profiles were stable across baseline nights. Both pyridoxine and diazepam produced a localized and significant decrease in power at 0-3 and 4-7 Hz in rolandic cortex. These drugs were also effective in protecting against MMH induced seizures. The findings to date suggest that a specific EEG "anticonvulsant signature" may be derived for drugs which are clinically effective in various types of seizure conditions.

188.14 16 CHANNEL SPIKE "RECOGNITION PRINTOUT" SYSTEM FOR EEG. Bradford Merrill* and Reginald G. Bickford. UCSD, La Jolla, CA 92093.

In spite of numerous attempts at spike recognition (Carrie, Frost, Lopez da Silva, Zeterburg, Gose, Luders) clinical EEGers do not trust pure computer approaches.

We have designed a system (using the LSI-11 "MINICEARS"* microprocessor and graphics printer) to select "probable spikes", on line, from 16 channels of EEG, and print them out in two compilations: 1) Spike Pack - locates spikes on a head diagram, and 2) Spike Slice - prints spikes in a 0.2 second EEG background sample across sixteen electrodes. The alignment accuracy, extra time lines and event separation of the matrix ("Digigraphic") spike slice enhances the diagnostic utility (Fig. below).

The algorithm depends on slope, duration, and amplitude parameters and is adjustable, on line, to customize the selective process to the characteristics of the patient's spike. The values of parameters used in selection of a particular spike are printed alongside the spike slice. The recognition performance has been tested on the spike data tape of Gose (1974), and is adequate for preliminary recognition.

Because final validation is done by the eye of an experienced EEGer, the method is considered appropriate for clinical application. The recognition parameters provide significant data in spike categorization, and give important insights to advance the process of spike definition and recognition. By appropriate manipulation of parameters, the system can also recognize "spike wave" and other transients. The performance gives promise of wide clinical utility, including the "anti-convulsant efficacy" estimate of Frost.

Spike Slice - Epileptic Patient. Focal P3 Spike*

188.15 RELATIONSHIPS BETWEEN THE ANTAGONISM OF ELECTRICALLY-INDUCED MAXIMAL SEIZURES BY PHENYTOIN (PHT) AND CENTRAL NERVOUS SYSTEM (CNS) LEVELS OF ADENOSINE 3',5-MONOPHOSPHATE (cAMP) AND GUANOSINE 3',5-MONOPHOSPHATE (cGMP) IN FROGS AND MICE. S.W. Johnson* and W.K. Riker* (SPON: L. Gronke). Dept. of Pharmacol., Univ. of Oregon Health Sciences Center, Portland, Oregon, 97201.

The discovery that seizures are associated with large increases in CNS levels of cAMP and cGMP has prompted much speculation about relationships between cyclic nucleotides and seizures. Because many anticonvulsant drugs antagonize the rise in cAMP and cGMP levels associated with seizures, it was hypothesized that PHT, a prototypic anticonvulsant drug, may modify the pattern of electrically-induced seizures by this mechanism. To test this hypothesis, we first defined the complete PHT dose-effect curve for the prevention of tonic hindlimb extension (THE), the classic assay endpoint for anticonvulsant efficacy, in frogs (Rana pipiens) and mice (CF #1). We then examined the effects of PHT on cyclic nucleotide levels in the CNS of these animals before and after corneal electroshock. CNS levels of cAMP and cGMP were also measured in quaking mice (qk/qk), a myelin-deficient mutant strain which seize spontaneously. All animals were sacrificed by immersion into liquid N_2, and cAMP was assayed by competitive protein binding while cGMP was assayed by RIA.

In agreement with the results of others, PHT antagonized the electroshock-induced increase in levels of cAMP and cGMP in cerebrum and cerebellum, respecitvely, from CF #1 mice. However, the effective dose-range of PHT for significant reduction of the elevated levels of cAMP and cGMP was 2-5 times higher than that for prevention of THE in 95% of mice. The effective dose-range of PHT for preventing tonic flexion and clonus was nearer to that for alteration of cyclic nucleotide levels, but these endpoints have less relevance to anticonvulsant efficacy than does the classic endpoint, prevention of THE. Also, the greatest reduction of cyclic nucleotide levels occurred at a dose (100 mg/kg, s.c.) which produced toxic signs in mice. In frogs, the electroshock-associated increase in levels of cAMP and cGMP in the CNS was not altered by PHT even when the doses administered were up to twice the ED 95 for prevention of THE. Quaking mice, sacrificed during inter-ictal periods, did not have abnormal levels of cAMP or cGMP in cerebrum or cerebellum, and a dose of PHT (15 mg/kg, s.c.) which abolished all seizure activity did not alter levels of these cyclic nucleotides. Since these data from mice and frogs show that the anticonvulsant effect of PHT is dissociated, by dose, from effects on CNS cyclic nucleotide levels, it is doubtful that the alteration of cyclic nucleotide levels is a mechanism by which PHT exerts its anticonvulsant effect.

188.16 THE SUBSTANTIA NIGRA: SITE OF GABA-MEDIATED ANTICONVULSANT ACTIVITY IN RATS. M.J. Iadarola and K. Gale, Neurology Research Lab, VA Hospital, Durham, N.C. 27705, and Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

Microinjection of the GABA-receptor agonist, muscimol, bilaterally into the substantia nigra (SN) protected against seizures produced by bicuculline (.25 mg/kg i.v.), pentylenetetrazol (PTZ, 40 mg/kg i.v.), and maximal electroshock (MES). Two procedures were used for microinjection: 1) Muscimol (25, 50 and 75 ng in 0.4 ul saline over 5 min) was infused while rats were under ether anesthesia, and the rats were tested with MES or PTZ at 2.5, 5 and 8 hr after surgery, 2) muscimol (10ng in 0.2ul saline) was infused via chronic indwelling cannulas, and the rats were tested with PTZ or bicuculline 20 min later. Complete protection against tonic hindlimb extension in the MES test was obtained up to 5hr after 75ng, and at 2.5hr after 50ng; partial protection was obtained with 25ng at 2.5hr and 50ng at 5hr. Complete protection against PTZ-induced major clonic seizures and tonic forelimb extension was obtained 20 min after 10ng muscimol; protection against clonic and tonic components of bicuculline-induced seizures was obtained 20 min after 10ng muscimol. All of the above results were significant in comparison to saline-microinjected control rats. At 8 hr after microinjection of muscimol, no significant protection was obtained in any seizure model. At all doses tested, muscimol caused hyperactivity, accompanied by stereotyped sniffing and gnawing; the duration of this behavior was dose-dependent, lasting 2hr after 10ng and 6hr after 75ng.

The irreversible inhibitor of GABA-transaminase, gamma-vinyl-GABA (GVG), was microinjected bilaterally into SN (5ug in 0.5ul saline) and rats were tested with MES, PTZ and bicuculline at 6 and 24 hr after GVG. At both times GVG completely protected against tonic hindlimb extension induced by MES and tonic forelimb extension induced by bicuculline; partial but significant protection was obtained against PTZ. Injections of GVG into forebrain areas (thalamus, striatum, cortex), into superior colliculus, or into hindbrain areas (pontine tegmentum), were without anticonvulsant effects, despite marked elevation of GABA (3-5X) in the vicinity (3mm radius) of the injections. Anticonvulsant effects of intranigral GVG were correlated with a 2-3X increase in GABA in SN; by 4 days, seizure activity and GABA content returned to control levels. No changes in spontaneous motor activity or reflexes accompanied the GVG microinjections.

Our data suggest that GABAergic synapses in the vicinity of the SN may be critically involved in the control of seizure propagation.

188.17 IN VITRO AUTORADIOGRAPHIC LOCALIZATION OF MUSCARINIC CHOLINERGIC BINDING SITES IN RAT HIPPOCAMPAL FORMATION: EFFECTS OF AMYGDALA KINDLING. D. D. Savage and J. O. McNamara, Departments of Medicine (Neurology) and Pharmacology, Duke University; and Epilepsy Center, VA Medical Center; Durham, NC 27705

Kindling has been proposed as a useful model for the study of limbic epilepsy. We have found that kindling induced by electrical stimulation of the amygdala results in a decrease of approximately 25% of the total number of ^{3}H-quinuclidinylbenzylate (QNB) binding sites in membranes of hippocampal formation (HPF). This reduction was most striking in the dentate gyrus of HPF. We have implemented the in vitro autoradiographic technique of Young and Kuhar (Brain Res. 179:255, 1979) to characterize the regional distribution of muscarinic cholinergic receptors in rat HPF and to determine the anatomical localization of the kindling-induced reduction in ^{3}H-QNB binding sites.

Slide mounted 8 μm coronal sections of whole brain containing dorsal HPF in cross section were used in these experiments. Slides were incubated with 0.75 nM ^{3}H-QNB for one hour at 25° C in the absence or presence of of 1 μM atropine and rinsed ten minutes in ice cold buffer (120 mM sucrose, 50 mM Na^+-K^+ phosphate, pH 7.4). Preliminary experiments indicated that the specific binding reaction was saturable, reaches equilibrium within 45 minutes and has an apparent affinity constant (K_d) of 0.05 nM ^{3}H-QNB. Specific binding was 95% of total ^{3}H-QNB binding.

Autoradiographic analysis of ^{3}H-QNB binding to HPF in normal rats demonstrated the presence of dense bands of silver grains over the dendritic fields. Specifically, the highest grain densities were observed over the stratum (s.) moleculare of both the superior and inferior blades of the dentate gyrus and the s. radiatum and s. oriens of the CA1 region of hippocampal gyrus. Grain densities 40 to 80% lower than those measured above were observed in s. granulosum and hilus of dentate and across the entire CA3 field of hippocampal gyrus. These results are similar to the in vivo autoradiographic decription of ^{3}H QNB binding in HPF by Kuhar and Yamamura (Brain Res. 110:229, 1976).

Preliminary autroadiographic analysis of HPF from an amygdala kindled rat indicates a significant reduction (25%) in grain density in the s. moleculare of dentate (30.9 ± 1.6 grains/1600 μm^2) compared to the electrode implanted unstimulated control (39.8 ± 2.2 grains/1600 μm^2). Experiments are in progress to determine which cell constituents contain the ^{3}H-QNB binding site reduction in s. moleculare.

189.1 MEMBRANE PROPERTIES OF RAT LOCUS COERULEUS NEURONS. S.A. Shefner, R.A. North and S. Nishi.* Neurophysiology Laboratory, Department of Pharmacology, Loyola University of Chicago, Maywood, IL 60153.

Intracellular recordings were made from 40 neurons in the locus coeruleus (LC) in slices (about 300 μm thick) cut from rat pons. Resting membrane potentials ranged from -45 to -60 mV and were stable for up to several hours. Neuronal input resistances varied widely (222 MΩ ± 32 MΩ, mean ± S.E. mean, n = 13). Electrotonic potentials were close to exponential with time constants of up to 80 ms. Action potentials evoked by passing depolarizing current pulses had an amplitude of 64 ± 1.5 mV (n = 11), maximum rate of rise of 168 ± 12 V/s and rate of fall of 89 ± 10 V/s (n = 9). Spike duration at half-amplitude was 1.0 + 0.6 ms (n = 10). The action potential was followed by a hyperpolarization of amplitude 12.8 ± 1.3 mV (n = 11) and duration of 100 - 500 ms. This after-hyperpolarization reversed in polarity at a membrane potential of about - 100 mV. Increasing the intensity of the depolarizing current caused an almost linear increase in the frequency of action potential discharge until this became asymptotic at 60 - 100 Hz. Focal stimulation of the slice at a distance of up to 500 μm from the recording electrode evoked graded depolarizing synaptic potentials in some LC neurons. In most cells hyperpolarization increased and depolarization decreased the synaptic potential amplitude. These properties of LC neurons were in sharp contrast to those of adjacent cells in the mesencephalic nucleus of the trigeminal nerve, which had ten times lower input resistances, much shorter duration action potentials and could not be activated synaptically.

189.2 EXCITATORY AND INHIBITORY ACTIONS OF PUTATIVE NEUROTRANSMITTERS ON CULTURED CEREBELLAR NEURONS. Donna L. Gruol. Arthur V. Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037.

Organotypic cultures of cerebellar cortex were prepared from 20 day rat embryos. After 1 month in culture, medium sized neurons (25 μ) with 1 or more thick, branching process, thought to be Purkinje neurons, were selected for electrophysiological studies. Intracellular recordings were made using conventional electrophysiological techniques. The recording media consisted of modified Hank's BSS, pH 7.4. All experiments were done at room temperature. Putative neurotransmitters were applied from large tip (5 μ) micropipettes by pressure or by superfusion. Pressure pipettes contained 50 μM solutions of GABA, glycine or glutamate or 0.05 to 5 mM norepinephrine (NE). Intracellular recordings were obtained from over 160 neurons in 27 cultures. Because of the small size of the neurons, membrane potential (Vm) varied over a large range (-30 to -60 mV) depending on the degree of injury during electrode penetration. Under optimal conditions Vm ranged from -50 to -60 mV and could be maintained for several hours. Virtually all neurons studied displayed spontaneous activity included epsps, ipsps and action potentials.

The cultured neurons were sensitive to several putative neurotransmitters thought to mediate synaptic transmission in the cerebellum. In all cells tested, glutamate (Glu) was excitatory (n=31) while GABA was inhibitory (n=68). Glycine was ineffective (n=8). The GABA and Glu responses were associated with Vm changes and an increase in membrane conductance. The mean reversal potentials for these responses were -20 mV for Glu (n=3), -51 mV for GABA when K+-acetate recording electrodes were used and -33 mV when KCl electrodes were used. These data suggest that the Glu response in cerebellar neurons is at least partially mediated by an increase in Na+ conductance while the GABA response is mediated by an increased Cl- conductance. The reversal potential for the spontaneous ipsps was similar to that for GABA (n=2). Both the GABA response and the ipsps were depressed by 1 μM bicuculline. NE applied by pressure or superfusion was relatively ineffective at concentrations below 1 mM (n=41). When tested in the mM range (n=16), NE was inhibitory in the majority of neurons (n=10), reducing the spontaneous activity (epsps, ipsps, spikes) in a dose-dependent, reversible manner. The depression of the ipsps by NE did not appear to involve a depression of postsynaptic receptor sensitivity since the GABA response was unaltered (n=4). These data support the hypothesis that Glu is an excitatory transmitter in the cerebellum while GABA and NE are inhibitory transmitters.

189.3 ELECTROPHYSIOLOGICAL PROPERTIES OF NEOCORTICAL NEURONS MAINTAINED IN VITRO. B.W. Connors, M.J. Gutnick* & D.A. Prince. Dept. Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305

We investigated membrane and synaptic properties of neurons in coronal slices (350-500 μm thick) of guinea pig sensory-motor cortex maintained in vitro (37°C). Neurons impaled at all subpial depths between 150-1700 μm had high resting potentials (-75 ± 8mV, mean ± S.D., n = 40), input resistances (R_Ns) of 24 ± 13 MΩ, and time constants of 8 ± 4.5 msec (n = 35). Sixty percent of neurons showed apparent increases in R_N during depolarization (anomalous rectification, AR). In the remainder R_N was ohmic or showed apparent decreases during depolarization (delayed rectification). AR was greatly enhanced by reduction of K^+ conductances (intracellular CS^+ injection, extracellular Ba^{2+}), but was abolished by blocking Na^+ conductance (gNa) (extracellular TTX, intracellular QX-314, removal of external Na^+). Ca^{2+} current blockade (extracellular Mn^{2+} or Co^{2+}) had relatively little effect on AR. The data indicate the presence of a voltage-sensitive, noninactivating gNa^+ in most neocortical neurons. Action potentials (amplitude = 92 ± 9 mV; duration at base = 1.7 ± 0.4 msec; n = 20) could be elicited from all neurons. Single spikes displayed a slowly decaying depolarizing afterpotential (DAP), with no hyperpolarizing undershoot. Prolonged depolarizing pulses generated repetitive firing and variable degrees of progressive spike broadening. Repetitive action potentials could elicit long, Mn^{2+}-sensitive afterhyperpolarizations in some cells. Spikes were invariably blocked by TTX, intracellular QX-314 or perfusion with a Na^+-free medium. However, intracellular injection of Cs^+ or TEA led to the generation of broadened spikes with prominent DAPs. Slow spikes in these neurons persisted when gNa^+ was blocked, were inhibited by external Mn^{2+} or Co^{2+}, and probably represent calcium-dependent electrogenesis. A small number of untreated cells generated intrinsic, all-or-none burst potentials when depolarized with current. These neurons were always located between the subpial depths of 900-1300 μm (deep layer IV, upper V), although the more characteristic, nonbursting cell types were also seen at these depths. Most neurons exhibited spontaneous, exclusively depolarizing synaptic events. Focal cortical stimulations of moderate intensity evoked depolarizing PSPs in all cells. Membrane polarization uncovered EPSP and IPSP components of these responses. Repetitive stimulation at rates as low as 0.5 Hz caused a rapid, reversible depression of the longer latency IPSPs.

Neocortical neurons in vitro have properties very similar to those which have been recorded in vivo. Our studies have characterized some of the ionic mechanisms underlying these properties.

189.4 MEMBRANE PROPERTIES OF NEOCORTICAL NEURONS IN THE IN VITRO SLICE PREPARATION. C.E. Stafstrom, P.C. Schwindt*, & W.E. Crill, Dept. of Physiol. & Biophys., and Medicine, Univ. Washington Sch. Med., Seattle, WA 98195.

Neurons in layer V of motor cortex project to segmental motor systems of the spinal cord, and are believed to represent the final pathway for cortical neuronal activity leading to the initiation of movement. These pyramidal tract (PT) neurons have been classified as "fast" and "slow" according to their axonal conduction velocities, but relatively little information is available regarding the passive and active properties of these cells. In order to investigate their membrane characteristics in more detail, we have developed an in vitro slice preparation of cat motor cortex.

After craniotomy, 400μ thick slices from area 4γ (Hassler & Muhs-Clement, J. Hirnforsch. 6: 423-436, 1964) are maintained in an oxygenated chamber by standard techniques (eg, see Schwartzkroin, Brain Research 85: 423-436, 1975). Intracellular recordings obtained from layer V have revealed that cells in the slice retain the electrical and firing properties reported in intact animals. Pial or white matter stimulation evokes orthodromic and antidromic impulses, respectively. Input resistances (4-10 MΩ) and time constants (6-12 msec) agree closely with reported values. The cells demonstrate marked anomalous rectification and membrane potential overshoots to subthreshold current pulses. Spike potentials characteristic of fast and slow PT cells are seen. Repetitive firing can be elicited by prolonged depolarizing pulses. The cells show no accomodation to ramp currents as long as 1 second. When exposed to penicillin in epileptogenic doses (5 mM), "paroxysmal depolarization shifts" can be evoked by orthodromic stimulation and occur spontaneously as well.

These results indicate that the cat cortical slice can be used to investigate passive and active properties of both normal and epileptic neurons. The preparation also allows comparison between cell types in different layers, and may permit elucidation of cortical circuitry. In addition, the largest cells will facilitate anticipated double-electrode voltage clamp experiments.

Supported by the Veterans' Administration and NIH Grant GM 07266.

189.5 CALCIUM IONS: SLOW DIFFUSION IN THE HIPPOCAMPUS. M.E. Morris[1] and K. Krnjević[2], [1]Depts. Anaesthesia & Pharmacology, Univ. of Toronto, Toronto, Ont., and [2]Depts. Anaesthesia Research & Physiology, McGill Univ., Montréal, PQ, Canada.

The time course of the alterations in extracellular ionic levels which are evoked in synaptic regions of the CNS by neuronal activity must depend on the diffusion characteristics of the particular ions. In the present study, microelectrodes were used to measure changes in extracellular Ca^{2+} concentration $[Ca^{2+}]_o$ produced by iontophoretic release of Ca^{2+} in the CA1 pyramidal cell layer of the hippocampus of the rat, anaesthetized with urethane. Inter-tip separations of electrodes were 7-50 µm. The effective transport number (n) for the release of Ca^{2+} from electrodes *in situ* (calculated from $m = In/zF$, with m being the estimated flux, I the applied current, z ionic valency, and F the Faraday constant) was only 6.82 (S.E. ± 1.54) x 10^{-3}, which is 1/60th that for Ca^{2+} movement in a simple solution of 0.1 M $CaCl_2$. This probably reflects Ca^{2+} binding at the tip of microelectrode and may explain the difficulties frequently experienced in releasing Ca^{2+} in tissue. Ejection currents of 30-200 nA produced increases of $[Ca^{2+}]_o$ of 0.05-3.0 mM above tissue resting levels of 1.3-1.5 mM. A very slow time course for both rise and decay of $[Ca^{2+}]_o$ were consistently observed with different electrodes and different animals. When curves, calculated from the diffusion equation for a continuous point source, were fitted to experimental data points - especially for the decay phases - with a computer graphic system, a mean diffusion coefficient (D) for Ca^{2+} of 0.077 (S.E. ± 0.0101) x 10^{-6} cm^2/s was obtained. This is ≈ 1/100th the values of D for self-diffusion of Ca^{2+}, or the apparent D observed following release of Ca^{2+} from microelectrodes in saline or agar. It contrasts sharply with the tissue diffusion rates for tetraethylammonium (with solely extracellular location) and for K^+ (with both intracellular and extracellular components of diffusion) which are about 1/5th of diffusion rates in aqueous solutions (Lux & Neher, Exp. Brain Res., 17:190, 1973; Krnjević & Morris, Can. J. Physiol. Pharmacol., 52:852, 1974; Nicholson et al., Brain Res., 169:580, 1979) and may reflect the reversible binding of Ca^{2+} to cell surfaces and/or intercellular macromolecules. Even brief Ca-inward currents arising from neuronal activity will therefore produce relatively prolonged depressions of $[Ca^{2+}]_o$, with a more profound influence on synaptic function. Such a possibility is in keeping with the time course of the $[Ca^{2+}]_o$ falls and associated events which are evoked in the hippocampus by repetitive stimulation (Krnjević et al., Can. J. Physiol. Pharmacol., 58: 579, 1980).

Supported by the Medical Research Council of Canada.

189.6 ELECTROPHYSIOLOGICAL STUDIES OF THE INPUT FROM THE AMYGDALOID COMPLEX TO THE DENTATE GYRUS OF THE RAT. S.R. Thomas*, S.Y. Assaf*, T.V.P. Bliss* and S.D. Iversen*. (SPON: M.S. Eison). National Institute for Medical Research, Mill Hill, London NW7 1AA and The Psychological Laboratory, Downing St., Cambridge CB2 3EB.

We have studied electrophysiologically a disynaptic input from the lateral nucleus of the amygdaloid complex to the dentate gyrus, which corresponds to that recently described anatomically (Krettek, J.E. and Price, J.L., J. Comp. Neurol., 178:255, 1978).

In rats anaesthetized with urethane (1.5 g/kg, i.p.) single-pulse stimulation of the lateral nucleus of the amygdaloid complex (AL) evoked long-latency (up to 22 msec) positive-going synaptic wave responses in the granule cell-body layer of the dentate. The AL-evoked responses resembled the effects of low-intensity stimulation of the monosynaptic perforant path (PP) input to the dentate from the entorhinal cortex, but were of longer latency (up to 22 msec compared with up to 7 msec for the PP) and exhibited relatively large variations of latency and amplitude. When population spikes were evoked by AL stimulation they were potentiated by repetitive activation. Paired-pulse experiments revealed a potent facilitation (up to 200% of control) of PP-evoked population spikes in the dentate by a preceding pulse to the AL; the optimal interval for this effect was 50 to 70 msec.

Analysis of the depth profiles indicated that the AL input is restricted to the outer zone of the main PP termination on the dendrites of the granule cells, a zone which receives input mainly from the lateral portion of the entorhinal cortex (Steward, O., J. Comp. Neurol., 167:285, 1976). Micro-infusion of procaine solution (0.5 ul of 30ug/ul over 1 min) directly into the PP reversibly eliminated the DG responses evoked by PP and AL stimulation on the EC side of the infusion, while the response to a PP electrode on the DG side of the infusion site was unaffected, indicating that the AL input travels via the PP.

The results show that the lateral nucleus of the amygdaloid complex has a potent input to the dentate gyrus, which is probably a routed via synapses in the lateral entorhinal cortex. We are currently investigating in greater depth the possibility that this apparently disynaptic input will support long-term potentiation in the dentate.

190.1 AMINO ACID RELEASE FROM CEREBELLAR CULTURES: Brian R. Pearce* and Gary R. Dutton, Department of Pharmacology, University of Iowa, Iowa City, Iowa 52242.

Our dissociated cell cultures of early postnatal rat cerebellum have been characterized for cell type and proportion (Brain Res. 183: 241-246, 1980; Brain Res. 199: 473-481, 1980), thus enabling us to correlate biochemical results with specific cell type. With the use of a novel perfusion apparatus we have determined that these cultures contain a population of neurons (∿ 7% of total cells) which accumulate [^{3}H] GABA and then release it in a Ca^{2+}-dependent manner in response to K^+-stimulation (J. Neurosci. Methods 3: 255-259, 1981; Brain Res. 206: 485-489, 1981). We have tentatively identified these cells as stellate and basket neurons. However, the most numerous neurons in the cultures are thought to be granule cells (∿ 85%). The neurotransmitter of this cell type, while still in doubt, is thought to be glutamate.

Our autoradiographic studies show that granule cells in these cultures do not accumulate exogenous [^{3}H] glutamate, uptake being confined to the glial cells. Consequently we investigated the Ca^{2+}-dependent, K^+-stimulated release of endogenous glutamate and GABA along with several other amino acids (aspartate, alanine, leucine, taurine and glutamine). Data indicated that only GABA and glutamate were released under these conditions.

With these findings and the fact that these results were not observed in experiments using glia-enriched cultures, we conclude that GABA and glutamate are probably utilized by cerebellar neurons as neurotransmitters--the latter being the transmitter of the granule cell.

190.2 PASSIVE ELECTRICAL PROPERTIES USED TO DISTINGUISH SOMATIC FROM DENDRITIC RECORDING SITES IN CULTURED NEURONS. J.K. Engelhardt, K. Ishikawa*, and D. Katase*. Dept. of Neurology, USC School of Medicine, Los Angeles, California 90033.

The identification of the structure from which one is recording is a major problem for electrophysiologists working in the mammalian CNS. This problem has been partially solved with the recent introduction of dye injection techniques. Unfortunately, these techniques involve time consuming histological processing before electrophysiology can be correlated with morphology. We report here the preliminary results of work designed to establish electrophysiological criteria for the intracellular location of the recording electrode.

Experiments were performed on the NG 108-15 neuroblastoma-glioma cell hybrid. This preparation was selected because electrophysiological and biochemical studies indicate that this cell line may serve as a useful model for alpha motoneurons (Hamprecht, B., Int. Rev. Cytol., 49:99, 1977). Cells were seeded at a low density on 60 mm plastic tissue culture dishes and examined with KCl filled intracellular microelectrodes following the development of neurites (3 to 7 days after plating). Microelectrodes were inserted into the soma or neurite of a cell under direct visual control, and the voltage responses to long pulses of hyperpolarizing current were recorded. This data was analyzed using a theoretical model developed by W. Rall (Exptl. Neurol., 2:503, 1960) in which a lumped RC model for the cell body is connected to one end of an infinitely long cable. The membrane time constant (τ_m) was determined from the data and Rall's equation 9 was solved in order to determine the coupling constant (ρ) at $t=\tau_m$. This analysis revealed that when the electrode was in the soma of a cell, ρ was small (3.5 or less) indicating a dominance of the lumped RC terms. When the electrode was in a neurite, ρ was indeterminantly large, indicating a dominance of the infinite cable terms. The key to the success of this technique appears to have been that the electrical properties were determined in a high conductance region of the cell current-voltage relation. When the membrane conductance was high, the space constant was short and the geometry of the cell near the electrode determined the response.

190.3 EFFECT OF LASER MICROBEAM SURGERY UPON SPONTANEOUS ACTIVITY OF INTERCONNECTED MICROFRAGMENTS FROM CULTURED MOUSE SPINAL TISSUE. J.H. Lucas*, B. Horwitz, and G.W. Gross (SPON: J. Hines). Departments of Biology and Physics, Texas Woman's University, Denton, TX 76204.

An ultraviolet laser microbeam system (337.1 nm wavelength) has been used to isolate selected 'circuits' of small interconnected neuronal clumps in tissue culture from their surroundings by transection of large multi-process cables as well as of single processes. These interconnected spinal tissue microfragments (30-100 μm in diameter) from cultures of mouse spinal cord were examined as an intermediate stage in our on-going efforts to develop ordered two-dimensional cellular arrays. Standard techniques of extracellular recording demonstrated continued spontaneous electrical activity following laser surgery. Fluctuations in activity may have reflected mechanical disturbances accompanying surgery as well as interruptions of interfragment communication. Use of UV laser irradiation as a direct stimulus of electrical activity within clumps produced variable results including occasional intense bursts of activity. Indirect laser stimulation via small shock waves from substrate vaporization, however, consistently elicited immediate and sustained increases in frequency of spontaneous firing as well as the appearance of larger spikes. It is concluded that the laser is a useful tool for 'tailoring' systems of interconnected neuronal tissue microfragments. Further characterization of microfragments is being conducted through the use of histological techniques, electron microscopy and administration of various pharmacological agents to block inhibitory or excitatory components.

The high accuracy of UV laser microbeam methods also allows microsurgery on single neurons. Studies have been initiated to investigate changes in intracellular electrical activity during and following laser transection of neurites.

190.4 OXYGEN CONSUMPTION OF HYPOTHALAMIC TISSUE SLICES AFTER VARYING INCUBATION PERIODS. S.R. Kelso*, M.A. Lessler* and J.A. Boulant. Dept. of Physiology, Ohio State Univ., Columbus, Ohio 43210.

The in vitro brain slice preparation has emerged as a powerful tool in pharmacological and electrophysiological studies. During the first few hours of incubation, however, electrophysiological recordings are rarely attempted, since most investigators report that spontaneous neuronal activity is often absent. The current study examines the oxygen consumption of hypothalamic tissue slices to determine if this electrophysiological phenomenon correlates with metabolic activity.

The preoptic area and anterior hypothalamus (PO/AH) of male Sprague-Dawley rats (250-300 gm) was blocked and cut into 300μm slices. Eight PO/AH tissue slices were obtained from each rat. In each experiment, oxygen uptake was immediately measured in two of the slices. The remaining slices were placed in an incubation/recording chamber, continuously perfused with oxygenated (95% O_2; 5% CO_2) glucose medium (Yamamoto, Exp. Brain Res. 14: 423, 1972), and incubated at 36 ± 1°C for up to four hours. At periodic intervals, a slice was removed from the chamber for measurement of O_2 consumption. O_2 consumption was measured by modified YSI Model 53 Biological O_2 Monitors. Single slice O_2 uptake was determined at 35°C in a glucose medium equilibrated with room air. The slope of the oxygen uptake curve during the initial eight minutes after transfer from the incubation chamber to the O_2 monitor was used to calculate O_2 uptake. Slice samples were then removed quantitatively, dried to constant weight, and weighed with a semi-microbalance.

O_2 consumption of fresh PO/AH tissue was 6.12 ± 0.97 (μl O_2/hr)/mg dry weight. Similar oxidative levels were maintained throughout the entire 4 hour incubation. During the early incubation periods, however, the O_2 consumption of the slices showed greater variability, when compared with the slices having longer incubation periods. For example, the O_2 uptake (μl/hr/mg) at 90 minutes was 4.6 ± 1.2 (S.E.), compared to a 3-hour value of 5.6 ± 0.3 (S.E.). In a control experiment, slices incubated at high temperatures (45°C) for 30 minutes, showed no oxidative capacity. In addition, there was no consistent difference between slices taken from 1.5 mm rostral to 1.0 mm caudal to the anterior commissure/optic chiasm plane of section.

These experiments support the electrophysiological findings which indicate that the tissue viability does not diminish during these incubation periods. Furthermore, the O_2 uptake variability during early incubation may correlate with the previously reported variability of electrophysiological recordings.

190.5 RAT SYMPATHETIC NEURONS FORM ELECTROTONIC SYNAPSES WHEN THEY ARE MAINTAINED IN A SERUM-FREE, DEFINED MEDIUM IN VITRO. D. Higgins*, H. Burton and R.P. Bunge. Dept. Anatomy & Neurobiology, Washington University, Sch. Med., St. Louis, MO 63110.

Principal neurons from the superior cervical ganglia of rat fetuses (21 day) were maintained for more than 12 weeks in dissociated cell cultures in a serum-free, chemically defined medium (Bottenstein and Sato, PNAS 76:514-517, 1979) supplemented with 2.5S NGF (100 ng/ml). Non-neuronal cells were killed by the periodic addition of fluorodeoxyuridine (10 μM) to the medium. Under these conditions, neurons extended processes within 24 hours; by the end of the second week in vitro, these extremely fine processes, which course alone or in small bundles, formed a dense network over the tissue culture dish.

Intracellular recordings, obtained at various times between the 17th and 80th day, showed that these neurons could generate substantial action potentials (up to 90 mV; duration ∿4 msec) in response to depolarizing current injections. These responses were dependent on tetrodotoxin-sensitive Na^+ channels, cobalt-sensitive Ca^{++} channels, and tetraethylammonium (TEA)-sensitive K^+ channels. Prominent hyperpolarizing afterpotentials (> 10 mV and >100 msec) were present even when the Na^+ action potential was blocked. Iontophoretic application of acetylcholine close to the soma also evoked action potentials.

Simultaneous intracellular recordings were obtained from pairs (n >50) of neighboring neurons. In more than 50% of the cases stimulation of one neuron elicited very short latency (< 1 msec) postsynaptic potentials in the second neuron; under optimum conditions (pH 7.7, TEA= 5 mM) an action potential in one cell usually caused an action potential in the recipient cell. These synaptic interactions were not blocked by hexamethonium (100 μM), atropine (3 μM), phentolamine (5 μM), chlorpromazine (1 μM) or propranolol (0.3 μM), or by elevation of the Mg^{++}/Ca^{++} ratio; thus the excitatory synaptic interactions between cells grown in serum-free medium do not appear to be chemically mediated. Furthermore, in about 40% of the pairs, injection of hyperpolarizing (depolarizing) current into one neuron caused the second neuron to hyperpolarize (depolarize). These experiments indicate that rat sympathetic neurons, as late as the 21st embryonic day, can form electrotonic synapses when they are maintained in a serum-free culture medium. Because these neurons acquire the ability to synthesize catecholamines during the 2nd week of gestation and retain this capacity in defined media (Iacovitti, et al., this volume), we conclude that an initial expression of the adrenergic phenotype does not preclude an electrotonic mode of synaptic transmission. (Supported by NIH Grants NS 14416 and NS 09809).

190.6 TOXIC EFFECTS OF FOOD DYES ON NGF-STIMULATED NEURITES IN CULTURE Bibie M. Chronwall and Stephen J. Morris (SPON: Richard L. Irwin) Surgical Neurology Branch and Neurotoxicology Section, NINCDS, NIH, Bethesda, MD 20205.

Erythrosin B (EB, USFD&C Red 3, tetraiodofluorescein) and other halogenated fluorescein derivatives have widespread use as food and cosmetic dyes, as well as histological stains and mordant dyes for wool, silk and cotton. Some of these dyes also inhibit uptake of neurotransmitters into synaptosomes, inhibit brain Na^+-K^+ ATPase and block ouabain binding. There is evidence for EB interaction with a "receptor-like" recognition site which is associated with, but distinct from, the cardiac glycoside binding and ATP catalytic sites (cf. abstract by Silbergeld, Morris and Anderson, these proceedings). In addition brominated and iodinated dyes are potent type II photo-oxidizing agents which have been shown to destroy the functions of several enzymes and to crosslink membrane proteins. These effects can be distinguished by the requirement for exposure to light in the presence of oxygen.

We have investigated the effects of low concentrations of ouabain and these dyes on the nerve growth factor (NGF)-promoted growth and differentiation of chick dorsal root ganglia explants employing an improved culture technique. The ganglia are embedded in gels of polymerized native collagen producing neurites of > 3 mm length. Ouabain inhibits neurite outgrowth with an IC_{50} of ~ 5 μM which is comparable to the toxicity of the cardiac glycosides reported for other cells in culture.

The iodinated and brominated dyes also inhibit outgrowth with an IC_{50} of ~ 10 μM and in addition promote early retraction of growing neurites. Some of these dye effects are due, at least in part, to photo-oxidation of the NGF. Preincubation of dye + NGF in light (60 watt incandescent bulb 80 cm from sample for 24 hours at 4°C) inactivates the growth factor. NGF incubated with dye in the dark or in light in an argon atmosphere is fully active.

However, dye-treated NGF-stimulated cultures grown in complete darkness still show reductions in neurite length when compared to non-treated controls. This suggests that the dyes may also have a direct (ouabain-like) toxic effect on the cultures.

In addition, this improved culture system should provide a rapid and inexpensive in vitro test for screening potential neorotoxins which would effect neurite growth and development.

This work was supported in part by grant no. SFB 33 E5 to Prof. J.R. Wolf, Dept. of Anatomy, Univ of Goettingen, FRG, from the Deutsche Forschungsgemeinschaft.

190.7 CYCLIC AMP INDUCES REPETITIVE FIRING IN CULTURED EMBRYONIC RAT MUSCLE. James Blosser, James McManaman* and Michael Merickel. Dept. Neurology, Baylor College of Medicine, Houston, TX 77030.

Although there is ample evidence suggesting the importance of cyclic nucleotides in neural membrane events, their role in muscle activity is not well characterized. We have utilized primary cultures of rat embryonic skeletal muscle to study the effect of cAMP on electrical membrane properties. Treatment of these cells with cAMP results in the development of a repetitive spontaneous firing pattern characterized by a delayed onset and diminished afterhyperpolarization.

Hind limb muscle from newborn rats was dissociated and cultured for 7 days in Delbecco's modified essential medium containing 10% horse serum and 0.5% chick embryo extract. Intracellular cAMP levels were elevated by exposing cells to cholera toxin or membrane permeable analogs of cAMP.

Treatment of myotubes with cholera toxin did not have an immediate discernable effect on fiber twitch or membrane electrical properties. However, between 2 to 4 hours after treatment a gradual hyperpolarization (approximately 10 mV) of the resting membrane potential (RMP) and decrease in action potential (A.P.) afterhyperpolarization amplitude was noted. Within 24 hrs., the number of myotubes exhibiting spontaneous twitching increased and was correlated with increased A.P. spontaneous firing. At later times (24-30 hrs.) A.P.'s exhibited no afterhyperpolarization and virtually all cells were fibrillating, having lost a one-to-one relationship between A.P. firing and observable twitch. Repetitive firing of A.P.'s occurred at frequencies up to 10 Hz. A.P. frequency in those control cells which were spontaneously active did not exceed 1 Hz.

These effects were specific for cAMP. Cholera toxin, 8-bromo cAMP(10^{-3}M), dibutyryl cAMP(10^{-3}M), PCPT cAMP(10^{-4}M) and a phosphodiesterase inhibitor, RO201724, all elicited identical effects while 8-bromo-cGMP and dibutyryl cGMP(10^{-3}M) were ineffective. Further, cholera toxin increased intracellular cAMP levels up to 10-fold above basal levels within 1.5 hrs., well before any change in membrane electrical properties. If cells were pretreated with cycloheximide (1 μg/ml), the development of repetitive firing in response to cAMP was completely abolished. Cycloheximide decreased ^{35}S-methionine incorporation into protein by 90% and did not alter RMP, A.P. properties, or normal spontaneous firing. These results demonstrate that cAMP can alter electrical properties of embryonic muscle through a process which appears to require protein synthesis. (Supported by the Muscular Dystrophy Association, Kleberg Foundation, and NSF Grant BNS 7914115)

190.8 EVIDENCE FOR SYNAPTIC TRANSMISSION BETWEEN CILIARY GANGLION NEURONS IN CELL CULTURE. Joseph F. Margiotta* and Darwin K. Berg, Dept. of Biology, Univ. of Calif., S.D.; La Jolla, CA. 92093.

Chick ciliary ganglion neurons are parasympathetic cholinergic neurons that innervate smooth and striated muscle in the eye, and receive cholinergic input from preganglionic neurons in the accessory oculomotor nucleus. In cell culture the neurons develop high levels of choline acetyltransferase activity, and when grown with muscle, form functional cholinergic synapses on the myotubes. We now present physiological evidence that the neurons can innervate each other under these conditions as well.

Ciliary ganglion neurons from 8-day chick embryos were grown with skeletal myotubes at a density of 1-2x10^4 neurons/35 mm dish for 5-14 days in culture medium supplemented with 5% chick embryo extract. Intracellular recording from the neurons revealed discrete depolarizing potentials occurring in the absence of stimulation. The potentials varied from barely detectable amplitudes (< 1 mV) to events greater than 10 mV and were clearly excitable, sometimes triggering impulses. The potentials resembled ACh-mediated excitatory postsynaptic potentials (EPSPs) having rapid rates of rise, slow exponential decays, and sensitivity to blockade by cholinergic antagonists. The potentials were completely abolished by perfusing the cultures for 10 min with medium containing either 100 μM d-tubocurarine (d-TC) and 1.4 mM hexamethonium, or 25 μM d-TC alone. Partial recovery of EPSPs was observed after 10 min of washout for neurons that were continuously monitored throughout the drug treatment and perfusion changes. After 30 min of washout, other neurons tested in the same cultures showed EPSPs at frequencies comparable to control levels. Drug treatment did not prevent impulses in response to direct electrical stimulation, and did not affect the resting potential which averaged -53 ± 1 mV (mean ± SE; n=45) for all neurons.

When grown with muscle, 35 neurons out of 39 tested (10 cultures, 3 platings) displayed spontaneous EPSPs. The frequency of EPSPs ranged from 2/min to 180/min. Neurons grown without muscle in culture medium supplemented with 3% embryonic eye extract, also displayed EPSPs but much less frequently. Only 4 neurons out of 14 tested (5 cultures, 3 platings) showed spontaneous EPSPs; their rates varied from 2/min to 90/min.

These results indicate that ciliary ganglion neurons form functional excitatory cholinergic synapses with each other in cell culture. The formation of such synapses in culture may reflect the absence of the normal preganglionic input as has recently been found for frog parasympathetic neurons in vivo (Sargent and Dennis, 1981). (Supported by NIH grant NS 12601.)

190.9 EFFECTS OF THYROXINE ON MEMBRANE POTENTIALS OF DEVELOPING RAT SKELETAL MUSCLE CELLS IN CULTURE. S. R. Sampson and Rena R. Bannett*. Life Sci. Dept., Bar-Ilan Univ., Ramat-Gan 52 100, Israel.

Skeletal muscle cells in culture are a convenient model for the study of the development of biochemical and electrophysiological properties of this tissue. Despite the recognized importance of thyroxine (T_4) to normal growth and maturation, there are no reported studies on the influence of T_4 on these phenomena under conditions that preclude interaction with other hormones or the nervous system. Accordingly we have studied effects of T_4 on transmembrane resting potentials (Em) of myotubes obtained from 19-21 day-old rat embryos and maintained in culture for 5 to 21 days. At various times after fusion, T_4 was added to the growth medium to a final concentration of 10^{-7} to 10^{-6}M. Transmembrane potentials were recorded with 2.8M KCl-filled glass fiber microelectrodes. Em values increase with age from about 50mV at 3 days in culture to a plateau at about 72-75mV by the 7th day. Approximately 24 hrs after addition of the hormone, the mean Em recorded from T_4-treated cells was significantly higher than those in diluent-treated sister cultures (mean difference of 4-14mV), the effect beginning 4-5 days after plating. Possible explanations of this effect include an increase in membrane permeability to K^+, or activation of an electrogenic pump. To test the former possibility, we compared the relation between Em and external K^+ concentration in control and T_4-treated cells. Whereas the T_4-induced increase in Em persisted at each external K^+ concentration, there was no difference between the two groups in the slope of the line relating Em to $[K^+]_o$. To examine the role of an electrogenic pump, we studied the effects of ouabain and dinitrophenol (DNP). Ouabain (10^{-3}M) reduced the Em of both control and T_4-treated cells to approximately the same level within 30-40 min after addition to the culture. DNP (10^{-3}M) produced a similar effect. The onset of the ouabain effect occurred earlier in T_4-treated cells than in control cells and coincided with that of the T_4-induced increase in Em obtained after 4-5 days in culture. The results demonstrate the presence of an electrogenic sodium pump in rat skeletal muscle cells in culture, and further suggest that T_4 causes early appearance of this pump and stimulates its activity, leading to an increase in transmembrane potential.

190.10 SEROTONERGIC TRANSMISSION BETWEEN ISOLATED LEECH NEURONES IN CULTURE. Leslie P. Henderson. Dept. of Neurobiology, Stanford Univ. Med. School, Stanford, California. 94305

For studying synaptic transmission and synaptic neurochemistry, isolated leech neurones grown in culture provide distinct advantages. These cells maintain many of the electrical and chemical characteristics of their counterparts in the animal, and yet the simplicity of the culture conditions provides access to cell surface receptors free of glia and to synaptic terminals which, in the animal, occur at a great distance from the soma in the neuropil.

In the present experiments, the Retzius to Pressure sensory cell synapse was analysed. The presynaptic Retzius cell was found to synthesise ^{3}H-5-HT (serotonin) from its immediate precursor, ^{3}H-5-hydroxytryptophan. The presence of 5-HT in cultured Retzius cells was confirmed by staining with neutral red and by fluorescence induced by glyoxylic acid. The Retzius cells also released ^{3}H-5-HT into medium in the presence of elevated potassium (58 mM). This release was found to be calcium dependent and was blocked by elevated magnesium (25 mM).

The regional sensitivity of the post-synaptic P sensory cell to 5-HT (50 mM, pH 7.4) was studied by pressure ejection from a micropipette, Terminals of sprouts, especially those with growth cone-like structures, were found to have a higher sensitivity than either cell somata or non-terminal areas of processes. The responses elicited by ejected 5-HT were compared to those seen on P sensory cells in situ and to the synaptic response observed in cultured P cells upon stimulation of presynaptic Retzius cells. P cells in culture and in situ showed an initial hyperpolarising response that rapidly desensitised, but whose time course was similar to the synaptic potential seen between cultured Retzius and P cells. This initial response was often masked, both in cells in culture and in situ, by a depolarising response that did not desensitise.

While these results implicate 5-HT as a transmitter from Retzius to P sensory cells in culture, it remains to be determined what mechanisms underlie the slow synaptic potentials and whether additional transmitters are involved.

190.11 RECORDING OF SPONTANEOUS ACTIVITY FROM CULTURED MOUSE SPINAL NEURONS WITH LASER DE-INSULATED PHOTOETCHED MULTIMICROELECTRODE SURFACES. G.W. Gross, A.N. Williams*, Department of Biology, Texas Woman's University, Denton, TX 76204 and Stephen Popik*, Central Research Labs, Texas Instruments, Dallas, TX.

A matrix of gold conductors photoetched onto the floor of a tissue culture chamber has been used to record spontaneous activity from dissociated mouse spinal cord tissue (12-14 day embryos) growing on the multimicroelectrode surface. The two-dimensional electrode arrays (36-50 gold conductors 10-12 µm wide in a 0.5 mm by 1.0 mm area) were insulated with a polysiloxane resin and de-insulated with a laser shot at an energy density of 4.0 µJ/cm^2 and a wavelength of 337.1 nm. The hydrophobic insulation layer was oxidized with a butane flame to produce a hydrophilic surface for better cell adhesion. Recording was begun at nine days postseeding. Consistent spontaneous activity was recorded from microfragments of tissue measuring 50 to 100 µm in diameter. Maximum signal to noise ratios of 8:1 were achieved without the use of platinum black to reduce impedances which usually measured between 4 to 8 megohms. At 35°C, most microfragments revealed vigorous multiunit activity with high frequency bursts from several large units repeated at intervals of 1-5 seconds. Large units ceased firing at 28°C and all activity stopped at 25°C. Activity recovered to normal levels within two minutes after raising the temperature to 28°C. Careful changes of 50% of the medium during recording normally resulted in short activity increases followed by almost total cessation of activity which often lasted over one hour. This reveals that even with stationary, integrated electrodes small mechanical and pH fluctuations have a surprisingly severe effect on the spontaneous activity. Microfragments below 50 µm in diameter have not consistently shown spontaneous activity. Simultaneous recordings from directly interconnected tissue fragments are being initiated. We consider the microfragment an intermediate step between explants and totally defined two-dimensional networks. Microfragment activity has been monitored thus far for a maximum of three days; future experiments will follow activity for longer periods.

Supported by NIH grant 1RO1 NS 15167

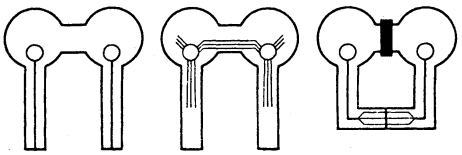
190.12

WITHDRAWN

190.13 CODING FOR A CENTRAL CONNECTION IS ALSO PRESENT IN THE PERIPHERY. Robert D. Hadley, Richard G. Wong* and Stanley B. Kater, Dept. of Zoology, Univ. of Iowa, Iowa City, IA 52242.

Identified neurons 5R and 5L of the snail, Helisoma are not electrically coupled in normal adult buccal ganglia. In response to proximal peripheral nerve crushes which sever the axons of these neurons, the short axonal stumps are resorbed. Upon culture, neurons 5R and 5L sprout and grow central neurites; forming a specific novel electrotonic connection between the neurons (Bulloch and Kater, 1981, Science 212:79-81).

Latent recognition between homologous neurons may be localized to narrowly defined neuronal regions, as are many synaptic contacts, or could be uniformly distributed over the cell surface. The problem of the distribution of recognition capability over the neuronal surface can be approached by in vitro culture of ganglia with manipulations to allow neurites to contact one another in the periphery.



When ganglia are cultured with closely apposed, cut peripheral nerve trunks and tightly ligated or severed commissures, 5R-5L neuronal interactions occur only in peripheral regions. In such ganglia specific 5R-5L electrotonic connections occur with a fidelity like that in central interactions. These data imply that: 1) axonal resorption per se is not necessary for the formation of this novel adult neuronal connection; 2) no special properties of the central neuropile are required for the connection; and 3) coding for such neuronal recognition is distributed over the peripheral elements of these neurons.

Supported by training grant MH 15172 (RH) and PHS grants NS 15350 and NS 09696.

190.14 ELECTRICAL AND CHEMICAL SYNAPTIC TRANSMISSION BETWEEN APLYSIA NEURONS IN DISSOCIATED CELL CULTURE. E. Proshansky*, S. M. Schacher*, and J. S. Camardo* (SPON: K. Weiss). Center for Neurobiology & Behavior, Depts. of Anatomy, Physiology, and Psychiatry, Columbia University, P & S, New York, N. Y. 10032.

The application of dissociated cell culture techniques to the invertebrate nervous system will permit increased access to the synaptic structures of identified neurons. Recent work has shown that mature, isolated neurons of the leech regenerate processes and form electrical and chemical synapses in culture (Ready and Nicholls, 1979). Aplysia neurons in culture also regenerate processes and form electrical synapses (Dagan and Levitan, 1980). We have established Aplysia neurons in dissociated cell culture and have found that: 1) in addition to electrical synapses, chemical synapses also routinely form between cultured neurons and 2) neuronal growth is increased in medium containing Aplysia hemolymph.

Neurons isolated by enzymatic and mechanical dissociation of ganglia from small adult Aplysia californica were plated in Leibovitz medium that contained 5% fetal bovine serum and was adjusted to the osmolarity of seawater. Within 36 hr following plating the cells sprouted 1-10 processes up to 8 μm in diameter. Electron microscopy showed that these processes, which in the light microscope appeared to be single structures, were in fact fascicles of several tightly apposed fine neurites. The addition of cell-free Aplysia hemolymph to the culture medium resulted in: 1) more rapid initiation of neurite outgrowth (by 12 hr); 2) a doubling of the rate of outgrowth and 3) richer neuritic arborizations.

Intracellular recordings made in artificial seawater showed that the resting and action potentials of cultured cells were comparable to those of cells in vivo. DC current injected into either member of a cell pair connected by neurites or with apposed cell bodies showed that as many as one-third of these cell pairs were electrically coupled. Coupling coefficients ranged from .1-.8. Chemical synaptic transmission was evident as early as 3 days in culture and occurred only between cells whose soma appeared to be in contact. Both EPSPs and IPSPs of up to 10 mV, with latencies of 8-60 msec, were observed. These synaptic potentials were reversibly blocked by high Mg^{++} solutions and their amplitude and polarity were sensitive to changes in postsynaptic membrane potential. As previously shown in vivo in Aplysia (Shapiro et al., 1980) we found that transmitter release was sensitive to changes in the presynaptic membrane potential. Release increased when the presynaptic cell was depolarized and decreased when it was hyperpolarized, suggesting that, in culture, synaptic release sites are electrically relatively close to the cell body. This ability to experimentally control the synaptic processes of cells in culture will prove useful in the analysis of transmitter release and its modulation, particularly when applied to neurons of Aplysia with known plastic properties.

190.15 **PROLIFERATING NEURON-LIKE CELLS IN MOUSE HIPPOCAMPAL CULTURES.** J.H. Peacock and C.R. Walker Division of Neurology, Univ. of Nevada Medical School, Reno, NV 89557

Immature neurons in cell cultures prepared from many regions of the central nervous system do not appear to undergo more than 1 or 2 cell divisions after initial plating. However, hippocampal cell cultures contain neuron-like cells which proliferate in standard growth media with 10% serum and without potassium augmentation. An increasing number of such cells are observed under phase contrast microscopy over several weeks in culture and the process of active cell division has been confirmed by ^{3}H-thymidine autoradiography.

Proliferating neuron-like cells (PNLCs) can be readily identified by their small size (soma diameter less than 10 μM), lack of neurites, and their tendency to occur in large groups of similar cells. Phase-dark and phase bright cells are intermixed. Some of these cells appear to develop long branching processes in month old cultures in areas where they attach directly to the surface of the culture dish.

The following electrophysiologic properties have been obtained from PNLCs in separate culture series including those with ^{3}H-thymidine label. Resting membrane potentials are high, 87.8±1.7 mV (mean ± S.E., n=23). Depolarizing current injection characteristically elicits graded peak-shaped potentials which lack inflection points on the rising slope and which are sometimes followed by a 2nd positive potential. Small anode break potentials are occasionally seen. Depolarizing activity persists in media containing 4 mM Na+ and either 8mM Ca++ or 8 mM Mn++ substituted for Ca++. After the depolarizing response, there is a prominent afterhyperpolarization (AHP) which can be reversed by steady negative currents. Depolarizing potentials and AHPs are blocked by Ni++ but not by TEA, 4AP, or chloride-free media.

PNLCs are responsive to GABA iontophoresis. These cells do not take up ^{3}H-GABA (29 nM) but do selectively take up ^{3}H-glutamate (22 nM) on the basis of autoradiographic studies.

Finally, PNCLs do not have immunohistologic staining for glial fibrillary acidic protein (courtesy of L. Eng and D. Bagley, Palo Alto VA Hosp.), a result which argues against the possibility that these cells are astrocytes. Thus on the basis of evidence for active membrane properties, GABA sensitivity, selective glutamate uptake, and absence of evidence for astrocytes we propose that PNLCs are neurons. It would not be suprising if PNLCs are granule cells which in the intact mouse hippocampus have their greatest proliferative activity for 3 weeks after birth.

Supported by Grant NS 12151.

190.16 CELL CULTURE AND CHEMICALLY INDUCED FUSION OF DISSOCIATED NEURONS OF DROSOPHILA. C.-F. Wu, N. Suzuki* and M.-m. Poo. Dept. of Zoology, Univ. of Iowa, Iowa City, IA 52242 and Dept. of Physiology, Univ. of California, Irvine, CA 92717.

We have obtained primary cultures of dissociated cells from brains and ganglia of third instar larvae of Drosophila. Morphology of the cultured cells have been studied with phase contrast and Nomarski optics and scanning electron microscopy. Within a few hours after plating, cells initiated axon-like processes with growth cones. More than 50% of cells showed features of neurons. Cells cultured for 24 hours exhibited one or more long processes with branches and formed contacts with other cells These differentiated cells have been maintained in culture up to one week.

Synthesis and accumulation of acetylcholine in the cultured cells were detected after one hour incubation with ^{3}H-choline. The amount of acetylcholine accumulated and the efficiency of conversion from choline to acetylcholine were comparable to those determined by using intact brains and ganglia.

Fusion of cultured cells was induced with polyethylene glycol (PEG). This treatment produced large multinucleated cells of the size up to 100 μm, in contrast to the sizes of untreated cells ranging from 1-10 μm. PEG treated cells had smooth and continuous surface as revealed by scanning electron microscopy. Continuity of the cell surface was further evidenced by very large bubbles of cell membrane induced by osmotic swelling of the fused cells. In contrast, aggregates of untreated single cells under the same condition formed small individual bubbles. Fused cells have been grown in culture medium for several days. One day after PEG treatment, fused cells showed processes with growth cone-like structures of large sizes.

Neurons obtained from adult lethal mutants and mutants with altered membrane excitability have also been cultured. This nerve cell culture system of Drosophila can provide easy access to electrophysiological and molecular genetic analyses of the development and function of neurons.

191.1 LOCALIZATION OF THE RECEPTOR SITE FOR RABIES VIRUS ON THE MOUSE DIAPHRAGM AND ON CULTURED CHICK MYOTUBES. Thomas L. Lentz, Thomas G. Burrage, Joan Crick* and Gregory H. Tignor*. Section of Cell Biology and Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT 06510.

The entry of rabies and other neurotropic viruses into the central nervous system has been explained by uptake of virus at nerve terminals and centripetal transport to the neuronal cell body. However, the receptor sites for virus binding and the mechanisms governing uptake or restriction of uptake of virus at nerve terminals have not been defined. In order to determine the site of rabies virus binding, we have investigated the localization of labeled rabies antibody following exposure of mouse diaphragm and cultured myotubes to rabies virus.

The diaphragm and its attached phrenic nerve was removed from several strains of mice. The preparation was immersed in oxygenated Tyrode's solution containing rabies virus (10^5 infectious units) for varying periods of time, after which the whole mount was stained directly for rabies antigen with FITC-conjugated rabies antibody followed by counterstaining for acetycholinesterase. Rabies antigen was found by immunofluorescence to co-localize with acetylcholinesterase-positive sites as early as 30 min. after immersion. During the early time periods from 30 min. to 1 hour, antigen was limited to junctional sites. However, at 4 hours, antigen was present at both junctional and extra-junctional sites. In addition, by 2 and 4 hours, antigen was found in nerves. Electrical stimulation of the phrenic nerve intermittently for the first 30 min. reduced the number of rabies antigen-positive sites detected.

Cultures of chick myotubes were readily infected by rabies virus, and a neurotropic variant of Sindbis virus (Ar86), but not by the non-neurotropic prototype strain of Sindbis, nor by vesicular stomatitis virus (Indiana strain). The rabies virus antigen in infected myotubes occurred in patches and resembled the distribution of high-density acetylcholine receptor sites as revealed by staining with rhodamine-conjugated α-bungarotoxin (α-BTX). Pre-incubation of myotubes for 2 hours with α-BTX (10^{-6}M) prevented rabies virus and Sindbis Ar86 virus infection of myotubes and reduced the amount of radio-labeled virus which attached to these cells. α-BTX (10^{-3}M) did not inactivate virus nor did addition of α-BTX to cultures after virus had been adsorbed prevent infection. Cultures treated with α-BTX were susceptible to infection 3 days after the toxin was removed.

These results suggest that the receptor site for rabies and possibly other neurotropic viruses is located at sites of high acetylcholine receptor density. (Supported by NIH grants AI12541 and AI11132, and NSF grant BNS 80-18520).

191.2 NITROIMIDAZOLE NEUROPATHY: A QUANTITIATIVE ULTRASTRUCTURAL STUDY OF AXONAL MITOCHONDRIA. Michael A. Casey and Robert D. Yates*, Dept. of Anatomy, Tulane Univ. Sch. Med., New Orleans, La. 70112.

Misonidazole (MIS; a 2-nitroimidazole) is being evaluated clinically as a radiosensitizer of hypoxic tumor cells at several radiotherapy centers throughout the world. However, multiple doses of MIS cause peripheral neuropathy in humans, (Dische et al., Br. J. Cancer, 35:567, 1977) and MIS-induced pathological changes resembling Wallerian degeneration have been produced in the peripheral nerves of rodents (Griffin et al., Neurotoxicol., 1(3): 653, 1980; Casey et al., Anat. Rec., 199(3): 47A, 1981). In addition, we have also observed that the myelinated axons of MIS-treated mice contain more mitochondrial profiles than untreated axons when viewed in cross-section. Axonal mitochondrial profiles have been reported to increase focally in the early stages of Wallerian degeneration (Webster, J. Cell Biol., 12:361, 1962). These data prompted us to conduct a quantitative ultrastructural analysis of axonal mitochondria on thin sections of peripheral nerves from mice treated with either MIS (0.5 mg/g) or a control series injected with saline (0.85%).

Following 5 weeks of daily IP injections the medial plantar nerves of mice were prepared for transmission electron microscopy. The volume density (V_d) of mitochondria per unit volume of axoplasm (of myelinated axons) was determined by differential point counting. The mitochondrial V_d (mean ± SEM) was significantly ($p < 0.05$) higher in the axoplasm of MIS-treated mice (5.04% ± 0.24) compared to the saline controls (2.74% ± 0.25). The mean mitochondrial diameter did not differ significantly between the two groups (MIS = 0.170 μm ± 0.004; saline = 0.172 μm ± 0.002), indicating that the increase in V_d was not due to mitochondrial swelling in the MIS-treated axons.

A similar study was performed with desmethylmisonidazole (DMM), a 2-nitroimidazole recently introduced into clinical trials which is expected to be less neurotoxic than MIS. Following 5 weeks of daily IP injections (0.5 mg/g) of DMM, no pathological changes were observed in the peripheral nerves. The axonal mitochondrial V_d was determined to be 2.53% ± 0.22. This value was not significantly different from the controls, but was significantly ($p < 0.05$) lower than MIS-treated. Thus, at equal doses DMM appears to be less neurotoxic to peripheral nerves than MIS.

These results indicate that axonal mitochondrial profiles increase significantly in experimental MIS neuropathy. The difference in mitochondrial profiles may represent an early structural change in mouse peripheral nerves similar to that previously described in Wallerian degeneration. More importantly, the quantitation of axonal mitochondria may prove to be a reliable morphological assay for use in screening nitroimidazoles (or other compounds) for peripheral nerve toxicity.

191.3 LONG-TERM STUDIES OF INDIVIDUAL CEREBRAL AXONS Harvey A. Swadlow. Dept. Psychol. (U-20), Univ. Conn., Storrs, Conn.06268

Little is known about the long-term stability of conduction properties in central axons. In the present study chronic extracellular microelectrode techniques were combined with antidromic identification of efferent neurons of the corpus callosum in order to begin to examine this question in cerebral axons. In adult Dutch rabbits, banks of stimulating electrodes were implanted in the splenium of the corpus callosum and, in some cases, in the contralateral hemisphere. Most microelectrodes consisted of 25 μm Pt-Ir wire insulated with Teflon and cut flush. Microelectrodes were implanted into superficial cortical layers near the border of visual area I and II. Thirty-one neurons have been studied for 10 days or longer (mean= 26 days). One cell has been studied for 101 days and at the time of this writing is still under observation. Initial antidromic latencies of the above cells ranged from 5.5-31.3 ms (median= 16.1 ms) and conduction velocities were approximately 0.4-2.2 m/s.

Some of the above neurons demonstrated a progressive increase (10 cells) or decrease (5 cells) totaling more than 4% of the initial antidromic latency. Increases in antidromic latency were of greater magnitude than were decreases in latency and in some cases occurred at a steady rate of nearly 1%/day for 6-10 weeks. The conditions leading to such variations in conduction velocity are under study. For the remaining 16 neurons which demonstrated stable antidromic latencies, 4 additional measures obtained on successive days were analyzed: (a) minimum inter-stimulus interval yielding two conducted impulses; (b) minimum inter-spike interval (the least interval between two conducted impulses); (c) maximum decrease in antidromic latency following a single prior impulse (the supernormal period); and (d) maximum increase in antidromic latency following tetanic stimulation with 10 or 20 prior pulses (the subnormal period). Minimum inter-spike interval was the most stable of these measures, with a total range of variations rarely exceeding 12% of the mean value. Measures of the supernormal and subnormal periods were also very stable. For each of these measures, the variations observed within a cell on successive days were much less than those seen between different cells of the same approximate axonal conduction velocity. In contrast, successive measures of minimum inter-stimulus interval (the traditional measure of the refractory period) were quite variable.

191.4 NERVE TERMINAL STRUCTURE AND QUANTAL OUTPUT IN DYSTROPHIC CHICKEN MUSCLE. J.S. Gunther* and M.S. Letinsky. UCLA School of Med., Dept. of Physiol., Ahmanson Lab. of Neurobiology, and Jerry Lewis Neuromuscular Research Center, Los Angeles, CA. 90024.

The relationship between nerve terminal quantal output and motor endplate structure was studied at identified endplates in the EDII muscle of normal and dystrophic chickens (lines 412 and 413) ranging from 8 to 20 wks ex ovo. The quantal content was determined in curarized muscle by the coefficient of variation method. Subsequently, the pre- and postsynaptic components of these same neuromuscular junctions were stained using combined tetranitroblue tetrazolium and AChE staining. Nerve terminal area was measured from camera lucida drawings and quantal output per square micron of nerve terminal area was calculated. Also, the structure of identified terminals was compared to large numbers of randomly selected terminal drawings to determine where the identified terminals fell within their respective distributions.

The structure of the dystrophic nerve terminals differed characteristically from normal. They were less compact, smaller in total area, and their synaptic boutons were smaller and connected by long, fine branching processes rarely observed in the normal terminals. Growing sprouts were frequently present within the dystrophic terminals. Nerve-evoked release from these dystrophic terminals varied greatly in quantal output. In some cases EPP quantal content was less than at the normal terminals, but in many cases it was comparable to normal levels, so that release per square micron of dystrophic terminal was actually greater. A few terminals within the dystrophic muscles appeared structurally and physiologically normal, with no difference in total quantal output or in release per square micron of terminal compared to normal. Instances of empty postsynaptic gutters were observed in dystrophic muscle (AChE staining in the absence of nerve terminal staining); and this morphological evidence of denervation was confirmed by failure to evoke an EPP. Morphological evidence of multiple innervation of individual dystrophic muscle fibers was confirmed electrophysiologically by grading stimulus strength to the nerve. Histological evidence of multiple innervation was abundant in dystrophic muscles, and rarely observed in normal muscle.

These experiments provide evidence for: (i) great variability in quantal output from dystrophic terminals showing evidence of structural pathology; (ii) the occurrence of denervation of dystrophic muscle fibers--confirmed histologically and physiologically; (iii) greater incidence of multiple innervation in dystrophic muscle.

191.5 PROPERTIES OF SPINAL MOTONEURONES IN A NEUROPATHY CAUSED BY THE TOXIN FROM TULLIDORA (Karwinskia humboldtiana). A. Hernández-Cruz* and E.J. Muñoz-Martínez. Dept. Physiol. & Biophys., Centro de Investigación y de Estudios Avanzados del I.P.N. México 14, D.F.

The neurotoxin from Tullidora (Karwinskia humboldtiana) produces a peripheral neuropathy characterized by segmental demyelination, nerve conduction block and functional denervation of hind limb muscles (Muñoz-Martínez & Chávez, 1979). This alterations are more intense in the distal portions of the hind limbs nerves, but it cannot be excluded that the motoneurones cell bodies are primarily affected. In the present experiments the properties of spinal motoneurones in cats treated with Tullidora were studied with conventional electrophysiological techniques. A single dose of Tullidora extracts were orally given to cats. Three to five weeks later treated animals showed hind limb flaccid paralysis. After barbiturate anesthesia, the soleus and the medial gastrocnemious muscles were activated through the nerve and through direct stimulation of the muscle bellies. The nerve elicited twitches were 50-95% smaller than the twitches obtained by direct muscle activation. In the same animals, membrane and action potentials of spinal (triceps surae) motoneurones were not different from normal values (88.67±11.6 mV and 68.11±3.4 mV, respectively); input impedance was slightly increased in these neurones.The afterhyperpolarization which follows the action potential remained unchanged in the case of medial gastrocnemious motoneurones, but it was consistently shortened in the soleus motoneurones. In some motoneurones from these treated cats, the amplitude of monosynaptic e.p.s.p. was normal (≈8.8 mV) but in other motoneurones from the same pool, the e.p.s.p. amplitude was significantly decreased.

We conclude that the neurotoxin from Tullidora does not primarily affect the cell bodies of spinal motoneurones. The observed changes are similar to those found after axotomy (Kuno, Miyata & Muñoz-Martínez, 1974), or partial denervation of the muscle (Huizar, Kuno, Kudo & Miyata, 1977).

191.6 PREVENTION OF DELAYED ORGANOPHOSPHORUS NEUROPATHY BY PHENYLMETHYLSULFONYL FLUORIDE (PMSF). A.B. Drakontides, T. Baker and W.F. Riker, Jr. Dept. of Anatomy, New York Medical College, Valhalla, N.Y. 10595 and Dept. of Pharmacology, Cornell University Medical College, New York, N.Y. 10021

Organophosphates like diisopropylfluorophosphate (DFP) are well known for producing a "dying-back" neuropathy in both humans and animals. A single 2 mg/kg intraarterial dose of DFP into the cat femoral artery results in uncoordinated muscle movements and diminished responsiveness to noxious stimuli in the injected limb. These deficits are at a peak 21-28 days after DFP administration. At this time functional and morphological changes occur in soleus α-motor nerve terminals. The stimulus-bound repetitive neural discharges generated by these terminals after tetanic conditioning (400 Hz for 10 sec) are severely impaired or lost, as is the obligatory post-tetanic potentiation of soleus muscle contractile response. From a random sampling of approximately 200 motor end plate regions of soleus muscle from treated legs of 8 DFP cats, only 5% of the motor nerve terminals were characterized as normal in their morphologic characteristics. All other motor nerve terminals had extensive structural alterations. These included the presence of lamellar whorls that filled the terminal and obscured or compressed synaptic vesicles close to the presynaptic membrane (73% of sample), and terminals that were fragmented and retracted from the junctional cleft, the cleft being filled by Schwann cell elements (22% of sample). Intramuscular nerves also contained lamellar whorls, and disrupted axoplasm.

PMSF is a protective inhibitor of the neurotoxic esterase which is associated with the development of the delayed organophosphorus neuropathy. Treatment with PMSF (30 mg/kg i.p.) 24 hours before the DFP administration prevented the delayed neuropathic changes. All motor nerve terminals examined from 3 cats treated with PMSF and DFP were normal in appearance. The morphological integrity of nerve terminals was corroborated by the functional capacity, in that stimulus-bound repetition of soleus motor nerve terminals was still evident and its incidence was greater than that seen in the delayed neuropathic cat. (Supported by NINCDS 01447.)

191.7 AGONIST-INDUCED RELEASE OF LACTATE DEHYDROGENASE FROM SKELETAL MUSCLE: AN ASSAY OF A MYOPATHY. J. P. Leonard. Section of Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853.

The release of cytoplasmic enzymes has often been used as an assay of cell damage. Increases in serum enzyme levels are diagnostic for certain diseases of heart and skeletal muscle (see L. P. Rowland, Arch. Neurol. 33:315). We have previously reported damage in mouse extensor digitorum longus (EDL) muscles in the vicinity of the neuromuscular junction (nmj) after prolonged treatment with the stable agonist carbamylcholine (carb) (Leonard and Salpeter, J. Cell Biol. 82:811). This damage was assessed on the basis of finestructural changes including: vesiculation of the junctional sarcoplasm, dilation of the sarcoplasmic reticulum, swelling of mitochondria and dissolution of Z-disks. The morphological damage is fully prevented by pretreatment with α-bungarotoxin (α-BGT) or use of a Ca^{++}-free Krebs bath (+5mM EGTA), indicating that the muscle damage is mediated by Ca^{++} and requires the activation of the nicotinic acetylcholine receptor at the nmj. In this study, we determined whether lactate dehydrogenase (LDH) release was a concomitant of carb-induced finestructural damage.

After 3 hrs. in Krebs alone (no carb) ∿1 unit (nanomole substrate/min) LDH is found in the medium per mg muscle wet weight. When 10^{-4} M carb is added for the first 20 min of the total 3 hour incubation time, 3 units are found in the medium, and when carb is present throughout the 3 hr incubation, 29 units are found. Ca^{++}-free (+5mM EGTA) medium or α-BGT pretreatment results in a return to control (no carb) values.

These results suggest that LDH release is controlled in parallel with the previously described morphological damage by prolonged Ca^{++} influx through the agonist-activated nmj. Agonist induced finestructural damage which occurs after anticholinesterase treatment (Ariens, Experientia 25:57) may also extend to the release of LDH from the sarcoplasm. Cytoplasmic enzyme release provides a rapid assay for studying damage induced by prolonged transmitter or agonist treatment of neuromuscular junctions.

191.8 MICROTUBULE BINDING AND EPILEPTOGENESIS MAY UNDERLIE THE NEUROTOXICITY OF COLCHICINE FOR DENTATE GRANULE CELLS E. Lothman, D. Stein* and G. Wooten, (Spon. J. Trotter), Dept. Neurol., Wash. Univ., St. Louis, MO 63110.

Recently Goldschmidt and Steward (PNAS 77:3047, '80) reported that injections of colchicine into the hippocampal formation destroys granule cells of the dentate gyrus while sparing hippocampal pyramidal cells. To better understand the mechanisms of this selective neurotoxicity we studied electrophysiologic, histologic and metabolic effects of microinjections of colchicine and related compounds into the rat hippocampus. Colchicine (0.6-6 nmol in 0.2-0.3μl of normal saline, pH 7.2-7.4) was delivered via a 32 gauge cannula into the dorsal and ventral hippocampus. Three to thirty days later both Nissl and Timm's stained sections of brains revealed the preferential degeneration of granule cells and mossy fibers described by Goldschmidt and Steward. In some rats studied less than 2 weeks after injection, especially with higher doses of colchicine (4-6 nmol), there was a pallor of hippocampal pyramidal cells. However, these cells appeared normal after 2 weeks with doses of 2-4nmol colchicine. Vinblastine (0.4-1.2 nmol), a vinca alkaloid that also binds to tubulin subunits, produced neuropathology like colchicine. However, injections of lumicolchicine (4-6 nmol), a derivative of colchicine devoid of tubulin binding activity, did not. EEG recordings at the site of colchicine injection showed interictal and ictal discharges beginning 15 minutes after colchicine and lasting for several hours. Limbic seizures characterized by automatisms, staring spells and wet dog shakes were associated with the EEG paroxysms. ^{14}C-2-deoxyglucose autoradiography demonstrated localized changes of glucose utilization in the first few hours after colchicine administration. There was a profound increase in the hilum of the dentate gyrus ("CA_4") and less marked changes over the apical dendrites of CA_3. Regional glucose utilization was normal 7 days after colchicine injection except for a moderate reduction in the atrophic dentate gyrus.

These studies confirm that a highly selective lesion of dentate granule cells can be made with intrahippocampal injections of colchicine. That vinblastine but not lumicolchicine mimics the neuropathological action of colchicine suggests that the mechanism for the neurotoxicity may be a consequence of disruption of microtubules. This action may have a variety of adverse effects on neuronal function (e.g., blockade of transmitter release or axonal transport). Further, the neurotoxicity appears to be associated with electrical seizures. The precise relationships among neurotoxicity, epileptogenicity and tubulin disruption remain to be elucidated.

191.9 SITES OF 2,5-HEXANEDIONE BINDING IN MAMMALIAN PERIPHERAL NERVE M.I. Sabri and P.S. Spencer. Institute of Neurotoxicology, Albert Einstein College of Medicine, Bronx, NY 10461.

2,5-Hexanedione (2,5-HD) is a primary neurotoxic agent that causes axonal degeneration when mammalian nerves are exposed locally or systemically. Affected regions of nerve fibers display giant axonal swellings containing accumulations of slow- and fast-transported organelles. The sites of 2,5-HD binding and the mechanism underlying transport blockade are unknown. We have approached this problem by studying the subcellular distribution of radioactively labeled 2,5-HD following administration to normal peripheral nerves in vitro and in vivo. In the first group of experiments, (1,6-^{14}C)-2,5-HD (3.7mCi/mMole) was intraneurally injected into the sciatic nerve of deeply anesthetized adult Sprague-Dawley rats. Animals were sacrificed after 20h by perfusion through the aortic arch with cold normal saline. Sciatic nerves were removed, pooled, weighed and cut into small pieces with a razor blade. Nerve segments were homogenized in cold 0.25M sucrose and subcellular fractions prepared by differential centrifugation. Total radioactivity was determined by solubilizing aliquots of fractions in 0.5 ml of Soluene at 50°C and adding 10 ml of liquid scintillation cocktail. High-affinity toxin binding was determined by washing aliquots of each fraction on a Millipore filter of 0.22um diameter with 3ml of cold 0.25M sucrose. Radioactivity was present in nuclear, mitochondrial, myelin, microsomal, and soluble fractions, and in a floating lipid fraction. The largest amount of 2,5-HD binding (about 38%) was present in the crude mitochondrial fraction: less was found in the crude myelin pellet (about 29%). However, when the fractions were washed with sucrose on a Millipore filter, most of the label in the crude mitochondrial fraction was removed. By contrast, most of the ^{14}C label in the crude myelin fraction remained bound to high-affinity binding sites. High-affinity binding (expressed as a percentage of total binding) to subcellular fractions was as follows: myelin fraction, 23.6%; mitochondrial fraction, 8.5%; soluble fraction, 8.0%; nuclear fraction, 6.5%; microsomal fraction, 2.8%; and floating fraction, 2.8%. A similar pattern of differential high-affinity binding was found in sciatic nerves incubated for 30 min in oxygenated Krebs Ringer containing labeled 2,5-HD. Pretreatment of the sciatic nerve with unlabeled 2,4-HD (a non-neurotoxic analogue) before in vitro incubation with labeled 2,5-HD resulted in a slight increase in total binding, particularly in the crude myelin fraction. Otherwise, 2,4-HD failed to alter the distribution of high-affinity binding. In summary, these data are consistent with the report of prolonged retention of 2,5-HD in sciatic nerve. Further experiments are needed to reveal the specific sites involved in the neurotoxic action of this compound. (Support: OH 00535 and OH 00851.)

191.10 The peripheral nerve in motor end-plate disease ("med" mutation) in the mouse.

Martine PINÇON-RAYMOND and François RIEGER
Groupe de Biologie et Pathologie Neuromusculaires
INSERM U 153 - 17, rue du Fer-à-Moulin 75005 PARIS - FRANCE

"Motor end-plate disease" is an hereditary neuromuscular disease of the mouse. Two allelic forms of the "med" mutation exist, both leading to death of the affected med/med animals, although med^J/med^J mice seem to be less clinically affected than med/med mice. Swelling and sprouting of the nerve terminals have been observed in all skeletal muscles studied (silver nitrate staining and light microscopy). Enlargement of the non-myelinated gap at the nodes of Ranvier in the peripheral nerves is frequently observed (ultrathin sections, electron microscopy); their morphology range from normal to clearly pathological. Several myelin abnormalities can be observed, such aberrant myelinated bodies, increased interlamellar distances or long Schwann cell processes, extending along bare axolemmal regions. This abnormality of the nodes of Ranvier and myelin may be observed at early stages of the disease (12-14 days after birth) and is sometimes accompanied by abnormalities of the axon, suchas protusions and excrescences of the axoplasm. In motor end-plate disease , as in some other animal or human neuropathies, the myelin and the axon seem to be both affected and could represent primary or secondary targets of the mutation or even express a more general cell (membrane ?) defect.

191.11 NICOTINE IMPAIRS CYTOARCHITECTONIC AND SYNAPTOLOGICAL MATURATION IN DEVELOPING NEOCORTEX. J.V. Waldman* and D.A. Kristt. Dept. of Pathology, The Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD 21205.

Despite evidence suggesting that nicotine exposure during brain development impairs brain function, morphological abnormalities have never been demonstrated. In this study, newborn Sprague-Dawley rat pups received two daily doses (1 mg/kg) of nicotine subcutaneously. The treatment period extended from the day of birth to six days of age. At the latter time, the animals were anesthetized and perfused transcardially with an aldehyde fixative. Following treatment, pups exhibited transient hyperactivity, but there was no cyanosis throughout this episode which began within five minutes of the injection and lasted for several minutes thereafter. All animals appeared to nurse normally and gained weight as usual. At 6 dpn, brain weights showed a tendency to be lower in the nicotine-treated group: mean, 0.51 grams; range, 0.45-0.57 grams as compared to control animals: mean, 0.57 grams; range, 0.54-0.60 grams (n=5 pups/group). Body weight was comparable in both groups: range, 12-16 grams. Synaptological analysis of superficial somatosensory cortex, which contains relatively large numbers of synapses at 6 dpn, was also undertaken. The number of synapses in the marginal zone (layer I) per 875 μm of inspected tissue is 50-60 in control animals (n=30) [Kristt, Brain. Res., 1979] and 16-25 in treated animals (n=2). In view of small brain size in nicotine-treated pups, the difference between treated and control animals may even be greater than experimentally observed. It should be noted that this synaptic density is approximately that of the newborn infant [Kristt, 1979], so that nicotine-treated animals appear to exhibit an almost complete retardation of synaptogenesis during the first postnatal week. Histological evaluation of cytoarchitectonics showed that, at 6 dpn, somatosensory cortex of treated animals had barely matured past the 3-dpn level. Between 3 and 6 days in normal rats, the unilaminar cortical plate develops a distinct trilaminar appearance. In contrast, nicotine-treated 6-dpn rats exhibit a cytoarchitectonic pattern more similar to that found between 3 and 4 days, i.e., a unilaminar cortical plate with only a slight suggestion of subdivision. Consequently, there also appears to be a retardation in cytoarchitectonic maturation, albeit less than that seen for synaptogenesis. These data suggest that nicotine may have an effect on the earliest phases of synaptogenesis and cortical development.

191.12 CARPAL TUNNEL PRESSURE INCREASES IN MONKEYS CHANGE ELECTROCUTANEOUSLY EVOKED AVERAGED RESPONSES IN THE MEDIAN NERVE. A. Lee Dellon*, R. Burke*, R A. Cowley*, and Richard J. Schneider. Johns Hopkins University and The Maryland Institute for Emergency Medical Services Systems, Baltimore, Maryland 21201.

Macaca mulatta monkeys were anesthetized with pentobarbital administered i.v. and supplemented as necessary. Ring stimulating electrodes were attached to the index finger and delivered isolated, constant current pulses (10/sec., 3-5 mA) of 100 microsecond duration. Evoked responses (potentials) were recorded from a surface electrode on the skin over the median nerve between biceps and triceps muscles in the elbow. A differential amplifer (ear reference) fed the responses to a signal averager which summed 765 sweeps of 25 msec. duration. A wick catheter attached to a pressure transducer was placed in the carpal tunnel. An intracath was used to increase pressure by dripping saline or ringers into the tunnel. Evoked potentials (EPs) were taken before and after insertion of the cannula and intracath as well as before and after pressure was increased and after the pressure increase was terminated.

Pressure effects were measured as the percent of control EPs A-beta and A-delta waves were, at given elapsed times. EPs provided a rapid, non-invasive method of monitoring these changes. Wave form changes were a function of time and pressure. A-beta waves at low pressures (10-30 mmHg) first increased in amplitude then decreased over a period of 5-6 hours. In this time a pressure of 20-50 mmHg was the minimum required to abolish the waves. Rapid abolition was seen with pressures in excess of 50 mmHg. A-delta waves increased in amplitude while A-beta waves were decreasing, but with higher pressures, A-delta waves were also eventually abolished. The time it took to return to normal conditions was inversely related to the amplitude of the pressure applied.

These conclusions were drawn: 1) Low pressures abolished EPs as effectively as high pressures but over a longer time course; 2) Initial facilitation of nerve conduction amplitude occurred with lower pressures; 3) A-delta waves were potentiated by initial pressure increases; 4) Higher pressures exerted for shorter durations depressed sensory waves more quickly but produced a shorter time course of recovery following termination of elevated pressure; 5) EPs should be an effective method of monitoring critical pressure increases in emergency situations.

195 SYMPOSIUM

SYNAPTIC REGULATION OF VOLTAGE-GATED CHANNELS

P.R. Adams (Chairman; Univ. of Texas), L.K. Kaczmarek (Caltech), M. Klein* (Columbia Univ.), H.C. Hartzell* (Emory Univ.), R.L. MacDonald (Univ. of Michigan).

The frog neuromuscular junction and the squid giant axon are the classical prototypes for chemical synaptic transmission and action potential propagation respectively. However many more recently studied electrical events in nerve or muscle cells share certain features of both and yet resemble neither. For example potassium currents in neuronal somata are often triggered by a chemical internal transmitter, calcium. Voltage sensitive channels that are controlled by more conventional external transmiters are the subject of this symposium. These transmitters mediate "slow" synaptic actions lasting seconds or more. In one case the transmitter opens channels that are normally closed, and which show rather weak voltage sensitivity (heart cells, to be discussed appropriately, by Hartzell). In the other cases various transmitters or synaptic actions turn off channels that may already be open, or at least openable. These channels open mostly at potentials positive to rest, though some of them may contribute to the resting potential. They influence all parameters such as threshold and spike shape and number. When turned off by appropriate transmitters, their absence makes itself felt as a change in the behavior of the cell when responding to more conventional inputs. Specific examples to be covered include neurons in Aplysia, bullfrogs, mice, rats and guinea pigs, in tissue culture, isolated ganglia or brain slices.

196 SYMPOSIUM

REPRESENTATION OF SPACE WITHIN SENSORY SYSTEMS. M. M. Merzenich* (Cochairman, UCSF), E. I. Knudsen (Cochairman, Stanford), G. F. Poggio (Johns Hopkins Univ.) and D. C. Van Essen (Caltech).

Recent physiological, anatomical and behavioral studies have provided new insight into how perceptual spatial constructs relate to and might be accounted for by neural constructs. Eric Knudsen shall describe results of studies within the homologue of the inferior colliculus (MLD) and within the optic tectum of the barn owl, revealing the nature of evident topographic representations of sound location within each structure. In the optic tectum, the relationship of overlapping auditory and visual field maps will be described, along with evidence for plastic changes of these emergent maps (created within the central nervous system by convergence of auditory inputs) resulting from deprivation.

Gian Poggio shall consider how the three dimensions of vision are represented within visual cortex. He shall emphasize the results of studies of the depth-selective response properties of neurons in Area 17 in alert adult primates. The representation of visual depth constitutes another instance (like sound location) in which a psychophysical dimension is derived from convergence of information from different sources within a sensory projection system.

There are numerous "visual field representations" within extrastriate cortex in primates, and investigators have recorded significant differences in the internal organization, fidelity of topography and completeness of visual field representation within them. David Van Essen shall outline the nature of these differences, considered as clues to their role in the processing of visual information and their contribution to visual perception.

Finally, Michael Merzenich shall describe results of studies of the somatosensory projection system that have revealed the topographic details of significant dimensional plasticity of "maps" of the skin surface within that system in adult primates. Some of the implications of those results shall be discussed, with consideration of how tactile form might be represented within this system.

Taken together, these reviews should provide a synopsis of the implications of recent investigations of these three sensory systems for the representation of space within them.

197.1 REGULATION OF SUBSTANCE P IN SYMPATHETIC NEURONS. J.A.Kessler, J. Adler,* M. Bohn, and I.B. Black. Division of Developmental Neurology, Cornell University Medical College, New York, New York 10021.

Mechanisms regulating the putative neurotransmitter substance P (SP), were examined in the adult rat superior cervical ganglion. Surgical section of the preganglionic nerves to the SCG significantly increased ganglion content of SP. Treatment with chlorisondamine, which blocks ganglionic transmission, also increased SP, whereas treatment with phenoxybenzamine, which reflexly increases sympathetic activity, reduced ganglion content of SP. These observations suggest that impulse activity of preganglionic nerves decreases ganglion SP through a trans-synaptic process.

To further characterize this process, neonatal ganglia were studied in vitro. Ganglion SP content increased 6-fold within 12 hours, and 30-fold within 24 hours in culture.The increases were completely prevented by cycloheximide, partially blocked by camptothecin and actinomycin D, and unaffected by cytosine arabinoside. Thus, protein and RNA synthesis, but not DNA synthesis are necessary for the increase in SP. Treatment with veratridine also completely prevented the rise in SP in vitro, and tetrodotoxin blocked the effects of veratridine. This suggests that sodium ion influx and membrane depolarization prevent the increase in SP. Immunohistochemical examination of cultured ganglia demonstrated that SP is localized within the perikarya and nerve processes of the principal sympathetic neurons. Our observations suggest that trans-synaptic impulses, through the mediation of post-synaptic sodium flux, decrease SP in sympathetic neurons.

197.2 DEVELOPMENT OF SUBSTANCE P AND SOMATOSTATIN IN SENSORY GANGLIA IN TISSUE CULTURE. J.E. Adler*, J.A. Kessler and I.B. Black (SPON: E. Bloom). Division of Developmental Neurology, Cornell University Medical College, New York, New York, 10021.

Substance P (SP) and somatostatin (SS), putative neurotransmitters, have been localized to small neurons in the dorsal root ganglion (DRG). SP appears to mediate somatic pain, and exerts an excitatory influence on neurons in the dorsal horn of the spinal cord. The role of SS is as yet undetermined but its post-synaptic action is inhibitory. We have compared development of these two peptides in the DRG in vitro.

Neonatal rat ganglia were placed in organ culture and SP, SS and total protein content measured. Ganglion SP content more than doubled during the first 24 hours, and increased 3-fold by 72 hours. In contrast, ganglion SS decreased significantly, while total protein was unchanged.

The rise in SP was further analyzed using metabolic inhibitors. Cycloheximide, an inhibitor of protein synthesis, completely blocked the rise in SP, whereas Actinomycin D, an RNA synthesis inhibitor, had no effect.

Our studies suggest that the contents of SP and SS vary independently in the DRG in culture. These observations are consistent with the contrasting physiologic roles of the two peptides and suggest that their relevant regulatory mechanisms differ.

197.3 SUBSTANCE P AND ENKEPHALIN CONTAINING PATHWAYS IN SPINAL CORD. V.M. Pickel, K.K. Sumal*, J. Chan*, D.J. Reis and R.J.Miller. Dept. of Neurology, Lab. of Neurobiology, Cornell Univ. Med. College, N.Y. and Dept. of Pharmacology and Physiological Sciences, The Univ. of Chicago, Chicago, Ill.

Substance P (SP) containing axon terminals in the substantia gelatinosa and other parts of the dorsal and ventral gray of the spinal cord are reportedly derived primarily from sensory afferents in the dorsal root ganglia and from descending bulbospinal pathways. These immunocytochemical and transport studies are limited by difficulties in detection of SP immunoreactivity in perikarya and processes of neurons in the normal adult nervous system. Using two complimentary experimental approaches to enhance detectable levels of the peptide in axons, we sought to determine by light microscopic immunocytochemistry (1) whether SP is present in as yet unidentified ascending or descending pathways in the rat spinal cord and (2) whether similiar methodology could be used to demonstrate pathways of another neuropeptide, enkephalin (Enk). The two experimental procedures are based upon either the enhanced visualization of neuropeptides in outgrowing axons of the fetal nervous system or the accumulation of immunoreactivity (pile up) in axonal segments located behind nerve transections. Frozen sections through the spinal cord and lower medulla of fetal rats at embryonic (E) days 16-21 or of adult rats sacrificed 24-72h after hemisection of the spinal cord at cervical segment (C) 2 were labeled for SP or Enk using the peroxidase-antiperoxidase method. In the fetal spinal cord, SP is localized to longitudinally oriented axons in (1) the dorsal funiculus corresponding to the tracts of N. gracilis and cuneatus, (2) the ventrolateral funiculus and (3) a restricted region below the central canal. The position of growth cones on the rostral portions of the processes suggested that axons in the dorsal funciculus belonged to ascending sensory neurons and that the axons in the ventrolateral funiculus and ventral to the central canal were descending pathways. The location and directionality of the SP containing pathways were confirmed in the lesioned adult spinal cord by the accumulation of reaction product in axons distal to the lesion in the posterior funiculus and rostral to the lesion in the ventral tracts. In contrast to SP, the results of both the developmental and lesion studies demonstrated that Enk was detectable only in a descending pathway located in the ventrolateral funiculus. This pathway may correspond to the previously described enkephalinergic bulbospinal projection. (Hokfelt, Neurosci, Let. 14, 1979)(Antiserum to SP generously supplied by Dr. S.E. Leeman. Supported by NIH grants MH24285, HL18974 and MH 00078)

197.4 COEXISTENCE AND CO-RELEASE OF ACETYLCHOLINE AND THE LHRH-LIKE PEPTIDE FROM THE SAME PREGANGLIONIC FIBERS IN FROG SYMPATHETIC GANGLIA. Yuh Nung Jan and Lily Yeh Jan* (SPON: G. Reiness). Dept. of Physiology, Univ. of California, San Francisco,CA 94143.

Stimulation of preganglionic C fibers (arising from the 7th and 8th spinal nerves) initiates two responses in C cells in lumbar sympathetic ganglia. One response, the fast epsp, lasts tens of msec and is mediated by acetylcholine. The other one, the late slow epsp, lasts for minutes and is mediated by a LHRH-like peptide (Jan et al. Proc. Natl. Acad. Sci. 76, 1501-1505; 77, 5008-5012; Nature 288, 380-382). Here we report electrophysiological and anatomical experiments which suggest that acetylcholine and the LHRH-like peptide are contained within, and released from, the same preganglionic C fibers.

(1) Intracellular recording demonstrated that a C cell often receives 3-5 different cholinergic inputs which have different thresholds. By stimulating the preganglionic nerves at different strengths, we found that each time a cholinergic fiber was recruited, initiating an additional fast epsp, a peptidergic fiber was recruited as well, causing the late slow epsp to grow larger. Thus the thresholds of cholinergic fibers correlate well with the thresholds of peptidergic fibers, suggesting that the same preganglionic fibers for C cells supply both cholinergic and peptidergic inputs.

(2) We marked all terminals on C cells either by filling preganglionic fibers with horseradish peroxidase or by using a monoclonal antibody specific for synaptic vesicles (W.D. Matthew, L. Tsavaler, and L.F. Reichardt, Cold Spring Harbor Reports in the Neurosciences, vol. 2), and then stained the same sections using antibodies specific for LHRH. At least 90% of all preganglionic terminals on C cells contained the LHRH-like immunoreactivity, suggesting that at least some terminals contain both the LHRH-like peptide and acetylcholine. Therefore, it appears that most, if not all, preganglionic fibers for C cells contain and release both acetylcholine and the LHRH-like peptide.

197.5 THE ORIGIN OF THE CHOLECYSTOKININ-CONTAINING EFFERENTS OF THE CAUDATOPUTAMEN IN THE RAT. M.C. Beinfeld*, D.K. Meyer*, W.H. Oertel and M.J. Brownstein* (SPON: C. Helke) Lab. Clinical Science, NIMH, Bethesda, MD 20205.

Large amounts of cholecystokinin octapeptide (CCK) are present in the caudatoputamen (cp) of the rat. By immunocytochemistry, the peptide is found in axons and nerve endings but not in perikarya in the cp. Since some perikarya in the substantia nigra stain for both CCK and dopamine, it has been suggested that this structure may provide some of its CCK-containing neuronal processes (T. Hökfelt, et al., Neuroscience, 5, 2093, 1980). The origin of CCK in the cp was investigated in this present study using immunocytochemistry to visual CCK containing projections to the cp, and a CCK radioimmunoassay to evaluate the effect of selective knife cuts on the CCK content of the cp.

The cp receives afferents from the amygdala, ventral tegmental areas, substantia nigra, dorsal raphe nucleus, several cortical areas, and the thalamus. Apart from the thalamus, all of these structures contain perikarya which stain for CCK. A surgical lesion of the nigral-striatal pathway completely reduced the dopamine concentration in the cp but did not decrease its CCK content. This result indicates that neurons in the substantia nigra contribute little CCK to the cp. A knife cut severing the afferents from the amygdala reduced CCK content of the cp by about 30%. Removal of those parts of the frontal, parietal, and occipital cortex which are accessible after a dorsal craniotomy had no effect on cp CCK content. A knife cut severing the insular cortex from the cp likewise had no effect on cp CCK content.

Immunocytochemical staining showed heavy staining for CCK in the claustrum and adjacent piriform cortex, revealing CCK containing perikarya in both areas, in addition to nerve terminals. This suggested to us that the cp might receive CCK-containing afferents from these areas. A knife-cut severing the claustrum and the piriform cortex from the cp decreased CCK content in the cp by about 70%. However, the close proximity of the CCK staining perikarya in the piriform cortex to the claustrum prevented selective destruction of the piriform cortex which might have enabled us to decide whether the cp receives its CCK-containing afferents from the piriform cortex and/or the claustrum.

The claustrum receives afferents from various cortical areas while the piriform cortex is part of the olfactory system. Thus, CCK might be the transmitter of claustral and/or piriformal neurons which mediate impulses from various cortical areas and/or the olfactory system to the cp.

197.6 VASOPRESSIN-REVERSIBLE CHANGES IN ANGIOTENSIN-CONVERTING ENZYME ACTIVITY IN INTERMEDIATE AND POSTERIOR PITUITARY LOBES AND HYPOTHALAMIC NUCLEI OF RATS LACKING VASOPRESSIN. J.M. Saavedra, C. Chevillard* and J. Fernandez-Pardal*. Laboratory of Clinical Science, Section on Pharmacology, NIMH, Bethesda, MD 20205.

Changes in angiotensin-converting enzyme (ACE) activity were noted in the intermediate, posterior and anterior lobes of the pituitary gland and in the nuclei paraventricularis and supraopticus of rats with inherited diabetes insipidus, which lack vasopressin (Brattleboro rats; di/di:homozygous for the trait; and di/+:heterozygous) when compared to homozygous (+/+) control Long Evans (LE) rats.

In the posterior lobe, ACE activity was higher in di/+ rats with respect to LE rats (+43%), and even higher in di/di rats (+170%). The same phenomenon, but more pronounced, was observed in the intermediate lobe (+288% and +828% for di/+ and di/di compared to LE rats). In both posterior and intermediate lobes, the changes in ACE activity were reversed by vasopressin treatment (3 U per rat twice daily for seven days).

In the anterior lobe of the pituitary, ACE activity was lower in di/+ with respect to LE controls (-44%) and even lower in di/di rats (-69%), and these changes were not significantly reversed by vasopressin treatment.

In the supraoptic nuclei, increased ACE activity was observed in di/+ rats (+57%) and in di/di rats (+90%). In the nucleus paraventricularis, there was no significant change in di/+ rats with respect to LE controls (+11%) but a decreased enzyme activity in di/di rats (-32%). In both supraoptic and paraventricular nuclei, vasopressin administration reversed the changes in ACE activity. No changes in ACE activity were observed in the subfornical organ.

Our results suggest the possibility of a regulation by vasopressin of the activity of ACE, and therefore of the renin-angiotensin system, at the neuropituitary level and in discrete magnocellular hypothalamic nuclei.

197.7 $ACTH_{1-24}$ ANTAGONIZES OPIOID-INDUCED ANALGESIA IN THE RAT SPINAL CORD. H.L. Fields, G. Belcher* and T. Smock*. Depts. Neurology and Physiology, Univ. Calif. San Francisco, San Francisco, CA 94143.

ACTH and the potent opioid peptide β-endorphin (βE) are derived from a common precursor. ACTH antagonizes morphine suppression of spinal evoked responses (Zimmerman & Krivoy, Prog. Br. Res. 39:383). βE produces behavioral analgesia when injected into the rat 4th ventricle and we have shown that this effect is reversed by $ACTH_{1-24}$ (Smock & Fields, Brain Res. 212: 202). The spinal cord dorsal horn is rich in opiate receptor and analgesia is produced by direct opiate injection into the lumbar spinal intrathecal space. We examined the interaction of $ACTH_{1-24}$ and opioid agonists on a behavioral measure of analgesia at the level of the spinal cord.

Drug and control injections were made into the lumbar subarachnoid space. Injections were made via PE-10 cannulae placed through a slit in the atlanto-occipital membrane in barbiturate anesthetized rats. Drugs were diluted in balanced ion solution. Tailflick (TF) latency to noxious heat (baseline 4-5 sec, cut-off 15 sec) was measured. No significant change in TF latency was produced by up to 15 μg ACTH (n=12).

In studies on chronically implanted, unanesthetized rats, ACTH (2-10 μg) produced a slight increase in TF latency in 15 of 21 trials (cf. Walker, et al, Science 210:1247). Higher doses of ACTH (35-40 μg) increased TF latency in 4 of 8 rats tested. However, in no case did ACTH cause TF latency to go to cut-off. Morphine sulphate (MS) (10-30 μg) increased TF latency in 17 of 23 trials (13 to cut-off) and βE increased it in 6 of 8 trials (4 to cut-off). Ten min following administration the mean increase in TF latency for rats receiving ACTH was 0.5 ± 0.2 sec compared to 4.5 ± 0.9 sec for rats receiving MS.

In contrast to its weak agonist action, intrathecal ACTH (3-10 μg) reversed MS analgesia in all 15 trials (10 rats) and reversed βE analgesia in 3 of 4 rats. Reversal was complete by 15 min in most cases. Injection of equal volumes of balanced ion solution and mannitol (Cortrosyn vehicle, Organon) produced no latency changes.

These studies extend previous demonstrations of opposing actions of $ACTH_{1-24}$ and opioid agonists on systems relevant to analgesia.

197.8 IN VIVO STUDIES OF THE RESTING AND EVOKED RELEASE OF CHOLECYSTOKININ (CCK) AND VASOACTIVE INTESTINAL PEPTIDE (VIP) FROM CAT CEREBRAL CORTEX AND VENTRICLES. J.-Y. Wang, K. Jhamandas, T.L. Yaksh and V.L.W. Go, Depts. of Pharmacology, Neurosurgical Res. and Gastroenterology, Mayo Foundation, Rochester, MN 55905.

The differential distribution of VIP and CCK in the CNS has been demonstrated by immunohistochemical studies and radioimmunoassays (RIA). Subcellular fractionation studies have shown that these peptides are high in brain synaptosomal fractions. Mapping with RIA, we found that these peptides are present in high levels in the cortex and periventricular tissue in the cat. To study the release of these peptides, we employed two in vivo superfusion preparations using chloralose-urethanized cats: a) cortical cups (two 1 cm plastic cylinders were agar-sealed on the surface after bilateral craniotomy and reflection of the dura); and b) ventriculocisternal perfusions (a 22 ga inflow cannula inserted into the lateral ventricle and an outflow cannula placed in the cisternal magna). In both preparations, animals were perfused at 150 μl/min with artificial CSF containing albumin/bacitracin. Changes in pupil size and blood pressure were recorded for each pharmacological manipulation. Levels of VIP and CCK were determined simultaneously using RIA in the same sample of lyophilized perfusate. The levels of VIP and CCK obtained from cortical or ventricular perfusion and the effects of adding picrotoxin in each preparation to the CSF are shown below for 3-5 cats.

	CORTEX		VENTRICLE	
	Basal Level[1]	Picrotoxin[2] (↑%)	Basal Level	Picrotoxin (↑%)
CCK	5.4 ± 1.1	113.2 ± 39.5	9.9 ± 1.24	350.8 ± 140.1
VIP	1.9 ± 0.4	180.7 ± 81.2	2.8 ± 0.8	260.2 ± 81.7

[1]μ ± S.E.; fmol/ml/10 min; [2]100 μg/ml.

Two depolarizing agents (K^+ and veratridine) were also observed to increase the release of CCK and VIP. Using a Sephadex G-50 superfine gel filtration column, the VIP-like immunoreactivity obtained from tissue extracts and the cortical and ventricular release samples revealed that all activity traveled in a single peak which co-migrated with authentic VIP-28. For CCK, the immunoreactive species in tissue co-migrated with 8, 33, and 4 amino acid peptide fragments. However, in the release sample, the activity migrated with the peak corresponding primarily to CCK-8 (with only a trace of CCK-4). These studies suggest that in vivo tissue stores of VIP and CCK can be released by pharmacological agents and their simultaneous release can be studied. (Supported by NS 16541 (TLY) and AM 20973 (VLWG).)

197.9 SIMULTANEOUS MEASUREMENT OF VIP AND CCK RELEASED FROM RAT AND CAT CORTICAL SLICES. P. Micevych, V.L.W. Go[1] and T. Yaksh, Depts. of Neurosurgery and [1]Gastroenterology, Mayo Fdn., Rochester, MN 55905.

Vasoactive intestinal polypeptide (VIP) and cholecystokinin (CCK) are polypeptides which were originally isolated from the porcine gut and subsequently have been shown to have a central nervous system distribution. The highest concentrations of CCK and VIP have been shown to be in the cerebral cortex. We examined the release of CCK and VIP, measured by radioimmunoassay (RIA) in the same sample, to compare the release of these peptides in response to a depolarizing stimuli. Both rat and cat cerebral cortical slices were studied to determine whether any species differences could be observed. In both preparations approximately 20 mg of cortical tissue was superfused with a modified Krebs-Ringer bicarbonated buffer at 37°C. The buffer continued 0.3 g/L bacitracin, 0.15 g/L albumin and 2 g/L dextrose. The buffer was continually oxygenated and superfused at a rate of 300 µL/min. Samples were collected every 10 min for a total of 50 min. The tissues were stimulated with potassium and veratridine to evoke CCK and VIP release. In the rat, spontaneous release of VIP was determined to be 2.25 fmoles/min/ml/mg while CCK simultaneously measured was 9.4 fmoles/min/ml/mg tissue. High potassium, 50 mM, elevated the release of VIP 2.4 fold to 9 fmole/min/ml/mg tissue and CCK rose 5.6 fold to 52.7 fmol/min/ml/mg tissue. The molar ratios (CCK:VIP) for both the spontaneous and evoked release were similar (basal was 4.2 and evoked was 5.8). The profile of CCK and VIP release from the cat cortex paralleled the rat release data. Removal of calcium from the superfusion buffer abolished the K^+ evoked release of VIP and CCK but had no effect on spontaneous efflux. Gel filtration column chromatography (Sephadex G-50 superfine) of rat tissue showed that the VIP immunoreactivity co-migrated with authentic VIP-28 while the CCK immunoreactivity is isographic primarily with CCK-8 though some activity appeared in the eluate containing the CCK-4 standard. These results are consistent with gel filtration chromatography of cortical tissue extracts which suggest that the primary molecular species in rat cortical tissue are the VIP-28 and CCK-8 peptides. These results are consistent with the notion that VIP and CCK may be cortical transmitters in cat and rat. Interestingly, although the tissue levels of VIP are high in rat and cat cortex the amount of released VIP measured in superfusates is significantly lower than released CCK in the same superfusates. These data may indicate that CCK although in lower concentrations in the cortex is more easily releasable in response to a depolarizing stimulus and thus may have an equally significant effect on cerebral cortical transmission as does VIP. (Supported by NS 16541 (TY) and the Mayo Foundation.)

197.10 ACTH INTERACTION WITH OPIATES AND ENDORPHINS IN VITRO. T. Smock*, H.L. Fields, M. Grossman*, S. Kansky* and J. Ramachandran*. Depts. Physiology and Neurology, and Hormone Research Lab., Univ. of California, San Francisco, San Francisco, CA 94143.

ACTH (one microgram intraventricularly) is capable of blocking analgesia produced by morphine or β-endorphin (Smock and Fields, Brain Res., in press). Similarly, small amounts of ACTH (1-24) oppose opiate effects on spinal nociceptive reflexes and on nociceptive neurons in the brainstem. Since ACTH binds weakly to the aggregate of opiate receptors in the brain (Akil et al, Eur. J. Pharmac. 64:1-8, 1980) the apparent antagonism could be mediated by direct competition for some subset of binding sites. In an initial test of this possibility, we examined ACTH effects on a number of model opiate receptor preparations.

Morphine effects on the guinea pig ileum (GPI, µ-receptor, ID50 41-44 nM) were not significantly affected by ACTH (1-24) at concentrations of up to 1 µM (ID50 in presence of ACTH 40-70 nM, n=5). ACTH had no independent effect on GPI twitch tension. Likewise, β-endorphin effects on the mouse vas deferens (δ-receptor) and rat vas deferens (ε-receptor) were unaffected by ACTH in a wide range of concentrations.

In the rat vas deferens, morphine enhances twitch tension in contrast to β-endorphin which is inhibitory (Huidobro et al, Br. J. Pharmac. 70:519-25, 1980). In our hands, the excitatory effect of morphine on the rat vas deferens was variable, obtainable only at high concentrations (ED50 48-106 µM) and was markedly attenuated by ACTH when the two were applied in molar ratios similar to those used in the rat brain to prevent opiate analgesia. Examination of ACTH effects alone revealed that the apparent antagonism resulted from opposing actions rather than competition. ACTH (1-24) inhibited the neuromuscular preparation independently (maximum effect: 32% inhibition, dose at half-maximum inhibition: 7-11 nM). The effect was shared by ACTH (1-39), α-MSH and synthetic fragments that included the ACTH sequence (4-10), but was not produced by ACTH (7-38) or by poly-lysine. Neither the morphine effects nor the ACTH effects were naloxone-reversible.

It was concluded that ACTH/opiate antagonism in the rat brain is probably not due to direct competition for an opiate receptor but may instead be due to independent interactions similar to those obtained for morphine and ACTH in the rat vas deferens.

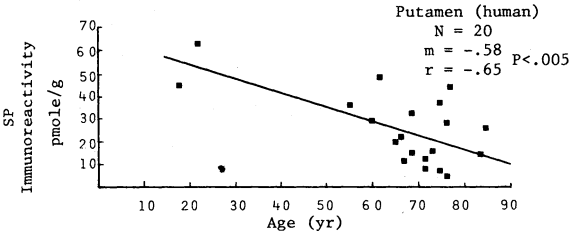
197.11 SUBSTANCE P LEVELS IN THE MAMMALIAN CNS IN AGING. S.H. Buck, H. I. Yamamura, T.F. Burks, and M.N. Rossor*. Dept. of Pharmacology, University of Arizona College of Medicine, Tucson, AZ 85724 and MRC Neurochemical Pharmacology Unit, Cambridge, England CB2 2QD.

Neurochemical changes that occur in the CNS of laboratory animals in aging include reductions in levels of certain neurotransmitters, reductions in activity of synthetic enzymes for these neurotransmitters, and declines in number of receptors for some transmitters. Similar decreases in neurotransmitter levels and in synthetic enzyme activities have also been observed in the human CNS in aging. Age-related changes in CNS neuropeptides have not been investigated in animals or in humans. We have obtained preliminary evidence of an age-related decline in human basal ganglia levels of substance P (SP) that does not occur in rodents.

SP levels were determined in acid extracts of tissues by RIA using an antiserum with cross-reactivity of 1% with physalaemin, 0.01% with eledoisin, and less than 0.00001% with each of 15 other neuropeptides. Extraction of SP was quantitative and assay of varying dilutions of samples revealed curves that were parallel to the standard curve.

In Fischer 344 rats 3, 10, or 27 months old (from NIA colony), there were no differences among the age groups in SP levels in frontal cortex, limbic system, corpus striatum, substantia nigra, hypothalamus, brainstem, or cerebellum. In post-mortem tissues from humans, there was no correlation of SP levels with age in frontal cortex, thalamus, or hypothalamus. In putamen, however, there was a significant age-related decrease in SP levels of about 6 pmole/g tissue/decade. Conclusive determination has not yet been made in human caudate or nigra.

These results suggest that there may be differences between rats and humans in aging in basal ganglia and that reductions in SP levels may contribute to human basal ganglia dysfunction in aging. (Supported by USPHS grants and by an RSDA to H.I.Y.)



197.12 POLYPEPTIDES AS STOCHASTIC LIGANDS. A. J. Mandell, P. V. Russo* and S. Knapp. Dept. of Psychiatry, University of California at San Diego, La Jolla, CA 92093

The presence of polypeptides with neurochemical, physiological, and behavioral activity in biogenic amine neurons is well established. Their role, thought to be regulatory, has not been mechanistically explicated.

Recent in vitro studies of time-dependent fluctuations in the activities of rat striatal tyrosine hydroxylase and rat raphe tryptophan hydroxylase, as well as in crude striatal membrane ^{3}H-spiroperidol binding, have demonstrated stochastic properties that are sensitive to polypeptide hormones as reflected by such ligand-sensitive indicators as moments, autocorrelation length, probability and spectral densities, and characteristic exponents.

TRH and its methyl analogues, somatostatin, and other polypeptide ligands appear to change the stability (sensitivity) of enzymatic and binding processes. Such statistical mechanical phenomena as randomization, coupling, and bifurcation among populations of dissipative, nonlinear protein oscillators may partially determine the responsivity of the system to other regulatory influences. The more diffusely circulating polypeptides may be long-range regulators, as more local neurotransmitters and ions are short-range regulators.

197.13 PARTIAL CHARACTERIZATION OF SOMATOSTATIN-LIKE MATERIAL IN THE BOVINE ADRENAL MEDULLA. A. Baird*, R. Benoit*, N. Ling*, P. Böhlen* and R. Guillemin, Laboratories for Neuroendocrinology, The Salk Institute, La Jolla, CA. 92037.

Immunohistochemical methods have demonstrated the presence of somatostatin-like immunoreactivity (SLI) in cells derived from the embryonic neural crest. In this report we present the detection of SLI in extracts of bovine adrenal medulla (BAM) and its partial characterization by gel permeation and reverse-phase high-performance liquid chromatography (HPLC).

350 BAM (950 g) were extracted in acid, defatted and pumped through a 7 x 25 cm column of octadecasilylsilica (ODS, Böhlen et al., 1981), the material retained on the ODS column was eluted with 60% propanol in 0.36 M pyridine formate, pH.3, lyophilized and 3.0 g applied to a Sephadex G-50 column. The amount of SLI in the ODS-retained fraction and the column effluent was monitored using an antibody generated against somatostatin (SS-14) which reads SS-14 and N-terminally extended somatostatin (SS-28) in an equimolar ratio. The ODS-retained material contained $\geq$5 ng of SLI per BAM, which, after G-50 chromatography, was resolved into three distinct forms. The greater part of the SLI (75%) eluted in a zone compatible with a peptide of 1.2k Daltons, while the remaining SLI was divided between a zone compatible with 2.5k Daltons and another located in the void volume (MW>10k). The fractions corresponding to the 1.2k and 2.5k Dalton zones of SLI were pooled and further analyzed by HPLC. No SLI was found in a similar extract of bovine adrenal cortex.

Our data suggest that there are three forms of SLI in the bovine adrenal medulla, but none in the adrenal cortex. Gel filtration indicates that these forms are consistent with the existence of SS-14- and SS-28-like peptides, as well as a putative precursor of higher molecular weight. Chemical and biological characterization of the two smaller SLI activities is now in progress.

198.1 MORPHINE DIFFERENTIALLY AFFECTS ICSS INTERACTIONS BETWEEN THE LOCUS COERULEUS AND THE MEDIAL FOREBRAIN BUNDLE. F. Gimino*, F. Villegas*, R. Alvarez*, J. Abreu*, M. Sano*, S. Steiner, S. Ellman*. Behavioral Physiology Lab., City College of New York, New York, N.Y. 10031.

The C-T monophasic pulse pair technique can be employed to produce behavioral interactions between brain loci. In this technique response rates elicited with simultaneous or near simultaneous stimulation of two ICSS sites can be shown to be significantly greater than the sum of the response rates elicited from each site stimulated individually.

12 albino Sprague-Dawley rats were implanted with electrodes aimed at Locus Coeruleus (LC) and medial forebrain bundle (MFB). Animals were shaped to respond for monophasic rectangular pulse pairs at a variety of current intensities.

In one condition, the C pulse was delivered to the LC at its within site intensity, and the T pulse was delivered to the MFB. In the reverse condition, the C pulse was delivered to the MFB at its within site intensity and the T pulse was delivered to the LC.

After completion of this procedure, animals were then administered subcutaneous injections of saline for 3 days followed by 6 days of 1.25mg/kg of morphine sulfate according to a counterbalanced design. The effects of these injections were observed on the response rates of animals in their within site condition. All subjects then received one injection day of naloxone HCL at 1.0mg/kg and morphine sulphate at 1.25mg/kg. Animals then received 3 more injection days of saline followed by a four day sequence of D and L amphetamine.

Subjects were then returned to baseline control rates of responding during a six day injection series of saline during which pulses were again "split" between electrode loci. The effects of morphine sulfate and D and L amphetamine were observed in this split pulse condition.

Two patterns of drug responsivity have been delineated on these test interactions. Animals demonstrating bidirectional interactions between the LC and MFB were also more responsive to d-amphetamine and evidenced morphine induced rate facilitations in both directions. Unidirectional animals displayed either an L or D-amphetamine sensitivity dependent upon the location of the C-pulse in either the MFB or the LC. These Ss were more responsive to morphine and when the interaction was D-responsive. Thus, the C-T "split-pulse" technique allows for the differentiation of interacting ICSS networks.

198.2 MORPHINE AND LOCUS COERULEUS LESION EFFECTS ON ICSS ARE SITE SPECIFIC. A. Tempel, S.J. Ellman*, C. Pavlides*, D. Ocheret*, S. Berman* and S.S. Steiner. Behavioral Physiology Lab., Dept. Psych., The City College of New York, New York, N.Y. 10031.

ICSS has been discretely localized within the CNS. Neuroanatomical and immunohistochemical studies have demonstrated that both opiate receptor sites and opioid peptides are discretely localized within the CNS. Therefore, it seemed likely that morphine would act at some discrete brain loci and not others. The following study was aimed at determining if morphine acts differentially at specific neuroanatomical loci to facilitate ICSS.

Rats were stereotaxically implanted with 2 pairs of bipolar stainless steel electrodes, aimed at various combinations of the following sites: fields of forel (ff), crus cerebri (cc), medial forebrain bundle (mfb), mammillothalamic tract (MT), zona incerta (ZI), and anteroventral thalamus (Thl). Stimulation consisted of monophasic rectangular pulse pairs. Animals received 7 days saline, 7 days morphine, 1 day morphine + naloxone, and 6 days saline. Acute, unilateral locus coeruleus (LC) lesions were then made in all animals. Following the lesion, animals were run for 21 days of saline to allow for complete degeneration. ICSS drug paradigms post-lesion were identical to the pre-lesion paradigm.

Electrodes localized in the MT, FF, MFB, CC and ZI showed an ICSS response rate facilitation under morphine administration. These facilitations were naloxone reversible. Although the thalamic electrodes supported ICSS behavior, morphine did not produce any alteration in ICSS response rates.

ICSS from electrodes located in the mammillothalamic tract and thalamus were unaffected by the LC lesion.

These results suggest that it is possible to use the lesion technique and pharmacological tools to delineate anatomical loci of reward.

198.3 ENDOGENOUS OPIOIDS & PLEASUREABLE BEHAVIOR

Angello de la Sierra, University of Puerto Rico Medical Sciences and Cayey Campus, Puerto Rico

Some years ago we observed that rats tolerated pain while self stimulating the medial forebrain bundle (MFB) pleasure area. Subsequently we measured the thresholds to foot shocks in both MFB and rats evidencing aversion after stimulation to the reticular area (RET). The results led us to assume that pleasurable behavior (increased rate of MFB stimulation) and analgesia (increased threshold to foot shock) shared the same neuronal mechanisms. Their opposites, ie, aversion with pain, shared also same neuronal mechanisms. When we injected Naloxone (2 mg/kg,IP) to MFB and RET groups, the former were no longer protected from pain while the latter's threshold to foot current was lowered. Unexpectedly, MFB-naloxone group explored their environment more actively and increased their H_2O and food intake. When ethanol was substituted for H_2O, consumatory behavior increased in proportion to Naloxone levels. MFB-naloxone groups learned faster to obtain concealed food but preferred many food-seeking trips than a prolonged single feeding. Data suggests that (1) high endorphin levels in obesity may be coincidental (2) ethanol may substitute for morphine and viceversa in the therapy of withdrawal symptoms of either one, (3) Naloxone may be useful in the management of amnesia, apathy or decreased learning performance. Data also suggests that (1) consumatory behavior may be more related to metabolic needs than to pleasure, (2) learning may be unrelated to pleasurable reinforcements.

198.4 ATTENUATION OF INTRAVENOUS HEROIN REWARD BY VENTRAL TEGMENTAL OPIATE RECEPTOR BLOCKADE. M.D. Britt* and R. A. Wise. Center for Research on Drug Dependence, Department of Psychology, Concordia University, Montreal, P.Q., Canada H3G 1M8.

Rats self-administering opiates will normally maintain a relatively constant rate of responding, but will increase their response rate if the dose per infusion is decreased or if opiate antagonists are administered in low doses (J.R. Weeks and R.J. Collins, Psychopharmacologia, 6, 267, 1964). This compensatory increase in self-administration is indicative of a functional decrease in the reward value of each infusion. The present experiment was designed to localize the site of rewarding opiate action by microinjecting opiate antagonists into various regions of rats involved in intravenous heroin self-administration. The hydrophilic opiate antagonist diallyl-normorphinium bromide (DNMB) was used for microinjections because the more commonly used antagonists are highly lipophilic and spread rapidly throughout the brain. In pilot studies microinjections of naloxone (5 µg) into any brain region tested resulted in compensatory increases in responding for heroin.

Rats were prepared with chronic jugular catheters and bilateral intracranial cannulae into either the nucleus accumbens (NAS), the corpus striatum (CS) or the ventral tegmental area (VTA). Following recovery the rats were allowed to lever press for heroin (50 µg/kg/infusion) for 4h daily. Microinjections of DNMB (2.5, 1.25 0.63 µg/0.5 µl saline) were given in a descending and ascending sequence so that each dose was tested twice in each animal. The injections of DNMB were given every other day at 1h into the session. On alternate days sham or vehicle injections were given for control comparisons. Systemic naloxone was also tested (0.1 mg/kg, i.p.) before and after the microinjection series.

All rats showed increased response rates for the hour following i.p. naloxone. Intracranial DNMB caused response accelerations only when injected at the higher dose and only when injected into the ventral tegmental area. Thus the reward-attenuating effects of systemic naloxone are mimicked by central DNMB when injected into the opiate receptor field of the VTA, but not when injected into the receptor fields of NAS or CS. These data fit well with reports of morphine self-administration into the ventral tegmental area but not other regions (M.A. Bozarth and R.A. Wise, Soc. Neurosci. Abstr., 6, 309, 1980) and suggest the VTA as the site of rewarding opiate action in the brain.

This work was supported by a NIDA postdoctoral fellowship to M.D.B. and by the Medical Research Council of Canada.

198.5 DIFFERENTIAL AVERSIVE EFFECTS OF HEROIN AND MORPHINE. L. Switzman*, T. Hunt*, M. Sossanpour* and Z. Amit. Center for Research on Drug Dependence, Concordia University, Montreal, Canada H3G 1M8.

In the conditioned taste aversion (CTA) paradigm ingestion of a novel flavor followed by morphine results in subsequent avoidance of the novel flavor by rats, indicating aversive stimulus properties of the drug. In a CTA experiment (single pairing, one-bottle test), six doses of heroin (.5 - 12.0 mg/kg, ip) and the Ringer's vehicle were tested for aversive effects. Heroin did not induce a significant CTA at any of the doses tested. In a second CTA experiment, three doses of morphine (4 - 12 mg/kg, ip) and the Ringer's vehicle were tested in an identical paradigm to that previously implemented. Morphine induced a significant CTA at two of the doses tested (8 and 12 mg/kg). A third experiment was carried out to determine the relative analgesic effectiveness of non-aversive heroin doses and aversive morphine doses. Using the hot-plate procedure drug- or Ringer's-injected rats were subjected to 4 repeated test trials. The dependent measure was paw lick latency. The heroin doses tested (2 and 4 mg/kg) resulted in analgesia equal to or greater than the morphine doses tested (8 and 12 mg/kg). Therefore, although heroin is more potent than morphine as an analgesic, heroin is less potent than morphine as a CTA-inducing agent. In a fourth experiment we attempted to maximize conditions to enable heroin to induce a CTA. Three doses of heroin (3, 6 and 9 mg/kg, ip) were paired with a novel saccharin solution. Five such pairings occurred with two water days intervening between each pairing day. On the third day following the final pairing the rats were presented with a choice of water or saccharin. Three additional heroin groups were run with the same procedure but each group received 3 injections spaced 20 min apart (0, 1, 2 and 3 mg/kg/injection) on each pairing day. Heroin still did not induce a CTA. The inefficiency of heroin as an aversive agent is discussed in terms of differing stimulus properties from those of morphine.

198.6 EFFECT OF SYSTEMIC MORPHINE ON CORTICALLY-EVOKED UNIT ACTIVITY IN THE CAUDATE NUCLEUS. T.C. Napier, J.H. Pirch and S.L. Peterson. Department of Pharmacology and Therapeutics, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

The caudate nucleus is well endowed with opiate receptors and is also known to receive extensive cortical inputs. The ability of morphine to alter cortically-evoked caudate unit activity was investigated in this study.

Sixteen gauge guide cannulas were permanently implanted directly above the caudate nucleus, and three bipolar stimulating electrodes were embedded in the frontal and motor cortex in male Sprague-Dawley rats. After recovery from surgery the animals were lightly anesthetized with sodium phenobarbital and replaced in the stereotaxic instrument, with the earbars inserted into implant earbar holders to circumvent pain produced by insertion into the auditory canal. A tungsten microelectrode was lowered through the guide cannula and a spontaneously active caudate neuron was located. The spontaneous activity was monitored throughout the experimental period. Monophasic square wave pulses (.25-5 mA; .3 msec; 1 Hz) were used for cortical stimulation. The optimal cortical site and threshold current necessary for driving the unit were determined. Under these experimental conditions, cortical stimulation typically evoked a response of approximately 10 msec latency. However, the latency varied according to the cortical site being stimulated. In those cells with sufficiently high rates of activity this evoked response was often followed by an inhibitory phase, usually lasting approximately 100-250 msec before returning to the control spontaneous rate. Morphine sulfate, in cummulative doses of 1,5,10,20 and 30 mg/kg, was injected at ten minute intervals via a tail vein cannula. Naloxone (1 mg/kg iv) was given at the end of the experiment.

Less than 50% of the units demonstrated a morphine-induced depression of firing rate which was antagonized by naloxone. The majority of cortically-evoked responses were also unaffected by the doses of morphine used in this study. If the corticostriatal pathway plays a role in the actions of systemic morphine, then only a small portion of caudate cells which respond to cortical stimulation are involved. (Supported by USPHS BRSG RR05773 and MH29653 and by the Tarbox Parkinson's Disease Institute at Texas Tech University Health Sciences Center.)

198.7 EFFECTS OF MORPHINE AND NALOXONE ON FETAL RAT SPONTANEOUS ACTIVITY AFTER CHRONIC OPIATE EXPOSURE. M. L. Kirby and S. G. Holtzman*. Dept of Anatomy, Med. Col. of Georgia, Augusta GA 30912 and Dept. of Pharmacology, Emory Univ., Atlanta GA 30332.

Chronic maternal morphine administration during gestation causes changes in the offspring, of postnatal behavior and responsiveness to opiates. Acute opiate administration during late gestation causes a dose-related decrease in fetal spontaneous activity; however, it is not known what effect chronic opiate administration has on fetal response to morphine and naloxone. In the present study, pregnant Wistar rats were injected s.c. 4 times daily with 5 mg/kg/injection of morphine or 0.8 mg/kg/injection of levorphanol or dextrorphan (an equipotent dose) or 2 times daily with 10 mg/kg/injection of morphine. Control animals were injected with saline. A final group of pregnant animals was pairfed with the morphine-injected animals. Injections and pair feeding were initiated on day 12 of gestation. On gestation days 18-20 the effects of varying doses of morphine and naloxone on fetal activity in the pretreated animals were assessed by visual observation and quantification as reported previously. When challenged with varying doses of morphine, fetuses exposed twice daily to morphine showed a depression in spontaneous activity similar to animals pretreated with saline or dextrorphan or pairfed. Animals injected 4 times daily with morphine showed tolerance to the depressant effect of morphine. Levorphanol-treated animals were not tolerant to the depressant effect of morphine. All of the animals exposed chronically to morphine or levorphanol were hyperactive after challenge with naloxone while animals injected with saline or dextrorphan or pairfed were not responsive to naloxone. Even though these changes in responsiveness to morphine and naloxone were present in utero following chronic exposure to morphine, 30-day neonates which had been treated identically prenatally did not show changes in the analgetic response to morphine in the hotplate test. Supported by NIH Grant DA 02060.

198.8 DEXAMETHASONE EFFECT ON COLD-INDUCED AND MORPHINE-INDUCED HYPOTHERMIA IN RESTRAINED RATS. P.R. Marques* and J.N. McDougal (SPON: G.W. Van Hoesen) Dept. Pharmacology, Univ. Arizona Health Sciences Center, Tucson, AZ 85724.

The effect of morphine on thermoregulation in the rat is influenced by dose and restraint. Low doses (1-5 mg/kg) elevate the rectal temperature (Tr) of restrained and unrestrained rats whereas 25 mg/kg and above decrease the Tr of restrained rats. Unrestrained rats show less hypothermia at these higher doses. An hypothesis that restraint stress potentiates or entirely accounts for the morphine hypothermia at high doses was supported by studies in which dexamethasone (Dxm) pretreatment before 30 mg/kg morphine reversed the hypothermia. The assumption was that Dxm, via negative feedback inhibition of corticotropin and endorphin release from the pituitary prevented the stress hypothermia. We hypothesized that Dxm reversal or attenuation of morphine hypothermia is a consequence of the direct action of Dxm and related corticosteroids to support metabolic heat production. The Tr of Sprague-Dawley derived rats was monitored at 15 min intervals for 1 hr before and up to 4 hr after treatment. Rats pretreated with Dxm, (400 µg/kg at 24 hr and 200 µg/kg at 2 hr prior to 30 mg/kg morphine) and installed in a metal restrainer, returned Tr toward basal 1.25 hr earlier than saline pretreated rats given 30 mg/kg morphine (S-M). Control groups receiving saline instead of morphine (D-S, S-S) did not differ significantly from each other or from basal. Further studies in which the Dxm dose was doubled and the morphine dose halved enhanced separation of the curves. In this case, group D-M reached a Tr minimum of 3.68 $\pm$ 0.51 C below basal at 2 hr. Group S-M rats did not reverse the Tr decline until 4.80 $\pm$ 0.21 C. Significant group differences persisted throughout the 2.5-4.0 hr period of measurement. Exposure of non-morphinized rats to a low Ta (6 C) resulted in a similar rate of heat loss for both Dxm (400 + 200 µg/kg) pretreated and saline pretreated rats during the first hr. Dxm rats' Tr stopped the decline at 1.25 hr and at 1.75 C below basal; control rats lost heat for 2.5 hr to a 2.33 $\pm$ 1.0 C drop from basal. Sustained significant differences between groups emerged at 3 hours. These data are consistent with our hypothesis that Dxm attenuation of morphine hypothermia is secondary to increased substrate availability for thermogenesis. Enhanced morphine hypothermia in restrained vs unrestrained rats is more parsimoniously explained by postural factors such as increased body surface exposure and inability to adjust fur loft for insulation in restrained animals. Supported by USPHS grant NS15420.

198.9 PUPILLARY DILATION AFTER MICROINJECTIONS OF MORPHINE, NORMORPHINE AND CLONIDINE INTO THE EDINGER-WESTPHAL NUCLEUS (EW) IN THE CAT. Lawrence G. Sharpe and Wallace B. Pickworth. NIDA Addiction Research Center, Lexington, Kentucky 40583.

When administered peripherally, morphine and clonidine produce pupillary dilation in the cat but constriction in the dog. In the dog, these drugs appear to produce miosis through a central mechanism which activates parasympathetic input to the iris (Lee and Wang, JPET 192, 415-431, 1975; Sharpe, Pickworth and Martin SN, #967, 1977). In the cat, different sites have been proposed for the mydriatic actions of morphine and clonidine. Morphine may act peripherally to increase sympathetic tone (Wallenstein and Wang, Am. J. Physiol. 236, R292-R296, 1979), whereas clonidine may act centrally to inhibit parasympathetic tone to the iris (Koss, Eur. J. Pharmacol. 55, 305-310, 1979). Our purpose was to further assess the central site of these mydriasis-producing drugs in the cat. Morphine, normorphine, and clonidine (0.5 µl solutions) were microinjected via chronic indwelling cannulae into a region of the EW that yielded pupilloconstriction to electrical stimulation. Pupillary diameter was measured photographically in the awake cat acclimated to a sling restraint. All three drugs (3-100 nmol) produced dose-dependent pupillary dilation which began within 5 min and lasted throughout the 1-hr test period. The order of potency was clonidine > normorphine > morphine. Mydriasis did not occur if these drugs were microinjected in adjacent EW sites not yielding pupilloconstriction to electrical stimulation. We conclude from this data that the parasympathetic preganglionic cell groups controlling pupillary diameter may be the region from which peripherally administered morphine and clonidine act to produce mydriasis in the cat. These drugs may inhibit, either directly or indirectly, parasympathetic tone to the iris. Since the dog becomes miotic after microinjections of opioids and clonidine in the EW (Sharpe et al. SN, 1977) we further conclude that the neurochemical and/or neuroanatomical nature of this region may differ in the dog and cat.

198.10 THE OPIATE ANTAGONIST NALOXONE REVERSES THE ISCHEMIC NEUROLOGIC DEFICIT PRODUCED BY UNILATERAL CAROTID LIGATION IN GERBILS. Yoshio Hosobuchi,* David S. Baskin,* Sidney Woo* and Horace H. Loh* (SPON: N. M. Lee). Departments of Neurological Surgery and Pharmacology, School of Medicine, University of California, San Francisco, CA 94143.

Because of anatomic anomalies commonly found in the circle of Willis, homolateral ischemic brain damage and a consequent neurologic deficit (stroke) are produced in 30 to 50% of gerbils that undergo unilateral common carotid ligation. Under pentobarbital anesthesia (40 mg/kg), the right common carotid artery was occluded in 70 adult gerbils. Within 4 hours, 23 of them developed stroke (2 died within 4 hours) (Group A); 47 gerbils that were ligated did not develop stroke (Group B). In 14 of 15 Group A gerbils, 1 mg/kg of naloxone injected i.p. reversed the neurologic deficit within 2 to 5 minutes; 1 gerbil required an additional 1 mg/kg of naloxone to obtain reversal. Typically, reversal lasted 20 to 30 minutes, after which the neurologic deficit returned. However, reversal could be obtained repeatedly by injection of naloxone. Eight of 11 Group B gerbils injected i.p. with 15 mg/kg of morphine developed naloxone-reversible stroke within 10 minutes. Naloxone-reversible stroke was produced in the other 3 gerbils by i.p. injection of an additional 15 mg/kg of morphine. The stereoisomeric opiate agonist levorphanol (5 mg/kg i.p.) was given to 10 Group B gerbils, 8 of which developed mild stroke symptoms that were reversed by naloxone. Dextrophan (15 mg/kg), the enantiomer of levorphanol, was given i.p. to 10 Group B gerbils, none of which developed stroke. The delta receptor-specific enkephalin analogue Sandoz #FK33824 was given i.p. to 10 Group B gerbils at a dose of 15 mg/kg, which is 80 times the mouse ED_{50} analgesic dose. None developed stroke, although all were totally analgesic over 24 hours.

Naloxone reversal of stroke induced by cerebral ischemia is a novel observation. Our results strongly suggest that the action of opiates and naloxone on this neurologic deficit are stereospecific and mu receptor-specific. Recent findings of naloxone reversal of neurologic deficit caused by cerebral ischemia in a small group of patients are in accord with these findings in gerbils.

198.11 INTERACTIONS OF MIDBRAIN AND BULBAR OPIATE ANALGESIA SUBSTRATES IN RAPHE MAGNUS. J. Peter Rosenfeld, M. Heinricher* and C. McWilliams*. Depts. of Neurobiology & Physiology, and Psychology Cresap Neuroscience Laboratory, Northwestern University, Evanston, Ill 60201.

Morphine was microcannulated into periaqueductal gray (PAG: .7µg) and nucleus reticularis paragigantocellularis (PGC: .35µg in separate doses as well as in combination. Effects of combined injections of PAG and PGC doubled the baseline (behavioral) facial thermal-nociceptive threshold. The single injections raised the threshold to 140% of baseline. Combined injections of left and right PGCs had a similar effect.

The electrophysiological substrate of these interactions was studied by obtaining effects of morphine and fentanyl, microinjected into PAG and PGC, on single neuronal firing rates recorded in Nucleus Raphe Magnus (NRM) of urethene-anaesthetized rats. As of the date of submission of this abstract, **19** cells in NRM (baseline firing rates = 5-50 Hz) have been studied with the following results: 17 responded to nociceptive pinch with increased firing rate, 1 with decrease. In 13, .35µg (n=2) to 1µg (n=10) of morphine sulphate in PGC produced either excitation (n=2), inhibition (n=7), or no effect (n=4). In 6 other cells, PAG (.7µg) as well as PGC (.35µg) were both injected with morphine. Results: There were 3 cells in which conjoint effects were suggested: In 1 cell PGC injection led to inhibition, whereas PAG injection later led to excitation. In another cell, PGC injection produced excitation followed by PAG-produced inhibition. In the 3rd, PAG injection produced a mild inhibition followed by a profound PGC-produced inhibition, totally reversible with IP naloxone, 1 mg/kg. Of the 3 remaining cells, 2 were first PGC-injected with no effect, followed by PAG-produced excitation in one case, and no PAG effect in the other. Finally 1 cell was PAG-injected with no effect, then depressed by PGC.

198.12 EVIDENCE THAT THE ANALGESIC EFFECT OF MORPHINE MICROINJECTED INTO THE 4TH VENTRICLE INVOLVES AN ENDOGENOUS OPIOID LINK AT THE LEVEL OF THE SPINAL CORD. Steven R. Lane, Jon D. Levine*, Newton C. Gordon* and Howard L. Fields. UCSF, Depts. Neurol. and Oral Surgery, San Francisco, CA 94143.

Microinjection studies demonstrate that morphine can produce profound analgesia when injected at discrete sites within the CNS, including the periaqueductal gray, the ventromedial medulla and the spinal cord. These results can be explained by postulating that morphine activates an endogenous opioid mediated analgesia system (EOMAS). Evidence has accumulated that EOMAS exists and acts in part via enkephalinergic neurons with terminals in the superficial layers of the dorsal horn (Basbaum & Fields, Ann Neurol, 4:451, '78). The following studies were designed to study the dynamic interactions between spinal and supraspinal opiate sensitive sites in the production of morphine analgesia.

Fifty, 250-350g, male Sprague Dawley rats were chronically implanted with PE-10 tubing in the lumbar subarachnoid space. In addition, 4th ventricular guide cannulae were placed on the midline, 2mm posterior to the interaural line (15° head-tilt). Morphine, naloxone or vehicle were isovolumetrically injected either intracerebroventricularly (ICV) or through the spinal (SP) cannula. Analgesia was assessed in unanesthetized rats by measuring both the tail flick (TF) latency (3.5" baseline, 20" cut-off) and the threshold for "pain"-induced vocalization (PIV) produced by electrical stimulation of the base of the tail (1msec pulses, 100Hz for 200msec).

Results were comparable using either method of assessing analgesia. Microinjection of 15 µg of morphine either SP or ICV produced only partial analgesia. ICV injection consistently produced greater analgesia than SP. Simultaneous injection at both sites produced analgesia as strong as 10mg/kg systemic morphine (100% MPE on the TF). Ten µg SP naloxone partially reversed an established analgesic effect of 15 µg ICV morphine. The same dose of SP naloxone injected 15' prior to ICV morphine completely blocked the development of analgesia (n=6). Thus SP naloxone is much more effective in preventing the effect of ICV morphine than in reversing it once it is established.

Thus, ICV morphine produces more profound analgesia than SP morphine at a dose of 15 µg; ICV morphine can be reversed by SP naloxone; and SP naloxone is more effective in pre-blocking than in reversing ICV morphine effects.

These results are consistent with an interaction between spinal and supraspinal opiate sensitive sites in the analgesia produced by systemic morphine and supports the hypothesis that supraspinal morphine activates a descending system with an opioid link at the spinal cord level.

199.1 NON-OVERLAPPING PROJECTIONS OF MUSCLE AND CUTANEOUS AFFERENTS IN THE BRACHIAL SPINAL CORD OF ADULT BULLFROGS. S. Jhaveri* and E. Frank. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

The peripheral ends of primary sensory axons in the 2nd. spinal nerve of bullfrogs innervate the skin and muscle of the forelimb. The central projections of these sensory axons, as revealed by labelling the entire 2nd. nerve with horseradish peroxidase, terminate in two distinct areas in the gray matter of the brachial spinal cord: the dorsal and ventral neuropil regions. The contribution of muscle or cutaneous sensory fibers to these two neuropils was investigated by selective labelling of a single muscle or cutaneous nerve branch with horseradish peroxidase.

Individual branches of the 2nd. spinal nerve, innervating forelimb muscles or skin, were placed in a cuff containing horseradish peroxidase and lysolecithin. Following a 2-week survival period, the spinal cord was fixed using an aldehyde fixative, and processed for the visualization of the horseradish peroxidase reaction product, with 3,3',5,5'-tetramethyl benzidine as a chromogen. The muscle nerves studied incluced the medial, internal and external branches of the triceps nerve. Sensory afferents from these nerves projected exclusively to the ventral neuropil region. On the other hand, when the nerves backfilled were cutaneous nerves, such as the cutaneous branches of the ulnar or radial nerves, the labelled sensory afferents were observed to terminate only in the dorsal neuropil region of the spinal cord.

Thus, primary sensory afferents carrying information about two different classes of sensory modalities project to discrete areas of the spinal cord gray matter.

199.2 Transganglionic transport of WGA/HRP conjugate in the upper cervical cord of the cat. V.C. Abrahams, Dawne Downey*, Oriette Morris*, and Frances J. Richmond, Department of Physiology, Queen's University, Kingston, Ontario. K7L 3N6

We have used Wheat germ agglutinin/HRP (WGA/HRP) conjugates to trace the spinal and medullary destination of primary afferents from large dorsal neck muscles in the cat. These experiments have shed some light on the pathways followed by neck muscle afferents, but also raise questions about the axonal transport of WGA/HRP conjugates. The central cut end of C2 and C3 cat neck muscle nerves were exposed for 90-240 minutes to a concentrated solution of WGA/HRP freshly made from lyophilized powder (supplied by E-Y laboratories). After 2-4 days, the animals were anaesthetized and perfused with modified Karnovsky fixative. Sections were then cut through the C1 to C3 spinal segments and the medulla. An intense band of HRP staining was consistently present in the ipsilateral dorso-lateral part of the dorsal horn. Reaction product was concentrated in lamina II, with lighter and more scattered staining in lamina III, and some scattered staining in lamina IV. No staining could be seen in lamina I. Some light staining was also apparent at obex levels in a confined region of the lateral rim of the cuneate nucleus. No retrograde staining of motoneurons was observed. The pattern of spinal cord labelling with its concentration in lamina II suggests that WGA/HRP may be selectively transported in small fibres (a possibility raised on the basis of similar evidence by Brushart and Mesulem, Neuroscience Letters 17, 1980).

No evidence was found in these experiments for the retrograde transport of WGA/HRP and no retrograde labelling of motoneurons was seen. In contrast, a sample of WGA/HRP obtained from Sigma and used in identical experimental conditions, showed no evidence of transganglionic transport to sites in the spinal dorsal horn, but was readily transported in a retrograde direction and intense staining appeared in motoneurons after exposure of neck muscle nerves.

Our conclusions are that the small fibres, which are unusually abundant in neck muscle nerves (Richmond et al., Can. J. Physiol., 1976) may have terminals confined to a restricted lateral region of the substantia gelatinosa (suggesting that the substantia gelatinosa in this area may be somatotopically organized). In addition, it should be noted that the axonal transport properties of particular WGA/HRP conjugates may be dependent on the source of supply.

199.3 PROPERTIES OF NEURONS IN LAMINA X AND THE MIDLINE DORSAL HORN OF THE SACROCOCCYGEAL SPINAL CORD OF THE CAT. C.N. Honda and E.R. Perl. Neurobiology Program and Dept. of Physiology, University of North Carolina, Chapel Hill, N.C. 27514.

Light and Perl(JCN 186:133,1979) showed that in addition to the marginal zone, SG_O, and Rexed's lamina V, myelinated mechanical nociceptors often had terminal arborizations within the gray matter surrounding and dorsal to the central canal. Our preliminary results describe some details of the function and morphology of neurons located in the substantia grisea centralis (Rexed's lamina X) and the dorsally adjacent gray matter, part of the central canal region receiving this projection.

In anemically-decerebrate, unanesthetized cats, glass microelectrodes filled with horseradish peroxidase (HRP) were used to record unitary activity in the lower sacral and coccygeal spinal cords. Seventy-five units were functionally characterized and attempts were made to iontophorese HRP into them. In 29 cases where HRP marks were histologically recovered, we found 13 cells whose morphology was extensively delineated with HRP.

Three main categories of neurons were identified within lamina X and the region immediately dorsal to it. One group (27%) was excited only by low threshold mechanoreceptors associated with skin and hair; this group included units responsive only to very slowly moving stimuli. The second and largest group (46%) was excited by both innocuous and noxious stimuli; effective innocuous stimuli were gentle manipulations of skin and hair, or more rarely, subcutaneous tissue. Nociceptive properties of the second group were expressed as either 1) an increased sustained activity in response to noxious mechanical or heat stimulation of the low threshold receptive field or 2) noxious intensities of stimulation for a threshold response in adjacent areas. The third group (27%) was excited only by intense mechanical and/or noxious thermal stimulation of the skin. Units in all three groups usually had receptive fields crossing the midline. Background activity appeared in 20% of the sample, and included units responsive to slowly moving stimuli and those excited by high threshold mechanoreceptors from the skin and deep tissue.

The intracellularly marked neurons formed a heterogeneous population of cells with respect to perikaryal size (8 to 35 μm diam.), dendritic orientation, and localization. Their geometries gave no indication of how morphological features might correlate with functional properties. It appears that neurons of the midline dorsal horn region, described by Rexed as a medial fusion of the dorsal horns, are functionally similar to those of lamina X.

199.4 LIGHT AND ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL DEMONSTRATION OF ENKEPHALINERGIC INPUT ONTO DORSAL HORN THALAMIC PROJECTION NEURONS. M.A. Ruda. Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Thalamic projection neurons (TPN) represent a distinct population of dorsal horn neurons, most of which respond to noxious stimulation. These neurons convey noxious input to higher centers of the neuraxis. Enkephalin (ENK), an opiate peptide, is thought to mediate inhibition of the response of these neurons to noxious stimulation. Identification of the site of interaction between these two systems is thus crucial to our understanding of the mechanisms of pain and analgesia. This study identifies one site of synaptic interaction by simultaneously labeling ENK axonal endings and thalamic projection neurons in the medullary and spinal dorsal horns. Several large injections of a 50% solution of HRP were made into the thalamus of 4 adult cats. Following a survival time of 68-72 hrs, the animals were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde and the medulla and spinal cords sectioned on a vibratome. Tissue was processed first with cobalt chloride intensified diaminobenzidine to produce black HRP granules in retrogradely labeled dorsal horn neurons, and subsequently for leu-ENK using the peroxidase anti-peroxidase method of Sternberger to produce red-brown labeled varicosities. TPNs are concentrated in laminae I and V where they represent different morphological types of neurons. At the light microscopic level, numerous ENK varicosities outline the soma and proximal dendrites of large, multipolar TPNs in lamina V. However, in lamina I, only an occasional ENK varicosity is adjacent to the soma of a TPN. At the EM level, numerous ENK immunoreactive endings containing round, agranular synaptic vesicles, form asymmetrical synapses on the soma and proximal dendrites of lamina V TPNs. These neurons also receive a dense innervation from unlabeled endings, many of which contain flattened vesicles. In contrast, the soma of the lamina I TPNs receives few synapses, mainly from endings containing flattened vesicles, and are largely enveloped by glial processes. To date, no ENK endings have been observed synapsing on the soma of lamina I TPNs. These results indicate that lamina I and V TPNs differ with respect to the afferent input received on their soma. ENK synapses on lamina V TPNs demonstrate that one major site of opiate modulation of noxious input in the dorsal horn occurs directly on projection neurons. Moreover, this data indicates that opiates act, at least in part, on postsynaptic receptors located on TPNs.

199.5 ACTION POTENTIAL CHARACTERISTICS OF MYELINATED AXONS IN THE RAT SPINAL CORD: AN INTRA-AXONAL ANALYSIS. J. D. Kocsis, S. G. Waxman, and M. Bickford*. Dept. of Neurology, Stanford Sch. of Med., and V. A. Med. Ctr., Palo Alto, CA 94304.

Intra-axonal recordings were obtained in vivo from dorsal column (d.c.) axons of the rat spinal cord. The rats were anesthetized with urethane, artificially ventilated, and surgically prepared for acute electrophysiological experiments. Intra-axonal impalements were obtained with glass microelectrodes filled with KCl or K-citrate. The d.c.'s were stimulated locally with teflon-coated platinum-iridium wires. Axons having resting potentials of at least -60 mV and action potential amplitudes of 60 mV or greater were selected for analysis. Intra-axonal impalement was identified by the presence of resting potential and the ability of intra-axonal current passage to modulate action potential amplitude; hyperpolarizing current increasing and depolarizing current decreasing spike amplitude.

Impulse fractionation occurred spontaneously in depolarized axons and could be induced by depolarizing current injection. Fractionation also occurred at critical intervals during the relative refractory period (RRP). Threshold increased following depolarizing prepulses, and decreased following hyperpolarizing prepulses. These changes were both voltage- and time-dependent. Anode break excitation was often observed following hyperpolarizing prepulses. During passage of low level depolarizing currents, threshold reductions were observed in some axons.

Spike amplitude was reduced and spike width increased during the RRP. In about half the tested axons a supernormal period (SNP) was present as evidenced by a reduction in threshold following a previous action potential. The SNP duration was about 150 msec. The spikes were followed by either a depolarizing or hyperpolarizing after-potential. The SNP could be present during either type of after-potential. In some axons a hyperpolarizing potential of up to 20 mV amplitude with a time course of greater than a second, intermittently followed the action potential. Although the hyperpolarizing potential was often entrained to spike activity, it could occur independent of spike activity. The origin of this potential is not certain.

In mammalian dorsal column axons, threshold reductions have been observed 1) following a previous action potential, 2) during passage of low level depolarizing pulses, and 3) following hyperpolarizing prepulses. These results suggest that in addition to membrane potential levels, sodium inactivation may be an important determinant of membrane excitability for central myelinated axons. (Supported by the V.A. Medical Research Service and grants from the Multiple Sclerosis Society).

199.6 RESPONSES OF POST-SYNAPTIC DORSAL COLUMN NEURONS IN THE CAT. R.E.W. Fyffe*, P.B. Brown, Lillian M. Pubols and A.G. Brown*. Dept. of Vet. Physiology, Univ. of Edinburgh, Edinburgh EH9 1QH, U.K.

Single axons in the L5 dorsal columns were recorded with microelectrodes in chloralose-anesthetized, gallamine triethiodide-paralysed cats. All responded antidromically to stimulation of the dorsal columns at C3-C4 but failed to respond from C1-C2 above a section of the dorsal columns at C2-C3. Responses were recorded from 48 axons. Their conduction velocities ranged from 22 to 61ms^{-1} (38.3 ± 8.9 mean ±s.d.). Most (71%) had spontaneous discharges of short bursts of high frequency firing separated by a few hundred ms or even seconds of silence. Excitatory fields were of several types: 1. 21 units were excited by hair movement, displacement of glabrous skin (input from Pacinian corpuscles and/or Krause corpuscles and Type I slowly adapting receptors) and high threshold mechanoreceptors from within the area; 2. 11 units were similar but had no high threshold components; 3. 6 units had no glabrous skin component and responded to hair movement and light pressure and pinch of the skin and underlying tissues; 4. 2 units had responses indicating input from Pacinian corpuscles only; 5. 2 units responded only to hair movement. Many units (17%) (especially those with excitatory fields including foot and toe pads) had receptive fields made up of disparate parts. A feature of some (10%) units was the expansion in size of the excitatory field during recording, often after natural stimulation of the field and the area around it. Inhibitory fields were common (18 units) and were mainly of two kinds: 1. The inhibition, (usually elicited by noxious mechanical stimulation) was evoked from within the excitatory field with most of the inhibitory field proximal to it. Inhibition could be elicited by electrical stimulation of both ipsilateral and contralateral cutaneous nerves. Characteristically, it had a time course similar to that of primary afferent depolarization in the spinal cord, although in some units the inhibition was long-lasting, e.g. more than 300ms with a peak at about 120ms.

199.7 THE MORPHOLOGY AND LOCATION OF THE CELLS OF ORIGIN OF THE DORSAL COLUMN POSTSYNAPTIC TRACT (DCPST). G.J. Bennett, Z. Seltzer*, M.J. Hoffert, G.W. Lu*, N. Nishikawa* and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

We have labeled the cells of origin of the DCPST in the lumbosacral enlargement of cats using retrogradely transported and intracellularly injected horseradish peroxidase (HRP). In the retrograde transport studies, the dorsal columns of a caudal thoracic segment were partially transected. A small piece of HRP-containing polyacrylamide gel was placed into the transection. The cats were sacrificed and perfused 2-3 days later and their spinal cords were sectioned serially in the sagittal plane. HRP reaction product was developed with either cobalt chloride-intensified diaminobenzidine or with tetramethylbenzidine (TMB). Retrogradely labeled perikarya (12-50 μm) were most numerous within a band that extended dorsoventrally for 115 μm. The band was largely within layer IV (with a small excursion into layer III) throughout most of the dorsal horn. Near the horn's medial border, however, the band shifted ventrally into layer V. Labeled cells were also found in the gray matter around the central canal and, very rarely, in layer I. The ventral horn neurons that are labeled by HRP injections into the dorsal column nuclei (Rustioni and Kaufman, '77; Brain Res., 27) were not found. No cells were labeled when the dorsal columns were completely transected caudal to the HRP placement. In one experiment, all of the cells that had clearly visible nuclei were counted in TMB-reacted sections from segment L_7. We found an average of 41.5 cells (unilaterally) in each millimeter of the segment's rostrocaudal extent. This is about equal to the estimated density of spinocervical tract neurons (Brown, et al., '80; J. Physiol., 300) and about one-third the estimated density of spinothalamic tract neurons (Carstens and Trevino, '78; J. Comp. Neurol., 182). In the intracellular experiments, neurons were antidromically driven from cervical dorsal columns that were dissected free, severed rostrally, and insulated from the rest of the spinal cord. To date, all of the cells that we have stained have been in layer IV. They were all wide dynamic range neurons, i.e., they responded to noxious as well as to innocuous stimulation of their cutaneous receptive fields. Their dendritic arbors were elongated rostrocaudally (up to 1,450 μm) but relatively compressed mediolaterally (generally about 450 μm). Some cells had apical dendrites extending into the substantia gelatinosa. We conclude that the DCPST is an ascending pathway important in the transmission of information about noxious stimuli.

199.8 TASK-RELATED RESPONSES OF MONKEY MEDULLARY DORSAL HORN NEURONS. M.C. Bushnell, R. Dubner, D.S. Hoffman*, R.L. Hayes* and M.B. Taylor*. Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

In previous studies using behaving monkeys we described thermosensitive and mechanosensitive medullary dorsal horn neurons with additional responses independent of stimulus parameters or stimulus modality. The present study investigated these task-related responses in more detail and identified one output pathway in which they are involved. Rhesus monkeys were trained to release a panel when they detected one of the following events: (1) the termination of a warming stimulus (37°-43°C) on the face; (2) the onset of a noxious thermal stimulus (45°-49°C) on the face; (3) the onset of a light on the response panel. Single unit activity was recorded in the medullary dorsal horn (trigeminal nucleus caudalis) during the performance of the behavioral tasks, and projection neurons were identified by antidromic responses to stimulation of the ventral posterior medial thalamic nucleus. EMG activity was recorded from the lip musculature.

Medullary dorsal horn neurons responding to mechanical or mechanical and thermal stimuli also exhibited responses associated with the initiation of the trial, or the sensory cue for panel release, or both. These responses occurred only during performance of the task and were related to sensory events that led to the successful completion of the task, independent of modality, intensity, or location of the relevant stimulus. Such responses were not correlated with facial or arm and hand movements.

Several types of task-related responses were identified, and neurons of each variety could be antidromically activated from the thalamus. In some cells the task-related response occurred only at trial initiation, while in others the response occurred only after the signal for panel release, irrespective of whether that signal was a thermal or visual stimulus. However, the most common pattern of task-related activity was a transient or sustained response at trial initiation with an additional neuronal burst discharge in response to the signal to release the panel. Task-related responses always were associated with stimuli that were components of the sequence of behavioral events leading to reception of a liquid reward. Since neurons with task-related responses project to the thalamus, they could provide a gain-control mechanism for somatosensory information that the animal must use for successful completion of the task. Alternatively, they could be involved in the transmission of behavioral information to motor cortex to facilitate appropriate goal-directed motor behaviors.

199.9 TASK-RELATED NEURONAL RESPONSES AND BEHAVIORAL PERFORMANCE COVARY WITH THE RELIABILITY OF RELEVANT SENSORY CUES IN PREDICTING REINFORCEMENT IN A REACTION-TIME TASK. R. Dubner, D.S. Hoffman*, R.L. Hayes* and M.C. Bushnell. Neurobiology and Anesthesiology Branch, National Institute of Dental Research, National Institutes of Health, Bethesda, MD 20205.

During the monkey's performance of thermal and visual reaction-time tasks, neurons in the medullary dorsal horn (trigeminal nucleus caudalis) exhibit responses associated with the detection of sensory cues relevant to the successful completion of the task. These task-related responses do not code stimulus features and are not related to parameters of movement necessary for acquisition of the liquid reward (Bushnell et al., Neuroscience Abstracts, this volume). This report examines the effect of manipulating variables that alter the reliability of relevant sensory cues in predicting reinforcement on task-related neuronal responses and behavioral performance.

The reliability of occurrence of relevant sensory cues increases as a function of foreperiod length, the time between panel press and the onset of the cue. Reaction time, the time to release of the response panel following onset of the relevant sensory cue, is a measure of the monkey's performance proficiency. Task performance improved significantly (shorter reaction times) on long foreperiod trials (6.5-8.0 sec) as compared to short foreperiod trials (2.0-3.5 sec). We found that the magnitude of task-related neuronal responses following the onset of relevant sensory cues (a temperature decrease or light stimulus) also increased on long foreperiod trials.

The monkey's ability to predict reinforcement was reduced on experimenter-initiated trials in which the monkey had no control over panel release and reinforcement availability. Task-related neuronal responses usually were of less magnitude on reinforced experimenter-initiated trials, and were reduced further, or absent, when reinforcement was withheld. Lip movements, the behavioral performance associated with reception of the liquid reinforcement, also were reduced or absent on experimenter-initiated trials.

We conclude that task-related neuronal responses in reaction-time tasks are evoked by sensory cues that reliably predict reinforcement. More reliable sensory cues produce both increases in the magnitude of task-related neuronal responses and improvement in task performance.

199.10 STRETCH TRAUMA OF THE SPINAL CORD--OXIDATIVE METABOLISM AND ULTRASTRUCTURAL CHANGES. S. Yamada, D. Knierim,*G. Maeda,* R. Schultz.* Section of Neurosurgery, Loma Linda University Med. Cntr., Loma Linda, CA 92350

Dual wavelength spectrophotometry (Jöbsis) allows continuous recording of reduction/oxidation ratio (redox) of cytochrome a,a_3 in cerebral or cord mitochondria. A trauma of the lumbosacral cord was produced in experimental cats by applying traction of various weights on the filum terminale. Double beams, (590 nm-as reference, 605 nm-as sample) were projected to the sacral cord under traction with 0, 1g, 2g, 3g or 5g weight. 1) Transient oxidation of cytochrome a,a_3 in sacral cord mitochondria was measured in response to stimulation of the posterior nerve roots corresponding to the cord segments under examination. 2) After 6-minute period of traction with respectively 2g, 3g and 5g, each cat was sacrificed by fixative perfusion through the descending aorta for ultrastructural study.

Addition of each weight starting from 1g, resulted in increasing reduction of cytochrome a,a_3. Transient oxidation of cytochrome a,a_3 was diminished to 2/3 of normal amplitude under 1g, 2g, and 3g traction. After traction of 1g, 2g and 3g was released, normal transient oxidation returned. However, during 5g traction no oxidation was noted. For 5 minutes after 5g traction was released, transient oxidation of low amplitude occurred, but thereafter, no oxidation was elicited. The ultrastructural changes were prominent only after 5g traction; numerous membrane breaks were noted in neuronal and glial cells.

Low grade stretching (1, 2, and 3g traction) results in metabolic changes i.e. reduction of cytochrome a,a_3. High grade stretching produces structural changes, mainly membrane breaks, which contribute to ion leakage and energy loss. This may lead to irreversible neuronal damage.

199.11 EFFECTS OF SYMPATHECTOMY ON BLOOD FLOW, EVOKED POTENTIALS, EXTRACELLULAR POTASSIUM AND CALCIUM IONS IN EXPERIMENTAL SPINAL INJURY. W. Young*, I. Koreh*, E. S. Flamm. Dept. Neurosurgery, NYU Med. Center, New York, N.Y. 10016.

Contusion of cat spinal cord produces a characteristic pattern of neurophysiological loss [Young, W., et al, J. Neurosurg. 52:64, 1980]. Action potential conduction across the impact site is immediately lost, recovers transiently 1-2 hours later, but only to disappear again 2-3 hours after injury. We report experimental evidence for the role of extracellular potassium (K+) and post-traumatic ischemia in the initial and delayed loss of evoked potentials.

Two groups of 5 cats, anesthetized with 25 mg/kg IV pentobarbital, were studied. The T1-12 sympathetic ganglia were removed in one group 2 hours prior to injury and not in the other (control). Ion-selective microelectrodes were used to measure extracellular K+ and Ca++ ionic activities in the lateral columns of the thoracic cord. Blood flow was measured close to the site of ionic recordings with the hydrogen clearance method [Young, W., Stroke 11:552, 1980]. White matter conduction was assessed with somatosensory evoked potentials (SEP). The spinal cords were injured by a 20 gm weight dropped 20 cm onto the T7 cord. Systemic pressure and respiratory parameters were maintained within normal range.

In control cats, extracellular K+ rose precipitously from a pre-injury level of 3.2 mM to a mean of 52 mM, clearing out with a half-time of 45 minutes. SEP were lost virtually immediately after contusion but recovered transiently 1-2 hours after injury, as extracellular K+ returned towards baseline. Blood flow, however, began to decrease as K+ fell below 12 mM. SEP disappeared again when blood flow reached 50% of preinjury levels by the 3rd hour after injury. Extracellular K+ did not increase above 12 mM again despite the ischemia. In sympathectomized cats, extracellular K+ behaved in a similar manner except for a shorter clearance half-time of 30 minutes. The pattern of SEP change was identical to the controls except that there was no secondary loss at 2-3 hours. Ischemia did not occur as K+ normalized. Extracellular Ca++ ions in both groups fell from a pre-injury mean of 1.2 to 0.3 mM, recovering to baseline with a half-time of >1.0 hour.

These results suggest that contusion of spinal tissues causes massive exchange of ions across cellular membranes. The extracellular levels of both K+ and Ca++ ions return slowly towards pre-injury levels. Transient recovery of evoked potentials occurs as K+ falls, only to be lost again when ischemia sets in. Sympathectomy ameliorates the delayed post-traumatic ischemia and prevents the secondary loss of SEP.

199.12 PSYCHOPHYSICAL EVALUATION OF SOMATOSENSORY IMPAIRMENT IMPLICATING DORSAL (COLUMN) FUNICULUS INVOLVEMENT. Richard J. Schneider and Ronald F. Burke.* Maryland Institute for Emergency Medical Services Systems, Baltimore, Maryland 21201.

We trained monkeys and humans to discriminate between hair follicle displacements or electrocutaneous stimuli. In the former task, the amplitude or frequency of displacement of patches of hair on the anterior calf were varied. In the latter, current pulse trains of different frequency were applied to the skin over the peroneal or sural nerve. The ambiguity of these discriminations was manipulated. The subject was required to depress a manipulandum in response to one amplitude (frequency) and to refrain in response to the other. The stimuli were presented successively (10 sec. ISI) and pseudorandomly. Thus, four responses were possible - a correct depression (hit), an incorrect one (false alarm), a correct refrain (correct rejection), and an incorrect refrain (miss). These were used to calculate d-prime (sensitivity) and beta (response bias) scores according to signal detection theory (TSD). These measures were established in normal subjects and compared to either the same animals with peripheral nerve block, dorsal funiculus (DF) lesions or to human patients with multiple sclerosis (MS).

Discriminative capacity (d') was reliable and independent of response bias (β). Normal subjects established a given sensitivity level comparable for humans and monkeys, and not affected by hair density, sex or age. When (local anesthetic) peripheral nerve block was applied to monkeys, responding to both stimuli ceased below the affected area, but not above it or on the contralateral leg. Following DF tractotomy, however, d' was markedly diminished only to hair displacement below the level of the lesion on the ipsilateral side. Diminution in electrocutaneous d' was small in comparison. MS patients have a lower hair displacement d' than do normals. As long as the stimulator does not touch the skin, this holds true. Differences between normal and MS groups diminish when skin is also stimulated.

These conclusions are suggested: (1) Hair follicle displacement has particular advantages in evaluating DF damage in monkeys. (2) Electrocutaneous stimulus discrimination is not as useful in making such an assessment. (3) MS patients have less sensitivity to hair follicle stimuli than to electrocutaneous or touch stimuli.

200.1 REGIONAL VARIATION IN BZ_1 and BZ_2 BENZODIAZEPINE RECEPTOR SUBCLASSES IN 40 BRAIN AREAS OF THE MONKEY (CERCOPITHECUS AETHIOPS). M. Nielsen*, H. Simonsen*, I. Divac and C. Braestrup*. Psychopharmacological Research Lab., St. Hans Mental Hospital, DK-4000 Roskilde; Neurophys. Lab., Panum Inst., Copenhagen and A/S Ferrosan, Soeborg, Denmark.

Derivatives of β-carboline-3-carboxylic acid, including the methyl, ethyl and propyl esters have been shown to be potent inhibitors of brain benzodiazepine (BZ) receptor binding. ^{3}H-propyl β-carboline-3-carboxylate (^{3}H-PrCC) binds specifically to the benzodiazepine recognition site of BZ receptors in cerebellum (the BZ_1-receptor subclass). In other brain regions ^{3}H-PrCC labels only a subfraction of the total BZ receptor populations as labelled by ^{3}H-flunitrazepam (^{3}H-FNM). In the rat brain, BZ_1 receptors (identified by ^{3}H-PrCC binding) constitute ca. 50% of hippocampal and ca. 70% of cortical BZ receptor population. Remaining receptors are classified as BZ_2 receptors. By simultaneous estimations of ^{3}H-PrCC (0.3 nM final concentration) and ^{3}H-FNM (1 nM final concentration) binding, the fraction of BZ_2 receptors to total BZ receptors can be calculated (Braestrup and Nielsen, J. Neurochem. in press) provided that no variations in K_D values occur. The fraction of BZ_2 receptors has been estimated in 40 areas of the brain of Cercopithecus aethiops. We found high levels of BZ_2 receptors (30-50% of total BZ receptors) in some cortical areas, e.g. the prefrontal cortex and the hippocampus, in the amygdala and in the anterior portion of the neostriatum. The majority of cortical areas contain intermediate levels of BZ_2 receptors. Interestingly, low levels of BZ_2 receptors (less than 10% of the total BZ receptor population) was found in the posterior part of the neostriatum and in the globus pallidus. It is striking that high relative concentrations of the BZ_2 receptor subclass occur in the limbic system.

200.2 PROPERTIES OF THE BENZODIAZEPINE (BZ) RECEPTOR FROM DIFFERENT BRAIN REGIONS. Mathew M.S. Lo and Solomon H. Snyder, Johns Hopkins University, School of Medicine, Dept. of Neuroscience, Pharmacology and Psychiatry, Baltimore, Maryland 21205.

The pharmacological and biochemical properties of the BZ and GABA receptors were studied in different regions of calf brain. Soluble receptors were quantitated with a new and novel assay method which utilizes concanavalin-A to immobilize receptor glycoproteins. Soluble BZ receptors from different brain regions (as measured by [^{3}H] flunitrazapam (FNZ) or [^{3}H] propyl-β-carboline-3-carboxylate (PCC) binding) appeared to have similar pharmacologic properties. On the other hand, a large population of BZ receptors (e.g. cerebellum, ~ 90%; hippocampus, ~ 80%; cortex, ~ 60%; striatum, ~ 80%) remained in the detergent insoluble fraction: these were not solubilized even after repeated extraction with high concentration of detergent.

The stoichiometry of high affinity GABA:BZ sites is 2 in the soluble detergent extract and 1-4 in the insoluble fragments depending on the brain region studied. In contrast, the number of [^{3}H]FNZ sites always equals that for [^{3}H]PCC in either the soluble or insoluble fractions. Enhancement of [^{3}H]FNZ binding by GABAergic agonists was observed in the soluble and insoluble BZ receptors. Dependency on Cl^- ions was also found in both cases.

Insoluble receptor in certain brain regions exhibited pharmacological properties distinct from soluble receptors from the whole brain. For example, displacement of [^{3}H]FNZ by CL 218872 in the soluble BZ receptors from different regions appears to be a single class of sites with a low affinity (IC_{50} = 20 μM) - this ligand has been shown to bind preferentially to BZ type 1 receptors. However, high and low affinity binding of CL 218872 was observed in the insoluble membrane fragment of cortex, striatum, hypothalamus, superior and inferior colliculus. These results suggest the existence of a heterogeneous population of BZ receptors with one form preferentially isolated after solubilization with detergents.

200.3 THE LIGHT MICROSCOPIC IN VITRO AUTORADIOGRAPHIC LOCALIZATION OF ADENOSINE (A1) RECEPTORS. R.R. Goodman and S.H. Snyder. Johns Hopkins University, Sch. of Med., Dept. of Neuroscience, Pharmacology and Psychiatry, Baltimore, MD 21205.

Adenosine displays a number of receptor-mediated physiological actions, including dilation of coronary vessels, inhibition of platelet aggregation and inhibition of lipolysis. Adenosine also behaves as a neuromodulator or neurotransmitter, inhibiting neuronal firing and synaptic transmission and altering cyclic AMP concentrations in brain tissue. Adenosine regulates adenylate cyclase activity via two apparently distinct receptors, the A_1 receptor activation lowers adenylate cyclase activity, while A_2 receptors mediate augmentation of adenylate cyclase. The two receptors have different substrate specificities, and recently it has become possible to label A_1 receptors in brain membranes with ^{3}H-N^6-cyclohexyladenosine (^{3}H-CHA) (Bruns, R.F., Daly, J.W. and Snyder, S.H., Proc. Natl. Acad. Sci. USA, 77:5547-5551, 1980). We have utilized this ligand with the recently developed technique for the light microscopic in vitro autoradiography of neurotransmitter receptors (Young, W.S.,III and Kuhar, M.J., Brain Res., 179: 255-270, 1979), to study the localization of adenosine receptors in rat brain. Adenosine receptors are widely distributed throughout the grey matter areas of the central nervous system, but in the brain levels studied thus far occur in high concentrations only in certain brain areas. The highest density of adenosine receptors is found in the molecular layer of the cerebellum, with relatively low levels in the granule and pyramidal cell layers. Areas with very high concentrations of receptors include the marginal nucleus of the medial geniculate body, the superficial layer of the superior colliculus, the molecular layer of the hippocampus, the piriform cortex and layers I and IV of the cerebral cortex. Moderately high concentrations of adenosine receptors are found in the dentate gyrus of the hippocampus, several thalamic nuclei and in layers V and VI of the dorsal cerebral cortex. A moderate concentration of adenosine receptors was found diffusely throughout the corpus striatum. Low levels were found in layers II and III of the cerebral cortex, the amygdala and the hypothalamus. Lowest levels were found in white matter areas, particularly in the corpus callosum. The localization of high concentrations of adenosine receptors in specific synaptic-rich brain regions, as well as the finding of quite low concentrations of receptors in white matter areas, supports the role of adenosine as a central nervous system neuromodulator or neurotransmitter.

200.4 DOPAMINE RECEPTORS IN RAT AND DOG STOMACH: IDENTIFICATION WITH [^{3}H]-SPIROPERIDOL IN VITRO. A. M. Marchisio*, Y. Taché and R. Collu. Neuroendocrine Research Laboratory, Pediatric Research Center, Hôpital Ste-Justine and Université de Montréal, Montréal, Québec, H3T 1C5.

The role of dopamine (DA) as a neurotransmitter in the central nervous system has been known for several years. More recently, it has become increasingly evident that DA acts as a neurotransmitter also in the peripheral nervous system. Significant amounts of DA have been found throughout the mammalian body and in particular in the stomach mucosa. The neurotransmitter has recently been found to be able of reducing both basal and stimulated gastric acid secretion in man (Caldara et al., Gut 19: 724, 1978). In rats, cysteamine-induced duodenal ulcers and gastric-acid output were antagonized by dopaminergic agents and enhanced by DA receptor antagonists (Szabo, The Lancet 2: 880, 1979). More recently, the elevation of gastric pH induced in rats by the intracisternal injection of bombesin was found to be reversed by DA receptor antagonists (Taché and Collu, Gastroenterology 80: 1298, 1981). These data suggest the existence in the mammalian stomach of receptors for DA, which might play a physiological role in the regulation of gastric secretion. In order to verify this hypothesis we have performed several experiments with both adult male Sprague-Dawley rats and adult male mongrel dogs. Binding studies were done with [^{3}H]-Spiroperidol ([^{3}H]-SPIR) as ligand and as previously reported. Specific binding was defined as the counts in the absence of 10^{-6} M d-butaclamol minus those in its presence. Preliminary studies were performed to determine the ideal incubation time and pH. No change in binding was observed between 15-60 min while a decrease occurred afterward, and the highest specific bindings were obtained at pH < 4.5. Scatchard analysis of binding data revealed the presence of a single class of high affinity [^{3}H]-SPIR binding sites in the mucosa of the antrum of rat (K_D = 2.97 nM; B_{max} = 41.15 fmol/mg protein) and dog (K_D = 2.35 nM; B_{max} = 41.33 fmol/mg protein). No specific binding was identified in the mucosa of the corpus. Displacement studies with various agonists and antagonists confirmed the dopaminergic nature of the binding sites. These results indicate that dopaminergic receptors are present in the mucosa of the antrum of both rat and dog stomach which might be involved in the regulation of gastric secretion.

200.5 DEVELOPMENTAL CHANGES IN THE REGIONAL DISTRIBUTION OF HERPESVIRUS RECEPTORS IN THE MOUSE BRAIN. D. J. McFarland*, J. Hotchin and F. Baker*. NY State Dept. of Health, Albany, NY 12201.

Viral infection is initiated with the binding of a virion to specific receptors on the host cell membranes. The purpose of this work was to determine the regional distribution of receptors for herpes simplex as this may be one determinant of the localization of infection within the CNS. The MacIntyre strain of herpes simplex Type I was grown in human embryonic tissue culture cells with ^{3}H deoxythymidine-5-triphosphate(methyl-^{3}H) added to the medium. Duplicate experiments with mock-infected cells, treated identically throughout with the exception of addition of virus, were also performed to provide material for blank counts. Infected and control cell homogenates were then subjected to differential centrifugation. Tissue homogenates were incubated with labelled virus or with the control extract for 30 min at 37°C, centrifuged, washed twice, and the radioactivity in the pellets was determined. The specific of the binding of these suspensions was confirmed by the observation that binding could be blocked by neutralization with antiherpes antibody.

Crude brain homogenates were prepared from mouse cerebral hemispheres, hippocampus, cerebellum, brainstem, and liver. Nylar mice 4, 6, 10, and 66 weeks of age were employed.

Results expressed as H3 counts/min. in the pellets are shown in the table below. Each value represents the mean of 4 independent observations. An analysis of variance indicated that there was a significant interaction between the age of the animal and the tissue source ($p.< .02$). This effect is due to an asymmetrical distribution of binding in the mouse brain and liver. The distribution also varied with the age of the animal. These results demonstrate that herpesvirus receptors are not uniformly distributed within the CNS.

Region	Age			
	4 wks	6 wks	10 wks	66 wks
Cerebral Hemispheres	2092.8[1]	2218.0[1]	2270.3[1]	2441.5[1]
Hippocampus	2180.5[1]	1829.0[2]	2111.3[1]	2246.0[1]
Cerebellum	1133.5[2]	1223.8[3]	1212.5[2,3]	1027.3[3]
Brainstem	1891.0[1]	1841.3[2]	1529.3[2]	1639.0[2]
Liver	1056.3[2]	655.3[4]	1028.8[3]	1265.3[3]

Note: Means with same superscript do not differ significantly. All $p<.01$ except 6 wk CX vs BS ($p<.05$)

200.6 RECEPTOR AUTORADIOGRAPHY WITH TRITIUM-SENSITIVE SHEET FILM: ANALYSIS BY COMPUTERIZED DENSITOMETRY. J.M. Palacios, J.R. Unnerstall, D.L. Niehoff, L. Buhle* and M.J. Kuhar. Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Receptor sites for neurotransmitters and drugs have been localized at the light microscopic level after in vitro labeling of slide-mounted tissue sections. Autoradiograms have been generated by apposing emulsion-coated coverslips (Young and Kuhar, Brain Res., 179:225, 1979). In this communication we describe the use of ^{3}H-sensitive sheet film (^{3}H-Ultrafilm, LKB) for the generation of autoradiograms, its advantages and disadvantages.

We initially characterized the behavior of the film under conditions normally used for the identification of receptors. Standards were prepared by mixing known amounts of non-volatile radioactivity with brain tissue ground to a paste. This tissue was handled in the same way as samples used for the localization of receptors. The film was exposed to these standards for varying lengths of time, and the autoradiograms thus generated were evaluated by microdensitometry. In some instances, optical density was also determined by computer-assisted densitometry (Goochee et al., Ann. Neurol., 7:359, 1980). Optical density increased proportionally with exposure, and the limits in which accurate determinations of receptor concentrations could be made were defined.

As a model, this method was applied to the study of multiple receptor systems. For example, multiple benzodiazepine (BZ) receptors were studied by generating displacement curves using propyl-beta-carboline carboxylate (beta-CC) and triazolopyridazines (TPZ), agents which have a high affinity for the cerebellar, or Type-1 BZ receptor. It was shown that both beta-CC and TPZ displaced in a monophasic manner ^{3}H-flunitrazepam in the molecular layer of the cerebellum, while a biphasic displacement was observed in other areas such as the dorsal CA1 region of the hippocampus. The proportion of the different receptor sites can be accurately determined by these methods. The densities of receptors and the relative proportions of the different subtypes agree well with results obtained in tissue homogenates. Similar analyses have been done for multiple serotonin, muscarinic cholinergic, beta-adrenergic and dopaminergic receptors.

201.1 REQUIREMENT OF HYPOTHALAMIC SODIUM CURRENTS FOR THE LORDOSIS REFLEX. R.E. Harlan*, B.D. Shivers and D.W. Pfaff. The Rockefeller University, New York, N.Y. 10021.

Lordosis is an estrogen-dependent reflex necessary for reproduction in rats and many other species. Estrogen acts primarily on neurons in the hypothalamus, and in the ventromedial nucleus (VMN) in particular, to induce and maintain lordotic responsiveness. The mechanisms by which estrogen acts in the hypothalamus are inadequately defined. The present studies were designed to examine the role of sodium currents in the hypothalamus in the expression of lordosis in estrogen-treated rats. Drugs which interfere with sodium ion flux were infused (1 µl on each side) into the hypothalamus in awake animals, and the rats were tested periodically for lordosis and other postural responses. Infusion of vehicle (N=9) or the local anesthetics 0.5% bupivacaine (N=5) or 50% procaine (N=7) had no effect on lordosis or reflexes for righting, climbing or leg withdrawal. Even repeated infusions of 50% procaine (every 30 min for three infusions, N=3) had no effect.

Infusion of the neurotoxin tetrodotoxin (TTX) induced large deficits in lordotic, righting and climbing reflexes, though no decrement in leg withdrawal. Bilateral infusion of either 5 (N=7) or 10 (N=10) ng TTX decreased lordotic responsiveness significantly between 40 min and 8 h after infusion, with the nadir reached at 2 h (63% decrease for 5 ng) or 4 h (59% decrease for 10 ng). These doses also induced general sedation (though the rats were easily aroused by somatosensory stimuli) and loss of righting and climbing reflexes within 5-10 min following infusion. Recovery of these responses began 1-2 h after infusion, a time course clearly different from the effects on lordotic responsiveness. Infusion of 0.5 ng TTX (N=6) induced much smaller decrements in lordotic and other reflexes, while infusion of 25 ng TTX (N=2) resulted in death within 1 h. Control infusion of 10 ng TTX into the thalamus (N=6) resulted in a temporary loss in righting reflex, but no decrement in lordotic responsiveness.

These data suggest that local anesthetics either do not affect lordosis-relevant VMN neurons, or that the duration of disruption of sodium currents is too short to affect lordosis. The reversible decline in lordotic responsiveness following TTX infusion is probably due to sustained interruption of action potentials of lordosis-relevant neurons. Furthermore, these data are consistent with electrophysiological results (Bueno and Pfaff, 1976) indicating that estrogen increases the electrical activity of VMN neurons, and that these neurons must participate in lordosis control on a tonic rather than a reflex mount-by-mount basis.

201.2 SEXUAL BEHAVIOR AND SCENT MARKING IN MALE GERBILS: INDEPENDENT CONTROL BY THE MEDIAL PREOPTIC AREA - ANTERIOR HYPOTHALAMUS. D. L. Commins* and P. Yahr (SPON: A. Starr). Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

The anterior hypothalamus (AH) and medial preoptic area (MPOA) are implicated in the hormonal control of sexual behavior and ventral scent marking in male Mongolian gerbils (Meriones unguiculatus). However within the AH-MPOA, the loci involved in these two behaviors may not be the same. Testosterone (T) implants in the most anterior or most posterior portions of the MPOA of castrated males will reinstate scent marking. Similar implants in the middle portion of the MPOA do not.

In a related study, an attempt was made to selectively disrupt one or the other behavior by making radiofrequency lesions in a variety of sites within the AH-MPOA. Sexual behavior was most reliably disrupted by lesions in the middle part of the MPOA. Subcutaneous implantation of T at lesion or 6 wk later did not alleviate the decline. Some males that ceased mounting had been reliable markers preoperatively. Marking did not decline substantially after lesion surgery when these subjects were given supplemental T.

Three males showed impaired marking despite T treatment. Their sexual behavior also declined, although their lesions tended to be more anterior or posterior than the majority of the lesions that affected only sexual behavior.

A subsequent study attempted to verify that the anterior part of the MPOA (near the diagonal band of Broca) and the AH are particularly important in the control of marking. Gonadally intact males that marked reliably received lesions in one or the other location. In general, marking was not impaired. The same subjects were then relesioned to increase the size of the lesion. This resulted in a persistent decrease in marking in both anterior and posterior lesioned animals. These lesions typically included most of the MPOA, and in some cases may have disrupted gonadotropin release.

In a third study lesions were made simultaneously at these same anterior and posterior locations. Lesioned animals marked significantly less than sham-operated controls. After three weeks of testing, all subjects were castrated and implanted with 10-mm T capsules. Marking recovered at least partially in response to T therapy in some subjects, but not in others. Those that did not recover usually had extensive damage extending from the diagonal band of Broca to the AH.

The effects of lesions and of T implants suggest that the far anterior and far posterior MPOA are important in the neural control of scent marking. The areas involved are relatively widespread and overlap only partially the region of the MPOA that influences sexual behavior.

201.3 FEMALE SEX BEHAVIORS IN THE SOUTH AFRICAN CLAWED FROG, XENOPUS LAEVIS: GONADOTROPIN-RELEASING, GONADOTROPIC AND STEROID HORMONES. D. B. Kelley. Dept. of Psych., Princeton Univ., Princeton, NJ 08544

The goal of this study was to characterize certain female sex behaviors in the South African clawed frog, Xenopus laevis, and to explore the behavioral effects of endocrine manipulation. The responses of females to clasp assaults by sexually active males were observed. Two patterns of female responses predominated: in one, females exhibited extreme leg extensions and ticking vocalizations when clasped (unreceptive behaviors). In the other, the female responded to a clasp by adducting her thighs and increasing flexion at the knee; she did not vocalize (receptive behaviors). Clasp durations of pairs in which the female was unreceptive were short, generally less than 1 minute. With a receptive female, on the other hand, amplexus could last up to two days.

In intact females, injection of human chorionic gonadotropin (HCG) or of luteinizing hormone releasing hormone (LHRH) resulted in significant increases in receptivity. These hormones did not promote receptivity in ovariectomized females. Treatment with a combination of estradiol (E) and progesterone (P) restored receptivity to females. Either hormone when administered alone was ineffective in decreasing leg extension scores. The releasing hormone, LHRH, when given to ovariectomized, E + P treated females, further decreased their leg extension scores and led to the prolonged amplexus otherwise found only with HCG-injected intact females. The effects of LHRH on E + P treated, ovariectomized females may be independent of action on the pituitary since they are not mimicked by gonadotropin.

Hormones administered exogenously in this study are also present endogenously and have been shown to fluctuate with reproductive condition. Such hormonal fluctuations may serve to synchronize behavioral receptivity with ovulation and oviposition. One potential mechanism for the behavioral effects of such hormones is interaction with endocrine target cells in the central nervous system. Previous studies have outlined a system of estradiol-concentrating cells in X. laevis brain (Morrell, Kelley & Pfaff, 1975, J. Comp. Neurol.). The existence of neurons in X. laevis which are sensitive to progesterone and to LHRH remains to be investigated.

201.4 OVARIAN HORMONES AND EATING BEHAVIOR IN RHESUS MONKEYS. Joseph W. Kemnitz, Wis. Reg. Primate Research Ctr., Univ. of Wis., Madison, WI 53706

Food intake of 13 adult female Macaca mulatta was measured during a total of 51 menstrual cycles (1-7 cycles/animal). Four phases of the cycle were defined on the basis of coloration of sex skin and menses: early follicular (EF), 5 days beginning with the first day of menstruation; preovulatory (PO), 2-4 days prior to color breakdown; midluteal (ML), 5 days halfway between the day of presumed ovulation and the first day of subsequent menstruation; and late luteal (LL), the last 4 days before menstruation. Intake was lowest during the PO phase in 58% of the cycles, whereas lowest intake occurred during the EF, ML, or LL phases in only 28%, 2% and 12% of the cycles, respectively. Mean intakes (gm/day, ± SEM) were 137 ± 8 for the PO phase, 167 ± 11 for the EF phase, 184 ± 7 for the ML phase, and 186 ± 7 for the LL phase. Five of these animals were weighed daily during a total of 26 cycles. Body weight decreased during the follicular phase reaching a nadir one day before color breakdown (i.e., one day after presumed ovulation), and then increased during the luteal phase.

Although intake was, on average, lowest during the PO phase for 10 of the 13 animals, prominent individual differences in intake were observed. For example, average intakes during the ML phase for individual animals ranged from 134 gm/day to 312 gm/day. These values were not discernably related to age (which ranged from 5 to 17 years), body weight (which ranged from 4 to 10 kg), or parity (which ranged from 0 to 5 offspring). Likewise, magnitude of suppression of intake (PO intake/ML intake) during the PO phase was not attributable to these variables or to overall level of intake during the menstrual cycle. However, animals with longer inter-menstrual intervals tended to have higher average daily food intake.

Ovariectomized monkeys treated with estradiol and progesterone have been studied in order to investigate more directly the mechanisms of hormone-induced changes in food intake as well as the basis for individual differences in responsiveness to hormonal changes. Silastic capsules were used to vary serum concentrations of estradiol and progesterone. When estradiol was maintained at levels characteristic of the midfollicular phase or progesterone at levels characteristic of the early luteal phase, few statistically reliable effects of these treatments on food intake, body weight, fasting plasma glucose, glucose tolerance or glycosylated hemoglobin were observed. However, treatment with higher doses of estradiol did suppress food intake and body weight.

201.5 STUDIES ON THE EFFECTS OF PREGNANCY AND OF ESTROGENS ON ETHANOL INTAKE IN THE RAT. D. Sandberg* and J. Stewart (SPON: A. Giachetti). Dept. of Psychology, Concordia University, Montreal, Canada, H3G 1M8

Changes in consumption of a 10% ethanol solution and of tap water by pregnant rats was investigated over the course of gestation. Ethanol intake during the first two trimesters of pregnancy matched that of non-mated control animals. During the third trimester, however, ethanol consumption by the pregnant animals decreased. Water intake by the pregnant animals was elevated above that of control animals for most of the gestational period, and these changes did not appear to be related to decreases in ethanol consumption. In a second study decreases in consumption of an isocaloric sucrose solution were observed to occur during the same period of pregnancy, whereas consumption of a saccharin solution remained stable. These findings suggest that common factors control ethanol and carbohydrate intake in the pregnant rat and have led us to do a series of experiments on the effects of estrogens on ethanol consumption in the rat.

The effects of acute (one day) and chronic (18 day) subcutaneous administration of 5 µg estradiol benzoate (EB) on ethanol consumption were studied in ovariectomized rats in a free-choice situation. EB injections decreased ethanol consumption. A single injection led to a significant but transient inhibition of intake. Chronic injections caused an even more pronounced suppression. With continued EB administration, however, ethanol consumption returned to levels indistinguishable from those of control animals. This apparent tolerance to the suppressive effects of EB parallels that observed when food intake is measured in response to chronic estradiol treatment.

The final study tested the effects on ethanol consumption of MER-25, an anti-estrogen, which mimics estradiols effect on food intake and body weight. MER-25 administered daily subcutaneously in a dose of 10 mg/animal produced effects that were similar to those produced by EB, thus supporting the idea that the mechanism that leads to estradiol's inhibitory action on food intake is the same that leads to decrements in ethanol consumption. Additional studies demonstrating that neither EB nor MER-25 interfere with ethanol metabolism, and that EB does not produce a conditioned taste aversion in combination with ethanol further supports this conclusion. (Supported by a grant from the Natural Sciences and Engineering Research Council of Canada, AO-156.)

201.6 RATS HAVE REDUCED PREFERENCE FOR ALCOHOL DURING PREGNANCY AND FOLLOWING LACTATION. L. W. Means and H. B. Goy*. Depts. of Psychol. and Physiol. East Carolina Univ.,Greenville, NC 27834.

Recently it has been reported that non-alcoholic women (Little, R.E. et al. J. Stud. Alcohol, 1976, 37, 375), macaques (Elton, R.H. & Wilson, M.E. J. Stud. Alcohol, 1977, 38, 2181) and mice (Randall, C.L. et al. Pharmacol. Biochem, & Behav., 1980, 13, 150) show reduced alcohol consumption during pregnancy. The present study was conducted to examine alcohol preference in rats during cohabitation, pregnancy, lactation, and post-lactation. Eighteen 75-95 day old female Long-Evans rats were individually housed, given continuous free access to lab chow, and 10 hr. (8:30 AM-6:30 PM) daily access to a .01 M saccharine solution and a .01 M saccharine solution containing 5% ethanol (v/v) throughout the study. The solutions were presented in 100-ml calibrated drinking tubes whose positions were randomly changed. Following 3 days adaptation to the drinking schedule and 11 days of baseline preference readings, a comparably aged male was placed with each female during the 14 hours that the drinking solutions were not available. Upon determination of pregnancy of a female by presence of sperm plugs, the male was removed from her cage and another male was removed from the cage of a non-pregnant female. Thus, all males were removed by the end of the third night, when 9 females had been determined to be pregnant. Liquid consumption was monitored throughout pregnancy, lactation, and for 10 days post-lactation for the pregnant animals and during this same time period for the control animals. All pups were removed at 20 days of age.

Alcohol preference ratios (alcohol solution/total fluid) for both groups during each phase of the experiment are shown in the table.

Mean Alcohol Preference Ratio (Alcohol/Total Fluid)
± Standard Errors

Group	Baseline	Cohabitation	Pregnancy	Lactation	Post-Lact.
Pregnant	.76± .04	.60± .09	.36± .08	.50± .06	.35± .08
Control	.84± .04	.70± .09	.73± .06**	.62± .10	.60± .09*

**p < .01 * p < .05

The pregnant animals had significantly lower preference ratios than the control animals during both pregnancy ($t=3.80$, $df=16$, $p < .01$) and the 10-day post-lactation period ($t=2.15$, $df=16$, $p < .05$).

The strong decrease in alcohol preference during both pregnancy and following lactation strongly suggests that alcohol preference is modulated by reproductive hormones.

202.1 REDUCTION BY ATROPINE OF PHENCYCLIDINE-INDUCED HYPERTENSION. G. K. W. Yim, A. Malave* and M. P. Holsapple*. Dept. of Pharmacology and Toxicology, School of Pharmacy and Pharmacal Sciences Purdue University, West Lafayette, IN 47907.

The pressor effect of phencyclidine (PCP) has been attributed mainly to direct and indirect actions on the peripheral adrenergic system. The purpose of this investigation was to determine whether the anticholinesterase action of PCP might result in activation of central cholinergic pressor systems, and thereby contribute to the PCP-induced hypertension. Sprague Dawley rats, lightly anesthetized with urethane (1.25 g/kg i.p.) exhibited a dose-related pressor response (16.5 ± 2/3. 21.3 ± 3.7, 31.0 ± 2.6 and 26.8 ± 3.5% increases over control systolic blood pressure) following 0.1, 0.3, 1.0 and 3.0 mg/kg i.v. doses of PCP. After atropine pretreatment (0.8 mg/kg i.v.), the PCP dose-response was shifted to the right, and the magnitude of the pressor responses was smaller by about 50%. In contrast, methylatropine pretreatment (1.0 mg/kg i.v.) did not reduce the PCP-induced pressor responses. The bradycardia, which accompanied the PCP pressor response, was not affected either the atropine or methylatropine pretreatment. Apneusis was observed in 85% of 19 control animals receiving 1.0 to 3.0 mg/kg i.v. doses of PCP. The incidence of PCP-induced apneusis was 0% in 18 atropine pretreated rats, and 100% in 16 methylatropine pretreated rats. These results suggest that the central cholinergic actions of PCP contribute significantly to the hypertension and respiratory toxicity induced by PCP. (Supported by USPHS Grant DA 01916, a University of Puerto Rico Scholarship, and a Purdue Research Foundation Fellowship).

202.2 PHYSICOCHEMICAL PROPERTIES OF PHENCYCLIDINE AND PHENCYCLIDINE DERIVATIVES. M.R. Rosenfeld*, B. Pazhenchevsky*, H. Weinstein* and S. Maayani. Department of Pharmacology, Mount Sinai School of Medicine of the City University of New York, N.Y., 10029.

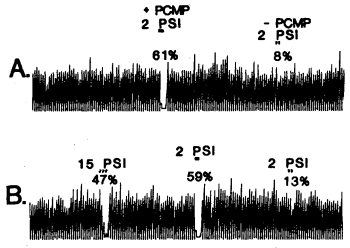
Some phencyclidine (PCP) derivatives were unexpectedly found to be devoid of PCP-like effects on behavior. Physicochemical measurements showed that their inactivity might have been due to low solubility, or decreased oil:water partitioning rather than to the pharmacodynamic properties of the drugs. In order to discriminate between these factors for PCP-like action we developed methods to determine the pK_a's and partition coefficients (P) of PCP analogs. Due to the relatively low aqueous solubility of both the protonated ($\leqslant 10^{-2}$M) and the non-protonated ($\leqslant 10^{-4}$M) species of PCP and its analogs, and because of the small U.V. extinction coefficient (ε= 420 at 263nm) neither a titrimetric method nor a spectrophotometric method could be used for the determination of these two parameters. Therefore, we devised a method that allows for the simultaneous determination of pK_a and P. It is based upon the distribution of radioactively labelled drug between an aqueous phase and an organic phase at varying pH. Four compounds were studied, ^{3}H-PCP, ^{3}H-m-amino PCP (NH_2PCP), ^{3}H-m-nitro PCP (NO_2PCP) and ^{3}H-PCP methiodide (CH_3IPCP). The choice of buffers--borate, HEPES or CAPS--was dependent upon the pH range to be tested. The organic phase was either iso-octane or 1-octanol. All compounds were routinely checked for purity by thin layer chromatography. An alternative method (method 2) was also used to estimate P. A summary of the results obtained at 25°C with iso-octane:borate or iso-octane: CAPS for NH_2PCP is given in the table below (mean ±S.D.).

	pK_a	P	P (method 2)
PCP	9.41 ± 0.04	6750 ± 200	6500 ± 120
NH_2PCP	9.57 ± 0.10	23 ± 6	33
NO_2PCP	8.23 ± 0.13	3337 ± 695	2362 ± 1309
CH_3IPCP	----	9.14 ± 0.62	1.50 ± 0.22

Both pK_a and P measurements for PCP were shown to be dependent upon temperature, i.e., increasing the temperature from 25°C to 37°C resulted in a 2.3% decrease in the pK_a. The method developed in these studies can be applied to other compounds which like PCP have an extremely low water solubility. This work was supported by NIDA grant DA02534.

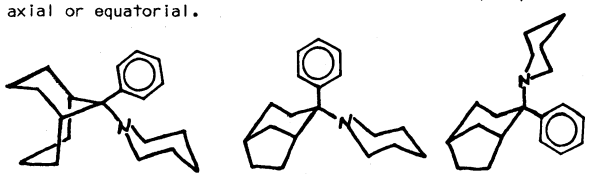
202.3 STEREOSPECIFICITY AND RECEPTOR SPECIFICITY OF PHENCYCLIDINE INTERACTIONS WITH RAT HIPPOCAMPAL PYRAMIDAL NEURONS. Paula C. Bickford, Michael R. Palmer, Kenner C. Rice*†, Barry J. Hoffer*, and Robert Freedman*. Dept. of Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262, and †NIAMDD, Bethesda, MD 20205.

The effects of phencyclidine (PCP) on rat hippocampal pyramidal neurons were studied using electrophysiological techniques. The predominant response of most pyramidal cells to local micropressure application of PCP was a decrease in firing rate. Biphasic responses and pure excitations were occasionally observed. The stereospecificity of PCP responses was studied with (+) and (-) isomers of 3-methyl PCP (PCMP). The (+) isomer was 4-15 fold more potent than the (-) isomer.



Catecholamine depletion by reserpine pretreatment markedly increased the dose of PCP needed to elicit effects on pyramidal cell discharge. The α-adrenergic antagonist phentolamine reversibly antagonized PCP-induced inhibitions, while having no apparent effect on excitations. In contrast, timolol, a β-adrenergic antagonist, did not alter the depressions, but reversibly antagonized the excitations. Although the interaction of PCP with other neurotransmitter systems, in particular cholinergic systems, can not be ignored, these results suggest a major role of noradrenergic transmission in the observed effects of PCP on pyramidal cell activity. (Supported by USPHS Grant # DA-02429).

202.4 THE PHARMACOLOGY OF SOME NOVEL RIGID PCP ANALOGS. B. Pazhenchevsky,* S. Maayani, S.D. Glick and H. Weinstein* (SPON: J.P.Green). Dept. of Pharmacol., Mount Sinai Sch. Med., C.U.N.Y., New York, New York, New York, 10029. The PCP derivative in which the cyclohexyl portion was replaced by adamantyl (ADM-PCP), was found to be a more potent muscarinic antagonist than PCP. Since substitution of the phenyl group in PCP by nitro and amino groups produces marked changes in muscarinic potency, it was interesting to see whether comparable changes could be observed for the adamantyl PCP derivatives. We found that the 2-adamantyl derivative of PCP competes with ^{3}H-atropine binding in a non-competitive manner (Hill slope = 0.4), but that a meta-NH_2 substitution on the phenyl ring of ADM-PCP restores the competitive nature of the interaction. One of the possible explanations for the increased antimuscarinic activity of ADM-PCP, as compared to PCP, is in the position of the aryl moiety relative to the cyclohexyl ring. To investigate this hypothesis we prepared three new analogs of PCP. The [3.3.1]bicyclononane derivative contains the same structural characteristics as ADM-PCP. The [3.2.1]bicyclooctane derivatives contain a conformationally immobile cyclohexyl group and should be rigid models of the two conformers of PCP in which the phenyl is either axial or equatorial.



[3.3.1] [3.2.1] [3.2.1]

These compounds were also shown to have a much higher affinity than PCP for the muscarinic receptor. ADM-PCP was inactive in a behavioral test that characterizes PCP-like action (Glick et al., Eur. J. Pharmacol. 59:103, 1979). Because we have found that the ADM-PCP is only sparingly soluble in water it could not be expected to be potent in vivo. The solubility of the meta-NH_2 derivative of ADM-PCP was only slightly higher and did not yield an active compound. The physico-chemical properties of the other derivatives are being studied in conjunction with their central activities in order to discriminate between negative results related to uptake and distribution from measured inactivity resulting from the pharmaco-dynamic properties of the drugs. Supported by NIDA grant DA-02534.

202.5 BIOCHEMICAL AND BEHAVIORAL EVIDENCE FOR CHOLINERGIC AND ANTI-CHOLINERGIC PROPERTIES OF PHENCYCLIDINE IN THE RODENT. K. M. Johnson and S. C. Wilkenfeld*. Dept. of Pharmacol., Univ. Texas Med. Br., Galveston, TX 77550.

Anticholinergic properties of phencyclidine (PCP) have been identified in several isolated tissue preparations including rat brain membranes. Whether this in vitro effect is important in producing abnormal behavior in animals is uncertain. For example, the reports that muscarinic agonists inhibit and antagonists potentiate PCP-induced stereotypic behavior must be considered in the light that the same is true for apomorphine and amphetamine-induced stereotypy. Furthermore, mice made tolerant to PCP were found to be partially tolerant to some of the effects of physostigmine and oxotremorine (OXO), a muscarinic agonist.

In a preliminary evaluation of the effects of OXO on PCP-induced ataxia in the rat, we found that the combination of 1 mg/kg OXO & 10 mg/kg PCP produced profound exopthalmia, lacrimation, and salivation. Four of the six rats died within 45 min, apparently of asphyxiation. This effect was further characterized in experiments using ICR mice. OXO (1 mg/kg) in combination with 3, 10, and 30 mg/kg PCP caused death in 1/5, 5/5, and 10/10 mice, respectively. The lethality of this combination was completely blocked by 1 mg/kg methyl atropine (MA), an antagonist which does not easily enter the brain. This data suggests that in some peripheral tissues PCP is acting like a muscarinic agonist rather than an antagonist.

In order to test for a central muscarinic activity, we measured the effects of PCP and PCP in combination with low doses of OXO-MA (to block the peripheral effects of OXO) on forced, coordinated motor activity using an inverted screen test. PCP in doses of 3 mg/kg and above significantly impaired performance in this test and appears to be a good index of PCP-induced ataxia. Pretreatment with 0.3 mg/kg OXO-1.0 mg/kg MA significantly shifted the PCP dose-response curve to the left, suggesting a muscarinic agonist action of PCP in the CNS.

In direct distinction to these studies, we have confirmed that PCP has antagonistic properties in the rat striatum. In this experiment, we evaluated the effect of PCP on the ability of OXO (in combination with MA) to elevate striatal DOPAC levels. OXO-MA elevated striatal DOPAC levels 71% above saline controls. Pretreatment with 6 mg/kg PCP reduced this effect to a non-significant 13%. (PCP alone had no effect on striatal DOPAC compared to controls). By comparison, pretreatment with 6 mg/kg atropine sulfate reduced the OXO-MA elevation of DOPAC to 11% (N.S.). Thus, in the striatum, PCP does appear to have antimuscarinic effects. (Supported by DA-02073.)

203.1 GLUTAMATE AND POTASSIUM IONS CAUSE SWELLING OF MÜLLER FIBERS IN THE CHICK RETINA. A. Van Harreveld. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Spreading depression (SD) in the isolated chick retina is characterized by an increase in transparency of the tissue. An increase in transparency was also recorded after applying glutamate or potassium ions in the bathing solution. These compounds may be involved in glutamate- and K^+-based SDs (Van Harreveld, J. Neurobiol., 9:419, 1978). It was postulated that the increase in transparency is due to swelling of the Müller fibers, which have a radial position in the retina and which, acting as light guides, might in the swollen state enhance the amount of light transmitted through the retina.

Chick retinas were prepared by cutting the eye in the equatorial plane and removing the vitreous body. The eye was stored at 32°C in a physiological solution containing 10 mM $MgCl_2$ which suppresses spontaneous SDs. A block of the retina was then isolated and subjected to freeze substitution which preserves the water distribution in the tissue more faithfully than chemical fixation. Retinas treated for 2 min with 30 mM KCl or 1 mM L-glutamate were compared with controls frozen without such treatments. Similarly treated material was chemically fixed. The retinas were examined with the light- and electron microscope. The Müller fibers (measured halfway between the vitreal surface and the ganglion cell layer) in freeze-substituted preparations of glutamate- and K^+-treated retinas were much thicker than in the controls. The mean diameter of the Müller fibers of 4 preparations was 1.54 µM in K^+-treated retinas, 0.98 µM in glutamate-treated ones against 0.44 µM in the controls. This swelling may account for the increased transparency of the retinas observed both in glutamate- and K^+-based SDs.

The chemically fixed preparations of the same material showed only a slight difference in diameter of the K^+- and glutamate-treated preparations as compared with the controls. It seems that the swelling of Müller fibers which existed at the end of the 2 min treatment with K^+ and glutamate was reversed during chemical fixation.

This investigation was supported in part by NSF grant BNS 784142.

203.2 NEGATIVE FEED-BACK FROM HORIZONTAL CELLS TO CONES IN THE CARP RETINA. M. Murakami* (SPON: E. Cosmos). Dept. Physiol., Keio Univ. Sch. Med., Tokyo 160, Japan.

In the isolated, perfused retina of the carp, Cyprinus carpio, properties of a feed-back pathway from horizontal cells to cones were investigated by means of electrophysiological and neuropharmacological methods. When horizontal cells were hyperpolarized by peripheral annulus illumination, a depolarizing synaptic potential was produced in cones at the center, suggesting that horizontal cells receive inputs from cones and exert a negative feed-back to cones. On the other hand, when a transient depolarization (EPSP) was induced in horizontal cells by application of a transretinal current pulse flowing from the receptor side to the vitreal side, an IPSP was evoked in cones. The IPSP was abolished when the retina was perfused with a GABA-containing Ringer solution, probably because of desensitization of the feed-back synapse. GABA also hyperpolarized the cone cell membrane, indicating the presence of GABA-sensitive site in the cone. These results suggest that the GABA-mediated negative feed-back operates from horizontal cells to cones in the dark, and ceases to function in the light.

Effects of GABA and its antagonists, picrotoxin and bicuculline, were investigated on spectral responses of horizontal cells. When the GABA-mediated feed-back was desensitized or blocked by these chemicals, remarkable changes were observed in spectral responses, due to selective suppression of responses to long wave-lengths. In particular, the depolarizing responses in the biphasic C-type (H2) cell were abolished, while the hyperpolarizing responses to short wave-lengths were retained, resulting in a monophasic spectral response curve. From these results, it was concluded that the GABA-mediated negative feed-back plays an essential role in neural mechanisms which convert the trichromatic process at the level of cones into the opponent color process in horizontal cells.

203.3 INTRACELLULAR RECORDING AND HORSERADISH PEROXIDASE MORPHOLOGY OF TREE SQUIRREL HORIZONTAL CELLS. J. Sherwood Charlton*, Harold F. Leeper* and Kenneth T. Brown. Univ. of California, San Francisco, CA 94143.

A new preparation has been developed for the study of mammalian retinal neurons using intracellular recording and horseradish peroxidase (HRP) injection. Several cell types have been recorded in the arterially-perfused eyecup preparation of the eastern grey (tree) squirrel, Sciurus carolinensis. This is a report of a study of horizontal cells (HC's). HC's respond to flashes of light with graded hyperpolarizations over at least a 4 log unit stimulus intensity range. Maximum responses of up to 35 mV amplitude were measured. In response to light stimuli of longer duration, hyperpolarizations decline to a plateau level. At the cessation of the stimulus, responses of most cells exhibit a rapid return to baseline (dark level). Others return slowly to baseline, possibly indicating rod input.

One morphological class of horizontal cell has been identified after staining with HRP. These cells exhibit the following characteristics: (1) The V-log I curves are single-limbed and the response returns rapidly to baseline at the cessation of illumination, suggesting that these cells are cone driven. (2) The dendritic fields of these cells are about 50 µm in diameter. (3) A single axon courses across the retina for more than 300 µm from the cell soma. (4) These cells have small receptive fields. Using a bar of light passed through the receptive field, length constants of 31 to 158 µm were measured. The mean was 95 µm, corresponding to a receptive field radius of about 400 µm, much smaller than found for HC's in mammalian and nonmammalian species.

The morphological features of these cells correspond to those of type 1 HC's identified in Golgi preparation by R. West (Vision Res., 18:129, 1978). West determined that this cell type contacts only cones. We measure a maximum spectral sensitivity in the green, with a λmax of 500 to 520 nm in these cone driven cells. This λmax is shifted from the 543 nm λmax of the only known cone pigment in this retina (Loew, E.R., J. Physiol., 251:48P, 1975). Our data suggest that the interactions responsible for an apparent blue sensitivity observed in our ganglion cell recordings and found in behavioral studies by P. Silver (Vision Res., 16:1235, 1976) may have begun by the horizontal cell level.

203.4 Development of Morphological and Biochemical Properties of the Dopaminergic System in Rabbit Retina. D.A. Redburn, C.K. Mitchell* and C.K. Hampton*. Dept. Neurobiol. & Anat. U. Tex. Med. Sch., Houston, TX 77025

Studies from our laboratory and others have demonstrated that in rabbit retina, the dopamine system is limited to a subset of amacrine cells with terminals located in a trilaminar arrangement in the inner plexiform layer. We have also shown that many of the retinal dopamine receptors are coupled to adenylate cyclase, thus suggesting that one consequence of dopamine transmission is an increase in intracellular cAMP formation. We have now analyzed the development of both pre- and post-synaptic markers of this dopamine system in rabbit retinas from one day to 30 days postnatal. Receptor activity was determined first in an in vitro binding assay using ^3H spiperone as a ligand and ADTN as a displacer. Secondly, dopamine stimulation of cAMP formation was assayed. Localization of endogenous dopamine was demonstrated by histofluorescence using the glyoxylic acid method. Specific increases in fluorescence after incubation in micromolar concentrations of dopamine were used as an indication of the high affinity uptake system for dopamine. Our results showed that at birth, endogenous and exogenously accumulated levels of dopamine were not detectable by histofluorescence, no appreciable amount of specific ^3H spiperone binding was observed, and dopamine had no effect on cAMP production. However, all pre- and post-synaptic dopamine markers showed dramatic increases in activity between post-natal days 5 and 9. Adult patterns of endogenous and exogenously-accumulated dopamine fluorescence were observed by day 12. In contrast, we observed a significant overshoot in receptor binding and dopamine-stimulated adenylate cyclase activity at days 7-9, followed by a decrease to adult levels by day 11. The apparent down regulation of dopamine receptors coincides with, and may be functionally related to, two other developmental processes which occur at day 11. First is the appearance of maximal, adult levels of GABA receptor activity. The second is the appearance of receptive field responses in ganglion cells which are directly and indirectly postsynaptic to both GABAergic and dopaminergic amacrine cells.

203.5 ULTRASTRUCTURAL LOCALIZATION OF SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN GOLDFISH RETINAL AMACRINE CELLS. D. Marshak*, D. Lightfoot*, T. Yamada*, and W. Stell (Spon. B. Bastian) Jules Stein Eye Inst., UCLA School of Medicine, Los Angeles, CA 90024.

The retina is a well-characterized neural network in which we have identified amacrine cells containing somatostatin-like immunoreactivity (SLI) (Yamada et al. (1980) Proc. Nat. Acad. Sci., 77: 1691-95). We have studied their ultrastructure and synaptic connections by electron microscopic analysis of serial sections.

Retinas of dark-adapted goldfish were fixed by immersion for 2 hrs at 4°C in .08M phosphate buffer pH7.8 with 4% paraformaldehyde and .05% glutaraldehyde. Tissue-chopped sections (100 um) were stained by the peroxidase-antiperoxidase method using a rabbit antiserum directed against the midportion of somatostatin 14; therefore, the serum recognized both large and small forms of SLI. After labeling, osmication, and embedding, serial sections were cut both parallel and perpendicular to the distal sublamina of the inner plexiform layer, in which the labeled processes ramified. Some sections were stained with lead citrate and uranyl acetate.

Labeled, varicose dendrites with ultrastructure characteristic of amacrine cells were found within a few micrometers of the edge of the thick section. Electron-dense labeling was concentrated on the outer aspects of clear synaptic vesicle membranes, on the outer membranes of mitochondria, and on synaptic densities. Large, dense-cored vesicles, which were not associated with synaptic specializations, were seen in a few labeled processes; smaller, electron-lucent vesicles were more abundant in labeled processes and concentrated opposite synaptic densities. Bipolar cells, identified by their synaptic ribbons, received synapses from SLI-containing cells at points distal to the ribbons. Labeled cells were also presynaptic to processes which, unlike those of amacrine cells, were relatively electron-lucent, had few organelles, and were not presynaptic. These appeared to be dendrites of retinal ganglion cells, but their identities could not be confirmed. Labeled cells were both presynaptic and postsynaptic to processes from other, unlabeled amacrine cells, which were identified by their presynaptic specializations. Control sections incubated with antiserum preadsorbed with synthetic somatostatin were not labeled.

These results suggest that neurons containing somatostatin-like immunoreactivity act through at least three different pathways in the inner plexiform layer of the retina.

203.6 DISPLACED AMACRINE CELLS OF THE RETINA. E. V. Famiglietti, Jr. Dept. Anatomy, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

It is universally accepted that there exist in the retina neurons generally similar in morphology to retinal ganglion cells, but lacking axons. Many have found it less easy, however, to accept the evidence that these "amacrine cells" may have their cell bodies "displaced" from the inner nuclear layer (INL) into the inner plexiform layer (IPL) or the ganglion cell layer (GCL). Most of the evidence to date on the existence of displaced amacrine cells is of a negative kind: lack of axonal staining in Golgi preparations, and failure of axonal transport to small cell bodies of tracers from the optic nerve. Recently, much stronger evidence has developed for the existence of one class of displaced amacrine cells which synthesize acetylcholine (Masland & Mills, '79; Hayden et al., '80). We have provided evidence from Golgi preparations that these are type b "starburst" amacrines, which always have cell bodies displaced to the GCL and branching in sublamina b of the IPL (Famiglietti & Siegfried, '80; Famiglietti, '81). Moreover, in an extensive survey of rabbit and cat retinas, we find a number of different morphological classes of displaced amacrine cells, both of type a and of type b: 3 classes in rabbit retina and 8 classes in cat retina. In addition, cell bodies of other amacrines are occasionally displaced from their conventional position in the INL.

Rabbit and cat retinas were prepared as whole mounts and processed according to a modified Golgi-Kopsch-Colonnier technique. Golgi-impregnated amacrine cells were studied in flat view. Their morphology and dendritic stratification was analyzed, in some cases with the aid of an image processing computer.

Rabbit retina contains at least two kinds of displaced amacrine cells, in addition to the type b starburst amacrines. One general class of amacrines, made up largely of displaced cells, is the "pseudopolyaxonal" amacrine (Famiglietti & Siegfried, '80). One subvariety has its cell body in the GCL and all of its branches in stratum (S) 5 of the IPL, while the other has its cell body most often in the middle of the IPL with its processes in S3. A third general class of displaced amacrine cell is morphologically less distinctive: wide-field and sparsely branched in S3.

In cat retina, medium-wide field, sparsely branched amacrine cells with cell bodies in the ganglion cell layer are of at least 2 varieties, and their dendrites are narrowly stratified in S1, in S3, or in S5. Type b starburst amacrines have also been found in cat, but thus far no "pseudopolyaxonal" amacrines. 5 other classes of displaced amacrines are medium- or narrow-field, have a variety of unusual morphologies, and branch either narrowly or broadly at various levels, collectively involving all 5 strata of the IPL. Because few examples of these 5 have been found, the occasional presence of their cell bodies in the INL cannot be excluded.

203.7 THE SYNAPTIC BASIS OF SURROUND ANTAGONISM IN OFF-CENTER GANGLION CELLS OF THE MUDPUPPY RETINA. Jack H. Belgum*, John S. McReynolds and David R. Dvorak* (SPON: L.T. Rutledge). Dept. of Physiol., University of Michigan, Ann Arbor, MI 48109.

Intracellular recordings were used to measure current-voltage relations for off-center ganglion cells under the following conditions: maintained darkness, central illumination, and surround illumination combined with existing center illumination. We have previously reported that center illumination causes a hyperpolarization associated with a large tonic conductance increase, and that this response has a reversal potential more negative than the dark membrane potential. While this response is predominantly due to activation of a tonic inhibitory input, a reduction in excitatory input from hyperpolarizing bipolars is also probably involved.

When surround illumination is added to existing center illumination, membrane potential is depolarized toward the normal dark potential, clearly antagonizing the center response. Current-voltage relations under these conditions show that there is also a decrease in conductance, and that the reversal potential for this depolarizing response is essentially the same as for the hyperpolarizing center response. This suggests that the surround stimulus acts through the same synaptic mechanism as the center response, shifting both inhibition and excitation back toward dark levels. In fact, at least some of the conductance increase must occur by reducing the light-activated inhibition, since the conductance decrease produced by surround stimuli can exceed the entire conductance of the cell in the dark.

Since the surround must, in part, reduce the light-activated inhibition, and since the center and surround effects reverse at the same hyperpolarized membrane potential, the most obvious conclusion is that surround illumination acts through the excitatory and inhibitory inputs that produce the response to center stimuli. Moreover, the changes in these two inputs in response to surround illumination must be in essentially the same proportion as the changes resulting from center stimulation. Since inhibition dominates the center response, it is apparent that disinhibition dominates the surround response. Because hyperpolarizing bipolars probably mediate the excitatory input, it is not surprising that this input possesses an antagonistic center-surround organization. The cells providing tonic inhibition have not been determined, but our results suggest that their receptive fields also have an antagonistic surround.

203.8 CAT RETINAL GANGLION CELL RESPONSES TO SPATIOTEMPORAL WHITE NOISE. M. C. Citron, J. P. Kroeker* and W. R. Levick*. Bioinformation Systems, California Institute of Technology, Pasadena, CA 91125.

Until recently modelling of ganglion cell responses has been based mainly on linear analysis. This is satisfactory for those cells in which the processes of spatial summation of excitation are approximately linear (X-cells) but it fails for Y-cells where spatial summation is very nonlinear. Weiner kernel analysis is a general mathematical method of dealing with nonlinear systems by which the output as a function of time is represented as a power series. The coefficients are kernels of corresponding order. Our experiments demonstrate the praticality and effectiveness of applying Weiner kernel analysis to cat retinal ganglion cells.

To measure the kernels, a spatiotemporal white noise (STWN) stimulus was applied to the receptive field. The stimulus consisted of a 16 by 16 array of square picture elements (pixels) the intensity of each independently modulated by a 16 level uniform, random signal. The train of impulses constituting the ganglion cell's response was binned synchronously at the picture change rate (31.5 Hz).

The first order kernel for each pixel was estimated from the crosscorrelation function of the response with the stimulus intensity sequence at the pixel. The second order kernel for each pair of pixels was estimated from the crosscorrelation of the response with the product of the intensities at the two pixels. Higher order kernels were not calculated.

From the arrays of calculated kernels we predicted the cell's response to several traditional stimuli, such as: (1) a small spot flashed on for 0.5 sec against a uniform background at each of 121 position over the receptive field (2) alternating gratings of several spatial frequencies, Actual responses to these stimuli were also recorded for comparison. The predicted receptive field map, based on 24 min of recorded response to the STWN stimulus closely matched the recorded receptive field map based on 16 min of sequential testing. In addition, the distictive bimodal character of the recorded response to the alternating grating was clearly present in our predicted response (based on the same 24 min response as above) and could be attributed to the second order kernel component. Thus, within the limitations of the Weiner kernel analysis, a range of ganglion cell behavior can be predicted. The use of the resulting first and second order kernels may be sufficient to classify many different types of ganglion cells.

203.9 THE NEUROPHYSIOLOGICAL BASIS OF PRESSURE PHOSPHENES; RESPONSES OF CAT RETINAL GANGLION CELLS TO EYEBALL DEFORMATION.
O.-J. Grüsser, U. Grüsser-Cornehls and U. Schreiter.
Lab. of Neurophysiology, Department Physiology, Freie Universität, Berlin, Germany (West) (SPON: M.M. LaVail)

Action potentials of single on-center and off-center neurons (X, Y) were recorded from the optic tract of anesthetized cats. The eyeball was mechanically deformed in total darkness at the temporal sclera for periods lasting 1 to 30 sec. Similar stimuli elicit in man pressure phosphenes first described by Alcmaion of Croton (5th century B.C.)

Two classes of neuronal responses were observed: An early activation appearing with a short latency of about 15-300msec after the beginning of the eyeball indentation or after the release of deformation. About 15 percent of the on-center and off-center neurons responded with such an early activation. On-center neurons were more frequently activated at the beginning of deformation than after the cessation of deformation. The opposite was found for the off-center neurons.

All retinal ganglion cells showed a "late" response to maintained deformation of the eyeball appearing with a latency of 0.8-2.8 sec. All on-center neurons (X, Y) exhibited (in total darkness) an activation period lasting 10-25 sec. All off-center neurons decrease their activity to 0 impulses/sec within 1-3 sec after the beginning of the deformation.

When the eyeball deformation was released during the late activation period of on-center neurons, the latter ceased abruptly and after a discharge pause of several seconds the neuronal activity of the on-center neurons slowly returned to the pre-deformation level. Some on-center neurons showed a transient overshoot of neuronal activity during this recovery period. Off-center neurons responded to the end of eyeball deformation with an activation period during which the neuronal activity in most neurons was higher than the pre-deformation level.

The late activation periods of on-center neurons and the corresponding inhibition of off-center neuron spontaneous dark activity are correlated well with the phosphenes filling the visual field after some seconds of sclera indentation. We assume that this activation of on-center neurons and inhibition of off-center neurons are caused by stretching of the horizontal cell membrane, which would lead to a depolarization of horizontal cells. The latter causes a depolarization of on-center bipolarcells and a hyperpolarization of off-center bipolar cells, which triggers the corresponding responses of retinal ganglion cells.

203.10 MONOCLONAL ANTIBODIES WHICH REACT SELECTIVELY WITH LARGE GANGLION CELLS.
S.E. Kornguth, R. Auerbach*, J. Grieves* and L. Kahan*.
University of Wisconsin, Clinical Science Center, Madison, Wisconsin 53706.

This report describes the preparation of highly specific reagents (monoclonal antibodies) which react selectively with large ganglion cells in retina. Large ganglion cells of mammalian retina are of particular interest because they are presumed to be the major cell population which relays information about moving targets from the retina to the brain. Hybridomas were generated by fusion of NS-1 myeloma cells (P3-X63-Ag8; Salk Institute) with spleen cells from BALB/CAu mice immunized against a cell preparation consisting primarily of large ganglion cell (>28 μm soma diameter) isolated from ox retinas. Of the 3840 culture wells prepared from four separate fusions, about 1500 showed positive growth. Preliminary screening of supernatants using a microElisa assay led to the selection of 30 antibody-producing populations. When these were tested by an immunoperoxidase histochemical method, immunoglobulins in two supernatants were found to react selectively with large ganglion cells. Stable clones from these two wells were subsequently isolated and expanded. The two monoclonal antibodies, one selective for the cytoplasm of large ganglion cells and the other directed at a cell surface component, appear to be both cell-type and species-restricted. On the one hand neither antibody was reactive on liver sections; however both were localized to ganglion cells on tissue sections, and could be absorbed by isolated ganglion cells. At the same time, the reaction of both monoclonal antibodies was markedly attenuated when tested on ganglion cells obtained from either dog or cat retinas, in contrast to earlier results obtained with conventional antibodies prepared in rabbits. By employing a highly enriched fraction of large ganglion cells both for the initial immunization schedule and for the microElisa screening assay we may have been able to prejudice both the generation and selection of hybridomas toward a particular neuronal type.

Supported by funds from the University of Wisconsin Medical and Graduate Schools and by a gift from Dr. and Mrs. Leonard Weiss.

203.11 LUMINANCE DEPENDENCE OF CAT SPATIAL VISION AFTER LESIONS OF AREA CENTRALIS.
T. Pasternak and D. Zehl. Center for Visual Science, University of Rochester, Rochester, NY 14627

The spatial contrast sensitivity and visual acuity of cats were measured behaviorally before and after argon laser lesions of the central retina. The lesions were bilateral, centered on the area centralis and 10° in diameter. The exact location of the area centralis and the dimensions of the lesions were determined from fundus photographs.

Spatial vision was tested over a 6 log unit range of luminances. Cats were trained under a two-alternative spatial forced-choice paradigm to discriminate vertical sinusoidal gratings from uniform fields of the same mean luminance. At the highest luminance tested (16 cd/m^2), the lesions resulted in reduced contrast sensitivity at higher spatial frequencies. Visual acuity dropped approximately ½ octave. As the luminance was reduced to scotopic levels spatial vision showed a similar impairment. Only at the lowest luminance tested (16 x 10^{-6} cd/m^2) were no deficits observed.

This result suggests that even at scotopic luminances the area centralis contributes to spatial resolution and contrast sensitivity of the cat. This may be accomplished by a relatively large proportion of rods present in the area centralis of the cat retina.

Supported by NEI grants EY01875 & P30 EY01319.

203.12 VISUAL ACUITY AND FOVEAL CONE DENSITY IN THE RETINA OF THE AGED RHESUS MONKEY.
J.M. Ordy, and K.R. Brizzee. Delta Regional Primate Res, Ctr., Covington, La. 70433 and Tulane University, New Orleans, LA 70118

Visual acuity plays a fundamental role in visually guided behavior of man and all diurnal primates. Acuity depends on optical and neural mechanisms. Optical factors include mechanisms for focusing an image on the retina. Neural factors include foveal cone and ganglion cell density, their ratio and eccentricity from the fovea, and a magnification factor in the geniculostriate system. Acuity has received considerable attention in studies of development. Only a small number of studies have dealt with changes in acuity in relation to changes in foveal cone density of the retina during aging. Specific aims of this study were to examine age differences in visual acuity among young adult (5 yrs.), middle age (12 yrs.) and aged (22 yrs.) rhesus monkeys in relation to foveal cone density in the retina. Acuity has been defined as the reciprocal of the least resolvable spatial detail measured in minutes of visual angle. The minimum separable binocular acuity mean of the young group was 0.83 ± 0.11, the middle aged acuity mean was 0.86 ± 0.12, and the acuity mean of the aged monkeys was 2.0 ± 0.70 minutes of visual angle. According to analysis of variance and multiple range tests, the 0.83' acuity mean of the young, and the 0.86' acuity mean of the middle age group did not differ significantly, whereas the 2.0' acuity mean of the old group differed significantly from the 2 younger age groups. Foveal cone density was determined norphometrically by assessment of cone inner segment (CIS) width, and absolute CIS number per 100μM along the horizontal meridian of the pure cone, rod-free 1° x 1° foveola. Foveal cone density decreased significantly from 44.16 per 100μM in the middle age group to 39.00 per 100μM in the old macaque group. Since the diurnal macaque is of the same taxonomic order as man, and the Visual systems of the two species are directly comparable in terms of acuity and the central receptive field organization of the retino-geniculostriate system, it may be concluded that the macaque may represent an attractive and valid model for studies of aging in photopic and scotopic vision of diurnal primates.

203.13 MAMMALIAN EYE TRANSPLANTATION. M.J. Perlow. Dept. Neurology, Mt. Sinai School of Medicine, New York, N.Y. 10029.

Previous studies have demonstrated that mammalian fetal nervous tissues, when transplanted into the substance of an adult brain can survive for prolonged periods of time without rejection, grow in size and mature into adult-appearing tissues. Transplanted neurons can synapse with host tissues and, in some cases, alter the behavior of the recipient animal in a manner consistent with the normal function of the grafted tissue (Perlow, Science 204:643, 1979; Gash, Science 210:1367, 1980).

As a first step in determining if eye transplantation can restore vision to blind mammals, whole fetal eyes were transplanted into the brain of enucleated adult rats. Whole eyes with some ocular adnexal tissues were obtained from 14-15 day gest. Sprague Dawley (SD) rats and sterotaxically injected into the brains of adult SD rats. The injections were made such that the tip of the injection needle terminated close to the lat. geniculate nucl. or sup. colliculus, in the substance of the cerebral cortex or in the lat. cerebral ventricle. The rats were enucleated several days after transplantation. Several months after transplantation the animals were killed. Frontal sections of the formaldehyde-perfused, paraffin-embedded brains were stained with cresyl violet. While there is considerable conn. tissue proliferation and cyst formation, examination of some of these sections, and sections from an earlier study (Freed and Perlow unpublished data), show that fetal rat eyes when homologously transplanted into an adult rat brain can (1) survive for prolonged periods of time without rejection and (2) grow in size and develop a structural organization similar to an adult eye. The individual tissues mature to such a degree that adult-appearing ocular and adnexal tissues are readily recognizable (cornea, lens, vitreous humor, hair follicles, sebacous glands). Retinal elements are frequently observed in the form of rosettes. A retina-like layered structure was only occasionally observed.

Coupled with previous studies on embryonic tissue transplantation and the recent demonstration that transplanted fetal retina can develop and make appropriate topographical projections into the brain stem of enucleated rats (McLoon and Lund, Exptl. Brain Res. 40:273, 1980), this study suggests that fetal eyes might eventually be transplanted to an enucleated adult animal in such a manner that they might be able to send efferent axons to the host brain. The ability of transplanted retina or whole eyes to transmit visual information to the host brain remains to be determined.

204.1 OPTOKINETIC AND VESTIBULAR RESPONSES IN MEDIAL PONTINE NUCLEUS NEURONS IN ALERT MONKEY. E. L. Keller and W. F. Crandall*. Smith-Kettlewell Institute of Visual Sciences, San Francisco, CA 94115.

The brainstem pathways responsible for optokinetic eye movements and visual sensitivity to the motion of large patterned fields in vestibular nucleus neurons have been recently the subject of intense investigation. A pathway from the pretectum to nucleus reticularis tegmenti pontis (NRTP) seems to be a major link in mediating this behavior in the rat, but studies in monkey have failed to find single neurons in NRTP whose behavior would support the existence of such a pathway in the primate. We now report that a group of neurons located ventral to NRTP in the medial pontine nuclei of monkey have a strong response to optokinetic stimuli. Unique features of the response of this group of cells include the following. The neurons responded with directional selectivity to the motion of large visual fields with the eyes fixed on a tiny stationary target. Both vertical and horizontal directional preferences have been noted in the recorded population of units. These cells do not respond to either moving or stationary discrete visual stimuli. They were modulated when the eyes pursued a discrete visual stimulus moving in the same direction as the preferred direction of OK motion. This indicates an eye movement sensitivity. During OK tests with abrupt onset of constant-velocity OK drum rotation and the eyes fixed, the unit response began about 120 ms following drum rotation and reached maximum discharge almost instantly. Sinusoidal tests with OK stimuli showed that the responses only slightly lag peak stimulus acceleration in the preferred direction even at frequencies up to 0.5 Hz. Most of these units were also tested for vestibular response both with the eyes fixed on a small stationary target rotating with the animal and during normal vestibulo-ocular response in the dark. All tested cells showed a vestibular response during suppression and during normal VOR. The directional preference of the vestibular response was always synergistic with the OK visual response. In contrast to the visual response, the vestibular response was close to being in phase with peak head velocity. In conclusion we suggest that a neural pathway through the pontine nuclei may be important in mediating OK behavior.

204.2 CAT NEURONS RELATED TO HORIZONTAL EYE POSITION LOCATED VENTRAL TO THE 6TH NUCLEUS. R. S. Remmel and R. D. Skinner. Depts. of Physiology and of Anatomy, Univ. of Ark. for Med. Sci., Little Rock, Ark. 72205.

Cats were prepared for alert recording by surgically implanting head-mounting bolts and a chamber over the cerebellum for micropipette insertion. A coil of wire was placed around the right eye for eye-position recording by the magnetic search coil technique. A bipolar electrode was permanently inserted into the right 6th-nerve root in the basis pontis.

In recording sessions the cat's head was bolted into position and an extracellular micropipette was lowered according to stereotaxic coordinates. The predominantly negative extracellular pulses and eye position signals were recorded on magnetic tape and photographed from an oscilloscope. The right 6th nucleus was located by observation of the field potential and of motoneurons antidromically excited by nerve stimulation. The depth of neurons could thus be accurately determined relative to this field potential. This report concerns neurons located within 1.5 mm ventral of the 6th nucleus. None of the described neurons could be antidromically excited from the 6th nerve.

Tonic neurons had firing rates which increased with rightward (ipsilateral) eye angle, with rates seldom exceeding 100 spikes/s. Tonic neurons usually had a threshold angle, to the right of which they began firing. Changes in firing rate usually preceded the start of saccades. Some tonic neurons showed a small increase or decrease in firing rate during saccades (a burst or pause), which was less pronounced than for most motoneurons. The correlation between eye position and firing rate was better for some neurons than for others.

Burst neurons were located near tonic neurons. The bursts for rightward (ipsilateral) movements typically had 18 spikes (26 maximum) and average frequencies during the burst of 170 spikes/s (230 maximum). Bursts began in general before and continued during saccades. Longer bursts with more spikes occurred for larger rightward saccades, while few or no spikes occurred for leftward or vertical saccades. Burst neurons were usually not tonically active. When the cat made a staircase of closely spaced saccades, the neuron produced corresponding bursts.

These neurons seem qualitatively similar to those in the paramedian pontine reticular formation of monkeys.

204.3 OCULOMOTOR NEURAL RESPONSES TO SINUSOIDAL HORIZONTAL LINEAR ACCELERATION IN MONKEYS.

R.Eckmiller.Division of Biocybernetics,University of Düsseldorf,D-4000 Düsseldorf,West Germany.

Sinusoidal time courses of linear acceleration perpendicular to the gravity vector were applied to Java monkeys sitting upright in a primate chair, by means of a slide track with feedback control. Movement frequencies ranged from 0.1 to 1.0 Hz. Maximum acceleration reached values of 300 cm/sec^2. The angle δ between the monkey's X-axis(ant. - post.) and the slide track axis could be varied ($\delta = 90^o$ for pure right-left movement). Single unit activity in the abducens nuclei and their vicinity was recorded along with horizontal EOG's from each eye independently. The monkeys were kept under light barbiturate anesthesia in order to reduce spontaneous eye movements to occasional slow drift movements. In a few cases small electrolytic lesions were made, and were later used for histological verification of the recording site in Celloidin sections.

Many brain stem neurons with a regular tonic impulse rate(IR) showed a strong dynamic response to linear acceleration, although their IR was not modulated by eye movements or be rotatory accelerations. These neurons indicate the existence of pure otolith afferents close to the abducens nuclei. Quantitative analysis of presumed abducens motoneurons revealed: 1. IR of all these motoneurons showed a slight increase in response to a chair acceleration to the contralateral side(at $\delta = 90^o$) and a decrease in the opposite movement phase, comparable to a α - otolith response. Rotatory acceleration stimuli around the vertical axis always led to much stronger IR-modulation. 2. IR-modulation gradually increased with increasing movement frequency. The gain relative to acceleration, however, decreased with increasing frequency. 3. The phase lag of IR relative to acceleration increased from almost 0 deg at 0.1 Hz to over 90 deg at 1 Hz. The phase lag at a given frequency varied considerably for different neurons. 4. Sinusoidal linear acceleration at different angles δ between 0^o and 180^o revealed that maximal IR-modulation was reached at about $\delta = 90^o$.

The results suggest a significant utricular input to primate abducens motoneurons.

Supported by DFG/Germany Ec 43/5.

204.4 MORPHOLOGY AND SYNAPTIC CONNECTIONS OF CAT OCULOMOTOR MOTONEURONE AXON COLLATERALS. R.F. Spencer, C. Evinger, and R. Baker, Dept. Anat., Med. Coll. of Virginia, Richmond, VA 23298, and Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016

Recent morphophysiological studies have demonstrated that all medial rectus and inferior rectus and some superior rectus motoneurones (MNs) in the cat oculomotor (Oc) nucleus have axon collaterals that arborize within the soma-dendritic domain of the MN of origin. Electrical stimulation of the IIIrd nerve, however, produces antidromic activation of Oc MNs without direct recurrent synaptic effects upon the MNs. The present study examined the morphology and synaptic connections of Oc MN axon collaterals stained by intracellular injection of horseradish peroxidase (HRP) and reconstructed from serial sections by light and electron microscopy.

In all cases, collaterals arose from the parent axon at a node of Ranvier and were unmyelinated throughout the extent of their course. The initial portion of the collateral was contacted by synaptic endings that contained either spheroidal or flattened synaptic vesicles. "Swellings" along the course of the collateral contained spheroidal synaptic contacts and, in some cases, presumed en passant synaptic contacts with postsynaptic membrane specializations were established predominantly with dendritic profiles. Collaterals were either unbranched or divided into 2 to 4 branches. Terminal branches established synaptic contacts with somata and dendrites of neurones both within the Oc nucleus and ventrolateral to the MLF.

The results indicate that a single MN axon collateral establishes synaptic connections with several Oc neurones. In contrast to spinal MNs, collateral synaptic endings of Oc MNs never were observed in relation to the soma-dendritic profiles of the MNs stained by intracellular HRP or other MNs labelled by retrograde HRP. In some cases, the postsynaptic neurone was identified as an Oc internuclear neurone (IN) labelled by retrograde HRP from posterior brain stem nuclei (i.e., abducens, prepositus hypoglossi). Given additional efferent projections of Oc INs to other brain stem nuclei (e.g., reticularis tegmenti pontis, facial, accessory abducens) and the cerebellum, synaptic connections mediated by Oc MN axon collaterals may be related to both oculomotor and facial motor systems.

204.5 CONTRACTILE PROPERTIES OF SINGLY INNERVATED MUSCLE UNITS CONTROLLED BY OCULOMOTOR NUCLEUS MOTONEURONS IN THE CAT. M.A. Meredith and S.J. Goldberg. Dept. Anatomy, Med.Col.Va.-VCU, Richmond,VA.

Conjugate eye movements are precise and synchronous in nature. Therefore, it has been presumed that the extraocular muscles involved in the generation of such movements present similar contractile properties. While the characteristics of lateral rectus motor units have been reported, the present experiments were conducted to examine the contractile properties of muscle units controlled by motoneurons which reside in the oculomotor (OC) nucleus.

Cats were anesthetized and the OC nerve was stimulated in the brainstem. In the orbit, the medial (MR), superior (SR) and inferior rectus (IR) and inferior oblique (IO) muscles were freed from their insertions and attached to individual strain gauges. The length of each muscle was adjusted to maximize its isometric twitch contraction tension. Cells in the OC nucleus were identified by their antidromic response to OC nerve stimulation. Single OC cells were penetrated with a micropipette and those which elicited contractile responses in a muscle, when intracellularly stimulated, were identified as motoneurons (MN) of that muscle. A variety of stimulus patterns were presented to the OCMNs and the subsequent muscle unit responses were recorded.

100 OC nucleus motoneurons were identified; 60 of which innervated MR muscle units, 20 controlled IR units, 15 were SR units and 5 were IO units. The contractile properties of singly innervated units from each of these muscles were similar: mean contraction time = 5.64 msec (range = 5.35-5.89 msec) and mean fusion frequency = 245 Hz (range = 235-260 Hz). These values for oculomotor motor units, however, are faster and higher, respectively, than reported for lateral rectus motor units. A recent report indirectly confirmed the authenticity of these contractile distinctions between OC and AB units: OC innervated retractor bulbi muscle fibers were faster and presented higher fusion frequencies than abducens nerve controlled fibers in the same muscle.

It has been demonstrated that extraocular muscle units innervated by OCMNs exhibit different contractile properties than reported for units controlled by MNs in the accessory and principal abducens nuclei.

204.6 AN IN VITRO PREPARATION OF THE MAMMALIAN OCULOMOTOR NUCLEUS. C. Evinger and J. Hounsgaard*. Dept. Physiology and Biophysics, New York Univ. Med. Ctr., 550 First Avenue, New York, N.Y. 10016

In alert animals the discharge patterns of oculomotor neurons are well documented. Nevertheless, little is known as to whether this pattern emerges solely from synaptic inputs or whether the motoneuron itself introduces some discharge characteristics in converting the synaptic input into action potentials. Resolution of this problem requires a detailed knowledge of motoneuron membrane properties. This abstract reports an in vitro slice preparation which has several advantages for studying oculomotor neuron properties and synaptic inputs. The guinea pig midbrain was sliced into 400 micron sagittal sections and bathed in an oxygenated Ringer's solution maintained at 37°C. These slices contained the oculomotor and trochlear nuclei and the medial longitudinal fasciculus (MLF). Despite the potential trauma of slicing, the neurons exhibited properties similar to those found in in vivo preparations. The input resistances, resting potentials, and spike height were normal. Intracellular injection of depolarizing current produced repetitive firing which adapted to a steady firing frequency within 50 msec of current onset. Consistent with in vivo studies, the neurons did not exhibit a primary range of repetitive firing. The slicing did not interrupt synaptic function since stimulation of the MLF generated postsynaptic responses in neurons and spontaneous synaptic potentials were observed. An advantage of the in vitro preparation was the stability provided by the absence of cardiovascular and respiratory pulsations. This allowed extended intracellular recordings from all elements in the oculomotor complex (including astroglia). Another advantage was the ease of altering the extracellular environment to study neuron properties. For example, application of tetrodotoxin (TTX) revealed the presence of a slow, TTX insensitive spike in oculomotor neurons. Thus, the normal behavior of neurons, the stability of recording, and the ease of modifying the extracellular environment suggest that the slice may be a useful tool in studying the oculomotor system.

205.1 POSTEMBRYONIC MODIFICATIONS IN THE TELEOST RETINA. Pamela Raymond Johns. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115.

Last year I reported that new rods are generated and inserted within differentiated regions of adult goldfish retina (Neurosci. Abst.6:639). Thymidine radioautography has revealed that dividing rod progenitor cells are scattered among mature rod nuclei in the outer nuclear layer (onl) in goldfish and also in Haplochromis burtoni, an African cichlid. I have now traced the ontogenesis of rods in the larval teleost retina and find that there, too, the formation of rods is unique.

Goldfish, newly-hatched to one-year-old, were injected with ^{3}H-thymidine and killed a few hours to several months later. Identification of photoreceptors in methacrylate sections was aided by bleaching the melanin in the pigmented epithelium with $KMnO_4$/oxalic acid, by staining with basic fuchsin and by assessing the level of incorporation of ^{3}H-fucose into outer segments.

At hatching, the photoreceptor layer in the goldfish retina is poorly differentiated. Outer segments are absent and the onl is a single row of columnar nuclei. These cells, which are post-mitotic, differentiate into cones. Rods appear at 3 days post-hatch and then gradually accumulate. The ratio of rods to cones is zero at hatching, 1:1 at 40-50 days, 6:1 at one yr. and 15:1 at 4 yrs. Rod nuclei throughout the retina were labeled with ^{3}H-thymidine injected at any age. Repeated divisions of labeled rod progenitors resulted after several months in about a 10-fold increase in the number of labeled rods over the number at 24 h following a pulse label. Dividing rod progenitors found in the onl of the larval retina were similar to those described previously in the adult. These cells derive from what appear to be clusters of undifferentiated neuroepithelial germinal cells whose nuclei are sequestered in the inner nuclear layer (inl). These neurogenic clusters are readily seen in larval retinas; they are easily overlooked in retinas from older fish where the "cluster" has often been depleted to a single remaining cell whose shape is sometimes like a Muller cell. Beginning at 3 days post-hatch, and continuing into adult life, proliferating cells appear to cross the outer plexiform layer from inl to onl. In the onl they become rod progenitors. This migration of cells is reflected in a progressive increase in the proportion of labeled nuclei in the onl compared with the inl, both with longer survival times and with advancing age at injection.

Preliminary observations of retinal histogenesis in another fish, the Japanese Medaka (Oryzias latipes), indicate that the retina is more precocious in this species: at hatching rods have already begun to accumulate, though they have not yet attained their final density. Delayed formation and continued addition of rods is probably a universal feature of retinal histogenesis in teleost fish. (Supported by EY00301).

205.2 TRANSPLANTATION OF NEURAL TISSUES IN THE SPINAL CORD OF THE ADULT RATS. G. D. Das* (SPON: R. W. Wallace). Dept. of Biological Sciences, Purdue University, West Lafayette, Indiana 47907.

During past several years we have demonstrated that embryonic neural tissues can be successfully transplanted invarious regions of the brains of neonatal or adult host animals. The transplants in the cerebellum or the forebrain region of the host animal grow differentiate and become anatomically integrated with the host brain. They are intraparenchymal transplants. This report is addressed to the nature of growth and anatomical integration of the neural transplants in the spinal cord of the adult rats.

In this study Long-Evans hooded rats were used. From embryos of 16 or 18 days gestational stages neural tissues from neocortical region, tectum, cerebellum and spinal cord were removed for transplantation. They were transplanted in the cervical or thoracic regions of the spinal cord of 4-6 months old host animals. The techniques of preparation of embryonic neural tissues, host animals, and transplantation were similar to those described earlier (Das, 1974; Das et al., 1979). Most of the host animals were sacrificed 4-6 months after transplantation, and some were kept for longer survival intervals. From each condition of transplantation portions of spinal cord, where the transplants were deposited, were removed and prepared for cresyl-violet stain Bodian stain, or Golgi-Cox impregnation. In order to study afferents to the transplants, in some animals surgical lesions were made rostral or caudal to the site of transplantation, and the spinal cords containing the transplants were processed for Fink-Heimer method of staining degenerating fibers.

Neural tissues from tectum, cerebellum or spinal cord of embryos did not survive in the spinal cord of the host animals. They were isolated and necrotic. The neural tissue from embryonic neocortical region survived, grew and became anatomically integrated with the host spinal cord. It contained normal-looking well-differentiated pyramidal and stellate cells. It was anatomically continuous with the gray matter of the spinal cord, and a number of fibers could be seen to course through the interface. At the regions where the transplant was apposed to the white matter of the host spinal cord a band of neuroglial cells was seen. Fibers were not seen to penetrate through this glial mass. Comparison between neural transplants in the spinal and those in the cerebellum or forebrain regions of the host animals indicated that the bands of glial cells observed in these cases were due to the modification in the technique which involved making lesions in the spinal cords just prior to the insertion of the transplants.

These findings showed that it is possible to transplant neural tissues in the spinal cord successfully, and that they receive afferents from the immediately available fiber tracts of the spinal cord.

205.3 TRANSPLANTATION OF ADRENAL CHROMAFFIN CELLS TO THE ADULT RAT BRAIN, W.J. Freed, J.M. Morihisa,* H.E. Cannon-Spoor,* L. Olson, A. Seiger, B.J. Hoffer,*, and R.J. Wyatt. (SPON: J.R. Stevens) Adult Psychiatry Branch, National Institute of Mental Health, Washington, D.C. 20032.

Adrenal Chromaffin Cells develop elongated processes and become morphologically similar to neurons when grafted to the anterior eye chamber or when grown in culture in the absence of corticosteroids (Olson, L., et al., Exp. Neurol. 70:414, 1980; Unsicker, K., et al., Proc. Natl. Acad. Sci. USA 75:3498, 1978). We have previously found that homografts of fetal rat substantia nigra (SN) in the lateral ventricle of rats with unilateral SN lesions can partially reinnervate the caudate nucleus and reduce apomorphine-induced rotational behavior. The purpose of the present study was to determine whether adrenal medulla grafts in the rat brain lateral ventricle can also reduce rotational behavior by reinnervating the caudate nucleus.

Unilateral SN lesions were produced in Sprague-Dawley rats by stereotaxic administration of 6-hydroxydopamine. Only rats with baseline rates of rotational behavior of at least 80 turns per 40 minutes after S.C. injections of 0.1 or 0.25 mg/kg of apomorphine HCl were used. Some of these animals (N=13) received intraventricular grafts of pieces of adrenal medulla and other (control) animals (N=15) received grafts of pieces of sciatic nerve. Two months after grafting, rotational behavior was again studied, and was found to be decreased in the animals that had received adrenal medulla grafts.

Falck-Hillarp fluorescence histochemistry showed surviving grafts in five of the six animals examined. Many of the cells had become elongated or had developed short, coarse processes, but few thin nerve fiber-like processes had been formed. Very few of these fibers had penetrated into the host caudate nucleus.

The findings indicate that grafts of adrenal medulla can reduce lesion-induced rotational behavior without reinnervating the caudate nucleus. This suggests that the behavioral effect was due to secretion by the graft of catecholamines or other substances which passively diffused to receptor sites in the caudate nucleus.

205.4 ALTERATION IN CORTICOSPINAL MICROCIRCUITRY FOLLOWING PYRAMIDOTOMY IN RAT. Deborah L. Claman* and Jerald J. Bernstein. Lab. CNS Inj. & Regen. V.A. Medical Center, Washington, D.C., Depts of Neurosurg. & Physiol., George Washington Univ. Sch. of Med.

Rat corticospinal tract (CS) somata lie in layer Vb somatomotor cortex. CS subpopulations may project to forebrain, midbrain, and pontine nuclei in addition to having multisegmental spinal cord projections. While most spinal cord injury affects both ascending and descending pathways, the CS tract can be transected without primary injury to the afferents on the receptive surface of the corticospinal neurons; somatic deafferentation is then due to axotomy. The present experiments continue a series of light and electron microscopic observations on the response of cortical layer Vb neurons to pyramidotomy at midmedulla. Since some CS neurons were partially deafferented by three days postoperatively (DPO) 4 additional groups of animals (N=5 per group) and 2 normals were prepared for electron microscopic analysis from 3 hours through 30 days after the pyramidal tract was unilaterally transected. The immediate effects of axotomy including the time course of somatic presynaptic bouton loss and glial mobilization are presently examined. Several features of the cellular reaction are apparent by 24 hours after surgery. Pathological nuclear crenations with abnormal condensations of nuclear chromatin on the inner nuclear membrane and associated vacuolated cytoplasm along the outer membrane are observed. There is also an abnormal clumping of nuclear chromatin in axotomized CS neurons. Presynaptic bouton ghosts with associated membrane profiles (somatic stripping) may be found by 1 DPO. Reactive and dividing neuroglia and increases in microglia are apparent. From 3 through 14 DPO an increasing number of neurons react to pyramidotomy. There are 3 correlations between bouton loss and neuroglial reaction: neuroglial cell processes may intervene between presynaptic bouton and bouton somata; neuroglial cell processes may be contiguous with postsynaptic specializaions without presynaptic boutons; neuroglial somata may overlie former postsynaptic specializations. The appearance of postsynaptic membrane specializations continues through 30 DPO. Between 14 and 30 DPO axonal growth cones are observed in depressions on the CS cell surface; they appear in areas of degeneration where there is vacated space. The persistence of postsynaptic membrane specializations and the observation of growth cones indicate that the CS neurons of origin may be receptive to reinnervation. Reinnervation might be a determinant for neuronal survival amongst those CS cells which do not necrose forming the basis of a reorganized spinal projecting neuronal pool for regeneration. (Supported by (NS-16979).

205.5 ABERRANT AXONS FROM THE DORSAL ROOTS AFTER CHRONIC SPINAL HEMISECTION IN THE CAT: THE DORSAL HORN, M.S. Beattie, J.C. Bresnahan and F.J. Liuzzi. Div. Neurosurg. and Dept. Anat., Ohio State Univ. Sch. of Med., Columbus, OH 43210

McCouch, et. al. (J. Neurophysiol, 21:205, 1958) were the first to describe apparent axonal sprouting of the dorsal root system in response to a rostral spinal hemisection. These observations were supplemented by those of Murray and Golberger (JCN, 158:19, 1974). The latter authors found evidence for terminal proliferation mainly in the base of the dorsal horn. In an attempt to further these observations of apparent axonal sprouting in the spinal cord following hemisection, we have employed the method of anterograde injury filling of the dorsal roots with horseradish peroxidase (HRP; Proshansky and Egger, Neurosci. Lett., 5: 103, 1977; Light and Perl, JCN, 186:117, 1979; Beattie, et. al., Brain Res., 153:127, 1978). This method provides a Golgi-like appearance of dorsal root axons suitable for observing axonal trajectories and morphological features. Additionally, the method allows subsequent electron microscopic analysis of the tissue.

HRP was applied bilaterally to cut dorsal rootlets rostral and caudal to a spinal hemisection (T13-L2) in 9 cats which had survived for 6 weeks to 3 months postoperatively. Most of the lesions included significant damage to the ipsilateral dorsal columns.

We observed two types of apparently aberrant axons at levels from one to seven segments caudal to the lesion. In several cases, large collaterals from labelled dorsal column axons were seen to diverge from their normal dorsal-ventral trajectories through the superficial dorsal horn to traverse laminae I and II in a lateral to medial orientation. These axons exhibited some large swellings along their course. Smaller straight fibers were seen to radiate from the apex of the dorsal horn in an atypical fashion, often ignoring their typical laminar distribution to the dorsal spinal gray. These axons also had occasional swellings along their course. Such axons were very rarely observed in normal material or contralateral to the lesion.

Since axons projecting rostral to the lesion were cut in these cases, it is not yet clear whether these abnormalities represent collateral axonal sprouting in response to denervation, collateral 'pruning', or both. Electron microscopic studies are underway to determine if these aberrant axons make synaptic contact within the superficial dorsal horn.

(Supported by Grants NS-14457 and 10165).

205.6 ACTIVITY OF MOTONEURONS AND INTERNUCLEAR NEURONS IN THE ABDUCENS NUCLEUS FOLLOWING PERIPHERAL AXOTOMY OF THE VIth NERVE. J.M. Delgado-Garcia*, R. Serra*, J. Ribas* and R. Baker (SPON: U. Kuhnt). Dept. Physiol. & Biophys., Seville Med. Sch., Seville, Spain and New York Univ. Med. Ctr., New York, NY 10016.

Our prior study demonstrated that the antidromic field potential recorded in the abducens nucleus following VIth nerve stimulation was reduced by more than 80% following peripheral axotomy. These changes began 2-4 days after axotomy, peaked at 10-15 days and returned to control values about 25-30 days later in parallel with recovery of muscle function. The present experiments were designed to record the activity of antidromically identified motoneurons and internuclear neurons in the abducens nucleus from the onset of axotomy to reinnervation. In seven cats stimulating electrodes were implanted intracranially upon the VIth nerve and in the medial rectus subdivision of the oculomotor nucleus. Eye movements were recorded in both eyes with the magnetic search coil technique. During the critical axotomized period, it was only possible to antidromically activate abducens motoneurons when adequate visual (optokinetic) and/or vestibular (head rotation) stimulation produced eye movements towards and/or maintained eye positions in the on-direction (i.e. abduction). Even then motoneurons showed a remarkable variability in antidromic latency as well as response to double shock stimulation indicating the need for additional synaptic input to compensate for the decrease in initial-segment excitability. Even so, the activity of axotomized motoneurons was qualitatively normal during most eye movements such as saccades, vestibulo-ocular reflex and fixation; however they clearly differed in their quick fatigability during fixed eye position and notably higher recruitment thresholds. Few motoneurons exhibited tonic activity for eye positions in mid-oculomotor range. On occasion, axotomized abducens motoneurons discharged before saccades in the off-direction without exhibiting any tonic activity for the preceding eye position. Quite in contrast, the activity of internuclear neurons and all eye movements produced by both the ipsi- and contralateral medial rectus muscles remained normal. Given the intermingled distribution of motoneurons and internuclear neurons in the abducens nucleus, we conclude that in spite of the altered physiological responses of motoneurons, the effects of axotomy are restricted to those cells. In addition, since these cells share common afferent input we conclude that supranuclear cells (e.g. inhibitory reticular and vestibular neurons) maintain normal physiological activity in spite of morphological and functional detachment of their synapses from motoneurons during the critical period.

Supported by Spanish Comision Asesora and USPHS Grants NS13742 and EY02007.

205.7 DIVERGENT NEUROPHYSIOLOGICAL AND AUTORADIOGRAPHIC SIGNS OF LESION-INDUCED REORGANIZATION IN THE ADULT CAT LATERAL GENICULATE NUCLEUS. U.Th. Eysel, U. Mayer* and U. Wolfhard*. Institute of Physiology, University of Essen, D-4300 Essen 1, West Germany.

Neurophysiological mapping of the retino-geniculate topography in layers A and A_1 of the adult cat lateral geniculate nucleus (LGN) more than 30 days after partial deafferentation by nasal retinal lesions yielded lesion-induced spreading of excitation from the normally innervated region into the formerly deafferented part of layer A by 200 µm beyond normal (Eysel et al., Brain Research, 181:285, 1980).

An autoradiographic approach was chosen to investigate possible morphological correlates. A strip of retina with blood supply and intact innervation was limited in the upper part by chronic photocoagulator lesions (survival-times 60 and more days) continued by subacute lesions (5-7 days survival-time) in the lower part. The width of this strip was constant. The intersection of the two types of lesions was at the elevation of the zero horizontal meridian. The projection of this area onto the LGN was marked by electrolytic lesions prior to the injection of 1mCi 3H-Proline into the eye. Autoradiographs of paraffin embedded serial sections were analysed. The width of the band of label in layer A of the contralateral LGN anterior to the electrolytic lesion (chronic deafferentation) was compared to measurements in the posterior part (subacute deafferentation). No increase of the spread of label in the range of 200 µm could be observed at the border of chronic deafferentation.

In the LGN of the cat, relay cell dendritic fields and optic tract input arborizations are overlapping in the range of 200 µm. Subthreshold peripheral inputs at the dendrites of deafferented cells may become able to excite the cells as a result of only small presynaptic changes (axonal sprouting, translocation of synapses towards the cell soma) or even without changes demonstrable with autoradiography (denervation supersensitivity). A completely different, possible mechanism could be the "axonization" of relay cell dendrites (Hâmori and Silakov, Neurosci.,5:2073,1980).The result emphasizes that structures not showing extended axonal sprouting may utilize other mechanisms to reactivate deafferented cells at quite a distance from the remaining normal cells. (Supported by the DFG, Ey 8/9).

205.8 FORELIMB PLACING DEFICITS CAUSED BY DAMAGE TO THE INTERNAL CAPSULE ARE REVERSED BY CORTICAL SPREADING DEPRESSION. David L. Wolgin and Priscilla Kehoe,* Dept. of Psychology, Florida Atlantic University, Boca Raton, Fla. 33431

Following unilateral damage to the internal capsule, rats failed to use the contralateral forelimb in reflexive placing reactions. In the most severely impaired animals, the deficit included loss of proprioceptive, tactile, whisker, chin, and visual placing. Spreading depression induced by applying potassium chloride to the sensorimotor cortex contralateral to the lesion reinstated placing in the impaired limb and abolished placing in the normal limb. As the spreading depression dissipated, placing in the impaired limb gradually deteriorated, while placing in the normal limb returned. In contrast, potassium chloride applied to the ipsilateral cortex did not reinstate placing. These findings suggest that the loss of forelimb placing following capsular lesions is due to tonic inhibition from the cortex contralateral to the lesion.

205.9 SUSTAINED FACILITATION OF EVOKED POTENTIALS IN THE CEREBRAL CORTEX FOLLOWING SHORT TRAINS OF HIGH-FREQUENCY STIMULATION, K.S. Lee. Max Planck Institute for Psychiatry, Munich, West Germany

An in vitro slice preparation containing the hippocampus and portions of the cerebral cortex was developed to examine the effect of brief bursts of high-frequency stimulation on cortical evoked potentials. Extracellular recordings were taken from layer III or IV of six cortical areas and evoked potentials were monitored in response to stimulation of the subjacent white matter. Following the delivery of short trains of repetitive stimulation (100-200 per sec for 0.5 sec), the peak negativity of the cortical potentials (i.e. the first calcium-sensitive component of the waveform) was increased in amplitude and usually showed a decreased latency. The increase in amplitude was usually non-decremental after 15-20 minutes post-stimulation; and, its stability was closely correlated with the capacity to induce a stable potentiation of hippocampal evoked potentials in the same slice. While the majority of experiments examined area 18, five other cortical areas exhibited similar changes. In some cases, these changes persisted for up to 4 hours, which was the longest post-tetanic interval tested. The non-decremental nature of the facilitation during this interval, however, suggests that the enhancement of cortical potentials could persist for a much longer period.

205.10 CHRONIC LITHIUM TREATMENT ATTENUATES RECOVERY FOLLOWING DAMAGE TO THE MESOTELENCEPHALIC DOPAMINERGIC SYSTEM. M. R. Kozlowski, J. Grisham*, J. F. Marshall. Department of Psychobiology, University of California, Irvine, CA 92717

This study examines the effect of chronic lithium treatment on behavioral recovery following damage to the mesotelencephalic dopamine (DA)-containing system. Male Sprague-Dawley rats were given lithium carbonate (1.25 mg/ml) in their drinking water for 3 weeks. The animals were then given an injection of 6-hydroxydopamine (6-OH-DA; 4.5 μg/2.25 μl) into the left ventral tegmental area in order to damage the ascending dopaminergic fibers. One half of the animals were maintained on lithium-free water for 4 weeks postoperatively (control group) while the other animals continued to receive water containing lithium (lithium group). All animals were tested for their orientation to somatosensory stimulation by applying a 4 g von Frey hair to 11 regions on each body surface. Orientation contralateral to the 6-OH-DA injection was expressed as percentage of ipsilateral orientation.

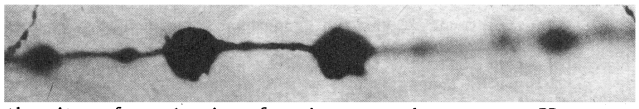
The intracerebral 6-OH-DA injection caused a large decrease in contralateral orientation to somatosensory stimuli in both groups at 3 days postoperatively (contralateral orientation 15% of ipsilateral). However, animals in the control group showed significantly greater contralateral orientation at 4 weeks postoperatively (90% of ipsilateral) than the lithium group (36%; t-test, $p < .01$).

The treatment of the two groups was reversed at four weeks postoperatively so that the lithium group now received unadulterated water while the control group was given water containing lithium. No change in the extent of recovery of contralateral orientation was seen in the control group during the subsequent 4 weeks. In contrast, the lithium group showed a 40% increase in orientation to contralateral stimulation during this time. This improvement was evident by 5 d after termination of lithium treatment and plateaued by 3-4 weeks. The extent of contralateral orientation in the lithium group at 8 weeks postoperatively (85% of ipsilateral orientation) was significantly greater than before termination of the lithium (t-test, $p < .001$) and did not differ significantly from that of the control group.

These results suggest that lithium interferes in a reversible fashion with the development of the neural changes underlying recovery after DA system damage. Chronic lithium administration is known to block striatal DA receptor proliferation following interruption of DAergic neurotransmission. Its effects on other forms of neuronal compensation for the injury are unknown. However, the present results are at least consistent with the hypothesis that DA receptor proliferation contributes to recovery following DA system damage.

206.1 EPILEPTIFORM HIPPOCAMPAL GRANULE CELL ACTIVITY IS NEUROTOXIC TO CELLS WHICH RECEIVE MOSSY FIBER INPUT. Robert S. Sloviter, Dept. of Pharmacology, Penn State Univ., Col of Med, Hershey PA 17033.

Sustained intermittent electrical stimulation of the perforant path (PP) of urethane-anesthetized rats for 24 hrs evokes epileptiform granule cell discharges and reproduces the selective pattern of hippocampal damage caused by kainic acid and other chemical convulsants (Sloviter and Damiano, Fed. Proc. 40:309, 1981; Neuropharm., in press, 1981). The present studies describe the nature of acute hippocampal pathology caused by continuous, relatively short duration PP stimulation at 20 Hz. Two hours of granule cell spiking results in abolished recurrent inhibition (RI) of granule cells as measured with the twin-pulse technique. Light microscopy of Nissl-stained sections also reveals severe damage to hilar interneurons. In the CA3 pyramidal cell region, a distinct band of pericellular spaces (presumably swollen glial elements) encompasses the cell body and proximal apical dendritic regions which receive mossy fiber input. Similar clear spaces often surround the somata in the CA1 region. In addition, relatively clear circular profiles are evident in the dentate molecular layer and in the distal apical- and distal basal dendritic regions of CA1. Light microscopy of hippocampi stained with the Rapid Golgi method shows these round, clear profiles to be cross-sections of spherical dendritic expansions (photo) which occur at



the sites of termination of excitatory pathways, e.g., PP, commissural and mossy fibers. If 2 hr-stimulated rats are allowed a 2 hr "rest" after stimulation and before perfusion, the dendritic expansions and pericellular swellings in CA3 and CA1 disappear, leaving hilar interneurons and CA3 pyramidal cells irreversibly damaged. *RI is still abolished at this time.* Rats were also stimulated at 20 Hz for 15 min to determine which of the two cell types are damaged first. This resulted in decreased RI and damage to hilar interneurons without involvement of CA3. Stimulation without granule cell spiking does not cause this pattern of damage. These results indicate that excessive activity in the hippocampal mossy fiber pathway is neurotoxic to the cells which receive this activity. In addition, dentate interneurons which may mediate recurrent inhibition of granule cells are the cells most sensitive to the neurotoxic effects of granule cell discharge. These results confirm the hypothesis of a causative relationship between epileptic neuronal activity and epileptic brain damage.

206.2 LOSS OF INHIBITORY SYNAPSES AT THE EDGES OF CHRONIC CORTICAL SLABS CAUSES THEIR EPILEPTIC SUSCEPTIBILITY. R. J. Reiffenstein and C. E. Ribak. Anaesthesia Research, McGill Univ., Montréal, PQ H3G 1Y6, and Dept of Anatomy, Univ. of California, Irvine, CA 92717.

Chronically denervated slabs of cat cerebral cortex that exhibit epileptiform activity have been studied by electron microscopy. Although previous ultrastructural, electrophysiological, and biochemical studies had indicated a persistence of GABAergic inhibitory synapses, the data from the present study indicates that the density of these synapses depends upon the location in the cortical slab. Somata of pyramidal neurons located adjacent to the edges of the slabs had few, if any, symmetric (GABAergic inhibitory) synapses. Instead, these neurons' somata were almost completely enveloped by layers of processes from reactive astrocytes. In contrast, pyramidal neurons in the center of the slabs appeared to have an almost normal number of terminals forming inhibitory, symmetric, axosomatic synapses, and no astrocytic layers surrounding them. Pyramidal somata located about 1 mm from the edges of the slabs had an intermediate number of such terminals. This loss of inhibitory synapses appears to have been selective, because the number of terminals forming asymmetric axodendritic (excitatory) synapses remains fairly constant all across the slabs, although fewer than in normal cortex. This correlates with the biochemical studies which have shown a loss of glutamate in chronic slabs. The selective loss of terminals forming symmetric synapses at the edges of the slabs indicates a localized loss of GABAergic inhibition. This is consistent with data showing a reduction in GABA content in the chronic slabs. Thus this loss of GABA probably occurs mainly at the edges of the slabs. Also the epileptic "focus" in the chronic slabs is likely to be pyramidal neurons that are (1) located at the edges of the slabs, (2) denuded of most or all of their axosomatic inhibitory terminals, and (3) projecting relatively active excitatory axons toward the centers of the slabs. It may be that the aspinous stellate cells which give rise to the GABAergic terminals are more sensitive than other neurons to the local anoxia which probably accompanies the isolation procedure.

206.3 A SELECTIVE LOSS OF INHIBITORY, GABA TERMINALS IN MONKEY EPILEPTIC FOCI. C.E. Ribak, R.M. Bradburne*, and A.B. Harris, Dept. of Anatomy, Univ. of Calif., Irvine, CA 92717 and Dept. of Neurol. Surgery, Univ. of Wash., Seattle, WA 98195

Previous immunocytochemical results of five monkeys with cortical focal epilepsy produced by alumina gel showed a severe decrease at seizure foci of axon terminals that contained glutamic acid decarboxylase (GAD), the synthesizing enzyme for the inhibitory neurotransmitter, GABA. These data indicated a functional loss of GABAergic inhibitory synapses at seizure foci, but did not show 1) whether this loss was caused by GABAergic nerve terminal degeneration or by a lack of GAD synthesis in GABAergic neurons and 2) whether this loss was selective for only this terminal type. To answer these questions, epileptic and non-epileptic cortical tissue from 3 of the 5 monkeys used in the previous study were re-examined in the electron microscope. The terminals that formed axosomatic synapses with layer V pyramidal cells and those terminals and glia in the adjacent neuropil were outlined on electron micrographs and measured with a Zeiss Videoplan image analysis system. The following statistically significant changes were noted. First, axosomatic symmetric synapse decreased from an average of 1.32 per 10 μm of somal surface in nonepileptic cortex to 0.25 per 10 μm of somal surface in epileptic cortex. This reduction represents an average loss of 80% of these terminals. Second, in the neuropil adjacent to these pyramidal somata, the number of terminals forming asymmetric and symmetric synapses in epileptic cortex was reduced 20% and 50%, respectively, in comparison to nonepileptic cortex. Lastly, a 50% increase of glial profiles occurred in epileptic cortex both in the neuropil and at sites adjacent to pyramidal cell somata. These data indicate that the previously observed loss of GABAergic nerve terminals at sites of focal epilepsy is caused by terminal degeneration. Also, since GABAergic terminals are more severely reduced at epileptic foci than other terminals, it appears that this selective loss of GABAergic terminals could cause seizure activity due to a selective loss of inhibitory function at epileptic foci. Finally, the most severe loss of GABAergic terminals occurred adjacent to pyramidal cell somata. Since these terminals chiefly arise from basket cells which may have high physiological activities, their loss suggests that these cells are most sensitive to trauma and/or ischemia. This notion is consistent with recent data from hypoxic monkeys which had selective degeneration of GABAergic terminals.

206.4 ANALYSIS OF NEURONAL INTERACTIONS IN NORMAL AND EPILEPTOGENIC BARREL CORTEX OF THE RAT. O.M. Sgro and R.N. Harner. Dept. of Neurology, Graduate Hospital, Univ. of Pennsylvania, Philadelphia, PA 19146.

Spontaneous and stimulus-related extracellular units were recorded at 420-1145 μ from the barrel cortex of 10 pentobarbital-anesthetized rats (6 mg/100 g) using a quadruple probe of high impedance (10 Megohms at 1 KHz) tungsten microelectrodes (spaced 50-200 μ apart) before and after the topical application of sodium penicillin (100,000 U/ml) to the cortex. Units were stimulated at rates of 0.5-1.0/sec by contralateral vibrissa displacement using a galvo-pen assembly. Unit activity was stored on FM tape for subsequent write-out and analysis using PDP-11/34 programs for the detection and classification of units and their interactions. Units were heterogeneous with respect to amplitude, duration, spontaneous bursting, relation to surface ECoG activity and stimulus sensitivity. Of the 34 pre-penicillin units investigated, 18 showed post-stimulus latencies of 9.9-27.8 msec with only 9 out of a possible 61 spontaneous or stimulus-induced interactions. After penicillin, 30 of 37 units were stimulus sensitive with post-stimulus latencies of 9.9-40.9 msec. Cross-interval histograms revealed 51 "tight" or "variable" one-way and two-way interactions with peak latencies of 0.5-12.0 msec.

Neuronal interactions recorded from nearby microelectrodes in normal somatosensory cortex were infrequent as was found in auditory cortex (Dickson, J.W. and G.L. Gerstein, J. Neurophysiol., 37:1239-1261, 1974). However, topical application of penicillin to the cortex strikingly increases interactions among nearby neurons. This method of analysis provides a reliable classification of units and their interactions which may prove useful in the further understanding of normal and epileptogenic mechanisms in cerebral cortex.

206.5 AN INVESTIGATION INTO THE MECHANISM OF ANTICONVULSANT INDUCED ELEVATIONS IN ENDOGENOUS γ-HYDROXYBUTYRATE CONCENTRATION IN BRAIN. O. C. Snead, III. Department of Pediatrics, Neuroscience Program, University of Alabama in Birmingham, Birmingham, Alabama.

Ethosuximide (ETX) and sodium valproate (SV) are anticonvulsants used specifically for petit mal epilepsy. Single dose administration of these drugs results in an elevation of brain concentration of γ-hydroxybutyric acid (GHB) a naturally occurring epileptogenic metabolite of γ-aminobutyric acid (GABA) (Snead, Neuropharmacology 19:47, 1980). The object of these experiments was to examine possible mechanisms of these anticonvulsant-induced changes in GHB concentration in rat brain.

SV and ETX were given alone and in combination with the GABA-T inhibitors aminoxyacetic acid (AOAA), γ-vinyl GABA (GVG) and γ-acetylenic GABA (GAB) and whole brain concentrations of GHB determined by electron capture gas liquid chromatography. In addition, the effect of SV, ETX and the enzyme inhibitors on the formation of ^{3} {H} GHB from ^{3} {H} GABA given intercerebro ventricularly (ICV)(Gold and Roth, J. Neurochem. 28:1069, 1977) was determined. Also the effect of ICV GABA, putrescine, and 1,4 Butanediol on endogenous brain concentrations of GHB was examined.

SV and ETX both produced a 60-70% increase in steady state brain levels of GHB. GAG and GVG administration also significantly elevated brain GHB concentration. The GABA-T inhibitors potentiated the anticonvulsant-induced increase in brain concentrations of GHB. The formation of ^{3} {H} GHB from ^{3} {H} GABA was augmented by SV, unchanged by ETX, and depressed by the GABA-T inhibitors. GABA and putrescine both produced significant elevations in brain GHB content but this increase was blocked by the GABA-T inhibitors. The 1,4 Butanediol also produced a significant elevation of GHB concentration. However, this was not blocked by GABA-T inhibitors.

These data suggest that ETX and SV may differ in the way in which they interact with GHB. The experimental results also raise the possibility that there may be a precursor for GHB in brain other than GABA.

206.6 EPILEPTIFORM BURST TERMINATION AND THE AHP IN HIPPOCAMPAL CA1 PYRAMIDAL CELLS. B. E. Alger and R. A. Nicoll, Depts. of Pharmacology and Physiology, UCSF, San Francisco, CA 94143.

Epileptiform bursting can be produced in the hippocampal slice preparation by perfusing slices with GABA antagonists. The burst descharge is followed by a potassium dependent after-hyperpolarization (AHP). We have recently reported that the AHP in hippocampal CA1 cells is substantially reduced by intracellular diffusion of the calcium chelator EGTA, the duration of the AHP being shortened by 60 - 80%, suggesting that the epileptiform burst AHP in CA1 cells is in large part a calcium dependent potassium potential. However two related issues remained unresolved: First, the nature of the early part of the AHP and second, the mechanism of burst termination. We wished to determine if the early part of the AHP is truly resistant to EGTA, i.e., due to another mechanism, or if it is generated at a site remote from the somatic EGTA injection. We have examined the early component of the AHP using bevelled electrodes containing 3 M KCl and 0.2M EGTA. We have confirmed our original report that the AHP is drastically shortened when EGTA diffuses into the cells over a period of 10 - 20 minutes. However in a number of cells the early phase is abolished, presumably due to the infusion of larger quantities of EGTA with these electrodes. This suggests that in these cells a remote calcium-dependent potassium potential contributes to the early phase of the AHP. Nevertheless, even in cells in which EGTA blocked the AHP, the duration of the depolarizing burst was not prolonged. Another mechanism might therefore be responsible for burst termination. Thus in 7 cells once the full effect of EGTA had been obtained we switched to a perfusion containing 2.5 - 5 mM tetraethylammonium (TEA). TEA reversibly prolonged the burst and no trace of the AHP remained. As reported by Schwartzkroin and Prince (Brain Res. 185:169, 1980), we find that TEA application to cells recorded without EGTA in the electrode increases the duration of the burst depolarization but does not affect the late portion of the postburst AHP.

We conclude that while the major part of the AHP is a calcium dependent potassium potential, the evidence suggests that potassium potentials play two roles following the epileptiform burst: 1) a TEA sensitive potential acts primarily to limit burst duration and 2) a late, calcium dependent potassium potential, while possibly contributing to burst termination acts primarily to limit the frequency of bursting.

206.7 MECHANISMS OF DEPOLARIZATION SHIFT GENERATION IN THE PENICILLIN-TREATED NEOCORTICAL SLICE. M.J. Gutnick*, B.W. Connors and D.A. Prince. (SPON: R.W. Angel)Stanford Med. Sch., Stanford,CA 94305.

The cellular manifestations of interictal epileptogenesis are synchronous, large amplitude, prolonged depolarization shifts (DSs) in neurons of the epileptic aggregate. To investigate these potentials further, we obtained intracellular recordings from coronal slices (350-500 μm) of guinea pig sensory-motor cortex maintained in vitro (37°C). Penicillin (3.4 mM) increased the amplitude and duration of postsynaptic potentials (PSPs) evoked by focal stimulation of the cortical surface or underlying white matter. Spontaneous DSs were never seen; however, stimuli evoked DSs which were very similar to those recorded in vivo. Large amplitude (20-50 mV) long duration (50-300 msec) DSs usually triggered short trains of fast spikes and were followed by a long (up to 2 sec) afterdepolarization associated with a large conductance increase. DSs occurred in an all-or-none manner, and by adjusting stimulus parameters alternation of DS generation and failure could be obtained. In these instances each stimulus generated a PSP of invariant latency. The intervals between PSPs and subsequent DSs fluctuated widely and were as long as 100 msec. Simultaneous recordings from pairs of neurons up to 1000 μm apart (n = 15) showed a remarkable synchrony of DS generations, failures and latency shifts. Paired neuronal and glial recordings suggested that large (2-3 mM) slowly decaying (1-2 sec) increases in $[K^+]_o$ occurred simultaneous with DS generation. The data indicated that DSs occurred synchronously in a radially-oriented column of neurons. Intracellular current injections did not alter DS latency or probability of occurrence. When voltage dependent Na^+ conductances were blocked with intracellular QX-314, changes in DS amplitude during intracellular current injection indicated a very high peak conductance and an extrapolated reversal potential of about -10mV. Following Cs^+ injection neurons could be depolarized above 0 mV, and stimuli then evoked short latency inverted PSPs followed by paroxysmal hyperpolarizing potentials with a latency and frequency of occurrence identical to those of DSs evoked at rest. Our data indicate that synaptic currents play a major role in DS generation in neocortical neurons. These and other data from normal neocortex (Connors, Gutnick & Prince, this vol.) lead us to suggest that a small, interconnected subpopulation of neurons with intrinsic bursting capabilities, located in the middle cortical layers, serves as the pacemaker for DS generation. Convulsant-induced disinhibition may allow these endogenous bursters to activate synchronously and favor the spread of ramifying, recurrent excitatory drives to deeper and more superficial neurons.

206.8 PHENYTOIN EFFECTS ON ACTION POTENTIALS OF FETAL MOUSE SPINAL CORD NEURONS IN CELL CULTURE. M.J. McLean* and R.L. Macdonald, Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109

Effects of phenytoin (DILANTIN,DPH) on action potentials and strychnine-induced paroxysmal activity were investigated using mouse spinal cord (SC) and dorsal root ganglion (DRG) neurons in primary dissociated cell culture. Cell were mechanically dissociated from fetal (12-13.5 days gestation) tissue and cultured for 1-3 months prior to electrophysiological study. Experiments were performed in phosphate-buffered balanced salt solutions (PBS). Intracellular recordings were made using 4M KAC containing glass micropipettes.

Recording from SC neurons bathed in 1 mM $MgCl_2$-containing PBS revealed spontaneous synaptic activity and variable rates of action potential bursting. Large paroxysmal discharges (PDE) were recorded from most cells after exposure to strychnine (10^{-6}M). DPH abolished PDE and reduced spontaneous activity to quiescence in a dose and time dependent manner starting from 2.5 μg/ml (~10 μM) at 90 min. Higher doses produced maximal effect earlier and prior to reduction of maximal rates of rise of action potentials ($\dot{V}_{max}$). Action potentials could be elicited from quiescent cells by intracellular current pulses, but repetitive firing was limited. Preincubation with DPH prevented strychnine-induced PDE.

To investigate the mechanism of these effects, we tested DPH in clinically relevant anticonvulsant concentrations on action potentials recorded in 10 mM $MgCl_2$-containing PBS to reduce spontaneous activity. $\dot{V}_{max}$ of both SC and DRG neurons was ~215 V/sec. DPH reduced this value for both cell types to ~100 V/sec in a dose and time dependent manner with maximal reduction at about 90 min and concentrations ranging from 2.5-40 μg/ml (~10-160 μM). Hyperpolarization by intracellular current pulses (using a bridge circuit or two microelectrodes) increased $\dot{V}_{max}$ to about initial levels. Long depolarizing pulses in SC neurons produced trains of action potentials sustained for the duration of the pulse (up to 500 msec). DRG neurons were not observed to fire repetitively unless injured. DPH reduced repetitive firing to only a few action potentials which decreased in rate of rise and amplitude without changes in resting membrane potential. Limitation of repetitive firing occurred prior to the reduction of $\dot{V}_{max}$. These changes may be due to accumulation of voltage-sensitive sodium channels in the inactivated state.

206.9 ELECTROPHYSIOLOGICAL AND BIOCHEMICAL CORRELATES OF FELINE GENERALIZED PENICILLIN EPILEPSY. Y.S. Siatitsas*, N.M. van Gelder and C. Menini* (SPON: Y. Lamarre). Montreal Neurological Institute and Université de Montréal, Quebec, Canada.

One or more of the following amino acid anomalies are associated with seizure prone nervous tissue: (1) a diminution of nervous tissue glutamic acid; (2) an exaggerated increase of glutamic acid in the biofluids or cortical superfusates; and (3) Some evidence exists that in association with the development of epilepsy, a disturbance occurs in the regulation of taurine and glutamic acid levels which normally are balanced relative to each other in nervous tissue. However no attempt has been made to test whether such metabolic changes may also accompany feline generalized penicillin epilepsy. If metabolic changes of this type are to be considered as close correlates of an epileptic condition, they must be demonstrated to precede the electrographic manifestation of the epilepsy. To test this hypothesis a sensitive method is needed to predict in terms of a physiologic parameter the onset of seizures and to correlate this with the onset of metabolic changes thought to lead eventually to seizures. Recent studies have demonstrated (35th Ann. Meet. Am. EEG Soc., Chicago, 1981) that an increase in the amplitude of the visual evoked potentials can predict with a 10 min accuracy the first electrographic appearance of epileptic discharges induced by systemic penicillin in the cat. This made it possible to biochemically sample cortical areas from the same animal before, at onset and after development of epilepsy. It was found that both glutamic acid and aspartic acid levels consistently diminished before the electrographic occurrence of epilepsy. After the development of epilepsy nervous tissue levels of these amino acids were further decreased, this now also being accompanied by a decrease in tissue taurine content and an increase in GABA. These findings, as well as the observation that a strong imbalance between tissue content of taurine and glutamate precedes the electrographic manifestations of epilepsy, suggest once more an involvement of glutamic acid in the epileptic process. Moreover, the temporal coincidence of changes in glutamic acid and the first increase of the visual evoked potentials seems to support a suggestion of a "cause and consequence" relationship.

206.10 TAURINE, GLUTAMATE AND EPILEPSY. Douglas W. Bonhaus*, Hugh E. Laird and Ryan J. Huxtable*. Dept. of Pharmacology, College of Medicine and Department of Pharmacology and Toxicology, College of Pharmacy, University of Arizona, Tucson, AZ 85721.

Taurine (2 amino ethane sulfonic acid) is a neuroinhibitory amino acid which may be a physiological modulator of neuronal excitability. Van Gelder has found correlations between the concentrations of taurine and glutamate in the brain and has proposed that taurine effects its neuroinhibitory action by altering the metabolism of glutamate. However, no biochemical relationship between taurine and glutamate has been established. We have found correlations in the concentrations of a variety of amino acid pairs in the brain (see Table), including those which are apparently not metabolically related. For example, the correlation coefficient between concentrations of taurine and glycine in rat brain cortex was 0.78, for the taurine-glutamate pair the correlation coefficient was 0.69. These correlations between concentrations of metabolically unrelated amino acids suggest that the relationship between taurine and glutamate may be due to the sharing of the same kinetic compartment. Thus, an increase in a kinetic compartment shared by glutamate and taurine would result in increased concentrations of both of these neuroactive amino acids. In the epileptic rat differences in amino acid correlations are found in brain regions having low electroshock threshold, such as the inferior colliculi, as compared to brain areas having higher electroshock threshold such as cortex. If these differences in correlations represent differences in compartmentalization of amino acids, then the proper compartmentalization of neuroactive amino acids such as taurine and glutamate may be important in the modulation of neuronal activity. The epileptic rat has a defect in taurine transport. In vitro synaptosomal uptake is decreased 50% and in vivo uptake of taurine into certain brain areas is decreased as much as 70%. Since some human epileptics have a defect in taurine transport and because the only biochemical difference that we have found between epileptic rats and normal rats is a difference in taurine uptake, we are currently investigating whether this defect is responsible for the seizure susceptibility of epileptic rats.
(Supported by USPHS grants NS 14405 and HL 13994)

AMINO ACID CORRELATIONS

Amino Acid Pairs	C.Coef	Amino Acid Pairs	C.Coef.
Taurine-Glutamate	0.69	Serine-Alanine	0.62
Alanine-GABA	0.85	Serine-GABA	0.60
PEA-Glutamate	0.66	Serine-Glycine	0.61
Threonine-glycine	0.69	Aspartate-Taurine	0.67

206.11 ISONIAZID INDUCED SEIZURES AND REGIONAL CEREBRAL ENERGY METABOLISM. D.W. McCandless*, M.S. Abel*, and F.C. Schwartzenburg, Jr.* (Spon: J. DeFrance). Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School at Houston, Houston, Texas 77030.

Isoniazid is a useful chemical convulsant in that it produces a reproducible seizure pattern, and unlike maximal electroshock, the preseizure state can be examined. In the present study, we have induced seizures in mice using isoniazid and examined energy metabolism in highly discrete brain regions. 20-22 gram female Swiss-Albino mice were injected IP with 200mg/kg isoniazid, and sacrificed 25 minutes after injection (preseizure), or at the onset of seizures (40 minutes). The brains were removed at -20°, and cerebral cortex and cerebellum were sectioned into 20 micron thick sections, and freeze-dried overnight at -40°. Subsequently the sections were brought to room temperature under vacuum and freehand dissected into layer I and pyramidal layer from the cerebral cortex, and molecular and Purkinje cell rich layers from the cerebellum. Using enzymatic cycling, selected energy metabolites were measured directly in these 4 discrete brain regions in controls, and preseizure and seizing isoniazid injected mice. Results from this study showed a decrease in ATP in the pyramidal layer of preseizing animals. ATP in the remaining areas was not decreased as compared to controls. Phosphoncreatine in preseizing mice was decreased in both cortical layers, but not in the cerebellum. In seizing mice, both ATP and phosphocreatine were decreased in all layers examined, but the percent decrease in metabolites was greatest in the cortex. Within the cortex, the greatest decrease in ATP and phosphocreatine occured in the pyramidal cell region. These data indicate that the cortex and cerebellum respond differently to isoniazid induced seizures, and may reflect the role of each in seizure production.

206.12 COLCHICINE INDUCED SEIZURES: MICROTUBULES AND EPILEPSY. J.C. Oakley*, S.R. Hameroff, and A.F. Reynolds, Div. of Neurol. Surgery and Dept. of Anesthesiology, Univ. of Arizona, Tucson AZ, 85724

We have initially tested the hypothesis that effects upon intraneuronal microtubules (MT), calmodulin, or associated proteins may produce epileptiform activity in rat cerebral cortex. Concentrations of colchicine 10^{-3}M and greater placed in a solution of 1-1.5% agar were applied to the pial surface of sensorimotor cortex in awake, locally anesthetized, paralyzed 0.2-0.4 kg rats. Electrical activity was characterized by epidural recording from four stainless steel screw electrodes located around the site of colchicine application and two in the homotopic contralateral hemisphere. The focal discharges were additionally characterized by extracellular single unit recordings in the region of the focus, which revealed typical burst discharges. Concentrations of colchicine 10^{-2} in agar or less required an incubation time of at least 2 hours to produce epileptiform activity. As concentrations were increased, the time to produce electrographic spiking decreased where a 10^{-1}M solution in agar generated activity within 1 minute. Agar alone, or vinblastine in agar did not cause seizures. Colchicine induced seizures were also observed in rats treated with neostigmine, a cholinesterase inhibitor.

Convulsant preparations attempting to model focal human epilepsy include topical convulsant metals, drugs, antimetabolites, freeze lesions, and electrical stimulation. To date no single mechanism unifies all models, however data from topical penicillin and alumina cream preparations suggest rises in intra-neuronal Ca^{2+} may mediate epileptic effects (Wyler & Schwartzkroin, Annals of Neurology 7:95, 1980). Colchicine inhibits MT polymerization and functions including axoplasmic transport and causes disassembly of MT-calmodulin arrays (Means & Dedman, Nature 285:73, 1980). Calmodulin mediates Ca^{2+} effects on MT and other organelles and regulates intracellular Ca^{2+} by membrane, MT, and Ca^{2+} binding effects. Some seizure causing metals (Al^{3+}, Co^{2+}, Fe^{3+}, Fe^{2+}, Hg^{2+}, tungstate) bind to MT, displace Ca^{2+}, and may cause MT dysfunction and depolymerization (Purpura et al, Exp. Models of Epilepsy, Raven Press, 1972; Reid & Sypert, Brain Res 188:531, 1980; Bonhaus et al, Toxical Letts 6:141, 1980). Anticonvulsant diphenylhydantoins and some barbiturates are known to bind to MT associated proteins and prevent colchicine induced disassembly (MacKinney, et al, J Pharm Exp Ther 204:189, 1978; Edstrom et al, Cell Tiss Res 162:35, 1975). Colchicine induced seizures could be mediated by alterations in MT trophic regulation of membrane proteins, or increased intra-neuronal calcium ion concentration caused by membrane protein effects or disassembly and release of MT-calmodulin bound Ca^{2+}.

207.1 THE A5 CATECHOLAMINE CELL GROUP: AN ELECTRICAL AND CHEMICAL STIMULATION STUDY. J.J. Neil and A.D. Loewy, Dept. Anat. & Neurobiol., Washington Univ. School of Medicine, St. Louis, MO 63110

The A5 catecholamine cell group projects to the intermediolateral cell column and to medullary sites (Brain Research, 174: 309 [1979]). Electrical stimulation of the A5 region elicits a rapid rise in blood pressure with no change in heart rate. However, electrical stimulation excites axons of passage as well as cell bodies. To activate the A5 cells more selectively, we have stimulated with monosodium-L-glutamate (L-glu).

The L-glu was mixed in artificial CSF (containing procion yellow to mark the injection sites) and pressure injected from a double-barrelled pipet with a tip 60-90 μ m across. One barrel, filled with agar/KCl, was used for electrical stimulation. In midbrain-hemisected rats anesthetized with Nembutal, electrical stimulation of the A5 region (10 μ A, 60 Hz, 0.5 ms pulses, 5s trains) consistently elicited a pressor response with no change in heart rate, as before. However, application of L-glu in 30 nl volumes led to a dose-related decrease in blood pressure and heart rate. The threshold for the depressor response was about 10 mM L-glu, and a maximal depressor response of 30 mm Hg was elicited at 500 mM. Similar L-glu concentrations were necessary to activate the motoneurons of the rat facial nucleus. The fibers of the seventh nerve, passing quite close to the area of injection, were not activated by the L-glu. Injections of 1.0 M NaCl in procion yellow or procion yellow alone had no effect on heart rate or blood pressure.

To determine if either the pressor or depressor response involved catecholamines, these experiments were repeated in midbrain-hemisected animals whose catecholaminergic neurons were destroyed with intraventricular 6-hydroxydopamine. While the pressor response to electrical stimulation was still present in these animals, the bradycardia and depressor response to L-glu were abolished.

These results suggest that activation of cells of the A5 region leads to a decrease in blood pressure and heart rate. (Supported by USPHS grant HL-25449 and GM 07200 and a grant-in-aid # 80-723 from the American Heart Association)

207.2 HYPOTENSION AND BRADYCARDIA AFTER STIMULATION OF THE RABBIT BRAINSTEM REGION CONTAINING THE A1 CATECHOLAMINE NEURONS: A NEW CNS VASODEPRESSOR AREA. W.W. Blessing and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Lesions of the ventrolateral medulla at the level of the area postrema cause hypertension and pulmonary edema in rabbits (Blessing et al., Circ. Res. in press 1981). Since the region contains A1 catecholamine cells it is possible that these neurons may inhibit sympathetic vasomotor activity. In the present study we tested this hypothesis by determining whether stimulation of the A1 region would cause a fall in mean arterial pressure (MAP).

In rabbits anesthetized with urethane, paralyzed with curare and artificially ventilated, the ventrolateral medulla at the level of the area postrema was stimulated with 10 sec trains of cathodal pulses (0.1 ms, 75 μA, 10 and 50 Hz). MAP and heart rate (HR) were recorded from a femoral catheter. Stimulation restricted to a region 3 mm lateral to the midline and 3 mm ventral to the dorsal surface of the medulla caused falls in MAP and HR The fall in MAP was maximal at 10 - 25 Hz; a pressor response was obtained at higher frequencies.

Threshold was 10 uA and MAP fall (25Hz,75uA) was 22 ± 4 mm Hg, with a fall in HR of 23 ± 6 bpm. Bradycardia but not hypotension was abolished by methylscopolamine (50 ug/kg i.v.) and propranolol (0.5 mg/kg i.v.). Catecholamine histofluorescence procedures demonstrated that the area from which the hypotension could be elicited coincided with the region containing the A1 catecholamine neurons.

Microinjection of L-glutamate (0.25 uL over 3 sec) bilaterally into the A1 region elicited a dose dependent fall in MAP and bradycardia. Injection of saline vehicle did not cause the same response. Threshold dose was 0.01 nmol; with 10 nmol MAP fell 35 ± 2 mmHg and HR fell 34 ± 12 bpm. L-glu injected into regions dorsal to the A1 area failed to elicit the response.

Since L-glutamate excites cell bodies rather than fibers of passage it is likely that electrical stimulation produced similar cardiovascular responses by a similar mechanism. We conclude that the ventrolateral medulla at the level of the area postrema contains neurons whose excitation results in a fall in blood pressure. These findings are consistent with the hypothesis that A1 catecholamine neurons function as a vasodepressor system.

207.3 CARDIOVASCULAR RESPONSES FOLLOWING 6-HYDROXYDOPAMINE LESIONS OF THE NORADRENERGIC A2 CELL GROUP. Healy, D.P.*, J.Y. Jew and A.C. Black, Jr. Dept. of Anatomy, University of Iowa, Iowa City, Iowa 52242

The noradrenergic A2 cell group, located wtihin the nucleus tractus solitarius (NTS) commissuralis, has been implicated in central cardiovascular (CV) control. We sought to investigate whether destruction of the A2 neurons using direct intraparenchymal injections of the neurotoxin 6-hydroxydopamine (6-OHDA) altered cardiovascular responses in normotensive animals. Although the adrenergic C2 cell group is located rostral to the A2 cell group and has also been implicated in CV control, C2 neurons should be unaffected since epinephrine-containing neurons are supposedly resistant to 6-OHDA. 4 μg/μl of 6-OHDA was injected bilaterally into the A2 area of the rat using a glass micropipette. Control animals received the same volume of the vehicle. Following these injections, measurements of heart rate, mean arterial pressure (MAP), MAP lability and baroreceptor reflexes were carried out in unanesthetized unrestrained animals for one week. The extent of the lesions was evaluated using fluorescence histochemistry and biochemical determinations of catecholamine content of tissue punched from NTS slices. It was noted that: 1. 6-OHDA lesioned animals displayed a significant bradycardia which lasted throughout the 7 day period. The bradycardia was reversed by i.v. atropine. 2. There were no differences in MAP or MAP lability between control and 6-OHDA treated animals. 3. The gain of the baroreflex was decreased after 6-OHDA (control 1.36±.11, 6-OHDA 0.77±.06 mmHg/msec.). 4. Catecholamine histofluorescent preparations from 6-OHDA animals revealed a marked reduction in fluorescent varicosities throughout the NTS. 5. Norepinephrine levels were decreased throughout the NTS of 6-OHDA animals. 6. After 6-OHDA treatment, there was a persistence of fluorescent varicosities which were derived presumably from the epinephrine-containing C2 cell group. NTS epinephrine levels were similar to those in controls. Knife cuts made rostral to the C2 cell group eliminated fluorescent terminals rostral to the knife cut, providing evidence that these terminals arise from the C2 cell group. Therefore, the adrenergic C2 cell group appears to be resistant to 6-OHDA, but the role of this cell group in NTS function still requires clarification. The results of our experiments indicate that the noradrenergic A2 cell group is involved in modulation of central vagal activity. (This work was supported by N.I.H. grants HL21914 and NS11650.)

207.4 ALTERED CARDIOVASCULAR CONTROL FOLLOWING SPECIFIC BRAINSTEM LESIONS IN THE RABBIT

M.J. West*, W.W. Blessing*, J.P. Chalmers* (SPON: P.R. Wilson)
Department of Medicine, Flinders University Medical Centre, Adelaide, South Australia, 5042.

There are two groups of norepinephrine neurons in the medulla - the A1 group in the ventrolateral medulla and the A2 group in the nucleus tractus solitarius. Lesions of the A2 neurons produce transient hypertension, bradycardia and loss of baroreflexes, but the cardiovascular functions of the A1 neurons have not been previously studied. We have investigated haemodynamic parameters in the conscious rabbit following bilateral electrolytic lesions 1 mm in diameter at 3 contiguous rostrocaudal levels in the ventrolateral medulla coinciding with the A1 group of norepinephrine neurons. Arterial blood pressure, heart rate and distal aortic blood flow were measured for 2 weeks following the lesions. Baroreflex function was determined from changes in heart rate and distal aortic blood flow induced by graded alterations in central arterial pressure produced by inflation of vascular occluders around the aorta and inferior vena cava. Nasopharyngeal reflex function was determined from changes in heart rate and distal aortic blood flow following activation of this reflex with saturated formaldehyde vapour.

After lesioning there was an initial rise in mean arterial pressure of 40 mm Hg in the conscious animal, associated with an increased distal aortic vascular resistance and profound bradycardia. Distal aortic vascular resistance remained elevated throughout the 2 week observation period but the blood pressure and heart rate returned to normal levels. The gain of the baroreceptor-heart rate reflex was initially diminished by 40% but returned to normal at 2 weeks. The gain of the mean arterial pressure - distal aortic flow relationship, was reduced by 50% throughout the 2 week observation period, indicating severe attenuation of baroreceptor ability to induce vasoconstriction in the distal aortic vascular bed. Bradycardia and vasoconstriction normally observed with activation of the nasopharyngeal reflex were less marked after lesioning but the changes were transient.

The results suggest that A1 norepinephrine neurons modify heart rate effects elicited through baroreceptor and nasopharyngeal reflexes, but that while they play a major role in baroreceptor mediated vasoconstriction by inhibition of sympathetic vasoconstrictor tone, they have little influence on constriction mediated through the nasopharyngeal reflex.

207.5 HYPERTENSIVE EFFECTS OF CEREBELLAR NUCLEUS FASTIGIUS LESIONS AND SINO-AORTIC DENERVATION IN THE RAT. C. K. Haun*, M. DeCuir* and N. Alexander. Depts. of Anatomy and Medicine, Univ. of So. Calif. Sch. of Med., Los Angeles, CA 90033.

Hypertension produced in rats by sino-aortic denervation (SAD) is characterized by frequent pressure "dips" which are usually associated with head or body movements (Eur. J. Pharmacol., 63, 117, 1980). As source of these dips our attention was attracted to the Nucleus Fastigius (NF) through recognition of this site's modulatory involvement in 1) equilibrium-related adjustments of posture and movement, and 2) vasomotor reflexes (Brain Res. 13, 595, 1969).

In adult male rats under methohexital, bilateral stereotaxic lesions of the NF made with radio frequency current, were followed a week later by bilateral SAD and aortic canulation, under Innovar anesthesia. Controls received sham lesions (no current), or SAD first and then were lesioned and canulated a week later. Arterial pressure was recorded via strain gauge and inkwriter throughout the day of canulation, and periodically, on the following 2 to 3 days. The rats were then autopsied. Their brains were fixed, serially sectioned and examined for lesion localization.

Animals with verified NF lesions were found to have elevated arterial pressures exceeding those of shams and animals in which SAD preceded lesioning; and they also showed typical signs of congestive heart failure (which was a frequent cause of death) -- dilated heart and great veins, edematous and/or hemorrhagic lungs, and engorged liver. The characteristic pressure dips of SAD rats were dramatically reduced or absent. Controls' pressure recordings were typical of SAD rats; their viscera showed no signs of heart failure. That portion of the NF responsible for the hypertensive changes when followed by SAD seems to be at or near the rostral pole of the NF, a region in which electric stimulation causes acute elevations of arterial pressure (Brain Res., Ibid).

207.6 NEURAL AND HUMORAL COMPONENTS OF THE PRESSOR RESPONSE ELICITED BY ELECTRICAL STIMULATION OF FASTIGIAL NUCLEUS (FN) IN RATS BEFORE AND AFTER SYMPATHECTOMY. A. Del Bo*, C. Ross, J. Pardal*, J. Saavedra, and D.J. Reis (SPON: M. Kumada). Lab of Neurobiology, Cornell Univ. Med. Coll. New York, NY 10021 and NIMH, Bethesda, MD 20014.

We sought to determine whether; (a) electrical stimulation of the FN in rat will elevate circulating catecholamines (CA); (b) the increase is selective for norepinephrine (NE), epinephrine (E), or dopamine (DA); (c) CAs released from adrenal medulla contribute to the pressor response elicited by FN stimulation after chemical sympathectomy. Rats were anesthetized (chloralose 60 mg/kg i.v.), paralyzed and ventilated. The cerebellum was explored with 10 sec pulse trains. Stimulation of rostral FN increased mean arterial pressure (MAP) and heart rate (HR), the fastigial pressor response (FPR). The threshold current was 18 $\pm$ 2uA and the response graded. At optimal frequencies (50-100 Hz) at 5 x threshold FN stimulation increased MAP 62 $\pm$ 3 mmHg and HR 79 $\pm$ 11 bpm (n=20). The latency was < 2 sec. The FPR was stimulus-locked. A prolonged FN stimulation (30 sec) increased serum NE from 199 $\pm$ 12 to 309 $\pm$ 49 pg/ml (n=9, $P<0.05$), and E from 108 $\pm$ 20 to 230 $\pm$ 77 pg/ml (n=9, $p<0.05$), but not DA (97 $\pm$ 16 to 102 $\pm$ 16 pg/ml, n=9, n.s.). The magnitude and the characteristics of the FPR were not modified by adrenalectomy (n=9), nor by midcollicular decerebration (n=6). Administration of 6-hydroxydopamine (6 OHDA, 100 mg/kg i.v.) 24 h prior to testing effectively destroyed sypathetic terminals abolishing the pressor responses to tyramine (up to 400 ug/kg) and shifted the pressor/dose response curves of NE and E to the left. After chemosympathectomy: the FPR was enhanced (70 + 2 mmHg, n=26), had a longer latency (6 $\pm$ 1sec), persisted longer (up to 4 min), and its tachycardia was replaced by vagal bradycardia (-122 $\pm$ 11bpm). The stimulus-intensity/frequency characteristics of the response were unchanged. Adrenalectomy only partially reduced the FPR after chemosympathectomy (41 $\pm$ 3 vs 70 $\pm$ 3 mmHg, n=11, $p<0.001$). The residual pressor response was not affected by phentolamine (3 mg i.v., n=10), but completely abolished by midbrain transection (n=5). We conclude: (a) In rats with intact sympathetic nerves the FPR is mediated via pathways descending below the midbrain and is associated with increase in serum NE and E; adrenal CA's do not contribute to the magnitude of the FPR. (b) In the absence of sympathetic nerves, CAs of adrenal medullary origin released by FN stimulation only partially contribute to the hypertension. (c) A circulating pressor factor released by FN stimulation from areas above midbrain may significantly elevate MAP in the absence of sympathetic nerves and adrenal medulla. (NIH grant HL 18974)

207.7 CEREBROVASODILATATION ELICITED BY ELECTRICAL STIMULATION OF DORSAL MEDULLARY PRESSOR AREA IN RAT. C. Iadecola*, M. Nakai*, E. Arbit*, and D.J. Reis. Lab of Neurobiology, Cornell Univ. Med. Coll. New York, NY 10021.

The aim of the present study is to establish whether in rat electrical stimulation of vasopressor areas in the dosal medullary reticular formation (DMRF) will modify regional cerebral blood flow (CBF). Adult male Sprague-Dawley rats were anesthetized with chloralose, paralyzed and artificially ventilated. Arterial pressure, heart rate and body temperature were continuously monitored; pCO_2, pO_2 and pH were maintained within physiological range. The left DMRF was stimulated electrically with a 10 min (1 sec on/1 sec off) train at 50 Hz at approximately five times threshold for the pressor response (30-70uA). The elevation of AP produced by DMRF stimulation was maintained in the autoregulatory range by controlled hemorrhage. Regional CBF was measured using C-14-iodoantipyrine as indicator, with regional dissection of the brain.

Electrical stimulation of DMRF increased CBF significantly bilaterally in 12 of the 13 regions studied. The average increase was 183 $\pm$ 9% (n-6; $p<0.005$) of controls, the greatest value being in parietal cortex (240%) and the least in the pons (147%). Besides the cerebral cortex, increases> 180% were found in the thalamus (205%), hippocampus (180%), hypothalamus (180%), and subcortical white matter (205%). In the cerebellum flow did not change. After unilateral cervical sympathectomy, the increase CBF in cerebral cortex, caudate nucleus, and hypothalamus, was significantly greater in the denervated than intact side ($p<.01$- .05, paired t-test).

We conclude that in the rat: (a) electrical stimulation of the DMRF increases CBF globally; (b) after acute sympathectomy, the increase in CBF is greater in those regions that receive a strong vascular sympathetic innervation; (c) neurons within or projecting through DMRF mediate a potent cerebral vasodilation, probably via intrinsic pathways in brain, and which is opposed partially by sympathetic neurons contained in superior cervical ganglion.

(Supported by NIH grant HL 18974 and NS 03346.)

207.8 NEUROGENIC HYPERTENSION PRODUCED BY LESIONS OF THE NUCLEUS TRACTUS SOLITARII ALONE OR WITH SINOAORTIC DENERVATION IN THE CONSCIOUS DOG. Karen L. Barnes and Carlos M. Ferrario. Research Division, Cleveland Clinic Foundation, Cleveland, OH.

Although destruction of the nucleus tractus solitarii (NTS) in the rat produces fulminant hypertension, in other species central baroreceptor deafferentation has produced equivocal results. Increased lability of pressure without hypertension has been observed in the cat, while parallel studies of lability and hypertension have not yet been performed in the dog. A number of factors might explain these conflicting findings. One possibility is the recent evidence which suggests that the distribution within the brainstem of baroreceptor fibers includes the area postrema, nucleus ambiguus, and ventral reticular formation as well as the NTS, making selective and complete denervation difficult. With this in mind, we produced restrictive vs. extensive bilateral lesions of the NTS in dogs. During the 5 weeks following NTS lesions the degree of hypertension and the change in the variability of both mean arterial pressure (MAP) and heart rate (HR) were related to both position and size of the lesions within the NTS and surrounding brainstem. Lesions restricted to the medial NTS and solitary tracts between the obex and 1 mm anterior caused transient hypertension and tachycardia for 1 to 3 days; thereafter both MAP and HR returned to normal. In contrast, dogs with more extensive lesions of the NTS reaching at least 3 mm anterior to obex had mild hypertension for at least 15 days, increased lability of MAP, moderate tachycardia, and decreased variability of HR. Subsequently both MAP and its variability reverted toward normal, but tachycardia and decreased variability of HR persisted. Peripheral sinocervical aortic denervation in dogs with mild hypertension 28 to 42 days after NTS lesion yielded surprising results; severe hypertension and marked tachycardia in these dogs were followed by death from heart failure within 6 hours.

The mild hypertension, not necessarily sustained, following bilateral NTS lesions suggests that this procedure only partially interrupts central baroreceptor pathways. On the other hand, the development of fulminant hypertension following combined central and peripheral baroreceptor deafferentation reveals the importance of baroreceptor input for maintenance of normal blood pressure.

207.9 THE ROLE OF THE ANTEROMEDIAL HYPOTHALAMUS IN DAHL HYPERTENSION. P. Ernsberger*, S. Azar*, and D.C. U'Prichard (SPON: W.D. Mink). Neuroscience Program and Dept. of Pharmacology Northwestern Univ. Chicago, IL 60611 and Dept. of Medicine, Univ. of Minnesota, Minneapolis, MN 55455

Anatomical and biochemical studies suggest that the paraventricular (PVN), periventricular (PVE), and suprachiasmatic (SCN) nuclei may participate in blood pressure (BP) regulation. Various radiofrequency lesions were placed in these structures in Dahl rats. The salt-sensitive (S) rat develops hypertension when given an 8% NaCl diet (high salt, HS), while the salt-resistant (R) rat remains normotensive. R and S rats were maintained from weaning on 0.3% NaCl chow, and put on HS 3 weeks postoperatively. BP was measured weekly through 14 weeks of HS and around the clock at 3 points. S rats with PVN-SCN lesions showed no change in BP with HS, with mean BP ranging from a maximum of 142±16 (week 5 of HS) to a minimum of 120±6 (week 13 of HS), values similar to those of R rats. In contrast, the BP of sham-operated S rats rose from 124±4 initially to 199±5 by 6 weeks of HS. In R rats with identical lesions, a transient increase in BP with HS was observed (lesion: 147±4, sham: 118±6, at 5 weeks of HS), which disappeared by 6 weeks of HS. The common extent of the lesions preventing hypertension in the S rats included the PVN, the SCN, and the PVE lying between them. The combined extent of the ineffective lesions included areas between the anterior optic chiasm and the ventral surface of the anterior commissure rostrally, and the SCN and adjacent PVE caudally. In no case was the PVN or the PVE ventral to it damaged. These lesions had no effect on BP in either R or S rats. Lesions of the PVN alone in S rats delayed the rise in BP with HS by several weeks. Lesions of the SCN alone had little effect on BP in either R or S rats. Plasma Na at time of sacrifice was unchanged after PVN-SCN lesions in S (lesion: 143±1, sham: 144±1 mEq/l) and R rats (lesion: 142±1, sham: 142±1). Similar results were observed with tail blood samples taken at two other times. At 11 and 12 weeks of HS, all rats were given injections of angiotensin (0.37 mg/kg, s.c.), and water intake was determined for 1 hour. PVN-SCN lesions had no effect on angiotensin-induced drinking in S (lesion: 8±2, sham: 12±2) and R rats (lesion: 9±2, sham: 13±2). PVN-SCN lesions prevented the renal hypertrophy which occurrs in S rats on HS (lesion: 6.8±.2, sham: 10.0±.4, renal mass/body weight, g/kg), while not affecting R rats (lesion: 8.7±.6, sham: 8.4±.3). The BP effects of these lesions are not due to alterations in circadian rhythms, since their hypotensive effect persists when BP is measured around the clock. The PVN and adjacent portions of the PVE may play a role in the initiation and development of Dahl hypertension.

207.10 ELEVATED SYMPATHETIC TONE IN NEONATAL SHR. D.C. Tucker and A.K. Johnson, Dept. of Psychology and Cardiovascular Center, University of Iowa, Iowa City, Iowa 52242.

Juvenile spontaneously hypertensive rats (SHR) have higher basal heart rates (HR) than Wistar Kyotos (WKY). In weanling SHR, both elevated sympathetic and depressed parasympathetic tone are observed (Hallback, in Onesti, Regulation of Blood Pressure by the CNS, 1976). The purpose of our present studies was to examine developmental changes in HR and to define the factors controlling this parameter in neonates of the SHR and WKY strains.

Rat pups were implanted with subcutaneous silver wire electrodes one day prior to testing. Recordings of EKG were made at 4, 8, 12, and 16 days of age from unanesthetized, unrestrained pups in their home cages. Pups from 8 WKY and 8 SHR litters were tested at each age. Injections of atenolol (1.0 mg/kg) and methylatropine (0.01 mg/kg) were made to determine the contribution of autonomic controls of HR. Both drug and saline control injections were standardized to a volume of 1 ml/kg.

While sympathetic influences were essentially equivalent in SHR and WKY at 4 and 8 days of age, by 12 days evidence of significantly elevated sympathetic tone in SHR was observed. Specifically, within 10 minutes after atenolol injection, the HR of 12-day old SHR decreased by 133±17 bpm (to 289 bpm); in 12-day old WKY, β-blockade resulted in a HR decrease of 70±12 bpm (to 292 bpm). Tonic parasympathetic control over heart rate was not observed prior to 16 days of age. In 16-day old pups, a methylatropine injection was followed by a HR increase of 55±8 bpm (to 460 bpm) in SHR and an increase of 70±11 bpm (to 451 bpm) in WKY. A combined muscarinic and β-adrenergic blockade was used to determine intrinsic HR. Similar developmental increases in intrinsic HR were seen in SHR and WKY pups.

The elevated heart rate seen in SHR during the second postnatal week seems thus to reflect high sympathetic tone rather than differences in parasympathetic influence or intrinsic heart rate. Since during the first postnatal week cardiac functioning in SHR seems relatively normal, this may be a period during which interventions altering maturation or adult functioning of the sympathetic nervous system might affect the developmental course of spontaneous hypertension.

207.11 CARDIOVASCULAR, CATECHOLAMINE AND RENIN RESPONSES TO HEMORRHAGE IN BRATTLEBORO RATS. R.L. ZERBE*, G. FEUERSTEIN, D.K. MEYER*, J. KOPIN. (SPON:D.C. JIMERSON) Laboratory of Clinical Science, Section on Medicine, National Institute of Mental Health, Bethesda, MD 20205

Abnormal baroregulation in Brattleboro rats (Di/Di) (J. Physiol. 296:267) suggests that vasopressin (VP) has a function in blood pressure (BP) control. Whether VP acts by direct vasoconstriction or by potentiating other pressor mechanisms is unclear. The former seems incompatible with the relatively weak pressor effects of VP in intact animals, whereas the latter is given credence by the demonstration of VP in CNS areas important in baroregulation. To investigate the latter possibility, we measured blood pressure (BP), heart rate (HR), plasma epinephrine (E), norepinephrine (NE) and renin activity (PRA) before and after acute hemorrhage (5cc/300gm over 5 min) in 9 Di/Di, 9 weight matched (WMC) and 8 age matched (AMC) Long-Evans controls under halothane-anesthesia (0.8% in oxygen). Hemorrhage and cardiovascular recordings were done via a femoral catheter. For each group, the mean values (±SEM) before (PRE), immediately after (0') and 30 min. after (30') hemorrhage are shown below. Significant differences ($P<0.5$) from Di/Di are indicated by *, significant differences from baseline values within each group are underlined.

	Di/Di			WMC			AMC		
	PRE	0'	30'	PRE	0'	30'	PRE	0'	30'
BP mmHg	83 ±3	22 ±1	41 ±2	88 ±2	26* ±8	71* ±6	88 ±4	27* ±1	57* ±6
HR bpm	285 ±8	220 ±12	261 ±12	319* ±6	206 ±11	266 ±9	293 ±13	198 ±7	248 ±9
E pg/ml	60 ±15	550 ±78	374 ±68	13* ±3	122* ±24	121* ±20	24 ±8	236* ±92	143* ±27
NE pg/ml	154 ±23	170 ±15	162 ±16	115 ±15	96 ±12	114 ±13	94* ±10	100 ±17	119 ±19
PRA ngAI/min/ml	86 ±6	102 ±7	148 ±6	42* ±4	54* ±5	69* ±6	43* ±4	72* ±8	103* ±9

These data show that Di/Di: 1) have higher basal PRA and E, 2) recover more slowly from hemorrhage and, 3) have a normal or enhanced increase in E, NE, and PRA. We conclude that VP deficiency does not diminish the response of other pressor hormones, and that the blunted blood pressure recovery after hemorrhage in Di/Di is probably due to the loss of peripheral effects of VP or other consequences of chronic VP deficiency.

207.12 THE INITIATION, PROPAGATION, AND TERMINATION OF "PLATEAU" WAVES. M.J. Rosner* and D.P. Becker, Division of Neurological Surgery, Medical College of Virginia, Richmond, Virginia 23298.

In cats undergoing fluid percussion brain injury, plateau waves begin to occur 18-24 hrs after injury. Onset and behavior of these waves have proven to be stereotyped allowing development of a precise and testable model which we present herein.

Cats weighing 2.5 to 3.5 kg undergo continuous monitoring of systemic arterial (SABP), intracranial (ICP) and central venous pressures as well as heart rate, end-tidal CO_2, temperature (controlled at 39° C) and EEG. General anesthesia is maintained using N_2O/O_2 (70:30); muscle paralysis is obtained with pancuronium bromide. The animal is maintained on a ventilator for up to 72 hours after injury.

The substrate for plateau wave occurrence is elevation of the ICP, decrease in the intracranial compliance, and generally intact autoregulation. For several minutes just prior to the development of the plateau wave there occurs a gradual rise in the ICP from 20 to about 35 mmHg. This is always accompanied by a modest and gradual decline in the blood pressure from 120 to 90 mmHg. This SABP drop seems insignificant until one examines the cerebral perfusion pressure (CPP); the CPP drops to 60 mmHg, a value near the lower limits of autoregulation. We believe this gradual rise in ICP to reflect autoregulatory vasodilation which is actually responsible for the ICP increase.

At a CPP of 60 mmHg the plateau wave begins. The initiation of the plateau wave may correspond to an additional vasodilatory stimulus: decreased O_2 delivery. Both factors together result in this rapid increase in ICP. As the wave develops, perfusion pressure drops below 50 mmHg, and brainstem ischemia then initiates a "Cushing" response. Adrenergic discharge and hypertension (150 mm Hg) restore the CPP to 70-80 mmHg, and autoregulatory vasoconstriction ensues. Because autoregulatory vasoconstriction lags behind increasing blood pressure, the ICP transiently rises even farther (but with no further decrease in the CPP). After this final ICP peak, the plateau wave aborts, and ICP quickly returns to baseline levels.

In summary, when ICP is moderately elevate, normally trivial decrements in blood pressure result in large drops in perfusion pressure. A cycle of autoregulatory vasodilation is initiated further increasing ICP until CPP falls to ischemic levels (<50mmHg). Brainstem ischemia stimulates a "Cushing" response with restoration of the CPP. The ICP transiently rises further due to the lag between the hypertension and autoregulatory vasoconstriction, but then dramatically returns to baseline. This model has been substantiated by using mild hypertension to correct low CPP in animals and humans with subsequent abolition of the plateau wave.

208.1 DOSE-RESPONSE CHARACTERISTICS OF BENZODIAZEPINE POTENTIATION OF GABA CHEMOSENSITIVITY ON SINGLE CHICK SPINAL CORD NEURONS IN CULTURE. C. Y. Chan* and D. H. Farb* (SPON:R. T. Wang). Dept. of Anatomy and cell Biol., SUNY Downstate Med. CTR., Brooklyn, NY 11203.

Benzodiazepines (BZD's) potentiate GABA chemosensitivity of embryonic chick spinal cord (SC) neurons in cell culture (Choi, Farb and Fischbach, Nature 269:732, 1977). The dose-response characteristics of BZD potentiation of GABA chemosensitivity on single neurons were determined. Neurons were impaled for intracellular recording and passing of current. GABA and BZD's were applied extracellularly at known concentrations by pressure ejection. The GABA response (a rise in conductance) was calculated from the voltage deflection elicited by constant d.c. pulses of 0.1 nA across the cell membrane before and during GABA application. BZD potentiation of GABA responses was measured as a percentage increase in the GABA-induced conductance rise. A complete dose-response curve was obtained for each neuron studied. Lineweaver-Burk analysis of the data yielded EC_{50}'s of 0.16μM for flunitrazepam and 1μM for flurazepam. These are respectively 32 and 36 times the K_I's from adult rat brain binding data. EC_{50} for chlordiazepoxide obtained by statistical approach was about 17μM, which was 34 times the binding K_I. The BZD RO5-4864 is known not to exhibit central behavioral effects and binds with very low affinity to central BZD receptors. As expected, no GABA potentiating activity was found using 0.1μM to 100μM RO5-4864 on single SC neurons; rather, it inhibited GABA responses.

Dose-response curves for GABA chemosensitivity were measured on 3 neurons. We found EC_{50} of 40μM, which is similar to statistically derived EC_{50} of 17μM (Choi and Fischbach, J. Neurophysiol., in press). We investigated possible involvement of $GABA_B$ receptors in BZD potentiation of GABA responses using baclofen, a selective $GABA_B$ receptor ligand (Hill and Bowery, Nature 290:149, 1981). No conductance or potential changes were observed when baclofen was applied to cultured SC neurons, whether or not they were prepulsed with flurazepam. It also had no effect on GABA responses or flurazepam potentiation of GABA responses when it was applied prior to GABA or flurazepam pulses. Thus, $GABA_B$ receptors do not seem to be involved in this system.

(Supported by NSF grant BNS 80-04811 to D. H. Farb and a Muscular Dystrophy Assoc. Fellowship to C.Y. Chan.)

208.2 HIGH AND LOW AFFINITY BENZODIAZEPINE BINDING TO EMBRYONIC CHICK CNS MEMBRANES, T. T. Gibbs*, L. A. Borden*, G. Shifrin*, and D. H. Farb* (SPON: D. A. Fischman). Dept. of Anatomy & Cell Biology, SUNY Downstate Med. Ctr., Brooklyn, NY 11203.

Benzodiazepines (BZD's) enhance GABA chemosensitivity and potentiate GABA-like synaptic transmission in cell cultures of embryonic chick spinal cord (Choi, Farb & Fischbach, Nature 269 (1977)342). This enhancement requires higher BZD concentrations than expected from studies of BZD binding to rat brain membranes (Squires & Braestrup, Nature 266(1977)732). To investigate the differences between the EC_{50}'s determined by electrophysiological methods (see Chan & Farb, accompanying abstract) and the high-affinity K_I's determined by radioligand binding, standard radioligand techniques were used to characterize the binding of BZD's to washed P_2 membrane fractions derived from both late (20 day) and early (7 day) embryonic chick brain (EBM) or spinal cord (ESM). The rate constants for association (k_f=5.2±1.6 x 10^7 M^{-1} min^{-1}, n=2) and dissociation (k_r=0.096 min^{-1}) of ^{3}H-flunitrazepam (FNZM) determined with late EBM were consistent with a K_D of about 2 nM. This is in general agreement with the value of 5.8±1 nM determined at equilibrium (n=2). Flurazepam (FZ) and chlordiazepoxide (CDPX) competed for this site with respective K_I's of 34±3 nM (n=4) and 450 nM (n=1). Similar results were obtained with late ESM. Binding of ^{3}H-FNZM to early and late EBM was enhanced 60-80% in 100-200 μM GABA. Enhancement of ^{3}H-FNZM binding by GABA was blocked by bicuculine. In addition, the BZD-binding complex of EBM was irreversibly labeled with ^{3}H-FNZM by exposure to UV light (Battersby et al., Eur.J.Pharmac.57(1979)277) and comigrated with putative rat BZD receptor in SDS-PAGE. These results on late EBM and ESM are in agreement with published K_I values of adult rat membranes. Thus the discrepancy between electrophysiological EC_{50}'s and binding K_I's is not due to species differences between chick and rat BZD receptors. Whereas BZD binding to late EBM & ESM was consistent with Michaelis-Menten kinetics (Hill coeff. ≃1 for FNZM, FZ and CDPX), this was not the case with early embryonic membranes. Binding of BZD's to early EBM or ESM exhibited non-linear Scatchard plots and Hill coeff.'s of ca. 0.4. This is inconsistent with Michaelis-Menten binding at a single site, and suggests either multiple BZD binding sites or negative cooperativity. Computer analysis of the data by non-linear regression indicates that these results are well described by a 2-site model with a high-affinity site (K_1) similar to that observed in late EBM & ESM and a second, lower-affinity site (K_2). The values obtained are: clonazepam, K_1≃1.8 nM, 81% of total, K_2≃3 μM, 19% (n=2); FZ, K_1≃40 nM, 70%, K_2≃13 μM, 30% (n=2); and CDPX, K_1≃500 nM, 80%, K_2≃40 μM, 20%. (Supported by NSF grant BNS 80-0487 to D. H. Farb and a MDA fellowship to T. T. Gibbs)

208.3 PURIFICATION AND CHARACTERIZATION OF BENZODIAZEPINE RECEPTOR. J.-Y. Wu, Y. Y. T. Su*, W. M. Huang*, J. Pachter* and P. Seu* Dep. Cell Biology and Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030

In our attempt to purify benzodiazepine (BDZP) receptor(s) from rat brain, we chose to use the crude mitochondrial fraction (P_2) pellet after lysis as the source of BDZP receptor and ^{3}H-flunitrazepam (FNZP) as ligand. The specific binding of FNZP to BDZP receptor was determined as 1.1 X 10^{-12} moles per mg protein of P_2 pellet. Clonozepam (10^{-4}M) was included in the incubation mixture as a control for non-specific binding. The purification of native BDZP receptor(s) involved the covalent labeling of the receptor with ^{3}H-FNZP by photoaffinity labeling as described [Battersby, Richards and Möhler, Eur. J. Pharmacol. 57:277 (1979)], followed by solubilization with 2% Triton X-100 and finally by column separation on gel filtration and hydroxylapatite. The subunit structure of BDZP receptor(s) was studied with ^{3}H-FNZP-labeled receptor preparations using SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Upon SDS-PAGE, two protein components, I and II, labelled with ^{3}H-FNZP were observed with a molecular weight of 45,000 ± 5,000 and 10,000 ± 2,000, respectively. The ratio of I:II was about 1:2. Similar results were obtained on SDS-gel filtration. The Triton solubilized BDZP receptor(s) could be separated into two components on Triton-gel filtration column and both components migrated as a single species on SDS-PAGE, corresponding to the fast-moving component, II, (MW 10,000). Furthermore the slow-moving component, I, (MW 45,000) from SDS-column could be converted into component II by treatment with Triton prior to SDS-PAGE. Hence, it is concluded that the basic subunit of BDZP receptor is component II, a 10,000 dalton polypeptide and component I, is a polymeric form of II. The different forms of native BDZP receptor(s) observed on Triton-gel column may represent different polymeric forms of component II. (Supported by NIH grant NS-13224).

208.4 PURIFICATION AND CHARACTERIZATION OF AN ENDOGENOUS BRAIN PEPTIDE THAT COMPETES WITH ^{3}H-DIAZEPAM BINDING. A. Guidotti, B. Ebstein* and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

An endogenous peptide which competes with ^{3}H-diazepam binding (EP) was extracted from fresh or microwaved rat brain in 20 volumes of hot (80°) 1 N acetic acid. After the pH was adjusted to 5, the 48,000 xg supernatant was dialyzed for 24 hrs against 0.1 N acetic acid. The dialyzate was concentrated and applied to a Sephadex G-100 column equilibrated in 0.1 N acetic acid. The fractions were tested for EP activity. Activity was associated with a protein peak which emerged after ribonuclease A (a marker for 14,000 daltons) and before β-mercaptoethanol (a marker for 78 daltons). An alternative method of extracting the EP consisted of treating frozen-thawed and well-washed crude synaptic membranes with 0.05% Triton X-100. The suspension was incubated for 30 min at 0°, sonicated for 30 sec and then centrifuged at 100,000 g for 60 min. From this crude extract EP was isolated by heat treatment at 95°C for 15 min and by chromatographing the subsequent 100,000 g supernatant on a G-100 column. This extraction procedure gives a profile similar to that shown after hot acetic acid extraction. The inhibitory material obtained from G-100 was further purified on a Biogel P-2 column equilibrated in 0.1 N acetic acid. The EP activity was associated with the protein peak emerging in the void volume and was destroyed by pronase and trypsin but not by phospholipase A_2, C or D. The purified EP, when subjected to electrophoresis on an SDS-12% acrylamide gel, revealed 2 major bands with molecular weight smaller than 14K. The EP extract from the Bio-Gel P-2 column was further purified by reverse phase HPLC on a BioRad ODS column with acetonitrile gradient. The protein peak and EP activity emerged at 40% acetonitrile. The purified EP inhibited ^{3}H-diazepam binding competitively. It does not inhibit the binding of ^{3}H-GABA, indicating that EP can be physically separated from GABA modulin. EP has no effect on the binding of ^{3}H-cyclohexyladenosine, ^{3}H-QNB, ^{3}H-etorphine or ^{3}H-alprenolol while it does inhibit effectively ^{3}H-propyl-β-carboline-3-carboxylate binding. EP displaces ^{3}H-flunitrazepam more effectively from cerebellar membranes than from hippocampal membranes.

208.5 OPTICAL ISOMERS OF 5-(1,3-DIMETHYL-BUTYL)-5-ETHYL BARBITURIC ACID (DMBB) BIND TO THE PICROTOXININ BINDING RECEPTOR. Maharaj K. Ticku, William C. Davis* and Cynthia A. Morency* (SPON: K. Blum). Dept. Pharmacology, Univ. Tex. Hlth. Sci. Ctr., San Antonio, TX 78284 and New England Nuclear Corp., Boston, MA 02118.

Depressant and convulsant barbiturates inhibit the binding of [^{3}H]-α-dihydropicrotoxinin (DHP) to membranes (Ticku & Olsen, Life Sci. 22:1643, 1978) and crude Lubrol-solubilized fraction (Davis & Ticku, J. Neurochem. in press, 1981). Gel filtration of the Lubrol fraction revealed that [^{3}H]-diazepam and [^{3}H]-DHP bind to two distinct fractions with apparent molecular weights of 61,000 and 185,000 daltons, respectively (Davis & Ticku, Neurosci. Absts. in press, 1981). [^{3}H]-DHP binding to the 185,000 dalton fraction was displaced by depressant and convulsant barbiturates. To investigate the possibility that the picrotoxinin binding site may represent a receptor site for barbiturates (Ticku, Br. Res. Bull. 5(2):919, 1980), we synthesized and radiolabeled the optical isomers of DMBB. [^{3}H]-DHP binding to the 185,000 dalton fraction was inhibited by both (+)DMBB (convulsant) and (-)DMBB (depressant), with shallow displacement curves. Specific binding of both [^{3}H]-(+)- and [^{3}H]-(-)DMBB was detected in the 185,000 dalton fraction. Scatchard analysis of the binding isotherms of [^{3}H]-(+)DMBB revealed downward curvature, suggesting heterogeneity of binding sites. [^{3}H]-(+)DMBB binding to the 185,000 dalton fraction was displaced by (-)DMBB, picrotoxinin and depressant and convulsant barbiturates. Likewise, [^{3}H]-(-)DMBB binding to the same fraction exhibited heterogeneity and was displaced by (+)DMBB, picrotoxinin and other barbiturates. These results indicate that barbiturates bind to the picrotoxinin binding fraction and support our earlier notion that the picrotoxinin site at the benzodiazepine-GABA receptor-ionophore complex may represent a receptor site for barbiturates. This site may be involved in allosteric regulation of the benzodiazepine-GABA receptor-linked chloride ionophores.

208.6 A POSSIBLE ENDOGENOUS LIGAND FOR THE SPECIFIC ^{3}H-PHENYTOIN SITE IN THE RAT BRAIN. L. Spero* and P. Kunashko* (SPON: W.E. Corrigall). Dept. of Pharmacology, University of Toronto, Toronto, Ontario.

We recently made the observation that two specific binding sites for ^{3}H-phenytoin exists in a synaptosomal fraction of rat brain. Other anticonvulsants used to treat grand mal compete for these sites but not those used to treat petit mal (Burnham et al., C.J.P.P. 1981, April). A large number of neurotransmitters were tested and found not to compete with phenytoin. We have now isolated a fraction following removal of proteins, lipids and salts then G25 and G15 sephadex gel chromatography, with a molecular weight of approximately 500-700 Daltons, which competes for ^{3}H-phenytoin, ^{3}H-muscimol and ^{3}H-diazepam binding. The phenytoin competing activity is lost after incubation with trypsin and chymotrypsin, using soybean trypsin inhibitor, or heat inactivation to prevent membrane degradation. This enzyme treatment does not influence diazepam or muscimol competing activity in the fraction. Cation exchange HPLC chromatography in potassium phosphate buffer pH 6.5 gives further separation into two fractions, the binding characteristics of these fractions are currently under study. Serial combination experiments with cold phenytoin and the G25 fraction support a common binding site for the two, when tested against ^{3}H-phenytoin. Similar results were obtained for the G25 fraction combined with cold diazepam or cold muscimol against ^{3}H-diazepam and ^{3}H-muscimol respectively. Phenytoin itself does not compete against ^{3}H-diazepam or ^{3}H-muscimol. The G25 fraction does not compete for binding against a large number of other radio-ligands tested. Diazepam (1-20 um) which enhances phenytoin binding also enhances the G25 fraction binding, this has not been observed for other benzodiazepine analogues. However, we have shown (Okazaki et al., 1981, in prep.) that (+)-bicuculline but not (-)-bicuculline also enhances ^{3}H-phenytoin binding, and G25 fraction competition.

The G25 fraction has also been tested in mice using the standard NIH, Maximal Electroshock Technique. When administered i/p the fraction protects mice against MES within five minutes, and this protection lasts for fifteen to twenty minutes, and is absent by thirty minutes. The ED_{50} for this protection is approx. 1.5 mg/kg of the crude G25 extract. No marked change in the behaviour of the mice was observed during this period. 209.1 DISTRIBUTION OF SOMATOSTATIN-LIKE IMMUNOREACTIVE MATERIAL IN THE CNS AND PERIPHERY OF A GASTROPOD. Y. Grimm-Jørgensen, with the technical assistance of M.J. Borkowski*and C. Sowers-Clift,*Dept. of Anatomy, The University of Connecticut Health Center, Farmington, CT 06032.

Published immunocytochemical studies indicate that somatostatin-like immunoreactive material(IRSRIF)is found in the nervous system and peripheral organs of many vertebrates and invertebrates. In the CNS of the gastropod Lymnaea stagnalis IRSRIF is associated with a cluster of neurosecretory cells thought to be involved in body growth (Roubos et.al.,VIII International Symposium on Neurosecretion,1981,in press).

In order to gain more information on the possible physiological roles of IRSRIF in gastropods,we have studied the distribution of IRSRIF in various organs of the pond snail Physa spp. IRSRIF was quantitated by radioimmunoassay after extraction with 2 N acetic acid and lyophilization.IRSRIF was found in the circumesophageal ganglia,the gastrointestinal (GI) tract and the hemolymph.

Within the GI tract,the highest concentration of IRSRIF was observed in the esophagus.Although the IRSRIF concentration of the large digestive gland was lower than that of the esophagus, the total amount of IRSRIF in the digestive gland contributed a larger proportion of the total IRSRIF to the GI tract than did other parts.

The IRSRIF content of the hemolymph changed with age.The IRSRIF concentration in the hemolymph of young animals (prior to egg laying) was 4-5 fold higher than that in the hemolymph of old animals.When old animals were forced to regenerate their shell by removal of the shell edge, the IRSRIF concentration of the hemolymph increased 100%.These findings suggest that in Physa IRSRIF may be involved in the regulation of body growth.

Attempts were made to gain information on the chemical identity of IRSRIF in ganglia and hemolymph.Acetic acid-soluble extracts were subjected to liquid chromatography on Biogel P-2. IRSRIF eluted with the void volume fraction, indicating that Physa IRSRIF is larger than 1500 daltons.The acid-soluble material was also subjected to thin layer chromatography on reverse phase plates and the IRSRIF content of 1 cm sections of the plate determined.Various peaks of IRSRIF were observed. Whereas a small but significant part of the total immunoreactivity from ganglia co-migrated with synthetic somatostatin, none of the IRSRIF from the hemolymph co-migrated with synthetic somatostatin.These results indicate that multiple forms of IRSRIF are present in the tissues of Physa and that the bulk of the immunoreactive material is not chemically identical with mammalian somatostatin.Supported by NIH Grant RO1 AM20929-04.

209.2 A NEUROPEPTIDE INDUCING ENHANCEMENT OF NEURONAL ACTIVITY IN CRAYFISH. H. Arêchiga and A. Huberman*. Dept. Physiol. and Biophys. Ctr. Adv. Studies, México 14, D.F. and Dept. Biochem. Inst. Natl. Nutr., México 20, D.F.

The electrical activity of crustacean nervous system has been shown to be modulated by a blood-borne peptide which is released from the sinus gland a neurohaemal organ in the eyestalk and induces a lowering of excitability, hence its denomination as neurodepressing hormone (NDH) (see Arêchiga, H. and Huberman, A. Peptide modulation of neuronal activity in crustaceans In The Role of Peptides in Neuronal Function. J.F. Baker y T.H. Smith, Eds. Marcel Dekker Inc. 1980). The presence is here reported of another peptide in the central nervous system of the crayfish which induces an enhancement of excitability.

The experiments were carried out in adult specimens of the crayfish Procambarus bouvieri (Ortmann), without distinction of sex. The central nervous system was divided in segments and extracts from each were prepared and succesively passed through Sephadex G-25 and G-15 columns. In a fraction previous to that containing NDH, carrying molecular specimens between 1500-2000 daltons a peptide was determined which increases the spontaneous activity of motoneurons at various levels of the central nervous system, and that of peripheral mechanoreceptors. This peptide is inactivated by trypsin and by heating. It is more abundant in the eyestalk than anywhere else, but is also present in the supraoesophageal ganglion and the thoracic ganglion chain. Within the eyestalk it is stored in the sinus gland. The electrical stimulation of this organ, or its incubation in high potassium solutions results in the release of this peptide. Once depleted from its peptide content, the eyestalk is capable of resynthesizing it after incubation in a proper aminoacid mixture. The site of synthesis is the medulla terminalis, in the region containing the perikarya of the neurosecretory cells whose endings are located in the sinus gland. This peptide therefore appears to act as a neurohormone, performing a physiological action opposite to that of NDH.

209.3 MORE THAN ONE PEPTIDE NEUROTRANSMITTER MAY MEDIATE BAG CELL ACTIONS ON CENTRAL NEURONS OF APLYSIA. B.S. Rothman#, L. Padgett#* and E. Mayeri†# #Dept. Physiology, Univ. of Calif., San Francisco, CA 94143 and †Dept. Basic Sciences, California College of Podiatric Medicine, San Francisco, CA 94115

A burst discharge of impulse activity in bag cell neurons produces four types of responses in various identified neurons of the abdominal ganglion (Mayeri et al., JNP 42:1165). The bag cell peptide, ELH, is the putative transmitter for two of these types of responses, prolonged excitation and burst augmentation. ELH has no effect on neurons in which bag cell activity produces the other two types of responses, prolonged inhibition and transient excitation (Branton et al., PNAS 75:5732; Rothman et al., Nsci Abstr 5:260). To identify transmitters for the other two responses we have purified various factors from extracts of the bag cells, using as an assay neurons with known responses to bag cell activity. 50 to 100 bag cell clusters were surgically removed from the rest of the abdominal ganglion and combined with 2-4 clusters which had been preincubated with ^{3}H-leu and/or -arg and -lys in order to radiolabel ELH and other bag cell peptides. The clusters were extracted in 0.5 M formic acid, centrifuged, and the supernatant applied to a gel filtration column (G50 Sephadex). To obtain ELH and the factors described below, eluents were further purified either by cation exchange chromatography or high performance liquid chromatography (HPLC).

In the 3-11K Dalton range, as indicated by the gel filtration purification step, there was an inhibitory factor that produced prolonged inhibition of cells L3 and L6, which are also inhibited by bag cell activity. The factor was associated with a radiolabelled peak that was distinct from ELH, suggesting it is a bag cell peptide, but not ELH. The effect was dose-dependent, had a threshold of 30 µg/ml, and at higher concentrations lasted more than 1 hr. In the 0-3K Dalton range there were several factors, some radiolabelled, which also inhibited L3 and L6, but with a faster onset and shorter duration than for the larger inhibitory factor. In addition there was a radiolabelled factor which produced transient excitation of L1 and R1. At a concentration of 200 µg/ml it duplicated the slow depolarization of these cells normally produced by bag cell activity.

The results suggest that in addition to ELH, which mediates two types of responses,there are several candidate transmitters for prolonged inhibition and one for transient excitation. Thus, the bag cells may synthesize more than one peptide transmitter, each one mediating a distinct action in the central nervous system.

209.4 MULTIPLE ACTIONS OF FMRF-AMIDE ON IDENTIFIED NEURONS IN THE ABDOMINAL GANGLION OF APLYSIA. L.S. STONE#* and E. MAYERI#†. #Dept. of Physiology, Univ. of California, San Francisco, CA 94143 and †Dept. Basic Sciences, California College of Podiatric Medicine, San Francisco, CA 94115.

FMRF-amide (Phenylalanyl-methionyl-arginyl-phenylalanine amide), first isolated from a molluscan ganglion (Price and Greenberg, Science 197:670) and later found immunocytochemically in the CNS of both invertebrates and vertebrates (Boer et al., Cell Tissue Res., in press), has been shown to produce excitation and inhibition in a variety of molluscan bivalve hearts (Greenberg and Price, Peptides: Int. of Cell and Tissue Function) and inhibition of a molluscan neuron (Cottrell, JP 284:130P).

We arterially perfused the abdominal ganglion of Aplysia californica with FMRF-amide dissolved in buffered sea water plus protease inhibitors. This produces widespread effects on identified cells of the ganglion, most notably: inhibition of left upper quadrant (LUQ) cells (L2,L3,L4,L6), inhibition of L10, and a biphasic exitatory-inhibitory response in L1 and R1. Massive vasodilation of the perfused artery also occurs.

The effects in the LUQ's, L1 and R1 were investigated in greater detail. When the peptide is applied via pressure ejection from small diameter polyethylene tubing placed adjacent to the soma of any one of these cells, the targetted cell, but not neighboring responsive cells, is affected. This indicates that the responses are direct and there are receptors on the somata. *The prolonged hyperpolarization of the LUQ's is dose-dependent with threshold below 100nM, saturates at about 10µM, and shows* little or no desensitization even during 30 minute applications. In L1 and R1 a rapid depolarization, usually with superimposed spikes, is followed by a prolonged, smaller hyperpolarizing phase. This is also dose-dependent with a somewhat higher threshold and saturation point (less than 1 and 100µM respectively).

The widespread effects of FMRF-amide in the ganglion suggests that it may play an important role as a neurotransmitter and/or neurohormone. It also provides evidence that peptides are capable of eliciting multiple and conjoint actions on central neurons just as has been found for non-peptidic transmitters.

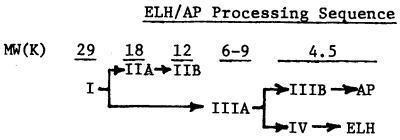
209.5 PROTEOLYTIC PROCESSING OF NEUROSECRETORY PEPTIDES BY THE BAG CELLS OF APLYSIA. R.W. Berry, J.T. Baylen*, and M.J. Trump*. Dept. of Cell Biology and Anatomy, Northwestern Univ. Sch. of Med., Chicago, IL 60611.

The neurosecretory bag cells of Aplysia produce and secrete two major peptide products: a highly basic 4,500 dalton (4.5K) egg-laying hormone (ELH), and a 4.5K acidic peptide (AP) of unknown function. Previous work has indicated that these peptides and an additional 12K product arise by cleavage of a 29K precursor, but the precise processing sequence and the structural relations among these proteins have yet to be established. Since detailed knowledge of the ELH/AP processing sequence might provide insight into multistep processing sequences in general, we have undertaken to identify the major members of this sequence by pulse-chase labelling, to characterize these proteins by sequential SDS-PAGE and isoelectric focusing, and to investigate their structural relationships by tryptic peptide mapping. The pulse-chase studies revealed eight major members of the processing sequence which have the precursor-product relations shown below:



All of these species except IIA and IIB are homogeneous by sequential SDS-PAGE and isoelectric focusing. The key features of the ELH/AP sequence are that the two secreted products arise from a single common precursor via three cleavage steps and a common intermediate form. The tryptic peptide mapping data are entirely consistent with this sequence and further indicate that the 12K material, which apparently represents a non-secreted endproduct, contains an additional copy of the AP peptide. Since the derivation of multiple secretory products from a common precursor, multistep processing, and unprocessed "extra" product copies are also found in the vertebrate processing sequence of proopiomelanocortin, these may be common features in the production of secretory peptides.

(Support: NIH NS 11519).

209.6 COEXISTANCE OF A NEUROPEPTIDE AND ACETYLCHOLINE IN AN IDENTIFIED MOLLUSKAN NEURON. P.E. Lloyd*, B. Masinovsky*, R.E. McCaman & A.O.D. Willows (SPON: R. Levine). Dept. Zoology, Univ. of Washington, Seattle, WA 98195, and City of Hope Medical Center, Duarte CA 91010.

Neuron B11 (formerly termed LDWC) is a large white appearing neuron located on the dorsal surface of each buccal ganglion in Tritonia. B11 is involved peripherally in the control of gut activity and centrally in the generation of cyclic bursting motor output from the buccal ganglia (Lloyd & Willows, Soc. Neurosci. Abstr. 6, 704; 1980).

B11 somata can be dissected free of the ganglia and their contents analyzed. They contain a cardioactive neural peptide that can be quantified by bioassay on an isolated snail heart. We have recently purified two cardioactive peptides from Aplysia nervous tissue that co-purify through gel filtration, aromatic affinity, and ion exchange chromatography. The two peptides can be resolved and purified to homogeneity as judged by quantitative amino acid analysis by reverse phase high performance liquid chromatography. The B11 peptide co-purifies through all steps with one of these peptides, termed small cardioactive peptide A (SCP_A), strongly suggesting that it is the same peptide. By comparing cardioactivity and amino acid analysis, we were able to determine the molar activity of SCP_A. The amount of SCP_A in a B11 soma is 1.9$\pm$ 0.3 pmoles (mean $\pm$S.D.: N>100).

A series of suggestive observations persuaded us to also assay for the presence of acetylcholine (ACh) in the somata of B11s. We used a radiochemical assay (McCaman & Stetzler, J. Neurochem. 28, 669; 1977) and found that a B11 soma contains 0.85$\pm$ 0.21 pmole ACh (mean $\pm$ S.D.: N=24).

The approximate volume of the B11 somata used for these analyses was 1 nl. Thus the concentrations of ACh and the peptide SCP_A in the cytoplasm of B11 is roughly similar at the 1-2 mM level. These are higher concentrations than those reported for transmitters (including ACh) in other Tritonia neurons.

B11 has a discrete peripheral target tissue, the foregut, which also contains ACh and SCP_A. Thus B11 and the foregut may provide an excellent system in which to physiologically study the actions of neurons that contain more than one bioactive substance.(NSF BNS 7906280 & NS 9339)

210.1 CONNECTIONS OF THE SUBFORNICAL ORGAN (SFO). R.W. Lind, G. W. Van Hoeson, & A.K. Johnson. Depts. of Psychology, Anatomy, & Neurology & The Cardiovascular Center, U. of Iowa, Iowa City,IA. 52242

The structures of the lamina terminalis (SFO, septum, median preoptic nucleus, and the organum vasculosum (ovlt)) have been independently studied over the years and each of them is thought to play a role in the control of bodily hydration. Anatomical studies of this area of the brain (Miselis, Neurosci. Abs. 1980; Hernesniemi, Acta Anat., 1972) have demonstrated that these structures are interconnected and Eng, et al, and Lind and Johnson (Neurosci. Abs., 1980) have reported that this circuitry is relevant to angiotensin-induced thirst. The present study investigated further the afferent and efferent connections of the SFO by using the horseradish peroxidase (HRP) technique.

Male rats received iontophoretic applications of HRP into the main body of the SFO. The marker was diluted to 20% in distilled water and pipettes with a tip of 20u were used. Injection parameters ranged from 0.5 uA x 30" to 2.0 uA x 150". Sections were reacted with tetramethyl benzidine and stained with neutral red.

A dense bundle of fibers was visualized issuing from the ventral stalk of the SFO containing both afferent and efferent connections. In agreement with Miselis' autoradiography data, we found that this bundle splits above the anterior commissure (AC), with some of the post-commissural fibers diverging caudally at the point where the columns of the fornix diverge laterally while others do not turn caudally until immediately above the AC. A substantial number of these post-commissural fibers appear to project to the paraventricular nucleus. (This observation was verified by the retrograde labeling of SFO neurons with HRP injections into PVN.) However, others by-pass this nucleus ventrally and were followed as far caudally as the median eminence.

The majority of fibers appear to pass anterior to the AC, tightly "hugging" it, with a few of them turning abruptly rostral at this point and continuing into the medial septum. As the main pre-commissural bundle continues ventrally through the median preoptic nucleus, it grows steadily more sparse, suggesting the presence of terminals throughout this nucleus. However, some fibers continue all the way to the ovlt where a few of them diverge laterally and project to the supraoptic nucleus.

Besides these efferent fibers, we also identified four sources of neural input to the SFO. The most prominent of these derived from cells in the triangular nucleus of the septum, with fibers entering the SFO by piercing the fornical commissure. Second, cells were observed in the medial septum. Third, neurons were labelled within the pre-commissural bundle anterior to the AC; fourth, cells were filled in the medial preoptic area.

210.2 LESIONS OF THE SUBFORNICAL ORGAN (SFO) BLOCK DRINKING TO PERIPHERAL BUT NOT CENTRAL ANGIOTENSIN. R.L Thunhorst*, R.W. Lind, & A.K. Johnson, (SPON: M.J. Brody) Dept. of Psychology and the Cardiovascular Center, University of Iowa, Iowa City, IA 52242

The SFO has been implicated in the control of fluid balance as a receptor for angiotensin (Simpson, et al., JCPP, 1978). While there is wide agreement that the SFO is sensitive to this hormone, its uniqueness as a central receptor is disputed (Buggy, et al., Science, 1975). The present study measures the ingestive behaviors of rats with lesions of the SFO, with particular attention paid to the thirst-inducing properties of angiotensin.

Thirty-three male rats that were screened for drinking to subcutaneous angiotensin (1.5 & 3.0 mg/kg) and hypertonic saline (4% & 12%, 10 ml/kg) received either an SFO (n=26) or a sham lesion (n=7). One week after surgery all animals were again tested with angiotensin and hypertonic saline at the same doses as pre-lesion. While control rats drank 2.4(±.7) mls and 3.7(±1.1) mls to the low and high doses of angiotensin, thirteen of the experimental rats were completely refractory to this stimulus. Furthermore, these thirteen rats drank significantly less than the controls to hypertonic saline at both the low dose (2.2 ± .8 mls vs 8.0 ± .9 mls) and high dose (9.0 ± 1.1 vs. 17.0 ± 1.5).

The rats that were refractory to peripheral angiotensin and the control animals were then implanted with intraventricular cannulae and tested for drinking responses to central angiotensin (50 & 500 ng). At the low dose the control animals drank 3.3 ± 1.0 mls vs. 2.4 ± .5 mls for the experimentals, and at the high dose the rats with sham lesions again drank more (4.7 ± 1.3 vs. 2.8 ± .4), though neither difference was significant. All rats that had received central angiotensin were then tested for feeding and drinking responses to food and water deprivation, respectively, and no group differences were observed (Food: $\bar{x}_e$=4.2 ± .6 g vs. $\bar{x}_c$=5.3 ±1.0 g; Water: $\bar{x}_e$=11.8 ± .9 mls vs. $\bar{x}_c$=13.4 ± 1.0 mls).

Brains were cut at 40μ with a freezing microtome and stained with cresyl violet. It was found that all experimental animals had some damage to the SFO but that the 13 animals that had failed to respond to peripheral angiotensin had lesions that included some part of the ventral stalk. Lesions in this location would sever neural connections between the SFO and periventricular structures of the anteroventral third ventricle (AV3V), which Miselis (Neurosci. Abs., 1980) and Lind, et al. (Neurosci. Abs., 1981) have described and implicated in angiotensin-induced thirst.

Our findings are consistent with the hypothesis that peripheral angiotensin induces thirst by acting in the SFO, and that angiotensin of central origin, which is also relevant for drinking behavior, acts in the region of the AV3V. A role for the SFO in osmotic thirst is indicated and requires further attention.

210.3 DISTURBANCES IN WATER BALANCE AFTER TRANSECTIONS OF SFO EFFERENT PROJECTIONS. Richard R. Miselis and Ricardo Eng. Anim. Biol., Inst. Neurol. Sci. Sch. Vet. Med., University of Penn., Phila., PA 19104.

The subfornical organ (SFO) of the rat has efferent neural projections to the nuclei of the anteroventral third ventricular area of the preoptic region and to some nuclei fo the hypothalamus, particularly the magnocellular nuclei (Miselis et al, Science, 1979). These terminal fields suggest a role in behavioral and physiological mechanisms of water balance. Transections of the SFO efferent projections in rats (SET rats) produce an obvious loss of drinking to i.v. angiotensin II (Eng, Miselis, and Salanga, Neurosci. Abst., 1980). Close examination of the water balance in this preparation reveals subtle problems in mechanisms of water conservation. First, SET rats (8 of 13) have a moderate polydipsia (18.9±1.4 vs. 12.1±1.1 ml of water/100g b.wt.) under ad libitum conditions. Their water-to-food ratios are elevated above controls (?.3±0.1 vs. 1.4±0.1). When food deprived all of the SET rats are polydipsic compared to control rats (7.4±1.2 vs. 3.9±0.6 ml/100g b.wt.). This polydipsia may be secondary to polyuria. In the immediate 24 hours post-operatively without access to water the SET rats are polyuric compared to controls (5.8±0.5 vs. 2.5±0.1 ml of urine/100g b.wt.). They remain polyuric although less so, and when tested at a later time under total deprivation still lose more water in the urine than control rats (3.3±0.4 vs. 2.3±0.2 ml urine/100ml b. wt.). When given access to water after a 24-hr total deprivation the SET rats drink the same amounts of water as the controls (2.6±0.4 vs. 2.5±0.4 ml water/100g b.wt.). Since they lost more water in the urine during the deprivation, their drinking response represents a deficit. The SET rats also do not conserve urine volume as well as control rats at 4 and 8 hours after a severe hypovolemic challenge caused by 5 ml of 30% PEG given s.c. They excrete 0.5±0.1 and 0.8±0.2 vs. 0.1±0.1 and 0.4±0.1 cumulative ml of urine/100g b.wt. at 4 and 8 hours respectively. These data reveal deficits in the control of renal mechanisms of water conservation when SFO efferent projections are disrupted. Since the SFO projects to magnocellular nuclei of the hypothalamus, the deficit in urine volume conservation may represent a loss of facilitation of antidiuretic hormone secretion.

210.4 EFFECT OF KNIFE CUTS OF SUBFORNICAL ORGAN EFFERENT PROJECTIONS ON DRINKING BEHAVIORS. Ricardo Eng and Richard R. Miselis. Inst. Neur. Sci., Dept. Anim. Biol., Sch. Vet. Med., Univ. Penn., Phila delphia, PA. 19104

In the rat, the subfornical organ (SFO) has efferent projections to the preoptic area and areas of the hypothalamus that are involved in water balance. The efferent projections exit the SFO via its rostral component en route to the anteroventral third ventricular area (AV3V) and the ADH-producing paraventricular and supraoptic nuclei of the hypothalamus. We have previously shown that in the rat knife cuts of these efferents interfere with the drinking response to iv angiotensin II (AII) but not to high doses of hypertonic NaCl (Eng et al. 1980). We now report that the knife cuts also produce polydipsia, increased water/food ratios, polyuria, and disorders of water balance. The same knife cut rats that were unresponsive to iv AII responded to intracerebroventricular (icv) AII (10 ng); 10.5+1.4 vs. 10.6+1.5 ml for the controls with similar latencies. The latter results support the findings of Findlay, Elfont and Epstein (1980) in the opossum. The route-dependent differential drinking response to AII suggests that there are two sets of receptors for monitoring AII levels in the blood and the CSF. We also tested the knife-cut rats to stimuli that presumably activate the renin-angiotensin system, namely isoproterenol (ISO) and polyethylene glycol (PEG), to two doses of an osmotic stimulus (iv 2 M NaCl), and to 24 hr. total deprivation. The knife-cut rats do not drink to sc ISO, their response being comparable to drinking observed after control injections of isotonic saline vehicle. At 50 μg/kg ISO the knife-cut rats drank 0.7+0.2 vs. 1.2+0.1 ml/100 g BW for the controls. At 100 μg/kg ISO the respective responses were 0.8+0.3 vs. 1.6+0.2 ml/100 g BW ($p<.025$, df=16). The knife-cut rats did not differ from controls in the hypotensive response following 100 μg/kg ISO. Thus, the drinking deficits were not due to a general behavioral impairment following excessive hypotension. In contrast, the drinking to a high dose of PEG (5 ml, 30%, sc) was not impaired by the knife cuts. The knife cut rats had subtle deficits to iv 2 M NaCl at a low dose (0.5 ml/30 min.). During the one hour observation period, the knife-cut rats drank 0.7+0.4 vs. 2.5+1.2 ml for the controls ($p<0.05$, df=8). The subtle deficits to NaCl suggest that the SFO may also mediate osmotic thirst. However, at a higher dose (1.0 ml/30 min.) the knife-cut rats responded normally. The knife-cut rats' water intake did not differ from controls in a 2 hr. access after 24 hrs. of total deprivation. In view of increased urinary excretion by the knife-cut rats, this response actually represents a deficit. These findings support the hypothesis that the SFO and its projection fields are part of a neural network for the regulation of water balance.

210.5 EFFECTS OF GONADAL STEROIDS ON WATER AND SALT INTAKE INDUCED BY ANGIOTENSIN IN THE FEMALE RAT. J. Kucharczyk, Department of Physiology, School of Medicine, University of Oetawa, Ottawa, Ontario K1N 9A9.

Water intake, food intake and voluntary exercise in the female rat are predictably influenced by changes in endogenous levels of the two principal ovarian steroids, estradiol and progesterone. During proestrus and estrus, food and water intakes decrease while activity increases and rats lose weight. At metestrus and diestrus, when plasma estradiol is relatively low, the pattern of behaviors is reversed. Food and water intakes decrease, voluntary activity drops sharply and females gain weight.

Recent work suggests that ovarian hormones influence water intake by interacting with extracellular thirst mechanisms mediated by the renin-angiotensin system:

1. Water intake elicited by microinjection of 1 p-mole of angiotensin-II (ANG-II) into the preoptic region (POA) of cyclic rats is significantly lower on days of vaginal estrus or proestrus than on days of diestrus and metestrus.

2. Drinking in response to S.C. isoproteronol (a β-adrenergic agonist which increases ANG-II biosynthesis) is also significantly less at estrus than at diestrus.

3. Prepubertal female rats given single daily injections of ANG-II directly into the POA do not show cyclic patterns of water intake. After the onset of puberty, the same intracranial dose of ANG-II produces a cyclic pattern of elicited drinking, which in turn is abolished by bilateral ovariectomy.

4. Fluctuations in ANG-II and isoprenaline induced thirst are not secondary to changes in overall fluid and electrolyte balance, since the volume of water ingested in response to cellular dehydration (central and peripheral administration of hypertonic NaCl and sucrose) does not vary with the stage of the estrous cycle and is unaffected by ovariectomy.

5. Interaction between mechanisms for extracellular thirst and those controlling the estrous cycle likely occurs within the POA. There is evidence that this area of the brain contains receptors for ANG-II (Brain Res. 122:299) and estrogen (Brain Res. 101:67). While injections of p-mole doses of ANG-II into the subfornical organ, organum vasculosum of the lamina terminalis and lateral ventricles of cyclic rats also consistently produce drinking, the volumes ingested to not vary with the stage of the estrous cycle. (Supported by MRCC).

210.6 INFLUENCE OF OVARIAN STEROIDS ON ANGIOTENSIN-INDUCED DIPSOGENESIS AND PROSTAGLANDIN E_1-INDUCED ANTIDIPSOGENESIS AND THERMOGENESIS. K. M. Skoog and Nancy J. Kenney, Dept. of Psychology, University of Washington, Seattle, WA 98195.

Estrogens reduce the drinking (Fregly &Thrasher, 1978) but not the pressor (Skoog & Kenney, 1980) response to angiotensinII (AII). Both estrogens and progesterone attenuate the pressor response following central injection of prostaglandin E_1 (PGE_1; Skoog & Kenney, 1980). We now examine the effect of estrogen or progesterone replacement following ovariectomy on drinking to intracranial AII, on the PGE_1 suppression of AII-elicited water intake and on PGE_1-induced thermogenesis.

Ovariectomized (OVX) rats were given daily subcutaneous injections of estradiol benzoate (EB; 1 µg/rat), progesterone (PROG; 5mg/rat) or their seseme-oil vehicle beginning 7-8 days prior to testing and continuing throughout the experiment. On the test days, 5 ng AII was injected intracerebroventricularly (IVT) through indwelling stainless-steel cannulae. On days 1 and 3, the AIIinjection was preceeded by a 1 ul IVT injection of the PG carrier solution. On day 2, 100 ng PGE_1 was injected prior to the AII. Water intake was monitored for 30 min following the IVT injections. Core temperature was measured prior to the IVT injections and at the end of the drinking test.

In the absence of PGE_1, EB-treated rats drank significantly less than did oil-treated rats to AII ($p<.01$). PROG- and oil-treated females did not differ in average water intake to IVTAII. IVT PGE_1 significantly attenuated drinking to AII in PROG-treated OVX rats ($p<.01$) but not in oil- or EB-treated rats.

Baseline core temperatures of steroid-treated and oil-control animals did not differ. Likewise, steroid replacement had no effect on the increase of core temperature which typically follows IVT PGE_1 treatment. All rats showed marked core temperature increases following PGE_1 injection ($p<.01$).

Thus, a physiological dose of EB (Henderson et al., 1977) attenuates drinking to AII. PROG does not alter responsiveness to this dipsogen, however. The failure of PGE_1 to reliably suppress drinking of oil- and EB-treated OVX rats suggests that a lack of progesterone may result in the failure of female rats to exhibit PGE_1 antidipsogenesis. Finally, ovarian steroid replacement (either EB or PROG) in OVX rats does not affect PGE_1-induced thermogenesis.

211.1 PRINCIPAL OLIVE (PO) COOLING IN BEHAVING MONKEYS PRODUCES MOVEMENT CHANGES RESEMBLING THOSE OF DENTATE DYSFUNCTION. Kennedy, P.R., Ross, H-G and Brooks, V.B. Dept. Physiology, University of Western Ontario, London, Canada N6A 5C1.

Selective cooling of PO (that projects largely to neocerebellum), caused replacement of brief, 'continuous' movements that oscillated at 6 Hz or above, by slower, 'discontinuous' ones that oscillated near 3 to 5 Hz. These changes of motor performance resemble those during cooling of cerebellar nuclei (J. Neurophysiol. 1973, 36:974).

A new gas cryoprobe with tip cooling was implanted in the flexible brainstem with x-ray assistance in 4 monkeys (J. Neurosci. Methods, 1979, 2:1 and 411). Monkeys were trained to make self-paced, intended, step-tracking movements consisting of elbow flexions (F) and extensions (X) between two targets that alternated at random intervals. In one monkey the cooling probe tip lay adjacent to the promontory of PO allowing selective cooling.

The most detailed evidence was obtained from 7 digitised cooling runs in which the temperature was adjusted to selectively cool 65% of arm area of PO and none of dorsal accessory olive (DAO) or reticular formation (RF). During this selective cooling, 13/20 F and 12/21 X movements oscillated at 3 to 5 Hz, compared with only 2/66 F and 3/66 X movements before and after cooling ($p<0.01$). Movetimes increased during selective cooling from 0.8 s for F and X, to 1.2 s for F and 1.1 for X ($p<0.01$). To outrule the effect of gas vibrating in the cooling probe, 2 controls were run with warm gas passing at the same rate as during cooling: Warm gas neither produced the 3 to 5 Hz oscillations nor the increased movetimes.

None of these effects were seen during cooling of DAO and/or RF in behaving monkeys. Instead, there was (1) a decrease in movement amplitude (or displacement amplitude in a different task), (2) drift of the arm towards flexion or extension depending on the tissue cooled, and (3) an increase in biceps EMG activity. These 3 changes were not seen during selective PO cooling.

The experiments demonstrate the importance of climbing fiber projections for correct cerebellar control of posture and movements, and suggest a role for PO different from that of DAO.

211.2 COMPLEX RESPONSE PATTERNS IN DENTATE NUCLEUS DURING VISUALLY JAL GUIDED ARM MOVEMENTS. W.A. MacKay, H.C. Kwan, J.T. Murphy and Y.C. Wong*. Dept. of Physiology, Univ. of Toronto, Canada, M5S 1A8.

The aim of this study was to analyze single unit activity in the dentate nucleus during voluntary arm movements in terms of motor output parameters and sensory cues. Microelectrode recordings were made in chronically prepared macaque monkeys trained to perform a cyclic visual tracking task with the right arm. By means of horizontal elbow flexion-extension in a manipulandum, they maintained a cursor on top of a target line displayed on a videomonitor in front of them. The target line moved between two fixed positions at 1 sec. intervals. During the tracking task, controlled ramp torque pulses were delivered to the forearm in either direction. Of 193 ipilateral units studied in the cerebellar nuclei, only 27 were clearly related to the task. No task-related cells have yet been found in the fastigial nucleus, and no nuclear units have been uniquely correlated to movement parameters about a single joint (although several fibers in the overlying white matter have displayed such a correlation). Where task-related neurons occurred, they were clustered together. In the dentate, unit discharge was generally modulated phasically and bidirectionally (either more or less firing) and also was usually responsive to visual motor cues. Task-related units were not responsive to other arm movements such as reaching. Neurons which were directionally selective resembled the "joint position" cells of Thach, but the change in discharge rate associated with a particular joint angle was probably not a direct consequence of somatosensory input. Torque disturbances delivered to the forearm did not produce a directionally selective response, and visual influences were demonstrable, dependent on motor state. Many neurons not classified as task-related did modulate their activity in phase with the elbow movements, but only at the onset of a series of trials (volitionally initiated). Another group of non task-related cells showed a correlation with reaching movements. No dentate cells have yet been found with activity patterns correlated to isolated finger movements. In general, clusters of dentate neurons appear to be involved in the regulation of specific movements which may be classified by functional synergies rather than by discrete joint rotations. Furthermore, the regulation appears to be operative under a finite set of conditions.

211.3 ALTERATIONS IN THE RESPONSE OF PURKINJE CELLS TO MOSSY FIBERS WHEN AN ASSOCIATED CLIMBING FIBER INPUT IS EVOKED BY PERIPHERAL STIMULI. T. J. Ebner and J. R. Bloedel. Departs. of Neurosurgery and Physiology, University of Minnesota Minneapolis 55455.

Experiments were performed in decerebrate, unanesthetized cats to examine the relationship between the Purkinje cell responses to mossy fiber and climbing fiber inputs responding to the same peripheral stimulus. Purkinje cells identified by the presence of spontaneous complex spikes were recorded in the anterior lobe of the cerebellum using conventional electrophysiological techniques. A natural peripheral input was applied with a displacement controlled vibrator which produced a brief (100 msec) flexion of the ipsilateral wrist. Peristimulus time histograms of the simple and complex spike activity of each cell were constructed during 100 presentations of the peripheral input. The trials used to construct the simple spike histogram were further subdivided based on whether or not a climbing fiber event occurred in response to the peripheral stimulus. Simple spike histograms were then constructed from the trials in each group and normalized based on the number of trials in each histogram. These two histograms were compared to determine whether the simple spike response to the peripheral stimulus was different when a climbing fiber response was also evoked. In many Purkinje cells, the increase or decrease in simple spike activity due to the forepaw flexion was considerably greater when a climbing fiber response occurred. In fact, for some cells a component of the response to the mossy fiber input only occurred when climbing fiber afferent input was present. These results support previous work showing that the change in simple spike activity evoked by a peripheral stimulus can be affected by the occurrence of a climbing fiber input. Specifically, when a climbing fiber input to a Purkinje cell is evoked by a peripheral stimulus, the changes in simple spike activity produced by the same stimulus are often greater and/or different than when no climbing fiber input occurred. This work was supported by NIH Grant #2R01-NS-09447-10.

211.4 EFFECTS OF SPONTANEOUSLY OCCURRING CLIMBING FIBER INPUTS TO ONE PURKINJE CELL ON THE RESPONSES OF NEIGHBORING CELLS TO MOSSY FIBER INPUTS. J. R. Bloedel and T. J. Ebner. Departs. of Neurosurgery and Physiology, University of Minnesota, Minneapolis, 55455.

Recent experiments in our laboratory demonstrated that the magnitude of the excitability change evoked in a Purkinje cell by activating a mossy fiber input is dependent upon the time it occurs after a spontaneous climbing fiber input to the same neuron. The present study was performed to determine if the occurrence of a climbing fiber input to one cell is correlated with changes in the response of neighboring Purkinje cells to a naturally evoked mossy fiber input. The activity of two to four Purkinje cells was simultaneously recorded with glass microelectrodes in the anterior lobe of decerebrate unanesthetized cats. The cells were separated by 150-1000 u in various spatial relationships relative to the direction of parallel fibers. Once each cell of a set was isolated, a natural stimulus consisting of a tap on the dorsum of the forepaw and a flexion of the wrist was applied at various intervals after the occurrence of a spontaneous climbing fiber input to one of the cells. The simple and complex spike responses at each stimulus presentation interval were determined by constructing perievent histograms simultaneously for all cells in the set from 100 consecutive responses to these natural stimuli. An analysis of these results revealed that, in several sets, the response of any cell in the set to the mossy fiber input could be increased when evoked at intervals from 20-60 msec following the climbing fiber input to only one of these neurons, even when the spontaneous climbing fiber inputs of the neurons were not temporally correlated. This observation was not associated with a change in the excitability of the neighboring neurons resulting from the action of the climbing fiber input used to trigger the sweep. Effects of this type were observed between neurons separated by as much as 400 u in the sagittal plane or by 1 mm along the direction of parallel fibers. Based on these observations it is concluded that the occurrence of a climbing fiber input to a given Purkinje cell is associated with changes in the responsiveness of neighboring Purkinje cells to naturally evoked mossy fiber inputs. This work is supported by NIH Grant #2R01-NS 09447-10.

211.5 CLIMBING FIBER INPUT FROM MECHANORECEPTORS TO LOBULE VI OF THE CAT CEREBELLUM. Lee T. Robertson and Ethan Schrank*. Neurol. Sci. Inst., Portland, OR 97210.

Descriptions of cutaneous projections to the cerebellum have traditionally placed input from the face in lobule VI and input from the lower body in lobules IV and V. However, our previous studies of climbing fiber (CF) projections to lobule V have shown a more complex organization, including a connection with the ipsilateral face. This investigation of cutaneously elicited CF responses in the intermediate zone of lobule VI of the cat reveals a more complex topographic organization than shown by previous descriptions, including considerable input from all over the body surface.

The cats were anesthetized with sodium pentobarbital and extracellular recordings were made of single Purkinje cells. The CF responses were elicited by gentle taps to the body and by computer-controlled punctate stimuli. Receptive fields were delineated and latency and force thresholds were measured.

CF responses were isolated in 512 cells, of which 77% were directly elicited by cutaneous stimulation of various body surfaces (40% face, 45% forelimb, 8% midbody, and 7% hindlimb). The 157 receptive fields involving the face were distributed to: the ipsilateral ear (32%), tip of the nose (28%), mandible (25%), cornea (11%) and forehead (11%). This distribution was very different from that observed for lobule V face zone, where only a few fields included the ear, none involved the cornea, and many represented the oral cavity. Input from the forelimb elicited CF responses in lobule VI in 181 cells. The receptive fields of these cells included the shoulder and arm (23%), forearm (41%), and forepaw (36%). More than a third of the receptive fields for the forepaw were bilateral and symmetrical, a condition that was never observed in lobule V. The somatotopic organization for intermediate zone consisted of several elongated patches. Medially, the bilateral forepaw fields were located caudally and the face input was found rostrally; in the middle of the zone input from the lower back, rump, and abdomen were identified; and laterally, another forelimb patch was found rostrally and a small hindlimb area caudally.

These data, when compared with the organization of cutaneous input in lobule V, indicate that the same peripheral information is represented in multiple cortical areas. The different proportional representation of skin surfaces between various lobules does not simply reflect peripheral innervation density, but suggests distinct functional roles for each lobule.

211.6 GENESIS AND MODIFICATION OF THE GEOMETRY OF CNS HYPERSPACE. CEREBELLAR SPACE-TIME METRIC TENSOR AND "MOTOR LEARNING". A. Pellionisz and R. Llinas. Dept. Physiology & Biophysics, New York University Med. Ctr., 550 First Ave., New York 10016.

Understanding CNS function is related, in our view, to defining the properties of the geometry of its hyperspace. Tensor network theory treats such geometry formally (Neurosci.Abst.1978), interprets motor coordination as a covariant-contravariant transformation through a cerebellar (CB) metric tensor (Neurosci. Abst. 1979), and features this metric as furnishing the CNS with an internal space-time geometry (Neurosci.Abst. 1980).

A fundamental question here however, is how such metrics arise in the CNS. The CB is an excellent candidate in which to define such task because the musculoskeletal geometry is innate, and thus the CB metric must be ontogenetically constructed. However, given the curvature of motor hyperspace such metric cannot be constant, i.e. the connectivity matrix must be dependent on the position of the motor vector in this hyperspace. The climbing fiber (CF) system has been considered as actively changing the curvature of the hyperspace by altering the physiological transformation of motor vectors through the CB metric. (Neuroscience 1980. Vol.5. p.1125.)

As for the question of CB involvement in "motor learning" we suggest that the inferior olive provides a covariant CF vector (CFV) that is the inner product of the covariant correction vector (the difference between intention and execution) and the contravariant motor status vector, both being expressed in the non-orthogonal motor execution reference-frame. This "motor adjustment" by CFV is an ongoing function that refines motor performance without invoking synaptic plasticity or anatomical modification of the CB metric. The more general "motor acquisition" of new movements arises in this model as an extracerebellar generation of new intention vectors using the existing CB metric. Finally, "motor adaptation" (e.g. in vestibular compensation: Science, 1975, Vol.190. p.1230) requires for its acquisition and retention the CF system indicating that such "adaptation" involves an alteration of CB nuclear activity. We suggest such alteration to be based on the confluence of covariant CFV (through CF collaterals into the nuclei) and the contravariant CFV that is transformed through the CB corticonuclear network.

Indeed, we conclude that co- and contravariant confluence is the basis for the genesis of epigenetically formed metrics throughout the CNS. (Supported by USPHS grant NS13742 from NINCDS)

212.1 APPETITIVE STIMULI AROUSE THE VENTRAL WHITE CELL TO THE PROLONGED BURSTING AND SPIKE BROADENING THAT DRIVE CYCLIC BUCCAL MASS MOVEMENTS IN PLEUROBRANCHAEA. Martha Ulbrick Gillette*. (SPON: Rhanor Gillette). Dept. of Physiol. & Biophys. and Neural & Behav. Biol. Prog., Univ. of Illinois, Urbana, IL 61801.

It was previously reported that spontaneous bursting in a bilateral pair of neurons, the ventral white cells (VWCs) of Pleurobranchaea, drives rhythmic neural output like that of feeding behavior in the cut roots of the isolated buccal ganglion (Gillette, Gillette and Davis, 1980, J. Neurophysiol.: 43). Further, the ability of VWCs to drive motor output is specifically dependent upon spike broadening during repetitive firing. In isolated ganglia, quiescent VWCs can be stimulated to prolonged bursts and attendant spike broadening by agents which elevate intracellular cyclic AMP, which may be an intrinsic modulator of these neurons (Gillette, Gillette and Davis, 1978, Neurosci. Abst.: 4)

The present study was undertaken to establish the extrinsic activators of the VWCs and how these activators relate to the behavioral output of these neurons. All animals used in the study responded to appetitive stimuli (squid juice or 10% amino acid hydrolysate) with a bite/swallowing sequence. Aversive stimuli (10% ETOH or 1% Haemosol) were assessed by their ability to interrupt ingestion of an appetitive stimulus and induce rejection. Immediately after behavioral testing, a semi-intact preparation (head, buccal mass, esophagus, CNS) was made for intracellular recording from the VWC. In this semi-intact preparation, appetitive and aversive stimuli were observed to produce orienting and withdrawal movements, respectively, in the oral veil. Appetitive substances applied to the mouth stimulate prolonged burst episodes (3-5 min) in the VWC with changes in spike broadening and spike undershoot waveform resembling cyclic AMP-induced bursts. During these bursts, the esophagus shortens and the buccal mass undergoes vigorous cyclic movements. The durations of VWC bursts and interburst intervals are similar to bouts of ingestive activity observed when the whole animal is presented with a long, continuous string of squid (8 ft). The latency from presentation of the appetitive stimulus to response in the VWC depends on the appetitive history of the animal, and thus suggests a role for the VWC in behavioral arousal. When the semi-intact animal is presented with aversive stimuli, the VWC either hyperpolarizes or remains silent near resting potential, depending upon the preparation. These results support a role for the VWCs in the animal's response to food ingestion such that the VWCs command motor network output which initiates or intensifies vigorous swallowing behavior. Supported by NSF Grant BNS-79-18329 to R.G.

212.2 CEREBRAL NEURONS CONSTITUTING A COMMAND SYSTEM FOR LOCOMOTION IN APLYSIA. Steven M. Fredman and Behrus Jahan-Parwar. Worcester Foundation for Exprimental Biology, Shrewsbury, MA 01545.

Our studies have indicated that in Aplysia californica, the various parts of the control system for locomotion are anatomically separated and located in different ganglia. The pedal ganglia contain both the foot motor neurons and the oscillator circuitry which drives pedal waves during locomotion. The cerebral ganglion contains neurons that initiate locomotion. These communicate with the pedal ganglia neurons via the cerebro-pedal (C-P) connectives. Cutting the C-Ps abolishes all locomotor activity (Jahan-Parwar and Fredman, Behav. Neural Biol. 27, 1979). In the present study we have identified neurons in the cerebral ganglion which are part of the "command" system for initiating locomotion. Utilizing an isolated CNS-tentacle preparation, bursting neural activity previously shown to be a correlate of pedal waves (Fredman and Jahan-Parwar, Brain Res. Bull. 5, 1980) was recorded from the cut ends of pedal nerves. The cerebral neurons had a characteristic location within the ganglion and met several criteria for being part of a "command" system. All had axons in the C-P. The neurons exhibited a high degree of decussation with 90% (n=20) having an axon in the contralateral C-P. While none had axons in both C-Ps, bilaterally homologous neurons had common synaptic input. The neurons also exhibited polysynaptic interactions among themselves. The neurons were excited by stimuli which evoked locomotion in vivo and its neural correlates in vitro: Stimulation of the tentacles with food (seaweed) extracts and noxious stimulation of the head and tail. Increased firing by the cerebral neurons preceded both spontaneous and evoked pedal wave bursts. When intracellularly stimulated, each neuron either triggered units in the pedal nerves or increased the firing frequency of spontaneously active units. All could alter the firing of units in nerves both ipsilateral and contralateral to the side to which they projected. The influence of each neuron was not equal. Different cerebral neurons altered the activity of different units in the pedal nerves. More prolonged tonic depolarization of each neuron evoked patterned nerve activity which was a correlate of the pedal wave. This indicates that the individual neurons were sufficient to initiate the pedal wave motor program. While pedal wave bursts could occur when a given neuron was silent, hyperpolarizing a neuron frequently increased the interburst intervals. Our results suggest that the initiation of locomotion results from the collective action of these cerebral neurons on their followers in the pedal ganglia. This work was supported by PHS grant NS 12483 to BJP.

212.3 SOME EVIDENCE FOR SINGLE TRIAL LEARNING IN THE NUDIBRANCH MOLLUSC, AEOLIDIA PAPILLOSA. H.S. Orbach, L.B. Cohen and M.B. Boyle. Dept. of Physiology, Yale University School of Medicine, New Haven, CT 06510.

Previous experiments suggested that the gastropod, A. papillosa, was capable of associative learning using a food-aversion paradigm similar to that developed by Gelperin and collaborators with the land slug Limax. We have now attempted to demonstrate single-trial learning in Aeolidia with the aim of obtaining a learned behavior that could be accomplished by a semi-intact preparation.

Two protocols were used. For both protocols there were between four and seven animals in each of two groups. In the first, each group was exposed in a control trial to a different novel food and allowed to bite for three minutes. The foods were then reversed in the experimental trial, with 10 mM quinine administered after the animals had bit for three minutes. The animals' food preferences were then measured by measuring the time it took the animals to bite the control and experimental foods and by using Y-tube olfactometers. The differences in time to bite the control and experimental foods were computed for each animal. Although there was considerable scatter in the data, in each of three experiments the mean difference after one trial with quinine was greater than the mean difference before quinine. Olfactometry measurements also indicated a preference for the control food in each experiment. In two of the three experiments the p values were less than 0.1; in one, the p value was greater than 0.1. In the second protocol the animals were again divided into two groups. In the control trial one group was exposed to sea-water for ten minutes, the other to sea-water plus a seafood odor (flounder or scallop) for ten minutes. In the experimental trial the groups received reversed stimuli for five minutes, and quinine (2.5-5 mM) was then added for five minutes. The animals preferences for sea-water versus sea-water plus seafood odor were measured using the olfactometers. In the three experiments the Aeolidia that received quinine paired with odor showed a clear relative avoidance of the odor side of the olfactometer. In two of the three experiments the p values were less than 0.1.

Because of the scatter in the data our results must be interpreted cautiously. However, they do suggest the possibility of a robust, one-trial associative learning in Aeolidia that could be used for in vitro cellular analyses.

Supported in part by NIH grant NS08437.

212.4 APLYSIA LEARN THAT A SPECIFIC FOOD IS INEDIBLE. A.J. Susswein, S. Gev* and M. Schwartz*. Dept. of Life Sciences, Bar-Ilan Univ., Ramat-Gan, Israel 52100.

Aplysia were taught that either of two foods was inedible. Strong and stable biting responses are elicited approximately equally well by the green algae Ulva lactuca or by leaves of the vascular plant Hemesocallis fulva. Pieces of these foods were placed in a plastic mesh, allowing Aplysia to taste the food through the holes in the mesh, but preventing Aplysia from consuming the food. Mesh-enclosed food arouses feeding behavior, and elicits repetitive biting and swallowing responses, initially at a rate comparable to that produced by non mesh-enclosed food. By five minutes after onset of feeding, rate of feeding responses is slowed by 61.3 ± 31.0 (S.D.)%. Responses cease in a mean of 22.1 ± 16.7 (S.D.) min. Stimulation of the lips for comparable periods of time with non mesh-enclosed food does not produce a similar decrease of feeding responses, indicating that sensory adaptation or habituation of taste pathways is not occurring. Following training on mesh-enclosed food, animals still respond to the same food when it is not enclosed in the mesh, or to the alternate food even if it is enclosed in mesh. This indicates that the decrease in responsiveness to mesh-enclosed food is not due to fatigue, or to non-specific inhibition of feeding behavior. The data also indicate that Aplysia do not learn to stop responding to a specific taste, or to the texture of the net. These data suggest that Aplysia learn that a specific combination of taste and texture is inedible.

Supported by U.S.-Israel Binational Science Foundation Grant No. 2210.

212.5 ANALYSIS OF THE SYNAPTIC DECREMENT UNDERLYING HABITUATION OF THE GILL-WITHDRAWAL REFLEX IN APLYSIA. J. Byrne Dept. of Physiology, University of Pittsburgh School of Medicine, 15261.

Repeated stimulation of the siphon skin results in habituation of the reflex contractions of the gill (Pinsker et al, 1970). The habituation, in turn, is casually linked to a depression of the EPSPs in motoneurons from mechanoreceptor sensory neurons (SN) (Castellucci et al, 1970; Byrne et al, 1978). The present study was undertaken to examine the kinetics of the depression and its recovery, as a first step in formulating a quantitative model of the release process.

Intracellular recordings were made from sensory neurons and motoneurons in solutions of elevated Ca and Mg to block interneuronal contributions. A SN action potential was elicited with a depolarizing current pulse and the amplitude of the resultant EPSP in the motoneuron was monitored, while ten stimuli at an interstimulus interval (ISI) of 1,3,10,30, or 100 s were presented. To control for the state of arousal of the animal and long-term decrement of the SN synapses, animals were maintained in separate chambers, dissections performed under Mg anesthesia, and only a single decrement run performed on each cell. Each SN was rested 30 m prior to stimulation. The results represent recordings from 47 cells in 29 experiments. At least 9 cells were examined at each ISI. The synaptic decrements vary as a complex function of ISI. At an ISI of 1 s there is a rapid depression which reaches a plateau of 35% of control. In contrast, the depression at an ISI of 100 s is less pronounced showing a gradual decay to 68% of control with the 10th EPSP. Surprisingly, the decrements at ISIs of 3,10 and 30 sec were similar in time course and magnitude and are intermediate between the 1 and 100 s ISIs. There is also a complex relationship between spike interval and the depression of the second of two EPSPs. The 2nd EPSP is reduced to 57% of control with a spike interval of 1 s, 84% with 3s, 81% with 10s, 79% with 30s, and 88% with 100s. Thus, depression of the 2nd of 2 EPSPs or decrement of a train of EPSPs is not a monotonic function of spike interval. Indeed, the data suggest that there may be a slight underlying facilitatory process with short spike intervals. Preliminary results indicate that the recovery of synaptic depression following a train of 10 stimuli is not constant. Shorter spike intervals seem to produce more rapid recovery.

These data are inconsistent with a classical depletion model (Liley & North, 1953) for synaptic depression, and indicate that either a single complex function of time and ISI or multiple functions underlie synaptic depression at the sensory neuron synapse.

212.6 OLFACTORY CHOICE BEHAVIOR OF NORMAL AND MUTANT DROSOPHILA IN A CONFLICT SITUATION IN A SUCCESSIVE CONDITIONING PARADIGM. Yadin Dudai, Dept. of Neurobiology, The Weizmann Institute of Science, Rehovot 76100, Israel.

The behavior of wild-type Drosophila (C-S strain) and of the X-linked olfactory conditioning mutants, dunce^{DB38} (Dudai et al., PNAS 73:1684, 1976) and rutabaga and cabbage (Aceves-Pina and Quinn, Science 206:93, 1979; Tempel and Quinn, Neurosci. Abst. 6:589, 1980) was analyzed in an olfactory conditioning task. Populations of flies were exposed to an odorant, A (e.g., benzaldehyde) associated with an electric shock and later tested for choice between A and another odorant, B (e.g., 3-octanol), in a T-maze. The experiments were controlled for odor-bias and non-associative behavioral modifications. The fraction of normal flies in the non-shock odorant arm minus the fraction in the shock-odorant arm was 0.44±0.06 when measured 30 sec after training. A transient decrease was detected in memory within 2-4 min after training. Memory reached initial values again at about 5-10 min and decayed slowly ($\tau_{1/2}$≈45 min). Memory of dunce^{DB38} was 70% of normal, of rutabaga was 60% of normal, and of cabbage was 40% of normal 30 sec after training. Memory decayed rapidly in all the mutants to ~5% of normal at 7 min. Memory of heterozygotes was intermediate. Successive conditioning experiments were conducted to test whether the mutants store latent memory that cannot evoke a normal choice but may interact with newly acquired information. Flies were exposed to a shock-odorant, were exposed again a few minutes later to the same or another shock-odorant, and were then tested for their choice between A and B, so that the test was performed 30 sec after exposure to the last shock-odorant and 7 min after exposure to the first shock-odorant. Successive conditioning to A increased only slightly the selective avoidance of A in C-S and did not significantly improve immediate memory of the mutants. Conflicting conditioning, i.e., first to B and later to A, resulted in a marked decrease of selective avoidance in C-S and the mutants, except dunce. A shock in the presence of a non-relevant odorant 30 sec or 7 min before testing did not revive lost memory in the mutants or abolish their immediate memory, respectively. Taken together, the results suggest that all the mutants can form short-lived olfactory associations. Behavioral analysis, however, can separate the mutants into different types: rutabaga and cabbage, but not dunce, apparently can behave as though they store information for a longer period than that revealed by straightforward memory tasks, but this information reveals itself only by interaction with newly acquired information in a conflict situation. (Supported by the U.S.-Israel Binational Science Foundation, Jerusalem).

212.7 USE OF A LEARNING PARADIGM TO DEFINE BEHAVIORAL STATE IN AN INSECT. Robin R. Forman and Sasha N. Zill*. Dept. Biol., Univ. of Oregon, Eugene, OR 97403.

In invertebrates, many postural and load compensatory reflexes are variable and can exhibit changes in gain or sign depending upon the behavioral state of the animal (Bassler, Biol.Cyber. 24:47, 1976; DiCaprio & Clarac, J.Exp.Biol. 90:197, 1981). While learning paradigms have been widely used to define behavioral state in vertebrates (Evarts, Science 179:501, 1973; Bizzi, et al., J. Neurophysiol. 41:542, 1978), these paradigms have not been applied to invertebrate preparations. We here report the use of a leg position learning paradigm to investigate the role of an insect leg proprioceptor, the locust metathoracic femoral chordotonal organ, in actively maintained postures.

The femoral chordotonal organ monitors the angle of the femoro-tibial joint. Reflex effects of the chordotonal organ were examined by abruptly displacing the main ligament of the organ. Pulls to the ligament mimicked ligament shortening that accompanies flexions of the tibia, releases after initial pulls mimicked equivalent extensions.

In untrained animals, step displacements of the ligament elicited variable resistance reflexes in motoneurons to tibial muscles, as monitored myographically, that consisted of brief phasic discharges of slow motoneurons.

In learning experiments, locusts were trained to hold the tibia of one hindleg within a narrow (15-20°) range of joint angle in order to avoid heating of the head or mouthparts by a focussed lamp. After training, step displacements of the ligament resulted in prolonged compensatory bursts in leg motoneurons. These bursts were significantly greater in intensity and duration in animals that were trained and actively maintaining a joint position than in untrained animals, animals that had not learned after training, or yoked control preparations. Abrupt releases of the ligament demonstrated substantial hysteresis in motoneuron response. Similar hysteresis is seen in recordings of afferent activity from the femoral chordotonal organ.

These studies demonstrate that the reflex effects of input from the femoral chordotonal organ are consistently increased when an animal is induced to actively maintain a specified posture. We suggest that learning paradigms may be of use in investigations of postural mechanisms in other invertebrate preparations. Supported by NSF grant BNS 75-00463 and NSF grant SPI-7914916.

212.8 ULTRASTRUCTURE AND CONNECTIVITY OF IDENTIFIED NEURONS IN THE FLY'S BRAIN. H.Eckert and K.Meller*. Univ. Bochum, Animal Physiol., D-4630 Bochum, W.-GERMANY

Some 22 motion sensitive neurons in the lobula plate of the fly, Phaenicia, were identified by intracellular dye injection; they are believed to control torque, lift and thrust responses sind their responses to moving stimuli accord with those of the behavioural responses. Some of these cells can be recognized in semithin sections. By alternately cutting serial semi- and ultrathin sections, their synaptic structures were studied.

The axons of the 9 V-cells bifurcate in the lobula plate. The two main dendrites, second and higher order dendritic branches are all postsynaptic to small fibers; the highest density of synapses is found for the smallest dendritic branches. All synaptic structures are characterized by a high number of synaptic vesicles in the presynaptic cell, a presynaptic T-shaped ribbon and a thickening of the postsynaptic membrane. The axons are partially surrounded by 2-14 layers of membranes resembling myelinated axons. Within the protocerebrum, the axons possess pre- as well as postsynaptic structures, the former showing only a few synaptic vesicles. Associated with the V-cells is a VH-cell similar in appearance but possessing an additional dorsal branch which originates at the proximal edge of the lobula plate; it possesses postsynaptic structures at the level of the H-cell-dendrite. The 3 H-cells possess a large dendritic fan which is postsynaptic to small fibers. A second 'axonal arborization' in the central protocerebrum, as well as the axonal endings, possess pre- as well as postsynaptic structures. The axonal arborization is presynaptic to CH-cells. Most synaptic structures are characteristic for chemical synapses; membrane specializations probably indicating electrical synapses were also found. The 2 CH-cells are postsynaptic to H-cells and unidentified cells in the protocerebrum. In the lobula plate, pre- as well as postsynaptic structures were found.

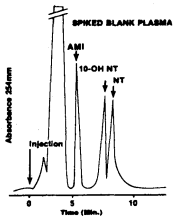
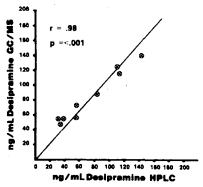
213.1 HIGH PERFORMANCE LIQUID CHROMATOGRAPHIC (HPLC) QUANTITATION OF AMITRIPTYLINE, NORTRIPTYLINE AND 10-HYDROXY-NORTRIPTYLINE IN HUMAN SERUM USING A RADIAL COMPRESSION MODULE. D.M. Martin*, W.R. Dixon*, A.L.C. Pottash and M.S. Gold.
Psychiatric Diagnostic Labs. of America, Summit, N.J. 07901 and Hoffmann La Roche, Nutley, N.J. 07110.

Accurate measurement of plasma tricyclic antidepressant concentrations and their psychoactive metabolites facilitates the effective clinical management of depression. Nortriptyline (NT) is the most widely studied tricyclic, with an established therapeutic response "window" of 50-140 ng/mL. However, in amitriptyline (Ami) treated patients the combined Ami and NT concentrations do not reliably yield a plasma level-response correlation. This may be due to conversion of Ami to both NT and a psychoactive hydroxylated metabolite. This hydroxylated metabolite (10-OH-NT) has been demonstrated to inhibit synaptosomal monoamine reuptake and is capable of reversing the "reserpine" syndrome in rats. This suggests that 10-OH-NT has antidepressant activity and emphasizes the need to include the hydroxylated metabolite when measuring total plasma antidepressant concentrations and correlating them to clinical effects. We report a rapid and sensitive HPLC procedure for the simultaneous measurement of AMI, NT, and 10-OH-NT in clinical plasma samples. The compounds were extracted from 1.0 mL of plasma at pH 10.5 into iso-octane:ether (9:1), the organic phase freeze dumped and taken to dryness under a stream of nitrogen. The reconstituted residue was injected into a HPLC using an isocratic system of 0.3% butylamine in methanol flowing at 1.5 mL/min through a HPLC radial compression module containing a silica gel cartridge. Detection was in the ultra-violet at 254 nm. Ami, 10-OH-NT and NT were readily separated under these conditions (Fig). The limit of sensitivity of the procedure was approximately 25 ng/mL for each compound. Over three hundred patient samples have been analyzed utilizing this technique, yielding a mean day-to-day coefficient of variation of less than 9%. It was noted that steady state 10-OH-NT levels were generally greater than NT levels in the same patient and in some instances it would appear that high levels of 10-OH-NT may be responsible for observed cardiovascular arrhythmias and/or reduced therapeutic response.



213.2 HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC) VERSUS GAS CHROMATOGRAPHY MASS SPECTROSCOPIC ANALYSIS (GC/MS) OF A TRICYCLIC ANTIDEPRESSANT IN HUMAN PLASMA. A.L.C. Pottash, D.M. Martin*, I. Extein, W.Z. Potter*, A.P. Zavodil* and M.S. Gold. Psychiatric Diagnostic Laboratories of America, Summit, N.J. 07901 and Clinical Psychobiology Branch N.I.M.H., Bethesda, Md. and Clinical Research Facilities, Fair Oaks Hospital, Summit, N.J. 07901.

Tricyclic antidepressants (TCA) are the most widely prescribed medications used in the psychopharmacological treatment of major endogenous depression. Steady state plasma concentrations of these compounds vary considerably between subjects treated with the same dose and can be influenced by pharmacokinetic and other factors. This makes therapeutic drug monitoring essential to insure maintenance of adequate plasma concentrations during a medication trial. Analytical techniques for routine monitoring of TCA's which have appeared in the literature are being utilized in the clinical laboratory. Variations in analytical methodology may explain the conflicting findings in some reports on the clinical utility of TCA levels. We have previously reported a HPLC method for monitoring TCA's and have recently completed a double blind study of this technique versus a GC/MS technique. Nine patients on varying doses of imipramine or desipramine were included in the study. The blood samples were drawn and the plasma split into two coded vials. All operators were blind to the code throughout the analysis. The HPLC assay procedure was reported by Martin, et al (Neuroscience Abstract, 1979). The GC/MS assay procedure was reported by Claeys et al (Biomed. Mass. Spec. 3:110, 1976). The results demonstrated a highly significant correlation between the GC/MS and HPLC assays ($r=.98$; $p < .001$; see figure). These data suggest the reported HPLC method compares well with existing GC/MS techniques and has the additional benefit of simplicity of instrumentation and ease of applicability for routine therapeutic monitoring in the research and clinical laboratory.



213.3 NEUROPHARMACOLOGICAL PROFILE OF WELLBUTRIN™ (BUPROPION): A NOVEL ANTIDEPRESSANT WHICH INHIBITS DOPAMINE UPTAKE. B. R. Cooper, K. Viik, T. Uicker; Department of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, North Carolina 27709.

Bupropion, a novel compound with antidepressant effects in man was found to reduce immobility in the Porsolt "Experimental Helplessness" forced swimming antidepressant test like imipramine or amitriptyline. Higher doses produced elevated locomotor activity in an automated open field and produced stereotyped sniffing. When bupropion or desmethylimipramine were given prior to intracisternal injections of 6-hydroxydopamine, bupropion produced a dose-related selective antagonism of the destruction of dopamine (DA) neurons beginning at 25 mg/kg i.p. Under the same conditions, desmethylimipramine produced a dose-related selective antagonism of the destruction of noradrenergic (NE) neurons. Bupropion also antagonized 5HT uptake in vivo at doses of 50 mg/kg i.p. or greater as judged from antagonism of p-Cl-methamphetamine-induced serotonin depletions. Studies of synthesis of ^{3}H-catecholamines from 2,6-^{3}H-tyrosine revealed that low doses (3 mg/kg to 12 mg/kg) decreased ^{3}H-DA formation and increased ^{3}H-NE formation. Higher doses led to an increase in ^{3}H-DA formation. A decrease followed by an increase in DA utilization was also reflected in changes in DOPAC levels in brain. It is felt that these changes in DA systems reflect the consequences of DA uptake inhibition on the activity of DA neurons. Thus low levels of DA uptake inhibition reduce DA neural activity via the dopamine being directed to presynaptic inhibitory autoreceptors while high doses of bupropion effectively prevent reuptake thereby calling into play mechanisms for synthesis of DA. The importance of dopamine neurons for the CNS pharmacology of bupropion was studied in rats with DA neural destruction produced by 6-hydroxydopamine. Destruction of DA neurons antagonized the effects of bupropion in the Porsolt antidepressant test and in tests of locomotor activity. Destruction of NE neurons had no significant effect on the locomotor stimulating effects of bupropion or on its actions in the Porsolt test.

Results indicate the importance of dopamine for the CNS pharmacology of bupropion in rat. Evidence of elevated 5HT and NE neural activity was also obtained after bupropion in rats. Since all three amines are theoretically implicated in human depression, clinical evaluation of the activation of all three monoamine neural systems by bupropion in depressed patients through monitoring DOPAC, 5HIAA, and MHPG·SO_4 levels in CSF is desirable. Such monitoring may provide the data required to determine the mechanisms of action of this drug, as well as provide insights valuable in bridging the gap between the effects of drugs in animal models and in human mental disease.

213.4 NOVEL ANTIDEPRESSANTS AND NEUROLEPTICS: EFFECT ON THE CENTRAL ADRENERGIC SYSTEM. R.L. Winsky*, S.H. Preskorn, R. Glotzbach*, and G. Irwin* (SPON: C.W. Hughes). Dept. of Psychiatry and Pharmacology, Univ. Kansas Medical Center, Kansas City, KS 66103.

Integrity of the blood:brain barrier (BBB) is of vital importance to normal cerebral functioning. The BBB appears to be regulated by central adrenergic neurons and this regulation can be influenced by administration of psychoactive drugs such as tricyclic antidepressants, TCA's (Preskorn et al., JPET 1980). In this series of studies, the effects of experimental antidepressant and neuroleptic drugs on cerebral permeability to water and blood flow (CBF) in the rat were studied. E_W --the cerebral extraction fraction for water--was determined by i.v. administration of a tracer solution of ^{3}H-water and ^{14}C-butanol as previously described. CBF was measured by comparing brain uptake of ^{14}C-butanol in an arterial blood sample withdrawn at a known, uniform rate (Preskorn, et al., Sci. 1981). The drugs tested have varying clinical effects and different neuropharmacological mechanisms. Amitriptyline, a norepinephrine reuptake blocker, causes an increase in E_W at a dose of 0.4mg/ kg i.v. This increase is mediated by the central adrenergic effects of the drug (Preskorn, et al., Neurosci. Abst. 1980). Three drugs (thioridazine, fluphenazine, and an analogue of loxapine) which block postsynaptic dopamine receptors did not alter E_W when given as a single i.v. dose of 0.4mg/kg. Neither did drugs which are predominantly dopamine or serotonin reuptake inhibitors: (a) bupropion and nomifensine, and (b) citalopram and trazodone, respectively. However, two drugs with predominantly central adrenergic mechanisms did alter E_W. Dothiepin--an analogue of amitriptyline--produced an increase in E_W similar to that of amitriptyline and the other TCA's. In contrast, mianserin--a drug having greater binding affinity for both alpha one and two adrenergic receptors than TCA's--reduced E_W.

These results should be interpreted cautiously because only one dose was employed. Yet, they do support the central adrenergic vasoregulatory hypothesis which states that this neuronal system has, as one of its functions, regulation of brain permeability and blood flow. Of the drugs tested, only those with known adrenergic mechanisms of action altered E_W. This in vivo animal model may be a useful adjunct to the biochemical and behavioral approaches used to assess the central effects of experimental drugs. This model is unique in that it reflects the in vivo effect of experimental manipulation on the interaction between the central adrenergic system and the cerebral microcirculation-- an end-organ which it directly innervates.

213.5 EFFECTS OF ANTIDEPRESSANTS ON THE CENTRAL CHOLINERGIC NERVOUS SYSTEM. Mark E. Goldman and Carlton K. Erickson, Div. of Pharmacology, College of Pharmacy, Univ. of Texas, Austin, TX 78712

The purpose of this investigation was to study the effects of antidepressants and anticholinergics on the cholinergic system after acute and chronic drug administration. Drugs were first divided into highly potent, moderately potent or weak anticholinergic categories based upon each compound's ability to displace ^{3}H-QNB from synaptosomal membranes. One antidepressant and one non-antidepressant with similar anticholinergic properties were chosen as representative agents of each anticholinergic potency category. In the first study, high affinity choline uptake was used as an indicator of the turnover rate of acetylcholine. Acute administration of amitriptyline or atropine (highly potent anticholinergics) increased choline uptake levels in the hippocampus and striatum. After 30 days pretreatment with either drug, an acute challenge dose no longer altered choline uptake in either region. The tolerance seen after chronic drug administration could not be attributed to hepatic mechanisms since the challenge was still ineffective in altering choline uptake levels in rats treated with SKF-525A (50 mg/kg; 60 min. prior to the challenge). Choline uptake levels were also unchanged following an amitriptyline challenge in rats chronically pretreated with atropine. Imipramine and thioridazine (moderately potent anticholinergics) increased choline uptake only in the striatum. After chronic drug treatment followed by a challenge dose, choline uptake levels were not significantly different from controls. Nomifensine and d-amphetamine (non-potent anticholinergics) are presently being evaluated. In the second study, changes in muscarinic receptor distribution and binding affinity were determined after chronic drug administration and 72 hr. withdrawal. Atropine caused an elevation of receptor density in the cortex, hippocampus and striatum. Amitriptyline elevated muscarinic receptor density only in the cortex. Imipramine, thioridazine, nomifensine and d-amphetamine did not alter muscarinic receptor density in any of the brain regions examined. None of the drugs altered receptor affinities after 72 hr. withdrawal. The results of these studies show that tolerance can occur to the central cholinergic effects of antidepressants. Since the central cholinergic actions of antidepressant drugs matched the central cholinergic actions of anticholinergic drugs lacking clinical antidepressant activity, we conclude that the effects of antidepressants on the central cholinergic nervous system are more closely related to the side effects of these drugs than to their mechanism of therapeutic action. (Supported by funds from the University of Texas.)

213.6 TRAZODONE ENHANCES LOCUS COERULEUS FIRING RATE: EVIDENCE FOR RELATIVE LACK OF α-2 ADRENORECEPTOR INVOLVEMENT. Welch, J. J., Kim, H. K.* and Liebman, J. Res. Dept., Pharma. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

α-2 Adrenoreceptor antagonism has been proposed as a possible mode of antidepressant action, particularly in the case of mianserin. Recently, it has been suggested (Clements-Jewery et al., Neuropharmacol. 19:1165, 1980) that α-2 adrenoreceptor antagonism may also be a property of trazodone, another clinically effective antidepressant. This mechanism was proposed to account for the ability of trazodone to increase the turnover of norepinephrine in rat brain. Using extracellular single unit recording techniques, we have explored this possibility by examining the effects of trazodone and other adrenoreceptor antagonists on noradrenergic locus coeruleus neuronal firing rate.

Intravenous administration of low doses of trazodone (0.5 - 4 mg/kg) enhanced locus coeruleus firing rate dose-dependently. This increase was comparable in magnitude to that following i.v. treatment with yohimbine (0.5 - 2 mg/kg), a known preferential α-2 antagonist. However, the α-1 antagonists, prazosin and WB-4101, were also found to increase locus coeruleus firing rate. Prazosin is believed to be devoid of α-2 blocking activity, but WB-4101 has α-2 as well as α-1 blocking properties.

The comparative ability of these drugs to antagonize clonidine's known suppressant action on locus coeruleus neurons is believed to be mediated through a direct agonist action on α-2 adrenoreceptors. When clonidine was administered by itself in small incremental doses, approximately 6 μg/kg was required to inhibit firing to 50% of baseline rate (ID_{50}). Pretreatment with yohimbine elevated the ID_{50} of clonidine markedly (to 90 μg/kg), presumably reflecting strong α-2 blockade. In contrast, trazodone only partially blocked the effects of clonidine (clonidine ID_{50} = 16 μg/kg), despite its marked effectiveness in elevating locus coeruleus firing rate by itself. Prazosin and WB-4101 also failed to attenuate the effects of clonidine.

These results indicate that trazodone may enhance the synaptic availability of norepinephrine by increasing locus coeruleus impulse flow. These effects, however, are unlikely to be mediated by α-2 noradrenergic receptors. Other factors, including α-1 receptor antagonism, are apparently capable of modulating locus coeruleus neuronal activity.

213.7 TRAZODONE: RECEPTOR BINDING BY A NOVEL ANTIDEPRESSANT. Duncan P. Taylor, Elizabeth M. Ashworth*, Jerry A. Becker*, and Deborah K. Hyslop*. Biologic Research Mead Johnson Pharmaceutical® Division, Evansville, IN 47721.

Trazodone HCl (Desyrel®) is a clinically effective and well-tolerated antidepressant (J. Clin. Psychiat. 40: 390). Its pharmacologic profile is quite different from that of known antidepressants inasmuch as it does not show the type of response exhibited by conventional tricyclic antidepressants in traditional animal test systems. Trazodone has been shown to block serotonin (5-HT) uptake with a high degree of selectivity compared to its potency toward uptake of catecholamines (Psychopharmacol. 63: 99). We have investigated the in vitro interactions of trazodone in a variety of radioreceptor binding systems. Trazodone is a weak inhibitor of binding at sites labeled by ligands for α_2, β, benzodiazepine, dopamine, glutamate, glycine, H_1 and H_2 histamine, and 5-HT_1 sites. In marked contrast to currently available antidepressant drugs, trazodone only weakly inhibits binding at muscarinic cholinergic sites, and this interaction is noncompetitive in nature. Chronic treatment of rats with tricyclic antidepressants leads to decreased in vitro binding at β and 5-HT_2 (labeled with [^{3}H]spiperone) receptors. Chronic oral dosing of trazodone (20 mg/kg, 28 days) leads to a significant loss of 5-HT_2 receptors without change in the number of β-adrenergic receptors. In combination with phenoxybenzamine (10 mg/kg), i.p. administration of 40 mg/kg trazodone resulted in decreased 5-HT_2 receptor binding after only four days of treatment, while neither drug alone had any effect during this time. Changes in β-adrenergic binding were seen only after 11 days' treatment with 100 mg/kg., i.p., trazodone. In this experiment, 5-HT_2 binding was reduced 45% while β-adrenergic binding was reduced 17%. These results suggest that changes in β-adrenergic binding are secondary to changes in 5-HT_2 binding. Trazodone and the tricyclic antidepressants are good inhibitors of 5-HT_2 binding in vitro. It is not yet known if this phenomenon is related to the selective inhibition of 5-HT uptake or if either effect is clinically relevant. In view of the time course of trazodone's action, the selective effect on the number of 5-HT_2 receptor sites following chronic administration may represent the mechanism of antidepressant action.

213.8 LITHIUM ISOTOPES: DETERMINATION OF ABUNDANCES IN PLASMA AND ERYTHROCYTES. K.W. Lieberman, *P. Karczmar* and P.E. Stokes. Division of Psychobiology, Department of Psychiatry, New York Hospital-Cornell Medical Center, New York, New York 10021.

Lithium (Li) is used in the treatment of the manic phase of manic depressive illness, but the reasons for its therapeutic efficacy remain unclear. Naturally occurring lithium (Li-N) which is used as the chloride salt in the treatment of manic patients is composed of 2 stable isotopes; lithium-7 (Li-7) is the major component (92.58%) and lithium-6 (Li-6) the minor component (7.42%). Results have been reported suggesting the 2 isotopes of Li have dissimilar membrane transport, behavioral and toxicological properties. Work up to this time has involved the use only of isotopically pure (99%+) Li-6 and Li-7 in the chloride form. Experiments that used mixtures of Li-6 and Li-7 were precluded because of the difficulties inherent in the methodology. An expensive and highly complex technique, mass spectroscopy, is the usual approach and for our purposes this was impractical. On the basis of the work of Brost. et al. (Anal. Chem. 51, 1512, 1979) we developed a method for the simultaneous determination of the isotopic abundances of Li-6 and Li-7 in plasma and erythrocytes that utilizes atomic absorption spectrophotometry, an economical and convenient technique. The analytical lines for the 2 Li isotopes are the resonance doublet at 670.8 nm. Determination of the Li isotopic composition in plasma and erythrocytes is based upon the method used when several compounds that are analyzed simultaneously possess overlapping ultraviolet or visible spectra. Absorbance measurements are carried out using Li-6 and Li-7 hollow cathode lamps. At a total Li concentration of 1.3 ppm and a Li-6 abundance of 7.42% the relative error in the determination ranged from 2-5%. For a total Li concentration of 1.0 and 1.5 ppm and a Li-6 abundance of 7.42% the relative now was larger, 5-10%. This technique will now enable us to do experiments with mixtures of Li isotopes so that we may further investigate to what degree biological systems differentiate between Li-6 and Li-7.

213.9 SHORT-TERM LITHIUM ENHANCES 5-HT NEUROTRANSMISSION IN RATS ADMINISTERED CHRONIC ANTIDEPRESSANT TREATMENTS. C. de Montigny, A.-T. Tan and G. Caillé*, Départ. de Psychiatrie et de Pharmacologie, Univ. de Montréal, Montréal, Québec, Canada H3C 3J7.

Lithium induces a rapid relief of depression in patients under treatment with but not responding to tricyclic antidepressant drugs (TCA) (de Montigny et al., Brit. J. Psychiat., 138: 252, 1981). The same observation has now been made in subjects having failed to improve with electroconvulsive shock therapy (ECT) (unpublished observations). It was postulated that, in these patients, the effect of lithium might be due to an enhancement of the efficacy of the 5-HT system superimposed to the sensitization of postsynaptic receptors already induced by TCA or ECT. This hypothesis was put to the test using the "5-HT syndrome" model in the rat.

Male-Sprague Dawley rats (200-250 g) received daily injections of imipramine (IMI) (5 mg/kg, i.p.) or saline (0.5 cc, i.p.) or were given ECT (150 V, 10 ms pulses at 50 Hz for 1 s) three times weekly for two weeks. Half of the animals in each group were also given lithium carbonate (27 mEq/g of food) during the last two days of the treatment period. Lithium blood levels ranged from 0.6 to 1.1 mEq/L. On the 15th day, all rats were challenged with tranylcypromine (TCP) (20 mg/kg, i.p.) and L-tryptophan (L-TP) (50 mg/kg, i.p.). The intensity of the 5-HT syndrome was rated 75 min later according to the criteria of Jacobs (Life Sci., 19, 777, 1976) by two evaluators unaware of the treatment.

In rats treated with IMI or ECT, the 5-HT syndrome produced by TCP and L-TP was slightly enhanced as compared with saline controls. In these controls lithium itself produced a marked increase of the syndrome, as already reported by Grahame-Smith and Green (Brit. J. Pharmacol., 52: 19, 1979). An even greater increase was observed when lithium was added to the IMI or ECT treatments. Notably, sustained myoclonia could be observed only in animals having received both antidepressant and lithium pretreatments.

In the last few years, several groups of investigators have demonstrated that chronic administration of TCA or ECT in the rat results in an increased responsiveness of forebrain neurons to 5-HT. The present data suggest that lithium addition to these antidepressant treatments can further enhance the synaptic efficacy of the 5-HT system. This finding is consistent with the hypothesis that lithium might exert its rapid antidepressant effect in TCA- or ECT-nonresponding patients by augmenting the action of the 5-HT system on postsynaptic neurons already sensitized to 5-HT. (Supported by MRC Grant MA-6444 and a CRSQ fellowship to C. de M.).

213.10 CHRONIC LITHIUM TREATMENT MODIFIES THE RESPONSES TO PAIRED PULSE STIMULATION IN THE IN VITRO RAT HIPPOCAMPUS. P.C. Rinaldi, G. Barrionuevo, M.E. Rosnowska*, K. Davila*, S. Tewari*, and G. Lynch. Dept. of Psychobiology and Dept. of Psychiatry and Human Behavior, Univ. of Ca., Irvine, Ca. 92717.

While lithium is presently employed in the treatment of a variety of psychiatric disorders and chronic alcoholism, little is known of its mechanisms of action at the level of the neuron. We have investigated this question by measuring several parameters of synaptic transmission in in vitro slices of hippocampus taken from rats chronically treated with lithium.

Li_2CO_3 was given to male rats intragastrically for 4 weeks (150 mg/Kg/day) producing a stable mean serum lithium level of 1.2 mEq/l. Controls received an equal volume of water in the same manner. After hippocampal slices were prepared, bipolar stimulation electrodes were placed both in the Schaffer commissural projections to the apical dendrites of CA1 pyramidal cells and in the alveus. Extracellular activity was recorded in either the s. pyramidalis or s. radiatum.

The response of neurons to the second of two paired pulses allowed us to examine both neural facilitation and inhibition under well-defined circumstances.

To examine "facilitation", the conditioning and test stimuli were delivered through a single electrode and recordings were made of population dendritic and population spike responses. Facilitation was calculated by plotting the mean amplitude of the second response in the pair both as a percentage of the control responses and as a function of interpulse interval. To measure "feedback inhibition", we antidromically activated the recurrent collaterals of the CA1 pyramidal cells and tested for the effects of this on the population spike elicited by subsequent stimulation of the Schaffer commissural projection. "Feedforward inhibition" was tested using two different Shaffer-commissural inputs. Inhibition was measured as the mean percent decrease in amplitude of the population spike recorded from the the test input.

Li rats exhibited enhanced facilitation as measured in percent increase in amplitude and shift in time course. Conversely the time course of feedback and feedforward inhibition for Li rats was typically shortened. Implications for the mechanism of Li action will be discussed.

213.11 **BEHAVIORAL ACTIONS OF LITHIUM IN AGED MURICIDAL RATS.** **P. Broderick† and V. Lynch*, St. John's University, Jamaica, New York, 11714.**

We previously published data (Pharmacologist 1978) which reported that lithium inhibited muricidal (mouse killing) behavior in isolated young (2 month old) male, Long Evans rats. These data report that lower doses of lithium are required to produce this same behavioral change in their older counterparts.

Male, Long Evans rats (600-700 gms), approximately one year old, were housed in individual cages, without bedding, in our animal care facility. Food and water were available ad lib. Albino mice (20 gms) were placed in each rat's cage and rats which repeatedly killed mice within a fifteen minute period were selected for the study. Then rats were treated intraperitoneally and acutely with lithium chloride (0.01-10 meq/kg). Testing for the inhibition effect of muricidal behavior took place one hour after drug administration, in the evening. Any rat which did not exhibit muricidal behavior while an albino mouse was present in the rat's cage for one half hour was considered to have the killer response blocked. An adjunct test, rotarod performance, which is typically used to determine the presence of ataxia, was completed concomitantly, in the same dose response range of lithium, to determine whether or not the response to kill had disappeared due to a motor disorder by lithium.

The results showed that the ED50 for the inhibition of muricidal behavior in these rats was 0.25 meq/kg, while the ED50 for any impairment observed via rotarod performance was 7.7 meq/kg. Saline and distilled water vehicle injections produced no effect on muricidal behavior. The dose of lithium chloride needed to block the killer response in older animals was four-fold less than that needed to produce the same behavioral change in younger rats.

Therapeutically, this study is of interest since comparison of the effects of lithium on young vs old rats appears to pattern itself after the clinical response of lithium in young vs elderly patients. Elderly patients may require lower doses of lithium due to lower renal lithium clearance (Schou, 1967), and this influence of lithium on kidney function can be shown in rats (Thomsen, JPET, 199, 1976). Further research will specify whether renal clearance is a factor in this particular animal model.

214.1 TRIGEMINAL MEDIATION OF AN OROMOTOR FRACTIONAL ANTICIPATORY GOAL RESPONSE. M. Jacquin* & H. Enfiejian* (SPON: H.P. Zeigler). Dept. of Anatomy, CMDNJ-Rutgers Medical School, Piscataway, N.J. 08854.

As well as their role in reinforcing feeding and drinking, orosensory stimuli (S) have another function which is essentially motivational. The fact that a reinforcing S can also function as an incentive poses theoretical problems. How does experience which coincides with the termination of behavior come to contribute to the initiation of the response (R) in a different situation? Learning theorists have proposed that incentive motivation arises through classical conditioning of a goal R to the S in the reinforcement situation. When the primary reinforcer is absent, a fractional anticipatory goal R is theoretically necessary for initiation and maintenance of operant behavior (Hull, 1943); e.g., in the absence of food or water in the lever pressing or paw reaching situation, anticipatory jaw-related movements and their concomitant somatosensory feedback may be necessary to bind these operant sequences together, resulting in eventual delivery of reinforcement. To test this hypothesis rats were subjected to either trigeminal motor root sections (V) or hypoglossal nerve sections (XII), eliminating jaw or tongue movements, respectively. Rats from each group provided pre- and postoperative data on either time spent feeding and drinking, meal frequency and duration in a simple home cage operant paw reaching paradigm, food or water-reinforced lever pressing, or lateral hypothalamic (LH) stimulation-reinforced lever pressing. Verification of the central projections of sectioned nerves by horseradish peroxidase histochemistry was carried out in a separate group to ensure their proper identification.

V or XII did not impair responsiveness to food or water in the home cage; in fact compensatory hyperresponsiveness was the rule. However, V produced marked reductions in meal frequency and duration in the operant paw reaching situation, while XII did not disrupt meal patterns. In the food- or water-reinforced lever pressing situation, rats with V performed at a level far below that of extinction/sham operated controls and rats with XII. The operant deficits produced by V are likely specific to food or water reinforcement since rats with V lever pressed for LH electrical stimulation at or above preoperative rates. Neither "motor deficit" preparation (V or XII) was capable of ingesting significant amounts of food or water, yet their R rates were strikingly different. How do these two preparations differ? V eliminates pre-ingestive jaw movements while XII does not. The operant deficits seen after V may, therefore, reflect a functional deafferentation produced by removal of somatosensory inputs which normally occur as feedback from jaw-related prefeeding or fractional anticipatory goal R's.

214.2 ONE-TRIAL PASSIVE AVOIDANCE LEARNING IN THALAMIC RATS. M. Pritzel*, M. Joosten*, I. Fix*, H. Mutawi* and J. P. Huston (SPON: M. Terman). Inst. of Psychology III, University of Düsseldorf, Düsseldorf, FRG.

A series of experiments was designed to investigate the possibility of passive avoidance learning in thalamic rats and to search for possible neuronal mechanisms underlying task performance. After bilateral removal of the telencephalon rats were subjected to an up-hill response test. In this test they are placed on a slanted surface with the body oriented downhill and the latency for turning up-hill is recorded.

The thalamic rats exhibited the up-hill response reliably and with a latency comparable to that of unlesioned control animals. To test for passive avoidance learning, the up-hill response was punished by an electrical tail shock. The up-hill response latencies were measured after response-contingent shock, response-noncontingent shock and conditions without shock. Only the response-contingent shock group showed a significant increase in the latency to emit the up-hill response on a testing trial 2 hrs later. The results suggest that thalamic rats, like normal control animals, are capable of learning the one-trial up-hill passive avoidance task. It was concluded that the necessary neuronal mechanisms for learning of the task must be represented at a subtelencephalic level.

We also investigated neuronal systems which might be critically involved in the mediation of the up-hill response by interfering with the vestibular-occulomotor information processing. The up-hill avoidance test was still performed by rats with bilateral lesions of the vestibular nuclei and/or whiskers trimmed and/or eyes occluded. It was found that a combination of vestibular lesions and occlusion of the eyes was necessary to prevent learning of the up-hill avoidance task. Thus, learning of the up-hill passive avoidance task does not depend on an intact telencephalon. As long as the animals can rely on a critical amount of sensory feedback, they are able to master the avoidance task on a diencephalic-mesencephalic level.

214.3 Trimethyltin Neurotoxicity: A Potential Neurobiological Tool For Learning and Memory. C.F. Mactutus, J.J. Valdes, J.S. Young, and Z. Annau. Dept. Environ. Hlth. Sci. The Johns Hopkins University, Baltimore, MD 21205.

The widespread CNS edema produced by triethyltin stands in marked contrast to the relatively specific neuronal degeneration of the hippocampus and limbic system produced by trimethyltin (TMT) (Am. J. Path., 97: 59-82, 1979). The present study assessed the neurotoxicity of TMT administered on a chronic dosing regimen, but over a different exposure route, shorter intervals, and lower doses than previously reported, as well as the utility of this preparation as a tool in studying the neurobiology of learning and memory.

Adult Long-Evans hooded rats received 3 i.p. injections, one/week, of either 2, 3, or 4 mg/kg TMT or ETOH vehicle (ns=12). Two-way avoidance performance, typically facilitated by hippocampal lesions, was assessed starting 24 hr after the last injection and continuing over 4 days, 25 trials/day. Four randomly selected rats from each group were sacrificed for neuropathological examination.

A significant body weight loss, observed only for the 4 mg/kg group, often culminated in death. In the remaining groups avoidance performance was facilitated following TMT exposure. Of particular interest was a dose related increase in response perseveration (i.e., avoiding in the same direction) in the TMT exposed rats. Across groups initial shock escape latencies were similar suggesting no alteration of motivation or pain thresholds. Initial adaptation responding was also comparable among groups indicating no alterations in activity levels, however, an increase in intertrial crossings (reactivity) was found in the 3-, but not 2-, mg/kg TMT groups. Preliminary data indicates similar changes in shuttle performance when TMT is administered after acquisition training but prior to a retention test.

Neuropathological examination confirmed extensive neuronal degeneration within hippocampal cell fields CA3 and CA4, moderate damage in CA1, and a sparing of the CA3a field. Neuronal alterations within the pyriform cortex and an enlargement of the 4th ventricle were also noted.

In summary, TMT produces relatively specific neuronal damage and does so at doses lower than initially suspected. Moreover, that low doses of TMT alter avoidance performance in the absence of changes in emotionality indicates the potential of this preparation for studying the neurobiology of learning and memory.

214.4 TRIMETHYLTIN, A SELECTIVE HIPPOCAMPAL NEUROTOXICANT, IMPAIRS LEARNING AND MEMORY OF A RADIAL ARM MAZE TASK. Thomas J. Walsh* Diane B. Miller* and Robert S. Dyer (Spon; D. E. Weil). Neurotoxicology Division, US Environmental Protection Agency, Research Triangle Park, NC 27711.

Trimethyltin (TMT) is a neurotoxic organometal which selectively damages the limbic system, in particular the hippocampus (Brown et al., Am J Path, 1979). Systemically administered TMT preferentially destroys pyramidal neurons in the CA3 and CA4 cell fields of the hippocampal formation. The presumed hippocampal involvement in behavioral and neural plasticity suggests that TMT may produce long term functional impairments of learning and memory. Indeed, memory loss was a symptom in two reported cases of accidental human exposure to TMT (Fortemps et al., Int Arch Occup Environ Hlth, 1978).

We examined the effects of acute TMT administration on the acquisition and retention of a radial arm maze task. In the first experiment, adult male hooded rats were intubated with either saline, 5, 6 or 7 mg/kg TMT 21 days prior to training in an automated radial arm maze. TMT-treated rats took significantly longer to enter and eat in all eight arms (i.e. acquire the task) and exhibited impaired selection accuracy, reflected in a tendency to repeatedly enter previously selected arms. In the second experiment untreated rats were trained for three weeks in the maze to achieve stable performance. Following this training period the animals were intubated with either saline or 6 mg/kg TMT and allowed 14 days before retention of the task was evaluated. Saline-treated rats retained the task, whereas the TMT-treated animals required extensive retaining, and exhibited perseverative responding throughout the period of testing. During testing, activity did not consistently differ between groups, and TMT-treated rats did consume all food pellets within any given test session. Therefore it is unlikely that the impairments in maze performance were secondary to changes in either locomotor activity or motivation. Rather, these data argue that TMT impairs learning and retention of the task. This study demonstrates that damage to specific hippocampal cell fields produces long-term deficits in learning and memory processes.

214.5 ACQUISITION AND EXTINCTION OF AN OPERANT RESPONSE FOLLOWING SELECTIVE DAMAGE TO ROSTRAL HIPPOCAMPAL PROJECTIONS IN RATS. T. A. Silverhart*, B. Osborne, and J. Seggie. Dept. of Psychology, Middlebury College, Middlebury, VT 05753 and Dept. of Neuroscience, McMaster University, Hamilton, Ontario, Canada.

It is well established that hippocampal lesions or total fornix transections result in an increase in resistance to extinction following continuous reinforcement. Although the rostral projections of the hippocampus are heterogeneous, few studies have examined these functionally. Recently, Gray (Gray, J. A., Handbook of Psychopharmacology, New York: Plenum Press, 1977) proposed a model to account for the extinction deficit following hippocampal damage that utilizes these differences. The present study examined the role of the rostral projections during the transition to extinction and tested Gray's model of separate functions for different portions of the fimbria-fornix. The response to the transition to extinction of an operant lever press response was examined in rats with total fimbria-fornix transections (n = 8), medial fornix lesions (n = 11), fimbria lesions (n = 7) and operated controls (n = 7). The measure of total lever presses was supplemented by making a detailed analysis of behavior (frequency, duration, sequencing, and topography) and by measuring plasma corticosterone levels.

Analysis of total lever press responses showed that all four groups acquired the response at the same rate and that total fimbria fornix transections increased resistance to extinction. Rats with medial or fimbria damage responded in extinction at intermediate levels but at levels not significantly higher than controls. The detailed analysis examined food related behaviors (lever press and food cup check bouts and bout durations), trips away from food cup and lever, trip duration and topography shifts as indexed by biting lever presses. The frequencies of lever press bouts for total and medial groups were significantly higher than control or fimbria groups. For frequency of food cup bouts, totals were higher than all groups, and medials were higher than fimbria or control levels. When compared to controls or partial transected groups, the total group exhibited altered sequencing with short duration trips away interspersed with food behaviors. All groups except totals exhibited topography shifts while neither medial, fimbria or total groups reacted to extinction with the normal corticosterone elevations.

Gray's model suggests that the medial group would respond to the transition to extinction like totals and that the fimbria group would respond like controls. The present results do not support this model. A possible explanation in terms of additive effect for damage to separate regions is offered.

214.6 PERFORMANCE DEFICITS INDUCED BY HIPPOCAMPAL DISCONNECTIONS ON REFERENCE-MEMORY TASKS. R. Pico*[1,3], L.K. Gerbrandt[1,2] and J.L. Davis[3]. 1) Dept. Psychology, Calif. St. Univ., Northridge, CA 91324, 2) Neurosciences Res. Progr., Mass. Instit. Tech., 165 Allandale St., Boston, MA 02130, 3) Psychobiol. Lab., V.A. Hospital, Sepulveda, CA 91343.

Ideally, hypotheses accounting for the behavioral effects of hippocampal disconnections will be explicitly applicable to all experimental procedures where permanent performance deficits are found after damage to hippocampal connections. This series of experiments was designed to explore some of the potential limits of applicability of the working-memory and place-mapping hypotheses of hippocampal functioning (Olton, D.S. et al., Behav. Br. Sci., 2:313, 1979; O'Keefe, J.O. and Nadel, L., Behav. Br. Sci. 2:487, 1979).

Fimbria/fornix connections were electrolytically lesioned in 7 rats (FFX) and sham lesioned in 7 rats (SHC). In the first phase of the experiment, rats were trained to obtain food pellets at the end of each of the 8 arms of a radial maze on the basis of 4 topologically invariant extramaze cues that were aligned at the end of 4 of the maze arms. These cues were rotated independently from all other cues. On half of the arms, rats were rewarded after every choice to that topologically defined arm (reference-memory arms). On other arms, they were rewarded only on their initial choice (working-memory arms). FFX rats were compared to SHCs in their probabilities of visiting previously unchosen arms relative to topological cues. FFXs performed near chance levels both on working-memory and on reference-memory arms, whereas SHCs had high, stable probabilities of visiting unchosen arms on either section of the maze. Subsequent tests were run to determine whether rats could discriminate working and reference memory arms.

In the second phase of the experiment, prior reference-memory arms were again rebaited after each choice, but prior working-memory arms were continually unbaited, turning these also into reference-memory arms. The effects of random deletions of 1, 2, or 3 cues within the topological set were then tested. Finally, the effects of topological randomization of cues were tested. These and additional results will be presented.

214.7 HIPPOCAMPAL LESIONS DISRUPT DISCRIMINATION REVERSAL LEARNING OF THE RABBIT NICTITATING MEMBRANE RESPONSE. W.B. Orr* and T.W. Berger (SPON: A. Caggiula). Psychobiology Program, Dept. of Psychology and Dept. of Psychiatry, University of Pittsburgh Pittsburgh, PA 15260.

The effect of hippocampal lesions on reversal of a two-tone discrimination task was measured using classical conditioning of the rabbit nictitating membrane response. Three different groups of New Zealand white rabbits were conditioned. One group received bilateral aspiration lesions of the hippocampus and the parietal neocortex overlying the dorsal hippocampus; a second group received bilateral aspiration lesions of just the parietal neocortex; a third group (operated controls) was anesthetized and received a midline incision. All surgical procedures were performed prior to conditioning, and animals in all groups (including operated controls) were chronically implanted with a headstage used to hold devices for transduction of nictitating membrane movement during conditioning. Animals were allowed 2-3 weeks for recovery. Training for all groups consisted of two-tone discrimination conditioning using either a 1K Hz or a 10K Hz tone (counterbalanced) as the CS+ or the CS-, respectively. Corneal airpuff served as the UCS. A 750 msec ISI was used, with a 20, 30 or 40 min. ITI (average: 30 min). A total of 96 CS+ and 96 CS- trials were given each day (pseudo-random sequence), the last half of which were used to determine criterion behavioral performance. After reaching a conditioned response (CR) rate of $\geq$ 85% to the CS+ and $\leq$ 15% to the CS-, the CS+ and CS- were reversed. Reversal learning was terminated when animals reached a CR rate of $\leq$ 90% to the new CS+ (the previous CS-) and < 50% to the new CS- (the previous CS+), or when 56 days (8 weeks) of training were completed.

Results showed that animals in all three groups -- hippocampal lesion, cortical lesion and operated control -- learned the initial discrimination at the same rate. On the average, animals required approximately 4 days to reach the initial discrimination criteria. In contrast, rabbits with hippocampal lesions required significantly longer than either cortically lesioned or operated control animals to reach criterion for reversal learning. While rabbits in the latter two groups typically completed reversal learning in 14 days, animals with hippocampal damage maintained consistently high rates of responding to the CS-, with some animals failing to meet the reversal criteria within 56 days.

Supported by The McKnight Foundation, NSF grant BNS80-21395 and NIMH grant MH00343.

214.8 FOOD DEPRIVATION DIFFERENTIATES SEPTAL AND HIPPOCAMPAL LESION-INDUCED EXPLORATORY PATTERNS. S.D. Berry and D.A. Yutzey. Dept. of Psychology, Miami Univ., Oxford, OH 45056 and Dept of Psychology, Univ. of Connecticut, Storrs, CT 06268.

Among the many behavioral effects of septal or hippocampal lesions, alterations in reactivity to novel or biologically significant stimuli are observed frequently. However, in some conditioning experiments, it is difficult to separate the effects of lesions on learning from the interaction of lesions with motivational variables. This study, therefore, examined the impact of a strong motivational variable (food deprivation) on the patterning of exploratory behavior following lesions of either septum or hippocampus.

Twenty-six male, hooded rats, 90-122 days of age, were tested for amount and patterning of exploratory behavior in an octagonal runway under dim illumination. The lesion groups were: Septal (N=9), Hippocampal (N=5), Electrolytic Control (N=5), Cortical Control (N=3), and Normal (N=4). Two weeks after surgery, behavioral testing was initiated, with each subject allowed to explore the runway for two 3 minute sessions per week for a total of 12 weeks. After 2 weeks of testing under ad libitum feeding conditions, a 23 hr deprivation schedule was begun, with food intake restricted to produce a 10% drop in body weight each week. During this phase, tests were run at 90, 80, 70, and 60% of pre-deprivation weight. During a "refeeding" phase, the rats were put on a 22 hr deprivation schedule, and their weights were allowed to increase 10% per week back to the initial levels. Ad libitum feeding was allowed during the last 2 weeks. During each testing session, records were made of the latency to start locomotion, amount of locomotion, reversals of direction in the runway, and rearing.

Initially, both septals and hippocampals were hyperactive, although their latencies to start were longer. They also ran significantly farther than controls before reversing their direction of locomotion. Under deprivation, both groups, although still hyperactive, approximated the control group in the distance run before reversing. During the "refeeding" phase, the septal group immediately (although still at 60% body weight) resumed its lesion-induced exploratory pattern, while the hippocampal group remained similar to controls for the remainder of the experiment.

These data are consistent with studies showing differences between septals and hippocampals in the permanence of lesion-induced disruptions of learning, but extend them to include unlearned responses to motivational conditions.

214.9 THE EFFECTS OF HOME CONTEXTUAL CUES ON SPONTANEOUS ALTERNATION AND CONDITIONED PLACE AVERSION IN RATS WITH SEPTAL OR HIPPOCAMPAL LESIONS. T. Wigal*, C. R. Goodlett*, S. B. Eisenberg*, N. E. Spear, J. H. Hannigan, P. J. Donovick, R. G. Burright* and R. L. Isaacson. Department of Psychology, State University of New York at Binghamton, Binghamton, NY 13901.

Spontaneous alternation deficits typically found in rats with septal lesions have been alleviated by the presence of home contextual cues. This series of experiments examined the influence of home litter shavings on rats with septal or hippocampal damage on both a conditioned place aversion and a spontaneous alternation task.

Sixty-four Sprague-Dawley rats were given either bilateral electrolytic septal lesions or control surgery. Total aspiration lesions of the hippocampus, cortical lesions or sham control surgery were performed on 48 additional rats. All subjects were lesioned at 60 days of age and handled for one week postoperatively before undergoing place aversion conditioning. Training consisted of 12 inescapable shock presentations on a VI schedule in the black compartment and an equal exposure to the white compartment without shock. Rats of each lesion type were trained and tested with either clean shavings or 7-9 day old home shavings placed beneath the apparatus. At test, rats were placed in either the black (unsafe) or the white (safe) side, and the latency to cross was recorded. No shocks were delivered during testing.

Regardless of placement, septals, in the presence of home shavings, did not cross into the opposite compartment. This freezing behavior was not seen in septals tested over clean shavings, although both groups showed avoidance deficits relative to controls. The hippocampectomized rats did not exhibit consistent freezing behavior in either shavings condition.

Spontaneous alternation, tested 1-2 months postoperatively, indicated that septals, as seen previously, showed reliable alternation when tested over home shavings, but not when tested over clean shavings. Hippocampal subjects did not show response alternation in either shavings condition.

The results of these studies suggest that rats with septal lesions are more responsive to home contextual cues than hippocampal animals. The modification of septal deficits by the stimulus conditions of the task is consistent with the proposed role of the septum in sensory integration. Behavioral changes following hippocampal damage were less modifiable by these environmental manipulations.

214.10 POSTERODORSAL SEPTUM AND GO-NOGO DISCRIMINATION IN RATS. G.N.O. Brito and G.J. Thomas, Center for Brain Research, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

The effects of lesions in the posterodorsal septum on the performance of a successive GO-NOGO discrimination task in a double runway were investigated in this study. Rats were trained preoperatively for 11 sessions [6 S+ (GO) and 6 S- (NOGO) trials per day according to a balanced sequence, 1 session/day] to perform GO-NOGO discrimination in a double runway, in which the two alleys, placed side-by-side, were made sensorially distinct (at least visually and tactually) from each other. Rats were reinforced (2 Noyes pellets of 97 mg each) for running in the S+ alley, and they were not reinforced for running in the S- alley. The rats were then divided into 2 matched groups. One group (N=12) received small bilateral stereotaxically guided electrolytic lesions in the posterodorsal septum (1 ma. for 10 sec) and the other group (N=9) served as operated control. After postoperative behavioral testing, lesions were evaluated from celloidin-embedded, cresyl-violet stained histological material.

The results showed that rats with posterodorsal septal lesions, when tested 2 wk postoperatively, ran significantly more slowly on the S+ trials and faster on the S- trials on the first postoperative session compared with the last preoperative session. Control rats were unaffected by the control surgery and the 2 wk-recovery period. Although the septal group did not differ from the control group in sums of median speeds on S+ trials across 7 postoperative sessions, septal rats ran significantly faster than control rats on the S- trials.

The results are consistent with the internal inhibition hypothesis of septo-hippocampal function, i.e., rats with septal lesions might be more distractible than normal rats and so they are more likely to disregard the availability of crucial cues for the successful performance of GO-NOGO discrimination. However, the results are not consistent with the working memory theory of septo-hippocampal function because septal lesions impaired performance of GO-NOGO discrimination, and this task involves reference, but not working, memory processes.

214.11 THE EFFECTS OF MAMMILLARY BODY LESIONS ON SPATIAL VERSES OBJECT REVERSAL LEARNING IN MONKEYS. E.J. Holmes, S. Jacobson, B.M. Stein* and N. Butters. Lab. for Neurosurg. Neurobehav. Res., Boston VA Med. Ctr., Boston, MA 02130.

Despite numerous experimental studies, the specific roles of the mammillary nuclei in learning and memory remain unclear. Recent investigations in monkeys have revealed that the fornix and hippocampus are important for spatial reversal learning (i.e., periodically reversing responses to one of two paired response sites), but not for object reversal learning (i.e., periodically reversing responses to one of two choice objects). We thought it would be of interest to extend these findings on reversal learning by examining the effects of bilateral mammillary body (MB) lesions (in monkeys) on the acquisition of spatial and object reversal tasks.

The mammillary nuclei were ablated using a sub-temporal, micro-surgical approach; that is, the left temporal lobe was gently elevated and the ipsilateral 3rd cranial nerve transected to reveal the base of the hypothalamus. The mammillary nuclei were located by utilizing the origin of the pituitary stalk and the median eminence as neuronal landmarks. The operated control subjects received unilateral 3rd cranial nerve transections alone.

The results of the spatial reversal task showed that although the experimental and control animals did not differ in the initial acquisition of a position habit, the monkeys with MB lesions were markedly impaired in reversal learning relative to the operated control subjects. In the object reversal task, however, the subjects with MB lesions and control subjects were found to be the same, not only in initial learning (i.e., learning to discriminate between the two objects), but also in learning to reverse their responses between the two objects. Moreover, a lack of impairment by the subjects with MB lesions in the object reversal task was obtained even though the control animals found this task to be more difficult. Thus, as with fornix and hippocampal ablations, the impairment in attaining the spatial reversal task by monkeys with MB lesions does not appear to simply reflect an inability or deficit to reverse acquired responses, but rather an impairment in adapting to the spatial requirements of the task.

214.12 Delayed Extinction of a Classically Conditioned Response in the Rabbit Induced by Locus Coeruleus Lesions: Involvement of the Neocortex and the Hipppocampus. David A. McCormick* and Richard F. Thompson. Dept. Psychology, Stanford University, Bldg. 420, Jordan Hall, Stanford, CA 94305.

Recent investigations have shown that extinction of instrumental conditioned behavior in rats can be prolonged through selective depletions of neocortical and hippocampal NE. In addition it has long been known that hippocampal lesions result in a marked extinction deficit. Previous studies in this laboratory have shown that hippocampal unit activity increases during conditioning before behavioral learning takes place. Likewise more recent investigations have shown that the hippocampal unit activity seen in the trained animal decreases during extinction with a faster initial time course than does the behavior. It is thus hypothesized that the extinction deficit seen in NE depleted animals could be an expression of a dysfunction of the hippocampus and related structures.

Multiple unit recordings were taken from the CA1 field of the hippocampus in normal and lesioned animals during behavioral training and extinction. The training paradigm consisted of a tone CS paired with a corneal air puff UCS to elicit NM extension. After a criterion of 8 conditioned responses out of 9 consecutive trials, the animals were given one additional day of training (117 trials) and were then extinguished with 4 days of unpaired training (104 tone alone, 104 air puff alone trials per day). After training was complete each brain was dissected into 12 parts: (left and right) anterior half of cortex, posterior half of cortex, hippocampus, caudate, hypothalamus, and cerebellum. The NE levels in each of the parts were analyzed using a LCEC system. The multiple unit activity from the hippocampus will be analyzed and its relation to extinction discussed.

Animals with bilateral electrolytic lesions of the locus coeruleus (LC) were found to show a marked extinction deficit. This deficit was found to be significantly correlated with each of the total hippocampal, anterior cortical and posterior cortical NE levels. However, this deficit was not significantly correlated with caudate, hypothalamic or cerebellar depletions. These results suggest that the hippocampus and neocortex are involved in the extinction deficit following lesions of the LC NE system in classical conditioning.

214.13 CONDITIONED FLAVOR AVERSION: DISRUPTION OF ODOR-TASTE POTENTIATION BY REVERSIBLE AMYGDALA LESION. F. Bermudez-Rattoni*, K.W. Rusiniak*, and J. Garcia*. (SPON: J.P.Lieb). Depts. Psychol. and Psychiat., Univ. Calif., Los Angeles, CA 90024.

When odor and taste are presented in compound and followed by delayed LiCl, taste potentiates odor; odor becomes as strong as taste. Taste may "index" or "gate" odor into feeding (emetic) mechanisms (Palmerino, C.C., Rusiniak, K.W., & Garcia, J., Science, 208: 753, 1980). The amygdala receives both odor and taste afferents. Therefore, we infused procaine (i.c.) to disrupt amygdala function during odor + taste - LiCl pairing and then tested odor and taste components. Rats implanted with bilateral 25 ga. cannulae in the amygdala received 3µL of 10% procaine infused over 3 min., 15 min. before the odor-taste CS (n=10), 0-min. after the CS (n=10) or 1-min prior to US (n=10). Controls (n=9) received normal acquisition and procaine prior to water on a control day. Almond odor and .1% saccharin were the CSs, 190 mg/kg LiCl i.g. was the US. Water consumption averaged 1000 licks; procaine treatment did not suppress water consumption. There was a time dependent effect on odor aversions [$F(3,35) = 7.5$, $p<.01$] and taste aversions [$F(3,35) = 5.01$, $p<.01$]. Pre-CS amygdala lesion disrupted odor ($p<.05$) but not taste, indicating a role for the amygdala in odor and/or odor-taste integration. Post CS or pre-US procaine facilitated both odor and taste ($ps<.05$), indicating that procaine did not disrupt the illness US; facilitation may be due to non-specific aversive stress. These preliminary data suggest the amygdala is involved with the integration of odor and taste during illness-induced aversions, disrupting either odor perception, odor-taste pairing, or odor-illness associations. 214.14 SELF-STIMULATION OF THE CAUDATE-PUTAMEN IN THE RAT. A MAPPING STUDY. R.A. Prado-Alcalá and R.A. Wise. Physiol. Dept., Sch. Med., Natl. Univ. México, México 20, D.F. and Psychol. Dept., Concordia Univ., Montreal, P.Q., Canada H3G 1M8.

Brain stimulation reward is closely associated with dopaminergic elements in the ventral tegmental area. High pressing rates and low thresholds for intracranial self-stimulation (ICSS) are seen when electrodes are placed in the layer of dopamine (DA) cells in the nigral and ventral tegmental regions (1). ICSS is also readily obtained in most DA terminal fields (e.g., septal area and nucleus accumbens). However, there has been some controversy regarding the rewarding properties of electrical stimulation of the caudate-putamen nucleus (CPU), which has the greatest DA inervation in the forebrain. Several authors have reported that the CPU does not support ICSS (2), while others have described ICSS from the medial aspect of this structure (3) or from some other regions of the CPU (4).

In the present experiment we conducted a systematic mapping involving the anterior-posterior, dorsal-ventral, and medial-lateral regions of the CPU, using a moveable electrode to test 4-12 sites in a vertical penetration (250 um steps) in each animal. Rate of responding was assessed at currents ranging from 60 uA down in 2 uA steps to the lowest current that would sustain responding (threshold). In addition, we determined the relative density of DA (as revealed by glyoxylic acid-induced fluorescence histochemistry) surrounding the stimulation sites.

ICSS was observed in more than 80% of the sites tested, although there was not a clear correlation between DA density and pressing rates or thresholds. The highest pressing rates (40-60/min) were seen with the most medial placements, and progressively lower rates were seen as the electrode tips stimulated the tissue of the middle and lateral aspects of the CPU. Peak ICSS rates were found to be inversely related to thresholds.

These results indicate that all regions of the CPU are capable of supporting ICSS, and that the most rewarding stimulation is obtained from the medial aspect of this structure.

214.15 HYPOTHALAMIC SELF-STIMULATION IN RATS WITH ONE HEMISPHERE ISOLATED ANTERIOR TO THE MIDBRAIN AND THE OTHER HEMISPHERE DEVOID OF THE TELENCEPHALON. J. P. Huston, M. Pritzel* and W. Buscher*. Institute of Psychology III, Univ. of Düsseldorf, Düsseldorf, FRG.

In rats the telencephalon of one hemisphere of the brain was removed. Furthermore, the other hemisphere was isolated from the parts posterior to the diencephalon by a precollicular transversal cut. In this preparation self-stimulation was tested via electrodes implanted in the lateral hypothalamus - medial forebrain bundle (LH-MFB) area of both hemispheres before and after the lesions. Self-stimulation by lever pressing in a Skinner-box was still exhibited with stimulation delivered to either hemisphere. This was the case following either a unilateral detelencephalization, a unilateral precollicular transversal cut, or a combination of both operations. Lever-pressing underwent extinction when reinforcement was withheld.

If, as is likely, the complex response of lever-pressing is dependent on telencephalic structures, it must have been generated by the hemisphere with the intact forebrain. This forebrain, however, being isolated from its brain stem, can function only via the remaining diencephalic interhemispheric connections to the contralateral detelencephalized hemisphere.

To investigate possible interhemispheric pathways in this preparation, the tracer horseradish peroxidase was injected into the LH-MFB region of one hemisphere and its trace of migration to the contralateral hemisphere was examined. The results revealed that the thalamic commissure most likely transmitts information from the LH-MFB to the contralateral part of the brain. In addition, the supraoptic decussation as well as diffusely organized interdiencephalic connections provide possible pathways for interhemispheric intercourse.

214.16 BRAIN STEM ELEMENTS ESSENTIAL FOR THE CLASSICALLY CONDITIONED NICTITATING MEMBRANE RESPONSE OF RABBIT. J. E. Desmond*, N. E. Berthier, and J. W. Moore. Dept. of Psychology, Univ. Mass., Amherst, Mass. 01003

Unilateral radio-frequency lesions of the dorsolateral pons produced a loss of conditioned extension of the nictitating membrane response in the ipsilateral eye. Conditioned stimuli (CSs) included auditory, visual, and tactile modalities, and the unconditioned stimulus (US) was electrostimulation of the facial region near the eye. Lesioned animals could be classified into those with profoundly disrupted conditioned responding (n = 9) and those with but slight disruption of conditioned responding (n = 12). Disrupted animals gave conditioned responses on less than 5% of trials; nondisrupted animals and sham-lesioned controls (n = 6) gave conditioned responses on over 90% of trials, on the average. The two grouping did not overlap. Unconditioned responding in both eyes was unaffected by lesions.

Two types of experiments were employed. Animals received lesions either before training (acquisition) or after training (retention). Lesions in the critical zone produced comparable results, i.e., little or no acquisition of ipsilateral conditioned responses in the first case and virtually complete loss of conditioning in the second case. Conditioning of the contralateral response was unimpaired in both instances.

Histological analysis from disrupted and nondisrupted cases indicated that the parabrachial region of the dorsolateral pons contains elements essential for conditioned responding in this preparation. This region of the brain stem is approximately 2-4 mm rostral of the accessory abducens nucleus, the nucleus containing motoneurons principally responsible for defensive eye ball retraction (e.g., Berthier, N. E., and Moore, J. W. Neurosci., 6: 427, 1980). Extension of the nictitating membrane in rabbit is due to eye ball retraction, and the relevant muscles are the retractor bulbi muscles innervated by the 6th cranial nerve (e.g., Berthier, N. E., and Moore, J. W. Physiol. Behav., 24: 931-937, 1980). The anatomical interconnections between the critical region of the dorsolateral pons and the relevant motoneurons are under investigation.

214.17 The effects of local cooling in the temporal lobe of monkeys on delayed-match-to-sample. James A. Horel and Dorothy E. Pytko*. Dept. of Anatomy, Upstate Med. Ctr., Syracuse, NY 13210.

Five monkeys were trained on a delayed-match-to-sample task. The animals faced 3 rear-projection screens. Four hundred colored slides of objects were used as stimuli. A sample stimulus was projected to the center screen and the animal was rewarded with a squirt of juice to its mouth for pressing this screen 10 times. The sample stimulus was then extinguished and a delay of 0, 15, 30 or 45 sec (randomly selected) was begun. At the end of the delay a stimulus that matched the sample and one that did not appeared at the two side panels and if the animal pressed the panel that matched the sample it was rewarded.

After the animals had learned the task to better than 90% correct at all delays, they were operated. One temporal lobe was removed and guide tubes were placed over the intact temporal lobe. A steel nut was also affixed to the skull to attach a cryoprobe holder. A Benita cryogenic probe was used to make reversible functional lesions. Freon was injected into the expansion chamber of the tip. A vacuum jacket provided insulation for the shaft. A thermocouple soldered to the metal tip permitted continuous monitoring of tip temperature. The tip was 4mm long and 1mm in diameter. An insulated wire used for marking tip position was also attached to the probe.

During testing the cryogenic probe was lowered to position through one of the guide tubes and the animal was run on the task for 20 trials. The temperature of the metal tip was then lowered to -6°C and the animal was run for another 20 trials. Alternating blocks of 20 control and experimental trials continued until the animal was run 160 trials. The probe position was then marked for the Prussian-Blue reaction with the marking wire and the probe was removed.

At most placements, performance during cooling was identical to that during control trials. At some placements, there was a clear drop in performance at all delays during cooling, at others only the long delays were affected and two placements not in the temporal lobe produced a drop in performance at only the short delays. Most of the loci where the cold disrupted performance were in the anterior 9mm of IT. Only two placements out of 13 produced an effect in IT posterior to this area, disrupting performance at all delays. But all 12 placements in the anterior tip of IT produced a clear deficit during cooling. Five of these anterior placements produced an effect at all delays and 7 produced deficits concentrated at the long delays. The behavioral consequences of the cooling were completely reversible. Where the cold produced an effect, performance returned to normal when the cooling was stopped. Supported by NSF Grant BNS 80-40301

214.18 LATERALIZATION OF STORAGE OF VISUAL INFORMATION IN CATS WITH UNILATERAL SUPRASYLVIAN LESIONS.* Franco Lepore, Maurice Ptito, Serge Couture, Dom Miceli and Maryse Lassonde. Laboratoire de Psychologie, Univ. de Montréal, C.P. 6128, Montréal, P.Q. and Laboratoire de Neuropsychologie Expérimentale, Univ. du Québec, C.P. 500, Trois-Rivières, P.Q., Canada.

It has been postulated that the lateral suprasylvian area is important in learning and transfer of visual pattern discriminations. It is not clear, however, whether the storage of the engram occurs primarely within the lateral suprasylvian area and is then transmitted to the homologous contralateral region via the corpus callosum. The aim of the present study was to investigate the involvement of lateral suprasylvian area in both storage and transfer of visual information. Six adult cats were used in the experiment. Under deep general anasthesia, they underwent sectioning of the optic chiasma and unilateral destruction of the lateral suprasylvian area (LSSA). After an adequat recuperation period, they were trained monocularly on a variety of visual pattern discrimination tasks in a two-choice "thompson" box. Training on different pattern discriminations was performed with the eye ipsilateral to the LSSA lesion and the contralateral eye (intact side). In this part of the experiment no transfer capacity was assessed. Once performance criteria were achieved (90% correct, 3 sessions in a row) for all tasks and with each hemisphere (intact and lesioned), the cats were subjected to a split of the corpus callosum. They were then tested on the same tasks with the contralateral eye for transfer of visual information to the untrained hemisphere. In the analysis of data, 3 criteria were considered: the number of errors during the first 40 trials (IP), the number of errors to final criterion (EC) and the index of transfer derived from Murdock's formula. The results showed that the learning capacity of the lesioned hemisphere (LSSA lesion) is identical to that of the intact hemisphere suggesting that the lateral suprasylvian area is not as essential to learning as generally reported. Moreover, when we looked for the mnesic trace in the naive (untrained) hemisphere (contralateral to the previously trained eye for a given pattern), the visual pattern discrimination acquired with the intact hemisphere first was poorly represented in the lesioned hemisphere. Contrastly, the acquisition of the task with the lesioned hemisphere first was transferred normally to the intact side. These results suggest that the lateral suprasylvian area is involved in a storage mechanism for visual input transmitted via the corpus callosum.

214.19 FOREBRAIN SEROTONIN DEPLETION AND THE ATTENUATION OF THE LATENT INHIBITION EFFECT. David Berry, Joan F. Lorden, and Edward J. Rickert.* Dept. of Psychology, University of Alabama in Birmingham, Birmingham, Alabama 35294.

Forebrain serotonin (5HT) and norepinephrine (NE) have been implicated in processes underlying an animal's ability to ignore stimulus information which has no signal value. For example, in the latent inhibition (LI) paradigm, animals are pre-exposed to a stimulus (A) in the absence of reinforcement. In normal animals, pre-exposure retards learning if A is later used to signal reinforcement. Animals with raphe (Solomon et al., 1979) or dorsal noradrenergic bundle lesions (Mason & Lin, 1980) show an attenuation of the LI effect. These experiments suggest that similar deficits result from NE and 5HT depletion. However, using the blocking paradigm, Lorden et al., (1980) were able to distinguish between the effects of NE and 5HT depletion. In this procedure animals receive pretraining trials in which stimulus A predicts reinforcement followed by trials in which a compound stimulus (A + a new stimulus, B) predicts reinforcement. When tested to B alone, normal rats and rats with raphe lesions showed no evidence of learning to B; however, NE-depleted rats were unable to ignore this redundant or irrelevant cue.

In order to clarify the role of forebrain 5HT and NE in the LI effect, rats with 6-hydroxydopamine lesions of the dorsal NE bundle or 5, 7-dihydroxytryptamine lesions of the dorsal and median raphe nuclei were compared to vehicle-treated controls. Rats trained to make an operant response were pre-exposed to a stimulus which was then paired with footshock. Vehicle-treated and NE-depleted rats displayed the LI effect and failed to suppress operant responding in the presence of the cue paired with shock. 5HT-depleted animals, however, showed an attenuation of the LI effect. In a control condition in which there was no prior experience with the stimulus, all groups responded similarly. Selective depletion of NE or 5HT was verified by fluorometric assays. These results support the view that 5HT depletion, like NE depletion, impairs an animal's ability to exclude irrelevant stimulus information, but suggest that different mechanisms account for the deficits in NE and 5HT-depleted animals.

A second experiment examined the effects of NE and 5HT depletion in a paradigm which combined features of LI and blocking. Rats were pre-exposed to a stimulus (A) which was later presented in compound with a novel stimulus (B). The A/B compound predicted footshock and rats were tested in extinction for their response to B. Normal and NE-depleted rats behaved similarly; however, the response suppression of the 5HT-depleted group was attenuated in the presence of B. Serotonin but not NE-depletion appears to result in an inhibitory deficit. (Supported by NSF Grant BNS 80-14675).

214.20 ELECTROLYTIC LESION OF ENTORHINAL CORTEX CAUSES SEIZURES. R. M. Dasheiff and J. O. McNamara. Departments of Medicine (Neurology) and Pharmacology, Duke University; and Epilepsy Center, VA Medical Center; Durham, NC 27705

Destructive lesions of the entorhinal cortex (EC) are routinely employed to define anatomical pathways and study such diverse processes as neuronal plasticity and learning. We have consistently observed, and electrographically recorded, seizures in rats with electrolytically induced destruction of EC. Adult male Sprague-Dawley rats had EC lesions as described by other investigators, Brain Res. Bull. 2:31, 1977, and Brain Res., 131:241, 1977; controls were sham operated. Recording electrodes were placed bilaterally into the septal dentate gyrus of the hippocampus in all rats. The EEGs were interpreted by JOM who was blind to the protocol. Evidence of epileptiform activity (EA) was found in 19 of 20 EC lesioned rats as defined by either clinically observed seizures, electrographic seizures or spontaneous interictal spikes (SIS). No control rats had seizures and only 1 of 25 displayed SIS. The clinical seizures resembled the limbic seizures induced by kindling or kainic acid. Some of these behaviors are difficult to differentiate from normal rat behavior, or subject to misinterpretation as "fits of imbalance". However, electrographic recordings confirmed the true nature of these behaviors as seizures. The seizures could be suppressed by phenobarbital (PhB). The EA was intermittent but extremely frequent. It occurred as early as 8 hrs after lesion, peaking at 48-72 hrs, and had remitted by day nine. Right, left or bilateral EC lesions were equally effective in inducing EA. To test anatomic specificity further, other lesions were made in the septum, hippocampus, or frontal cortex without EA. Amygdala lesions induced SIS only. Biochemical changes of muscarinic cholinergic receptors due to these seizures is discussed by us in another abstract in this volume. Neuronal rearrangment (septal sprouting induced by EC lesion) occurred in the presence and absence (blocked by PhB) of seizures. The mechanism underlying these seizures following the lesion is unclear, but could result from a convulsant agent produced by the lesioning technique for which the EC is extremely susceptible. Alternately, the acute and massive deafferentation of EC input to other limbic structures could result in disinhibition and epileptogenesis. These seizures represent a potentially confounding variable for the interpretation of experiments involving electrolytic lesions of EC.

214.21 LESIONS OF THE STRIA TERMINALIS ATTENUATE THE EFFECT OF AMYGDALOID STIMULATION ON *RETENTION OF AVOIDANCE RESPONSES.*
K.C. Liang* and James L. McGaugh, Department of Psychobiology, University of California, Irvine, 92717, U.S.A.

Considerable evidence indicates that posttrial electrical stimulation of the amygdala affects retention of learned responses. These experiments were designed to determine whether the effect of amygdaloid stimulation on memory is blocked by transecting the efferent pathways of the amygdala: the stria terminalis (ST) and/or the ventral amygdalofugal pathway (VAF).

Bipolar electrodes were implanted bilaterally into the basolateral/basomedial nuclei of the amygdala of male ARS Sprague-Dawley rats (60 days old). Half of these rats also received bilateral radiofrequency lesions of the ST (ST-) or knife-cut transections of the VAF (VAF-), while others received sham operations on either pathway (ST+ or VAF+). Two weeks after surgery, animals were trained and, 24 hours later, tested in a one-trial inhibitory avoidance task (1 mA, 2 sec footshock). Two weeks later, they were trained and tested in an 8-trial one-way active avoidance task (640 μA footshock). Immediately after the training, half of the rats received amygdaloid stimulation (AS) (100 Hz, 0.2 ms pulses, 50 μA/electrode, 30 sec), while others served as implanted controls (IC). The 24 hour retention measures are shown in the table. In the ST+ rats, amygdaloid stimulation impaired retention in both the inhibitory and active avoidance tasks. Lesions of the ST did not significantly affect retention of the IC rats. However, the ST lesions blocked the impairing effect of amygdaloid stimulation in both tasks. In the VAF+ rats, amygdaloid stimulation impaired retention in the inhibitory avoidance task. After transecting the VAF, both the IC and AS rats had poor retention. In the active avoidance task, the retention of the IC/VAF+ rats was rather poor and was enhanced by amygdaloid stimulation. Transecting the VAF altered neither the retention of the IC rats nor the enhancing effect of amygdaloid stimulation. The present findings suggest that the memory modulatory effect of amygdaloid stimulation in rats is mediated through the output influences of the ST.

	ST+	ST-	VAF+	VAF-

215.1 PHYSIOLOGICAL AND BEHAVIORAL COUNTERREGULATORY RESPONSES TO INSULIN-INDUCED HYPOGLYCEMIA. P. Christopher Coburn* and Edward M. Stricker. (Sponsor: I. Hanin) Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

In intact rats deprived of food for 90 minutes before testing and during the test itself, iv injection of 2U/kg of regular insulin was found to induce a rapid reduction in blood glucose to 50-60 mg/100 ml followed by a gradual recovery to basal levels of 100-120 mg/100 ml within the 4-hr period of observation. After iv injection of 4U/kg, blood glucose remained depressed longer and some rats succumbed to hypoglycemic shock. Higher doses invariably led to hypoglycemic shock. In contrast, when food was made available during the test intact rats were able to tolerate iv doses of 10U/kg or higher. These observations draw attention to the ability of the rat to consume food, and its gastrointestinal tract to deliver the ingested calories, so as to adequately compensate for acute glucoregulatory challenges.

Food may be necessary to deal with marked insulin-induced hypoglycemia but it is not sufficient. Adrenal enucleated rats that had been deprived of food for 90 minutes before testing often do not tolerate an iv injection of 2U/kg insulin, even when food is available during the test. However, these animals were much more tolerant of insulin when it was delivered subcutaneously, so that its impact on blood glucose was not so rapid. Under such circumstances, adrenal enucleated rats were able to tolerate doses of insulin as high as 20U/kg when food was available. Also, they had no difficulty tolerating an iv dose of 2U/kg insulin in the absence of food when rats were tested 3 weeks rather than 3 days after enucleation, by which time the sympathetic response to insulin-induced hypoglycemia had improved so much that near normal glucose regulation occurred despite the absence of adrenal medullary secretions.

These observations emphasize the importance of integrated physiological and behavioral responses to insulin-induced hypoglycemia, and provide another example of the joint roles of physiology and behavior in the maintenance of homeostasis. Supported by NIMH grant MH-25140.

215.2 OBESITY AS A DELAYED CONSEQUENCE OF VIRAL INFECTION IN MICE D. R. Buskirk, M. J. Lyons and J. B. Zabriskie, Laboratory of Microbiology and Immunology, The Rockefeller University, New York, NY 10021

Previous work in our laboratory has shown that 20-30% of a strain of NCS mice infected at 4-5 weeks of age with canine distemper virus (CDV) develop obesity 3 to 4 months after recovering from the acute infection (M. J. Lyons et al., manuscript in preparation). The virus used in these studies had been maintained by serial passage in vivo in suckling mouse brain, and is highly virulent for mice. We report now that canine distemper virus maintained exclusively in vitro in Vero green monkey kidney cells is capable of eliciting obesity in mice with a latency of 3 to 4 months after injection. In addition, obesity can occur as a delayed symptom when the mice are injected with fewer than 100 plaque forming units of this virus, a dose incapable of causing noticeable symptoms of acute infection in juvenile mice. Obesity has been observed to follow intraperitoneal as well as intracranial injection of CDV, but preliminary results suggest that intracranial injection is more effective.

Histopathological sections of mouse tissue revealed adipose tissue directly comparable to that observed in genetically obese mice, or in mice affected by the gold thioglucose technique. Brain sections of these animals revealed no signs of inflammation, and immunofluorescence has not revealed the presence of viral antigens in the brains studied. The hypothalamic nuclei of the obese mice show no remarkable pathological changes. Studies of the endocrine function of these animals and more detailed pathological observations are in progress.

Supported by a grant from the Multiple Sclerosis Society.

215.3 GLYCEROL EFFECTS ON HUMAN FEEDING, J. Grinker, The Rockefeller University, N.Y., N.Y., and F. Bellisle*-lab de Prof. J. leMagnen, Neurophysiologie Sensorielle et Comportementale, College de France, Paris, France.

Glycerol has been proposed as a humoral signal reflecting the state of fat storage. Plasma glycerol levels and turnover rate are proportional to adipocyte size, total mass of adipose tissue and duration of short-term fasting. In animal studies, subcutaneous doses of glycerol produced decreased body weight (Wirtshafter and Davis, Science, 1977). In studies in our laboratory, both subcutaneous (160 mg kg/day via Alzet minipump) and oral administration (1g/kg/day) of glycerol but not equicaloric glucose produced temporary decrements in food intake and body weight gain of lean and obese rats. (Grinker et al., Brain Res. Bull., 1980). Within 3 to 4 days of beginning treatment, recovery in food intake and body weight was observed. Obese human inpatients maintained on 600 kcal liquid formula/day showed no differential response to glycerol or glucose as the primary carbohydrate in the diet. Outpatients on 1000 kcal/day with glycerol supplements failed to show greater diet adherence or reduced hunger compared with equicalorie glucose supplements (Leibel et al, Metabolism, 1980). These human studies investigated the effects of glycerol on perceived hunger and weight loss when caloric intake was already restricted in contrast to animal experiments using freely feeding rats.

We now report that oral administration (15 gram in 30 ml) of glycerol or equicaloric glucose failed to reduce subsequent food intake or alter the microstructure of feeding in normal weight volunteers. Four subjects received 6 trials of a citrus flavored preload (grapefruit juice adulterated with saccharin, glucose or glycerol)(Latin Sq. Design) one hour prior to test sandwich meals. The dose of glycerol is sufficient to produce marked elevations in plasma glycerol (Broyer et al., Le Nouvelle Presse Medicale, 1978). Total food intake was unaffected by glycerol or glucose administration. The microstructure of feeding (rate/food unit, number of swallows, number of chews) while changing over the course of the feeding bout was also unchanged by glycerol or glucose administration. These results make it highly unlikely that glycerol, or glycerol in relation to FFA levels (Grinker et al., 1980) is a specific satiety signal.

215.4 CARBOHYDRATE REGULATION IN RATS. C.L. Theall*, J.J. Wurtman, and R.J. Wurtman. Lab. of Neuroendocrine Regulation, Massachusetts Institute of Technology, Cambridge, MA 02139.

Previous research in this laboratory has suggested that rats select between two percentages of carbohydrate in the diet so as to maintain a constant percentage of carbohydrate in terms of total food consumption. It is thought that carbohydrate intake may trigger metabolic mechanisms that feed back on the rat's consummatory behavior, perhaps by affecting amino acid and neurotransmitter metabolism. The present experiments were designed to investigate this regulation in more depth.

Isocaloric agar-based diets were utilized in the present experiments. Six diet pairs ranged from 7.5 vs 17.5% to 27.5 vs 37.5% carbohydrate (wet weight percentages). One group of rats chose exclusively from dextrin-based diets, another group from sucrose-based diets. Each rat ate from one of the six diet pairs for one 10 day period followed by a different diet pair for each of two successive 10 day periods. The measurement for each diet pair was the percent of carbohydrate consumed versus the total grams of food consumed. Twenty Sprague-Dawley male rats were used in each experiment.

In Experiment I, 25-day-old rats weighed 69-85 g. Diet pair means for dextrin-fed and sucrose-fed animals were plotted as observed percent carbohydrate versus the expected percent carbohydrate if rats were randomly choosing carbohydrate. Linear regression analysis demonstrated that the dextrin-fed rats randomly selected whereas the sucrose-fed rats regulated carbohydrate intake. There was no difference between the regression lines for sucrose and dextrin. Due to a possible ceiling effect of the 27.5 vs 37.5% diet pair, these data were omitted in a second analysis. Both dextrin and sucrose lines differed from random selection. The mean percent carbohydrate consumed was found to be 20.3 and 22.5% for dextrin- and sucrose-fed rats, respectively.

Experiment II tested older animals weighing 225-260 g. Food was presented as in Experiment I. The results showed that the dextrin line differed both in slope and intercept. The dextrin and sucrose lines were not different from each other. The mean percent carbohydrate consumed was found to be 24.2 and 23.9% for dextrin- and sucrose-fed animals, respectively.

In conclusion, carbohydrate regulation is apparent in both dextrin-fed and sucrose-fed rats. The regulation is independent of the sweetness of the carbohydrate when either dextrin or sucrose are offered as the sole carbohydrate source. The overall mean percent carbohydrate consumed was found to be 22.7% of total food intake.

215.5 DIURNAL FEEDING AND THE INGESTIVE RESPONSES FOLLOWING GLUCOSTATIC AND OSMOTIC CHALLENGES ARE UNALTERED BY HEPATIC VAGOTOMY. Michael G. Tordoff*, Jill Hopfenbeck* and Donald Novin. Dept. Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

The hepatic branch of the vagus nerve was transected in 10 male and 10 female Long Evans rats. Sham surgery was given to 9 males and 9 females. All subjects were maintained on lab chow in a vivarium with 12:12 hr illumination (lights on at 0500). The following ingestive behaviors were observed:

Postoperative Body Weight. Daily body weight readings following surgery showed that hepatic vagotomized (HV) rats gained weight at the same rate as controls (SHM).

Diurnal Ingestion. Commencing 10 days postsurgery, food and water intakes during the light and dark periods were recorded for 3 days. Although males ingested more than females, there were no differences between same-sex HV and SHM rats in daytime or nighttime ingestion,or in day:night ratios.

Insulin. Commencing 20 days postsurgery, all rats were given injections of insulin (4, 8, 12 U/kg, IP). Each rat received, in counterbalanced order, each dose of insulin twice, with 3 days between injections. Food and water intakes were recorded every hour for 6 hr and at 24 hr postinjection. Insulin significantly increased ingestion in all groups, and although males ate and drank more than females, there were no differences between same-sex HV and SHM rats.

2-Deoxy-D-Glucose. Commencing 54 days postsurgery and using the same technique as for insulin injections, all rats were administered 2DG (125, 250, 500 mg/kg, IP). Each dose was given only once. 2DG caused significant increases in ingestion that were generally dose-related. No differences between same-sex HV and SHM rats were found.

Sodium Chloride. Commencing 85 days postsurgery, rats were given NaCl (10 ml/kg: 0.5, 1.0, 2.0 M), with 3 days between injections. Water consumption was recorded for the first 4 hr and 24 hr postinjection. Dose-related increases in drinking were found but no differences between same-sex HV and SHM rats were present.

Polyethylene Glycol (PG). On Days 102 and 106 postsurgery, rats received either PG (10 ml/kg: 30% w/v, SC) or saline. PG produced a long-lasting increase in drinking, but at no time was there a difference between same-sex HV and SHM rats.

Although several explanations for these results exist, they support the hypothesis that the hepatic vagus contains only a small fraction of the total complement of hepatic metabolic and osmotic afferents. (Supported by NS07687).

215.6 PREFEEDING SERUM GLUCOSE AND DIURNAL SERUM CORTICOSTERONE LEVELS VARY WITH BODY WEIGHT IN CHRONICALLY FOOD RESTRICTED RATS. John P. Heybach* & Peter C. Boyle* Central Research Department, General Foods Corp., White Plains, NY 10625 SPON: DOROTHY CHOU.

Thirty male S/D rats (310-330g), housed individually and maintained at 21°C with a 12h photoperiod (lights on 6am), were given ad lib access to tap water and powdered chow (Wayne) in food cups. Following a 14d acclimatization period rats were placed on a feeding regimen with food cups presented daily at 4pm and removed the next morning at 9am. Body weight (BW) and food consumption (corrected for spillage) were recorded daily at 9-10am. On days 7-35 of this regimen 2 groups (n=10/grp) were presented with 80% and 60%, respectively, of the weight (calculated daily) of control group consumption (n=10). On day 36 rats from each group (n=5/grp) were rapidly sacrificed by decapitation at either 9am or 4pm (just prior to daily food presentation). Trunk blood was collected and serum aliquots were used to determine circulating glucose (G) and corticosterone (B) levels. The mean BW across the three groups diverged over the 28d restriction regimen while within group food consumption remained relatively constant. At both 9am and 4pm circulating B levels were increased significantly across groups as body weight decreased. Circulating G levels did not differ across groups at 9am. However, at 4pm (just prior to daily food presentation) fasting serum G levels were decreased across the restricted groups as a direct function of the decrease in body weight. These results are consistent with a glucostatic theory of appetite and body weight regulation and demonstrate that prefeeding, fasting serum G levels covary with body weight during chronic food restriction. The data also suggest a degree of specificity of the lowered serum G levels with respect to the time immediately preceeding daily presentation of food that is not apparent in circulating glucocorticoid levels, which varied inversely with body weight across groups at both times of day.

		Control	80% Food Restriction	60% Food Restriction
BW $\bar{x}$ g		405 ± 4.6	345 ± 6.1	302 ± 6.3
Serum G	9am	135.5 ± 1.4	136.0 ± 2.1	138.0 ± 1.9
$\bar{x}$ mg/dl	4pm	142.6 ± 3.3	135.3 ± 1.8	127.4 ± 3.5
Serum B	9am	9.06 ± 0.8	22.0 ± 2.6	26.1 ± 3.6
$\bar{x}$ ug%	4pm	24.01 ± 2.5	34.9 ± 3.1	38.6 ± 2.3

215.7 MULTIPLE REGRESSION ANALYSIS OF SHORT-TERM AND LONG-TERM FOOD INTAKE IN INTACT AND SUBDIAPHRAGMATICALLY VAGOTOMIZED RABBITS. Paula J. Geiselman, James R. Martin, and Donald Novin. Dept. Psychol. and Brain Res. Instit., UCLA, Los Angeles, CA 90024; Dept. Behav. Sci., Swiss Fed. Instit., Zurich, Switzerland.

Individual differences in meal-patterning parameters and total food intake were modeled in intact and vagotomized rabbits with multiple regression analyses. During short-term periods (each of the four 6-hr periods during a 12:12 light/dark cycle) as well as long-term periods (24-hr measurements), satiety ratio (intermeal interval following meal/meal size) provided the best single-variable predictor of food intake, but the combination of meal frequency and meal size provided a significantly better prediction than satiety ratio alone in intact rabbits. These results suggest that satiety ratio, meal frequency, and meal size are functions of both short-term and long-term signals in intact rabbits.

In subdiaphragmatically vagotomized rabbits, satiety ratio was no longer the best single predictor of food intake during either short-term or long-term measurement periods, indicating that satiety ratio is not controlled by short-term signals in vagotomized rabbits. Following vagotomy, meal frequency provided the best single-variable predictor of short-term food intake, but the combination of meal frequency and meal size provided a significantly better prediction than meal frequency alone. The long-term analysis suggests that control of food intake during this time interval is more complex in vagotomized rabbits: A combination of several measures provided nonsignificant prediction of total food intake accounting for only 31 percent of the variance.

215.8 PREGASTRIC STIMULI ARE SUFFICIENT FOR THE HEDONIC VALUE OF A MEAL IN THE RAT. W. Van Vort* and G.P. Smith.(SPON: J.A. Sechzer). Dept. Psychiatry, Cornell Univ. Med. College and E.W. Bourne Behavioral Research Lab., New York Hosp., White Plains, NY 10605.

We previously reported that rats prefer a meal that is really fed to 60 min of sham feeding (Neuroscience Abst. 6:179.11, 1980). To clarify the contribution of postingestional elements of real feeding for the development of this preference, we investigated the preference for sham or real feeding when duration of feeding and volume of intake were similar or equal. Male Sprague-Dawley rats weighing about 350g were implanted with chronic gastric cannulas (GF). After recovering from surgery, rats were adapted to a 17h food deprivation schedule. At the end of a deprivation period rats were offered sweet milk. On alternate days the rats really ate the milk (GF closed) or sham fed the milk (GF open). For each GF condition, the diet was marked with a specific flavor (almond or vanilla) and offered at a specific location at the front of the cage (left or right) for each rat. Preference testing, conducted after a series of training tests, consisted of giving rats (GF closed) simultaneous access to both test diets in their usual locations for a 4 min period. Two groups of rats were tested. In the first group (n=9), the duration of sham or real feeding during training tests was limited to 20 min. On real feeding days rats ate 16.8±0.5 ml. On sham feeding days rats ate 38.9±0.7 ml and did not display satiety. After 15 real and 15 sham feeding trials, rats did not develop a preference. To evaluate the hedonic effect of volume ingested, the volume sham fed by the second group (n=12) was limited to the volume ingested on the previous real feeding day (15.9±0.2 ml). After 19 real and 19 sham feeding trials, the rats did not develop a significant preference.

Thus, under our conditions, when rats really feed and sham feed the same volume or for the same duration they do not prefer real feeding. Our results suggest that (1) food stimuli acting at pregastric sites are sufficient to elicit the reward of a meal in the rat; and (2) when sham feeding is prolonged for 60 min these stimuli become less rewarding.

215.9 AN ANALYSIS OF MEAL PATTERNS IN THE GENETICALLY OBESE MOUSE(ob/ob). **A.J.Strohmayer and G.P.Smith.Dept. Psychiatry,Cornell Univ.Med.Coll.,Manhasset,N.Y.11030**

The genetic obesity of the ob/ob mouse is characterized by hyperphagia.To determine which characteristics of feeding behavior(meal size,frequency or intermeal interval(IMI)),contribute to the hyperphagia we recorded 24 hr meal patterns under conditions of unlimited access to liquid food(EC116) and tap water.The mice used were 7-8 weeks old and in the dynamic phase of weight gain.

Obese male mice ate larger meals(*P<.05,see table) than lean males in the light and dark.Obese males also ate less frequent meals(P<.05)than lean males in the dark but not in the light.Obese females showed similar abnormalities;they ate larger(P<.05)less frequent(P<.05)meals than lean females in the dark but not in the light.

GENOTYPE	PERIOD	MEAL#	MEAL SIZE(ml)	IMI(min)
MALE				
LEAN(+/+)				
	LIGHT	13.8	0.16	64.2
	DARK	34.6	0.18	20.9
OBESE(ob/ob)				
	LIGHT	11.3	0.21*	65.3
	DARK	25.5*	0.26*	33.6
FEMALE				
LEAN(+/+)				
	LIGHT	13.6	0.22	50.1
	DARK	23.4	0.25	32.8
OBESE(ob/ob)				
	LIGHT	10.4	0.28	88.6
	DARK	14.0*	0.49*	43.4

Since this pattern of feeding has been shown to produce weight gain and increased body fat,(Fabry 1967), the hyperphagia of the obese mouse contributes to the development of obesity through:1)an increased caloric intake and 2)an obeseogenic pattern of feeding.(supported by NIMH#MH15455)

215.10 ANALYSIS OF AMINO ACID PATTERNS AND REGIONAL BRAIN SEROTONIN LEVELS IN THE GENETICALLY OBESE ZUCKER RAT. J. A. Finkelstein, W. T. Chance and J. E. Fischer*. Dept. Anatomy, N. E. Ohio Univs. Col. Med., Rootstown, OH 44272 and Dept. Surg., Univ. Cincinnati Med. Ctr., Cincinnati, OH 45267.

The genetically obese Zucker rat has been suggested as an appropriate model of juvenile onset obesity. Levels of norepinephrine are different in certain brain nuclei of the obese rats, but no data on regional serotonergic activity have been reported. Since CNS serotonin (5-HT) has been suggested as a mediator of satiety, we fluorometrically assayed brain 5-HT, tryptophan (Trp) and 5-hydroxyindoleacetic acid (5-HIAA) in the following regions: cortex (C), hippocampus (HI), corpus striatum (CS), hypothalmus (HYPO), remaining telencephalon-diencephalon (TEL-DI), mesencephalon (MES), pons-medulla and cerebellum (CB). In addition, amino acid levels were determined in plasma and cerebral cortex. For seven days prior to sacrifice, food intake was monitored in eight male genetically obese (fa/fa) and eight lean littermate (Fa/-) Zucker rats (10-12 weeks of age). Food intake and body weight were significantly elevated in fa/fa rats during this period. Although total plasma Trp was slightly elevated (non-significant) in fa/fa rats, free (unbound) Trp was significantly decreased. Other significant differences between fa/fa rats and their lean littermates were observed. Plasma levels of proline, alanine, valine, isoleucine, leucine, phenylalanine, threonine and methionine were elevated in fa/fa rats, while aspartic acid, glutamine, glycine and lysine were decreased. Brain serine, glycine, alanine, and valine were also elevated in fa/fa rats; glutamate, methionine, isoleucine, tyrosine and phenylalanine were decreased. Analysis of indole activity in brain regions revealed decreased Trp in CS, HI, C, HYPO and TEL-DI, decreased 5-HT in MES and CB, as well as decreased 5-HIAA in TEL-DI. The branched-chain amino acids leucine, isoleucine and valine compete with free Trp, tyrosine and phenylalanine for transport across the blood-brain barrier. Thus, the combination of decreased free Trp and elevated branched-chain amino acids in plasma apparently results in reduced levels of brain Trp. Similarly, the aromatic amino acids tyrosine and phenylalanine were also reduced in the brains of fa/fa rats. This reduction in brain Trp may be reflected as decreased 5-HT in MES and decreased 5-HIAA in TEL-DI. Whether these biochemical changes are the result or the cause of the hyperphagia in fa/fa rats remains to be determined.

215.11 CHRONIC INTRAVENTRICULAR INSULIN INFUSIONS REDUCE FOOD INTAKE AND BODY WEIGHT IN RATS. Deborah J. Brief* and John D. Davis, Dept. of Psychology, Univ. of Illinois, Chicago, IL 60680.

Insulin receptors and an insulin-like peptide have been identified in regions of the rat brain thought to be involved in the control of food intake and body weight. Direct application of insulin to hypothalamic cells modifies cell activity and reduces short-term food intake, while injections of insulin antibodies increase food intake. One study (Woods et al., 1979) has shown that chronic daily infusions of insulin into the lateral ventricle produce a reduction of body weight in baboons. The purpose of the present study was to examine the effects of chronic intraventricular insulin infusions on body weight regulation in the rat.

Guide cannulas terminating in the third ventricle were implanted in male albino rats adapted to a 12 hour light/dark cycle. Following recovery from surgery, food, water and body weight measurements were taken twice daily, at 9 am and 6 pm. After food intake on P.J. Noyes pellets appeared stable for 7 days, a permanent cannula which also terminated in the third ventricle and which was attached by polyethylene tubing to an Alzet minipump (implanted subcutaneously on the back), was cemented in place. The animals were infused with either a control solution (Ringer) or insulin (.5, 1 mU in Ringer) at a constant rate of 1 μl/hour for 7 days.

Only infusions of the higher dose of insulin (1 mU) produced a sustained reduction in body weight. By day 7 of the treatment period there was an average 16% reduction in body weight among the animals infused with 1 mU/day insulin, compared to approximately a 4% reduction in animals infused with Ringer or .5 mU/day insulin. The reduction in food intake occurred during the night portion of the diurnal cycle. The fact that day food intake was not affected in the 1 mU group suggests that the animals were not suffering from a toxic effect of insulin. Unlike the Ringer or .5 mU animals, which decreased body weight on the first night of infusion and began to recover during the infusion period, the 1 mU group continued to lose weight throughout the infusion, although the rate of loss decreased after the 4th day.

These results support the notion that brain insulin is involved in central regulation of body weight, possibly because it may modulate activity of cells or uptake of metabolites in the area surrounding the third ventricle which is involved in this function.

Woods, S. et al., Nature, 1979, 282, 503-505.

215.12 EFFECTS OF VAGAL ASSOCIATED GASTRIC AFFERENT STIMULATION ON MESENCEPHALIC AND HYPOTHALAMIC NEURONAL ACTIVITY. F. C. Barone, M. J. Wayner and I. Zarco de Coronado*. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210 and Depto de Fisiologia, Facultad de Medicina, U.N.A.M., Mexico.

Male rats were anesthesized with urethane and prepared for hypothalamic and mesencephalic single neuron recording. A gastric balloon was filled with 10-15 ml of water, 20-30 sec, and/or the whole left cervical vagus nerve was stimulated with multiple pulses or pulse trains of 0.5 msec pulse duration at 1-40 Hz, while simultaneously monitoring mesencephalic central gray (CG) unit activity. Data were collected from only those animals which displayed a constant bradycardia effect at a stable threshold to vagus stimulation and only those animals which did not exhibit any gastric pathology following the experiments were used for the analysis. Most CG neurons examined increased discharge frequency during vagus nerve stimulation and gastric distension. The magnitude of change in CG neuronal unit activity was directly related to the intensity of gastric or electrical stimulation. Since lateral hypothalamic (LH) neurons are also affected by gastric distension and vagus stimulation (Barone et al., Brain Res. Bull. 4: 267-282, 1979; Barone et al., Brain Res. Bull. 4: 381-389, 1979) and neurons in the CG project to and terminate on LH neurons (Barone et al., Brain Res. Bull. 7, in press), it was hypothesized that the CG mediates gastric afferent input to the LH. Therefore, recordings were obtained from the LH and neurons were tested for the effects of gastric distension and vagus stimulation. In addition, the effects of CG electrical stimulation, single pulses of 0-500 μA through a small concentric bipolar electrode, were determined. If all three stimuli affected LH unit activity in a similar manner, a series of small DC electrolytic lesions were made in the CG. Neuronal responses to gastric distension and vagus and CG electrical stimulation were then evaluated again. In addition, seven barrel electrodes were utilized to determine the sensitivity of these hypothalamic neurons to catecholamines and some endogenous opiates. Results indicate that small lesions confined within the CG attenuate the response of LH neurons to gastric afferent stimulation. (Supported by NIH Grant NINCDS USPHS No. 13543.)

215.13 RAT BRAINSTEM RESPONSES TO GASTRIC SIGNALS OF DISTENSION AND NUTRIENT AS EXAMINED WITH [^{14}C]2-DEOXY-D-GLUCOSE. W.G. Young, T.D. Tom*, and J.A. Deutsch. Departments of Neurosciences and Psychology, University of California, San Diego, La Jolla, CA 92093.

We have shown that the stomach of the rat regulates food ingestion based on two mechanisms of distension and nutrient content (Deutsch, Gonzalez, and Young, Br. Res. Bull. 5, suppl. 4, 55-57, 1980). The distension system depends on the integrity of the vagus nerve projecting from the stomach (Gonzalez and Deutsch, Soc. Neurosci. Abstr. 6, 519, 1980). The nutrient system has been further defined in terms of dietary and gastric interactions (Deutsch and Gonzalez, Soc. Neurosci. Abstr. 6, 528, 1980). This study presents evidence that specific areas in the brainstem do respond to the nutrient signals produced solely by the stomach when food is ingested.

Two groups of subdiaphragmatically vagotomized (VAG) and sham-operated (SHAM) anesthetized rats were injected with 2-^{14}C-deoxy-D-glucose (2-DG) and subjected individually to one of three conditions: gastric infusion with 5 ml of Vivonex standard diet, gastric infusion of 5 ml of saline, or no infusion. Emptying of the infusate from the stomach was arrested with previously described techniques (Young and Deutsch, J. Neurosci. Meth. 3, 377-384, 1981). 2-DG was preferentially taken up into the general area of and surrounding the nucleus of the solitary tract (NST) of SHAM rats infused with saline as compared to the SHAM controls. Additionally in the nutrient infused rats, the ventral aspect of the brainstem just lateral to the corticospinal tract also took up 2-DG. Presently, the specific areas have not yet been identified, but the uptake corresponds with the appearance of the lateral reticular nucleus (LRN) at the caudal end and the nucleus ambiguus (NA) at the more rostral end. However, when the vagus was transected in the VAG rats, saline infusion no longer produced an uptake by NTS area. Vagal transection, on the other hand, did not affect uptake in the area surrounding the LRN or the NA when nutrient was infused and the NTS response was still not present. We conclude that the vagus carries the distension messages from the stomach to the general area of the NTS, most likely the NTS specifically. Gastric nutrient messages project to the ventral lateral aspect of the brainstem surrounding the area of the LRN and the NA, and these are not vagally mediated. However, the vagus may still carry nutrient messages to the NTS that are not presently distinguishable from the accompanying distension.

215.14 ELIMINATION OF HYPOTHALAMIC HYPERPHAGIA AND OBESITY BY ADRENALECTOMY IN RATS. B. K. Bruce*, B. M. King, G. R. Phelps* and M. C. Veitia*. Department of Psychology, University of New Orleans, New Orleans, Louisiana 70122.

Two previous investigations into the effects of adrenalectomy (ADX) on ventromedial hypothalamic (VMH) hyperphagia and obesity have produced incongruent results. One study concluded that adrenalectomy produces a significant depression of hyperphagia and obesity (Mook, Fisher, and Durr, Horm. Behav., 6, 65-79, 1975). The other study reported that adrenalectomy had no effect (York and Bray, Endocrinology, 90, 885-894, 1972), but failed to include a sham ADX-VMH control group with which to compare the weight gain in ADX-VMH animals. The sequence of the surgeries differed in these two studies.

In order to reassess the role of adrenal hormones in hypothalamic hyperphagia and obesity, VMH or sham lesions were performed either 15 days prior to or after ADX or sham adrenalectomy (SADX). Body weight and food intake were recorded for 30 days after the second surgery. Adrenalectomy both reversed and prevented the development of hyperphagia and obesity in VMH-lesioned rats. The SADX-VMH group displayed a mean weight gain of 180 g in 30 days after the lesion, but the ADX-VMH animals did not significantly differ from the sham-lesioned groups in body weight or food intake. Animals with VMH lesions continued to display weight gains after SADX (240 g/45 days), while adrenalectomy in obese VMH animals eliminated all excess weight gain, and decreased food intake to below the level of all control groups. Adrenalectomy had no effect on body weight or food intake of animals with sham VMH lesions. As adrenal demedullation has been found to have no effect on hypothalamic obesity (Mook et al., 1975), it was concluded that adrenocortical secretions are necessary for the development and maintenance of VMH hyperphagia and obesity.

215.15 FEEDING AND DRINKING RESPONSES OF RATS WITH KAINIC ACID INFUSIONS INTO THE DORSOMEDIAL HYPOTHALAMUS. L.L. Bellinger, L.L. Bernardis and F.E. Williams*. Department of Physiology, Baylor College of Dentistry, Dallas, Tx 75246 and V.A. Medical Center, Buffalo, N.Y. 14215.

Male Sprague-Dawley (150gm) rats received bilateral infusions of Kainic Acid (KA) into the Dorsomedial Hypothalamus using the coordinates: AP,+4.2mm; Lat.,0.5mm, Depth 2.4mm above ear bar zero. After being anesthetized with Diabutal the rats were infused with 1µg of KA in 0.5µl saline. The infusions were conducted over 2.5 min. and the cannula left in place another 2.0 min. Saline infused rats served as controls (C). Following surgery the rats were given rat chow and water ad lib. The KA rats (n=9) were severely aphagic and adipsic. Mean weekly chow intakes (gms) for four weeks post surgery for the KA rats were 1.4±1.0, 2.6±1.4, 3.4±2.0 and 8.3±2.6 while the C (n=12) intakes were 15.3±0.5, 19.5±0.4, 20.5±0.1 and 19.0±0.4, all P<0.001. During this period the KA rats would also not eat a high fat diet but did eat a baked chow mix that contained 30% sucrose. At experiments end (37 days) three rats still would not eat chow. Mean weekly water intakes (ml) for four weeks post surgery for the KA rats were 2.4±1.2, 3.9±1.8, 7.8±2.9 and 12.6±3.8 while C intakes were 26.8±1.0, 35.5±2.0, 38.5±2.0 and 38.6±2.0, all P<0.001. During this time some but not all of the KA rats would drink some 30% sucrose water. At experiments end all rats were drinking water or sucrose water. All rats were injected with 2-deoxy-d-glucose starting four weeks post surgery. The C rats elevated their three hour food intake (gm) over saline infusions at both the 200 mg/kg (2.5±0.2 vs 4.2±0.5, P<0.01) and 400 mg/kg dose (0.5±0.1 vs 4.1±0.6, P<0.01) while the KA rats did not elevate their food intake over saline injections at either dose (2.0±0.4 vs 1.1±0.5; 0.4±0.1 vs 0.7±0.4). When food deprived for 24 hr and then refed both C and KA consumed a similar amount of food in the first hour of refeeding (expressed as % of baseline intake); however the 24 hr intake of the KA rats was significantly greater than C (314±13.1% vs 181±8.0%, P<0.001). During food deprivation the KA and C rats consumed a similar amount of water (expressed as % of baseline intake). The KA rats weighed significantly less than C six days post surgery and by experiments end were also significantly lighter (256±6.8 vs 314.8±3.9, P<0.001) and also demonstrated reduced linear growth (Δnaso-anal length 24.1±3.2mm vs 35.5±1.5mm, P<0.01).

Supported in part by BCD research funds and NSF Grant PCM76-84381.

215.16 CORRELATION BETWEEN HYPOTHALAMIC KNIFE-CUT AND DIETARY OBESITIES. Richard M. Gold. University of Massachusetts, Amherst, Massachusetts 01003.

Parasagittal hypothalamic knife-cuts in rats reliably produce excessive food intake, weight gain, and adiposity. However, the magnitude of these excesses varies considerably both within and between studies. Previous work has shown that several variables can greatly alter the rate of this weight gain. These include the strain, sex, and age of the rats, the palatability, fat content, and accessibility of the diet, and the availability of exercise. Considerable inter-rat differences remain even after these factors are held constant, and have generally been attributed to variability in the placement of the knife-cuts.

We have recently, however, found extreme and reproducible inter-rat variability in susceptibility to dietary obesity in response to junk foods obtained from supermarkets. This difference surely cannot be attributed to surgical variables, as no surgery is involved. We attribute this variability in susceptibility to obesity to inter-rat genetic differences. This genetic basis has been confirmed by selective breeding. This finding raises the possibility that variability in response to obesifying hypothalamic knife cuts is also due to inter-rat genetic differences.

Twenty individually housed adult female rats received a supermarket diet consisting of sweetened milk, cookies, and peanut butter for 22 days. Twenty rats from the same shipment served as chow fed controls. As predicted, the weight gains of the supermarket diet fed rats were extremely variable (mean 3.01g/day variance 22.17g) as compared with the chow fed controls (mean 1.58g/day variance 1.58g). During subsequent weight stabilization for 14 days on chow diet 61% of the excess weight was lost. Subsequently, under rigidly controlled conditions 3x3 mm bilateral parasagittal hypothalamic knife-cuts were made in the 7 most dietary-obesity prone, 7 least dietary-obesity prone (i.e., lean prone), and 12 former pellet-fed control rats. The remaining rats were sham operated. The formerly obesity-prone rats did not respond more vigorously to the knife cuts than did the formerly lean-prone rats, and there was surprisingly little variability in response to knife cuts amongst the former pellet-fed controls. Since genetic predisposition to dietary obesity does not predict the magnitude of the response to obesifying hypothalamic knife cuts, we return to the working hypothesis that, given standardized subjects, diet, etc., differences in weight gain in response to hypothalamic knife cuts are indeed due to individual differences in the disruption of hypothalamic neurocircuitry, the identification of which remains to be determined.

215.17 VENTROMEDIAL HYPOTHALAMIC LESIONS PRODUCE EXAGGERATED SHAM FEEDING. J.E. Cox* and G.P. Smith. (SPON: D.N. Lorenz). Dept. Psychiatry, Cornell Univ. Med. Coll. and E.W. Bourne Behavioral Lab., New York Hosp., White Plains, NY 10605.

Altered reactivity to gustatory stimuli may be an important factor in the hyperphagia that follows lesions of the ventromedial hypothalamus (VMH). We used sham feeding to directly assess lesion-produced changes in reactions to oropharyngeal food stimulation, without the confounding influences of stimulation at subsequent preabsorptive and postabsorptive sites.

Female Sprague-Dawley rats (approximately 300g) that had previously sustained electrolytic lesions of the VMH or sham brain surgery were implanted with gastric cannulas. VMH rats were then reduced to control body weights, after which all rats were adapted to eating a sweet milk diet following 3.5 h food deprivation. For sham feeding, gastric cannulas were opened and ingested food drained immediately and completely through collecting tubes. Testing comprised alternating days of normal and sham feeding, and 3 tests were performed for each condition.

During 1 h tests with gastric cannulas closed (normal feeding), VMH rats (n=6) overate, consuming 16.3 ± 1.5 ml (mean ± SEM) of milk diet, compared to 5.7 ± 0.5 ml for nonlesioned rats (n=6). Both groups increased their intake during sham feeding. Controls ate 13.0 ± 2.0 ml, an increase of 130% over normal feeding. By comparison, the increase by VMH rats was markedly exaggerated: VMH rats sham fed a mean of 57.0 ± 4.1 ml, an elevation of 250% over baseline.

The exaggeration of sham feeding by VMH rats is highlighted by preliminary observations of that shown by genetically obese and hyperphagic Zucker rats. After 3.5 h food deprivation, female Zucker rats (n=2) consumed 13.2 ± 0.2 ml of milk diet during 1 h tests of normal feeding and 24.2 ± 1.8 ml during sham feeding. Lean siblings (n=2) ingested 6.5 ± 0.8 ml and 11.5 ± 0.2 ml during normal and sham feeding, respectively. In contrast to VMH rats, Zucker rats increased their intake during sham feeding no more than nonobese littermates; both of these latter groups increased consumption 80% over normal feeding. Thus, though Zucker rats overate during normal feeding almost as much as VMH rats, they sham fed less than half as much.

The dramatic enhancement of sham feeding in VMH rats points to a disturbance in reactivity to oropharyngeal stimulation as a primary factor in overeating after hypothalamic lesions. Comparison with the sham feeding by hyperphagic Zucker rats suggests the specificity of such a disturbance for hypothalamic hyperphagia.

215.18 HYPOTHALAMIC OBESITY IN THE WEANLING RAT: DIETARY SELF SELECTION, RESPONSE TO STARVATION AND HIGH-PROTEIN DIET. L.L. Bernardis, R. Luboshitzky* and L.L. Bellinger, VA Med. Ctr. and SUNY at Buffalo, NY 14215 and Dept. Physiol., Baylor Coll. Dent. Dallas, TX 75246.

Weanling Sprague-Dawley rats received bilateral electrolytic lesions in the ventromedial hypothalamus (VMNL rats); sham-operated animals served as controls (CON). For two weeks after the operation the rats were fed lab chow. VMNL rats weighed as much as the CON but their Lee Index was higher ($p<0.01$). Caloric intake (CI) was normal but the VMNL rats laid down less ($p<0.05$) body weight (BW) and deposited more fat ($p<0.001$) for the CI. For the next 21 days all rats received three equicaloric (4.03 kcal/gm) diets of different macronutrient content. CI from all three diets was similar in both groups but the VMNL rats selected more ($p<0.02$) of the high-carbohydrate and less ($p<0.05$) of the high-protein diet. Intake from the high-fat diet was slightly but not statistically significantly higher in the VMNL rats. In terms of macronutrient intake the VMNL rats ingested more ($p<0.01$) carbohydrate (CHO) and fat ($p<0.05$) and the same amount of protein (PRO) as the CON. However, in percent of total macronutrient intake, the VMNL rats ate less ($p<0.01$) CHO and PRO ($p<0.01$) than the CON; fat intake was comparable. During a two-day fats the VMNL rats lost less BW and fat (both $p<0.01$) but regained both BW ($p<0.01$) and Lee Index ($p<0.05$) slower than the CON. During the subsequent refeeding period there was no difference in dietary selection between the two groups but in terms of actual nutrient intake the VMNL rats ate less PRO. During the following nine days all rats were fed a high-PRO diet (43.2%). Both VMNL rats and CON increased their CI over that of the previous periods but both groups ate similar amounts. BW gains were similar in both groups but the Lee Index remained higher ($p<0.02$) in the VMNL rats. During the next 31 days all rats were again fed lab chow. VMNL rats ate less ($p<0.01$) calories than CON, showed normal BW gains but retained their higher ($p<0.05$) Lee Index. They utilized CI similarly for BW gain but poorer ($p<0.001$) for fat deposition. At sacrifice, plasma glucose and total protein were similar in the two groups but white (epididymal) fat pads were heavier ($p<0.001$) and contained more fat ($p<0.001$) and less ($p<0.05$) protein than CON. It is concluded that the weanling VMNL rat selects more CHO diet and less PRO diet than CON but that in terms of actual percent macronutrient intake the VMNL rats ingest less of both CHO and PRO. It thus shows a pattern different from that of the mature rat with hypothalamic obesity.

216.1 SLOW POTENTIAL RESPONSES FROM RAT FRONTAL CORTEX TO A SINGLE PULSE CUE PRECEDING REWARDING MEDIAL FOREBRAIN BUNDLE STIMULATION: EFFECT OF AMPHETAMINE. J.H. Pirch, T.C. Napier and M.J. Corbus*. Department of Pharmacology and Therapeutics, Texas Tech University Health Sciences Center, Lubbock, TX 79430

We previously demonstrated, in the rat frontal cortex, negative slow potential (SP) responses to an auditory cue (click) which preceded rewarding medial forebrain bundle (MFB) stimulation (Pirch, Soc. Neurosci. Abst. 6: #274.4, 1980). This study was conducted to: 1) determine whether a single electrical pulse to the MFB can serve as a cue, as reflected by the development of SP responses to the pulse when it is paired with the train of rewarding stimulation; and 2) examine the effect of d-amphetamine on these SP responses. SP responses were recorded bilaterally from the frontal cortex of rats with permanently implanted silver-silver chloride electrodes. Trials were presented at variable intervals of 15 to 50 seconds and the interval between the single pulse and onset of the rewarding train was 2 seconds. The cue stimulus was a single 0.5 msec monophasic square wave pulse of the same current intensity as rewarding stimulation (100 Hz, 0.5 sec train). Appropriate current strength was determined by prior testing for self-stimulation. The single pulse by itself failed to evoke an SP response but after repeated pairing, large negative SP responses developed which were bilaterally equal. Training to the point of maximum SP response amplitudes generally required more trials with the pulse cue than with the auditory cue. Amphetamine (0.125, 0.25 and 0.5 mg/kg, SC) produced a dose-related depression of the SP response to the pulse cue, an effect comparable to that observed using an auditory cue with either food or MFB stimulation reinforcement. The results indicate that frontal cortex SP responses which develop in anticipation of a meaningful event are primarily independent of the type of cue which evokes the responses. Furthermore, amphetamine consistently suppresses these SP responses, regardless of the type of cue or reinforcement employed. 216.2 BRAINSTEM AND BASAL FOREBRAIN PROJECTIONS TO THE CEREBRAL CORTEX IN THE RAT. C.B. Saper. Dept. of Neurology, New York Hosp.-Cornell Univ. Med. Ctr., New York, NY 10021

Several brainstem and basal forebrain cell groups which have defined neurotransmitters and which project to the cerebral cortex have been implicated in control of cognitive function. A systematic mapping of brainstem and basal forebrain afferents to the cerebral cortex has therefore been undertaken to identify any additional such cell groups which might contribute to cortical regulation. Injections of wheat germ agglutinin-conjugated-horseradish peroxidase solution were placed into a variety of cortical sites, and the distribution of retrogradely labeled neurons stained by the TMB method was mapped.

Several cell groups were found to project topographically to all cortical areas investigated: 1) the noradrenergic locus coeruleus, 2) the serotonergic dorsal and superior central raphe nuclei, 3) a group of ventral tegmental neurons, at least some of which are dopaminergic and 4) the cholinergic magnocellular nucleus of the basal forebrain. Neurons in the area of the A1 catecholamine cell group also projected to the medial frontal cortex.

A major cortical projection system from the hypothalamus and dorsal pontine tegmentum was also delineated. A hypothalamic cell group was found, extending from the lateral hypothalamus at the premammillary level caudally and medially through the supramammillary area, which projected topographically upon all of the cortical areas studied. The more medial parts of this cell group appeared to project primarily to the medial frontal and cingulate cortex and the hippocampus, while more lateral neurons projected to the lateral wall of the hemisphere. The tuberomammillary nucleus appeared to have an extensive bilateral cortical projection.

In the pons, a group of neurons extending medially from the parabrachial nucleus across the central gray matter at that level was also found to project topographically in a medial-to-lateral fashion upon the cerebral cortex. The fibers from the pontocortical projection appeared to traverse the hypothalamus in a topographic distribution, passing through the hypothalamic areas which project to the same parts of the cortex. Evidence from other sources indicates that these pontine and hypothalamic cell groups are topographically reciprocally connected. This suggests that there may be a major system of topographically organized direct and relayed projections to the cerebral cortex from the dorsal pons and hypothalamus. The role of such a system remains conjectural but earlier physiological studies suggest that it may play a part in alerting and arousal mechanisms.

216.3 ROLE OF THE ANTEROMEDIAL CORTEX IN ORIENTING BEHAVIOR AND VISUALLY GUIDED LOCOMOTION OF THE RAT. T.M. Barth,*S.M.Parker* and H.M.Sinnamon. Lab. of Neuropsychology,Wesleyan University, Middletown,CT 06457

Unilateral damage to the frontal cortex projection areas of the dorsomedial thalamus produces multimodal contralateral neglect in man and monkeys. In rats damage to the homologous area, the anteromedial cortex (AMC), reportedly produced a type of visual neglect in a Y-maze. In this study we made unilateral lesions in the AMC to study its role in orientation to stimuli of different modalities and in the process by which orienting is used to guide locomotor-approach.

Simple orienting behavior was tested by presenting visual, auditory,olfactory and tactile stimuli on each side of the subject. Visually guided locomotion was examined in a cross maze in which a rat shuttled from pole to pole to obtain milk from an illuminated bottle under three testing conditions. In one condition, the bottle cues were visible to the rat at both the start and choice point, and thus visual information was continuously available to guide locomotion. In the second condition, cues in the left and right arms were available only at the choice point and not at the start point. In the final condition, the bottle cues were exposed only at the start point but not at the choice point,and thus the rat had to remember the location of the cue to guide locomotion.

Ten Sprague-Dawley male rats were pretested in the simple orienting test and pretrained in the three cross maze conditions. Six animals received unilateral AMC lesions and four served as unoperated controls. Animals with medial lesions made significantly more errors than controls when the cue was on the side contralateral to the lesion in all three cross maze conditions. Rats with lesions had greatest difficulty when the cues had to be remembered. In addition, animals with lesions made few errors in any condition when the cues were in the anterior field and on the side ipsilateral to lesions. There was no difference in simple orienting behavior between the experimental and control groups.

These data suggest unilateral AMC lesions produce a deficit that is similar to the neglect syndrome displayed by primates with damage in the homologous region. This deficit cannot be viewed as a simple sensory deficit because animals with lesions can orient to the contralateral side. This deficit is likewise not the manifestation of a motor bias (i.e.,circling) because subjects can approach cues in the anterior field. Currently smaller lesions of the AMC are being made in order to delineate the exact regions involved in these processes.

216.4 MODIFICATION OF ACOUSTIC STARTLE REFLEX AMPLITUDE BY BACKGROUND LEVEL AND PRESTIMULI IN TWO STRAINS OF MICE. J.E. Storm*, K.L. Hulebak* and L.D. Fechter. (SPON: M. Bleecker). Div. Env. Toxicology, Dept. Env. Health Sciences, The Johns Hopkins University, Baltimore, Maryland 21205.

The general properties of reflex modulation by both tonic background stimuli and punctate prestimuli has been demonstrated to apply to several reflex behaviors including the eyeblink elicited by an airpuff or tap to the forehead, and the startle reflex elicited by noise or electric shock. Such modulation occurs in several species including man (adults & infants), rats and rabbits, and is believed to be characteristic of reflex behaviors in general. For example, the amplitude of the acoustic startle reflex can be maximized when the response is elicited by a sudden intense burst of noise presented against a white noise background level in the neighborhood of 75dBA. Furthermore, the acoustic startle response can be inhibited when a brief white noise prestimulus, which by itself does not elicit startle, precedes the startle-eliciting stimulus by approximately 40-100msec.

In the present study, the amplitude of startle following a 10 kHz 120 dB SPL tone of 30 msec duration (incorporating a 5 msec rise and decay time) in adult ICR strain laboratory mice (Blue Spruce Farms) (n=8) was compared to that of adult grasshopper mice Onychomys torridus (n=8) in the presence of background white noise levels of 60, 75 and 90 dBA. Both species of mice showed maximum amplitude of startle in the presence of 75 dBA, and a marked reduction of amplitude in the presence of 90 dBA background level.

However, in a separate study with the same startle tone parameters, modification of the startle response amplitude by a white noise prestimulus was markedly different in the two species. In the presence of a 70 dBA background noise level, prestimuli of 80 dBA or 85 dBA were presented 0, 10, 40, 160 and 500 msec prior to the startle tone. Presentation of the prepulses 10 or 40 msec prior to the startle tone significantly inhibited the startle response of ICR strain mice (n=25), whereas prepulses did not inhibit the startle response of Onychomys torridus (n=28). The failure of preliminary stimuli to inhibit the acoustic startle reflex under such conditions is unique among all species studied to date. We are currently investigating the efficacy of light and pure tone prestimuli on inhibition of this reflex in order to evaluate the use of Onychomys torridus for further study of the neuroanatomical and physiological basis of reflex modulation.

216.5 HIPPOCAMPAL SUSTAINED POTENTIAL SHIFTS. John Fowler[a] and Lauren K. Gerbrandt. (SPON: Joseph Arezzo) Dept. of Psychology, California State University, Northridge, Ca. and Neuroscience Research Program, MIT, Boston, Ma. 02116

The neocortical arousal response consists of low voltage fast activity and can be elicited by novel stimulation of sensory modalities as well as by electrical stimulation of the reticular formation (Moruzzi and Magoun EEG J 1:455, 1949). The hippocampal arousal response is characterized by low frequency (2.5-13 Hz., depending on species), high amplitude synchronous waves and typically occurs simultaneously with the neocortical arousal response (Green and Arduini J. Neurophysiol 17:533, 1954). Because neocortical and hippocampal arousal responses have independently been associated with facilitory memory effects, one may speculate that potential field changes common to both arousal processes exist. During either the reticulo-cortical desynchronized EEG pattern or the highly synchronous hippocampal arousal pattern, negative sustained potential shifts typically develop over neocortex (Arduini et al. Arch. Ital. Biol. 95:137, 1957). Recent studies indicate these arousal concurrent sustained potential shifts can be recorded within the hippocampus during periods of hippocampal rhythmical slow activity (RSA) (Gerbrandt and Fowler Prog. in Brain Res. 154:109, 1980). In the studies reported here, sustained potential shifts and RSA were recorded from the hippocampus of locally anesthetized, curarized rats. Somatosensory stimulation was used to induce sustained potential shifts from a non-aroused irregular EEG background. Both laminar and reverse laminar profiles were recorded in order to assess the possible effects of tissue damage caused by the advancing electrode tip. Neither the form nor the amplitudes were appreciably different when forward and reverse profiles were compared at the same depth. The mean and maximal sustained potential shifts as well as the amplitude 3 seconds after stimulus onset were recorded at different depths. While there were minor variations in amplitude, the profiles were similar for all three measures. These shifts were correlated with the corresponding RSA amplitude profile. The two profiles were similar with the RSA amplitude being higher at all points prior to the "null" region. At the "null" point the sustained potential shifts were larger and continued to be so with the exception of the point 500 micrometers below the "null". Spontaneous sustained potential shifts were observed but were always concurrent with bursts of RSA. In several experiments an attempt was made to dissociate hippocampal sustained potential shifts and RSA by transecting the dorsal fornix. Information from the fornix transection experiments indicate that sustained potential shifts and RSA can be dissociated.

216.6 NALOXONE AUGMENTS ELECTROPHYSIOLOGICAL MEASURES OF SELECTIVE ATTENTION IN MAN. A. Arnsten, D.S. Segal, H. Neville and S. Hillyard. Psychiatry Dept., UCSD Med. Sch., La Jolla, CA 92093, Salk Inst., San Diego, CA 92138, Neurosci. Dept., UCSD Med. Sch., La Jolla, CA 92093.

In previous studies of rat behavior we observed that low doses of the opiate antagonist naloxone (NAL) increased the average time an animal spent per contact with stimuli in a novel environment (Arnsten, A. and Segal, D.S., Life Sci. 25: 1035, 1979). These findings suggested that NAL might enhance stimulus-directed behavior by altering attentional mechanisms, particularly since the opiate agonist morphine is reported to diminish the ability to concentrate in humans (Lewis, M.E. et al., Science 211: 1166, 1981). The pattern of NAL binding in primate cortex has also been interpreted as suggesting an opioid role in attentional processes (Jaffe, J.H. and Martin, W.R., in Pharmacol. Basis of Therapeutics, 6th Ed., p. 494, 1980). We examined the hypothesis that NAL might increase selective attention in humans utilizing an auditory event-related potential paradigm developed by Hillyard and associates (Science 182: 177, 1973; J. Exp. Psychol. Human Perception Performance 2: 313, 1976). Auditory event-related potentials were recorded from subjects who listened selectively to sequences of discrete tones, all of the same frequency, delivered to one of three perceived spatial locations: left ear, right ear, and center of the head (binaural). Subjects were instructed to detect occasional target tones of a slightly longer duration at the attended location. In this paradigm, the measure of selective attention was the amplitude of a broad negative component of the event-related potential to the tones when they were attended relative to when they were inattended (the "attention effect"). Typically, tones at the center of the head exhibited the smallest attention effect and were the least discriminable, while a larger attention effect was observed for the left and right tones. Naloxone (2 mg, IV, doubleblind, crossover design) significantly increased the amplitude of the attention effect to the left and right tones, but not to the center tones, as well as improving some aspects of behavioral performance. These findings indicate that NAL enhances electrophysiological signs of selective attention for more easily discriminable channels of stimuli, suggesting a role for endogenous opioid systems in early stimulus filtering (Treisman, A., Psychol. Rev. 76: 282, 1969).

This research was supported in part by USPHS Research Grants DA-01994-03 and NIAA-03504.

216.7 SELECTIVE ATTENTION-INDUCED CENTRIFUGAL INFLUENCES ON THE HUMAN RETINA. Robert G. Eason, Marta Oakley* and Lynn Flowers*, Dept. of Psychology, Univ. of N. Carolina, Greensboro, N. C. 27412.

It is known that about 10% of the mammals' optic nerve fibers, including humans, are of central origin (R. B. Livingston, Sen. proc., percept. & beh., Raven Press, 1978). Following Cajal's early description, a significant number of studies have provided data supporting their existence (Hasselt, Van P., Ophthal. Res., 1973, 4, 298-320). Yet their functional significance is not well understood; also, some workers are still skeptical of their existence in adults.

In 1969, Eason, Harter, and White (Physiol. & Beh. v. 4) demonstrated that the instruction to selectively attend (and respond) to flashes presented peripherally in the left and right visual fields results in larger visual evoked potentials (VEPs) over occipital cortex when the flashes in a given field are attended than when they are not. Since relatively early components of the VEPs were affected, it was postulated that cortically induced centrifugal activity associated with "stimulus set" differentially altered the inflow of relevant and irrelevant information at precortical synaptic relays. This neural filtering would permit relevant information to have a greater impact on arrival at visual cortex than irrelevant information.

Since centrifugal fibers project to the retina, cortically induced centrifugal influences produced by selective attention instructions should be measurable at the retina if the above hypothesis has validity. Detection of attention-induced changes in retinal activity not only would provide further evidence for the existence of functionally active centrifugal fibers in adult humans, but would show one aspect of their functional significance.

Using a paradigm similar to the 1969 study, averaged ERGs and scalp VEPs (over occipital cortex) were recorded from 16 young adults during peripheral stimulation of the right and left visual fields. The right eye only was used. The leading edge of the b-wave of the ERG was significantly greater ($p < .01$) to attended than to unattended flashes. Also, the earliest measurable component of the VEP (onset latency, 40-50 msec.; peak latency, 80-90 msec.) was significantly greater to attended flashes ($p < .05$). These results support the hypothesis that voluntary sustained selective attention involves the cortical induction of centrifugal neural activity which selectively filters certain dimensions of relevant and irrelevant information prior to its arrival at cerebral cortex. The results provide further support for the existence of functionally active centrifugal fibers projecting to the retina in adult humans.

216.8 NEURAL DETERMINANTS OF THE HEART RATE ORIENTING RESPONSE IN NEONATAL RATS. V. Haroutunian and B. A. Campbell. Dept. of Psychology, Princeton Univ., Princeton, NJ 08544.

Neonatal rats and human infants both respond to novel, mild sensory stimuli with phasic bradycardia (BR). This BR response has been interpreted as indexing orienting and stimulus processing and is termed the heart rate orienting response (HR-OR). Three experiments investigated the neural origins of the HR-OR.

Presentation of a novel auditory stimulus evoked pronounced BR in 19-20 day-old rats. This response was mediated by vagal efferents to the heart. Two stage bilateral vagotomy abolished the HR-OR. The right and left vagi were able to exert this inhibitory influence on cardiac rhythmicity relatively independently of each other since unilateral vagotomy was without effect on the HR-OR. Pharmacological blocakde of peripheral muscarinic receptors by low (.1 mg/kg) and intermediate (.5-2 mg/kg) doses of methyl scopolamine showed that the response was mediated through peripheral cholinergic systems. Peripheral sympathectomy by guanethedine (45 mg/kg/day X 15 days), which led to 70% depletion of cardiac norepinephrine, had little or no effect on the response. The relatively small influence of the sympathetic NS (SNS) upon the HR-OR was further shown by the negligible effect of propranolol on evoked cardiac responses, even though tonic heart rate decreased significantly in response to the beta adrenergic receptor blockade. These findings show that the HR-OR is almost exclusively mediated by vagal cholinergic efferents to the heart with the SNS playing a relatively minor role. The generality of these results was further shown by methyl scopolamine blockade of the HR-OR evoked by olfactory stimuli (isoamyl acetate) in 6-day-old neonates.

The influence of vagal cholinergic efferents upon phasic cardiac responses also extends to pain-evoked tachycardia (TA). Following presentation of the auditory stimulus in the experiments described above, each rat received one (.5 sec 1 ma) foot shock and the heart rate response was noted. Shock evoked TA in control, guanethedine, propoanolol, and unilaterally vagotomized rats. This TA response was blocked by methyl scopolamine and bilateral vagotomy. These findings show that both the TA and BR evoked by psychologically relevant stimuli are under direct neural control, and that this control is exerted through cholinergic vagal efferents to the heart.

216.9 PSYCHOPHYSIOLOGIC PERSONALITY ASSESSMENT ON THE BASIS OF CARDIO-RESPIRATORY ORIENTING RESPONSES. S.A. Corson, E.O'L Corson, and R.M. Andrysco, Dept. of Psychiatry, Academic Faculty of Early and Middle Childhood Education, Ohio State University, and Psychophysiologic Stress Research Center, 285 West Kenworth Rd., Columbus, OH 43214 USA.

We previously described stable constitutional (genetic) differences in psychophysiologic reactions of dogs exposed to repeated psychologically stressful situations induced by Pavlovian conditioning techniques with electrocutaneous reinforcement. Some dogs (e.g., beagles) showed high psychophysiologic adaptation (HA dogs). Other dogs (e.g., wirehair fox terriers, border collies, English shepherds) developed persistent, marked, almost inextinguishable reactions to the entire Pavlovian aversive room complex: tachycardia, polypnea, profuse salivation, vasopressin release, high energy metabolism, and high urinary catecholamines (low adaptation or LA dogs). Analysis of the development and extinction of orienting reflexes (O.R.) in these two types of dogs indicates that the LA dogs exhibit higher frequency and more intense, persistent, and highly fluctuating (poorly modulated) cardiac and respiratory O.R.s than those exhibited by the HA dogs, which show rapid O.R. habituation and good modulation of cardiac and respiratory functions. These observations suggest that the degree of modulation and the dynamics of development and extinction of orienting reflexes might serve as a basis for predicting the type and persistence of physiologic reactions an individual may exhibit to psychosocial stressors and his/her possible susceptibility to psychovisceral (cardiac and respiratory) pathology. Supported in part by NIH grant HL 20861 and The Ohio State University Graduate School Biomedical Sciences Support Grant.

217.1 ONLY ESTERS PROTECT THE OLFACTORY MUCOSA FROM INHIBITION BY THE VAPOROUS ALKYLATING AGENT, ETHYL BROMOACETATE. Rollie Schafer and Darrell W. Criswell. Department of Biological Sciences, North Texas State University, Denton, TX 76203

The vaporous alkylating agent, ethyl bromoacetate (EBA) inhibits the ability of the frog nose to respond to all odorants except the aliphatic amines (Criswell, D.W. et al., Science, 210:425, 1980). As a part of this study and continuing studies with other chemically active odorants, we have attempted to produce specific inhibition using the technique first reported by Getchell and Gesteland (PNAS, 69:1494, 1972). In this technique, the nasal mucosa is flooded with a solution containing a "protecting" odorant, then treated simultaneously with an inhibitory agent such as the protein-specific sulfhydryl reagent, N-ethyl maleimide (NEM). The expectation is that the odorant, present in excess, will occupy most of its receptor sites on the receptor neurons and protect them from interacting with the reagent.

We found that only isoamyl acetate and a few closly-related esters were capable of protecting the olfactory mucosa from the inhibiting effects of EBA applied in the vapor phase. Other odorants such as isoamyl sulfide, isoamyl alcohol, etc. did not protect. By contrast, isoamyl acetate served as a universal protector. It protected responses to itself and a wide variety of odorants from many different odorant classes.

Getchell and Gesteland and other experimenters who have since replicated their work all used ethyl-n-butyrate or similar esters to protect. Delaleu and Holley (Chemical Senses and Flavour, 5:205, 1980) used vaporous NEM to inhibit olfactory responses and also demonstrated protection by isoamyl acetate in the vapor phase. Thus, there is ample evidence that some esters protect, both in the liquid and vapor phases. But why is protection conferred only by esters? Perhaps protection involves some chemical or electrical effect other than simply occupying a receptor site which would otherwise react with the inhibitor. Experiments are underway to determine whether the protecting effect depends on depolarization of receptor cells rather than a site-blocking action of the protecting molecule.

217.2 HIGH RESOLUTION 2-DEOXYGLUCOSE AUTORADIOGRAPHY IN THE OLFACTORY EPITHELIUM AND BULB. Doron Lancet*, Charles A. Greer, John S. Kauer and Gordon M. Shepherd. Section of Neuroanatomy, Yale Univ. School of Medicine, New Haven, CT 06510.

We have employed high resolution 2-deoxyglucose (2DG) autoradiography to analyse cellular localization of odor-elicited activity in the vertebrate olfactory epithelium and olfactory bulb. Animals were injected with 3H- or 14C-2DG and exposed for odor stimulation to isoamyl acetate vapors at 10^{-2} to 10^{-1} saturation. The tissue underwent freeze substitution in acetone followed by plastic embedding. Sections cut at 1-4um were processed for nuclear emulsion autoradiography and examined for cellular localization of silver grains (cf. Sejnowski et al., Nature 287: 449, '80).

In the olfactory neuroepithelium of the mouse and tiger salamander increased 2DG uptake was found in the superficial supranuclear zone (not including the mucus layer) and in the basal layer. The latter uptake was mostly in the form of clusters of grains interspersed among basal cell nuclei; one possibility is that these clusters are related to exiting fascicles of receptor axons. In addition, thin, radially oriented grain clusters were seen between receptor cell nuclei. In all laminae the uptake was differentially distributed across the epithelial sheet suggesting spatial heterogeneity of odor-related activity. Uptake was high in the cells of Bowman's glands whereas it was low in the respiratory epithelium.

In the olfactory bulb of the rat and the salamander high 2DG uptake was seen in some regions of the glomerular layer. Individual glomeruli with uptake higher or lower than the tissue background could be clearly seen, suggesting the glomerulus as a unit of activity. Uptake in periglomerular borders often differed markedly from that of the adjacent glomerular neuropil. Of special interest were small grain clusters over individual periglomerular, mitral and especially granule cell nuclei. Immediately neighboring cell nuclei displayed background activity.

The results in the rat olfactory bulb confirm the work of Stewart et al. (J. Comp. Neurol. 185: 715,'79) using the Sokoloff method, and extend the analysis to the cellular level. The results in the olfactory epithelium show that the 2DG technique can be successfully applied to this peripheral tissue, and provide a basis for further analysis of olfactory receptor mechanisms. The data obtained at these two levels in the olfactory pathway provide insight into the neuronal correlates of olfactory processing.

217.3 IMMUNOFLUORESCENT LOCALIZATION OF PUTATIVE NEUROTRANSMITTERS IN OLFACTORY PATHWAYS. R. Jacobson*, R. Elde. University of Minnesota Medical School, Minneapolis, MN 55455.

The olfactory system has well defined connections with limbic, diencephalic and brainstem structures which are enriched with currently known putative neurotransmitters. This study extends the current knowledge of neurotransmitter localization at the level of the olfactory bulb (OB), olfactory nerve (ON), and centrifugal pathways.

Male rats (150-200 grams) were perfused with ice cold buffered 4% paraformaldehyde 2 days after intraventricular colchicine (50 µg), or 1 week after right OB transection at the junction with olfactory nuclei, or without manipulation. 10 µm sagittal cryostat sections were thaw mounted onto gel coated slides and processed with antisera to cholecystokinin octapeptide (CCK), somatostatin (SOM), substance P (SP)**, alpha melanocyte-stimulating hormone (α-MSH), serotonin (5-HT), and insulin using the method of indirect immunfluorescence.

Although the dipeptide carnosine is the only neurotransmitter candidate presently identified in ON, SP and CCK immunoreactive fibers were clearly seen in the ON and the glomerular layer of OB. Numerous α-MSH, SOM and 5-HT fibers were distributed throughout the OB and olfactory nuclei. Clusters of 5-HT fibers occurred in glomeruli. After OB transection, 5-HT, α-MSH, SOM and CCK immunoreactivity increased caudal to the cut with diminished staining rostrally, except for SOM which increased on both sides of the transection. CCK and SOM cell bodies in ipsilateral olfactory nuclei and SOM cell bodies in olfactory bulbs were revealed with either OB transection or colchicine treatment. Although OB contains among the highest concentrations of insulin and insulin receptors in brain, no specific insulin immunoreactivity was detected.

These data demonstrated ascending CCK and SOM olfactory pathways originating from olfactory nuclei. 5-HT afferents have been shown to be from raphe nuclei. We speculate that α-MSH may originate from recently described α-MSH cell bodies in lateral hypothalamus which is known to project to contralateral OB. The origin of CCK and SP in ON and the histochemical localization of insulin within OB are currently unknown.

217.4 PICROTOXIN SLOWS OLFACTORY BULB INDUCED WAVES. Wm. B. Forbes. Worcester Foundation for Experimental Biol., Shrewsbury, MA 01545.

The effects of a convulsive dose of picrotoxin on oscillatory slow-wave activity recorded in the main olfactory bulb (MOB) in five adult male Sprague-Dawley rats was studied. Side-by-side bipolar stainless steel electrodes constructed of 250 µ wire having a vertical tip separation of 1.5 mm were chronically implanted across the mitral body layer in the ventral portion of the MOB unilaterally. Sniffing was monitored via a thermocouple held in a chronically implanted nasal cannula. At least ten days following surgery sniffing and MOB E_G were monitored prior to and following a 2 mg/kg i.p. dose of picrotoxin. This dose induced at least one motor convulsion with a latency of 10 - 15 min in all animals studied. EEG changes were quantified using power spectral analysis and digital filtering. Spectra were computed having a Niquist frequency of 256 Hz with 0.5 Hz resolution.

A frequency component centered at 60 - 90 Hz was reliably observed in all animals studied. Comparison of filtered MOB activity with sniffing verified that this component comprised inhalation-induced spindles; viz. induced waves. Following picrotoxin administration, a time-dependent slowing of the induced wave component was observed such that the peak frequency of this component was reduced by 10 - 20% immediately prior to the motor convulsion. For several minutes following the termination of the convulsion, the absolute amplitude of the induced waves was dramatically enhanced. This enhancement was also seen following successive convulsions, when they occurred.

These results are interpretted as reflective of a depressive effect of picrotoxin on inhibitory transmission at the granule-to-mitral cell synapse. The data are consistent with the hypothesis that lowering the gain of the negative feedback loop between populations of MOB output neurons and presumed GABAergic granule cells decreases output neuron damping and thereby lowers the frequency of induced wave oscillations.

217.5 ORTHODROMIC RESPONSE PROPERTIES OF OLFACTORY BULB OUTPUT NEURONS IN THE RAT CORRELATE WITH AXONAL PROJECTION PATTERNS.
Stephen P. Schneider* and John W. Scott. Department of Anatomy, Emory University School of Medicine, Atlanta, GA 30322.

Anatomical experiments and our recent electrophysiological studies have shown that olfactory bulb (OB) output neurons, the mitral and tufted cells, can be distinguished by their efferent projections. We now report on an investigation of differences in orthodromic response properties between these cell types.

In this study, three populations of OB units were classified on the basis of antidromic activation: OT units were activated from the olfactory tubercle (OT) but not from the posterior piriform cortex (pPC); pPC-OT units were activated from both regions; and LOT units were activated only by stimulation of the lateral olfactory tract (LOT) at the level of the olfactory peduncle. The orthodromic responses of antidromically identified units were studied during stimulation of the olfactory nerve layer (ONL) at different sites using a linear array of seven bipolar electrodes.

Stimulation of the olfactory afferents excited 95% of the LOT and 96% of the OT units but only 59% of the pPC-OT units. The pPC-OT units also tended to have a higher threshold for excitation than the other unit types. The pPC-OT units responded to orthodromic stimulation with single spikes, even at suprathreshold stimulus currents; whereas 80% of LOT and 38% of OT units showed multiple spikes at suprathreshold currents. The LOT and OT units responded with significantly shorter latencies to orthodromic stimuli than did the pPC-OT units. Finally, LOT and OT units were excited by stimulation of a significantly greater number of ONL sites than pPC-OT units.

These data suggest that OB neurons projecting to anterior olfactory regions, such as the anterior olfactory nuclei, anterior piriform cortex, and the OT, are more responsive and may be excited from a larger region of the olfactory mucosa than those cells projecting to the pPC. Based on anatomical studies and our previous electrophysiological results, we conclude that a predominance of the cells belonging to the first category are tufted cells and those of the second are mostly mitral cells. Our data are consistent with the hypothesis that mitral and tufted cells function differently in the processing of primary olfactory information and that these differences correlate with axonal projection patterns.

217.6 ELECTROPHYSIOLOGICAL EVIDENCE FOR VAGAL INFLUENCES UPON THE NEURONAL ACTIVITY OF THE OLFACTORY BULB.
R. Guevara-Aguilar, D.E. García Díaz* and H.U. Aguilar-Baturoni. Depto. de Fisiología, Div. de Investigación, Fac. de Medicina, Univ. Nal. Autónoma de México, México 20, D.F.

Previous experiments performed in our laboratory suggest that the sympathetic part of the autonomic nervous system exerts a modulatory influence upon the olfactory structures. This study was undertaken to test whether or not the parasympathetic also contributes to modulate the olfactory system. The results were obtained from rats (280-320 g body weight). The rats were anesthetized with chloral hydrate (460 mg/kg). The neuronal activity of the ipsilateral or contralateral olfactory bulb was recorded, using a micropipette with a 3 μ diameter tip, during vagal stimulation was verified by its bradycardia effects and heart rate was continuously monitored. Data were collected from 11 cells in 8 animals, 36.3% of the population (4 neurones) showed a significant increase in their frequency and the other 63.3% (7 neurones) showed a decrease in the discharge frequency. We observed that the neuronal activity was recorded from a narrow band of 1500 μ wide. These results suggest that the autonomic nervous system exerts a very important influence upon the olfactory system.

217.7 ULTRASTRUCTURAL CHARACTERIZATION OF SYNAPTIC TERMINALS OF OLFACTORY BULB AFFERENT FIBERS AND ASSOCIATION FIBERS IN THE PIRIFORM CORTEX OF THE OPOSSUM.
M. Behan and L. Haberly, Department of Anatomy, University of Wisconsin, Madison, WI 53706

As part of an ongoing analysis of the neuronal circuitry in the olfactory cortex, electron microscopic autoradiography has been used to characterize synaptic terminals of olfactory bulb (OB) afferent fibers in layer Ia and terminals of intracortical association fibers in layers Ib, II, and III of the opossum piriform cortex. Injections of tritiated amino acids for study of association terminals were made in the rostral part of the piriform cortex and labeled terminals studied in the caudal part (>5mm from injection sites). Injections in the olfactory bulb were carefully placed to avoid involvement of the anterior olfactory nucleus.

The most distinctive features of OB terminals are the presence of evenly-spaced round vesicles, an overall light appearance, asymmetrical synaptic contacts that are convex outward, and an astrocytic glial wrap. No labeled terminals with these features have been observed deeper in the cortex than approximately 50 μm below the center of the layer Ia-Ib boundary. OB terminals usually contact 1-3 dendritic spines, although occasional contacts onto dendritic shafts are observed. These results indicate that terminals of OB fibers in the opossum are very similar to those in the rat (Westrum, Z. Zellforsch., 98:157, 1969) and mouse (Caviness, et al., Br. Res. 134:13, 1977).

The most distinctive features of association fiber terminals are the presence of tightly-packed round vesicles, an overall dark appearance, and straight, asymmetrical synaptic contacts with dark post-synaptic densities. Contacts onto single dendritic spines are most numerous, although occasional contacts onto more than one spine or onto dendritic shafts are present. Small vesicles are often found in dendritic spines contacted by both association and OB terminals but these do not appear to be synaptic vesicles. Terminals with pleomorphic vesicles and symmetrical contacts that are found at all depths in the cortex do not appear to be labeled at greater than chance levels from either anterior piriform cortex or olfactory bulb injections.

Preliminary measurements of vesicle size distributions in OB and association terminals with a computer-coupled graphics tablet indicate that they are very similar and cannot be used to distinguish these two terminal populations. However, due to their very different ultrastructural features, very few OB terminals could be mistaken for association terminals and vice versa, even though considerable morphological variation is present in both populations.

Supported by NSF grant #BNS8012067.

217.8 AN EXAMINATION OF COUPLING BETWEEN EEGS OF TWO OLFACTORY STRUCTURES.
S. L. Bressler. Dept. of Physiol.-Anat., Univ. of Calif., Berkeley, CA 94720.

This study deals with the relation between the olfactory bulb (OB) and olfactory cortex (OC), comparing the EEGs recorded from multiple sites in each structure. The relation between small bulbar and cortical areas is examined by measuring the shared frequency and phase between their EEGs. The question is asked whether all pairs of bulbar and cortical local areas are actively coordinated (coupled), or whether some pairs show a greater degree of coupling than others. The test of coupling is whether the relation of bulbo-cortical phase to shared frequency is consistent with bulbar driving of OC.

Neural activity in the OB is manifested as a 35 to 85 c/sec sinusoidal burst in the EEG. Bulbar activity is relayed to the OC by pulse activity in mitral cells, whose axons leave the OB to form the lateral olfactory tract (LOT) which terminates in the OC. Pulse activity on axons in the LOT is synchronous with the bulbar EEG. The density of pulses in the LOT provides oscillatory input to cortical pyramidal cells at the same frequency as the bulbar burst. During states of behavioral arousal, similar bursts occur in OC. Anatomically, the axonal projection from OB to OC is diffuse; i.e. small bulbar areas project to almost the entire OC, and small cortical areas receive fibers from all parts of the OB.

Tungsten microelectrodes were chronically implanted at 9 sites in the OB of 10 rabbits. A 10 by 6 rectangular electrode array (300 micron stainless steel wires embedded in dental acrylic at 0.8 mm spacing) was placed epidurally on the surface of the OC. EEGs from all bulbar and cortical electrode sites were simultaneously recorded onto magnetic tape using a 64 channel A-D converter. For selected bulbar and cortical sites, 50 burst pairs were analyzed for shared frequency and phase.

Results demonstrated that for some pairs, the relation between phase and frequency was well-behaved and consistent with bulbar driving of OC. For other pairs, phase was distributed over the whole range of 0 to 360 degrees. These results were interpreted to mean that, although the anatomical projection from OB to OC is diffuse, coupling occurs between the activities of only certain select regions. A possible explanation is that in any animal, only a fraction of the possible synaptic pathways between OB and OC are functionally operative. Supported by MH06686.

217.9 CONNECTIONS OF THE MAIN AND ACCESSORY OLFACTORY BULBS IN THE TOAD, BUFO MARINUS. S. Jiménez-Dietsch and E. Kicliter. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, P.R. 00936.

In anuran (tailless) amphibians olfactory projections have been studied only in the frogs Rana pipiens and Rana catesbeiana. In order to ascertain whether the results found in these species are representative of anurans we have studied the projections of the main and accessory olfactory bulbs of the toad, Bufo marinus, with an anterograde degeneration technique. Small electrolytic lesions were placed in either the main or accessory olfactory bulbs of 24 B. marinus. After survival periods of 3-10 days the animals were re-anesthetized and perfused intracardially with 10% formalin. Sections of the brains were stained with the Ebbesson-Heimer stain and the locations of anterograde degeneration were determined. After main olfactory bulb (MOB) lesions degeneration was traced caudally through the lateral olfactory tract along the periphery of the lateral pallium to the caudal pole of the hemisphere. Degeneration after MOB lesions was also traced in the medial olfactory tract which distributes to rostral portions of the medial and lateral septal nuclei, rostral medial pallium, and to the nucleus of the diagonal band. After accessory olfactory bulb lesions degeneration was traced through the postolfactory eminence, the striatum, nucleus accumbens and nucleus of the diagonal band to pars lateralis of the amygdala. These results are in general agreement with the results of previous studies of Rana except that previous investigators have not reported a projection of the accessory olfactory bulbs to the striatum. This result suggests that the striatum and pars lateralis of the amygdala may be part of the same cell group. (Supported by PHS grant NS-07464).

217.10 THE EFFECT OF INTRANASAL ZINC SULFATE TREATMENT ON SUCKLING BEHAVIOR AND ODOR-INDUCED ACTIVITY IN THE NEONATAL RAT OLFACTORY BULB. William B. Stewart, Charles A. Greer and Martin H. Teicher, Sec. Neuroanatomy, Neurosurgery and Gross Anatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

We have correlated the behavioral effects of zinc sulfate ($ZnSO_4$) treatment with odor-induced 2-deoxyglucose (2DG) uptake in the developing rat olfactory bulb.

Eight - nine day old rat pups received intranasal irrigation with either 0.9% NaCl, 1% $ZnSO_4$, or 5% $ZnSO_4$. One and 5 days following treatment the rats were tested for suckling behavior and for vibrational responses to the anesthetized dam and a heating pad. Six days following treatment the pups were injected with 200μCi/kg of ^{14}C-2DG and placed, in groups of 3, in an odor chamber where they were exposed to a 10^{-1} flow dilution of amyl acetate. The brains were then processed for autoradiography.

At 1 day following treatment none of the $ZnSO_4$ pups attached to the dam's nipple, while 89% of the saline pups attached within 5 min. At 5 days none of the 5% pups attached while 67% and 100% of the 1% $ZnSO_4$ and saline pups, respectively, attached. On the vibrational tests of maternally directed behavior, similar results were obtained. At one day following treatment neither of the $ZnSO_4$ groups could discriminate between the dam's ventrum, dorsum, or a heating pad. At 5 days post treatment, the 1% group had recovered to control levels while the 5% group was still unable to differentiate. On day 13 postnatal, the saline control pups had gained 5.5g, the 1% $ZnSO_4$ pups had gained 3g and the 5% pups had lost 2.7g.

The 2DG results may be summarized as follows. The saline pups had large regions of increased focal 2DG activity in the glomerular layer of the olfactory bulb. In marked contrast, the 5% $ZnSO_4$ pups did not have distinct focal 2DG activity. The 1% pups had 2DG foci in the glomerular layer but to a lesser extent than the saline control pups. The olfactory bulbs of both the 1% and 5% pups were smaller than the saline pups. This was particularly evident in the nerve and glomerular layers.

These results are consistent with those of Singh et. al. (Physiol. & Behav. 17: 373, 1976) who demonstrated deficits in suckling behavior following 5% $ZnSO_4$. Our results extend these findings demonstrating that 1% treatments produce only temporary deficits. Also, the 2DG results on the functional organization within the olfactory bulb correlate well with the behavioral findings. Overall, the combined use of behavioral and 2DG methods provides a powerful strategy for assessing functional capacity and recovery of function in sensory systems.

217.11 CONTACT IS IMPORTANT FOR VOMERONASAL-MEDIATED MALE ATTRACTION TO FEMALE HAMSTER VAGINAL SECRETION. J.B. Powers, M. Bergondy* and L. Bopeley*. Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240.

The olfactory (OLF) and vomeronasal (VN) systems are critical for mediating the male hamster's response to chemosensory cues which stimulate copulation. These 2 systems may play different, but complementary roles in producing these behavioral effects. Specifically, the OLF system may respond to distal (volatile) cues, whereas the VN system may require proximal (non-volatile) cues for its activation.

To test the hypothesis that the VN system is not adequately stimulated by volatile odorants, 16 male hamsters were pretested to assess their relative attraction to 1 of 2 anesthetized conspecific stimulus Ss. These were an OVX female treated with E and P, and a gonadally intact male. Tests were conducted in a box with copper screen flooring below which (5cm) could be inserted 2 drawers containing the stimulus Ss. Tests lasted 2 min and the time each test S spent sniffing the floor over either of the 2 stimulus Ss was recorded.

Preference for the stimulus female was robust as evidenced by the different amounts of time spent investigating over the 2 Ss (40 vs 3.6 secs). Test males were then given intranasal zinc sulfate (ZS) to produce an OLF deafferentation or were given saline (SAL) as a control procedure. In behavior tests 2 days later SAL Ss maintained their preference for females (31 vs 2.9 secs) whereas the ZS Ss did not (3.6 vs 2.6 secs). Thus under these conditions males with only the VN system functional (ZS) did not persist in their response to chemosensory cues.

To evaluate these results further, we used 2 anesthetized, castrate hamsters as stimulus Ss, 1 of which was swabbed with female hamster vaginal secretion (FHVS). Two tests were given over successive weeks with the experimental condition of contact vs no contact with the stimulus Ss being counterbalanced among the test males which received either ZS or SAL 2 days before each of the 2 weekly tests. Among the SAL Ss, preference for the FHVS-swabbed castrate was evident independent of whether contact with the stimulus Ss was or was not permitted. In contrast, the males with only the VN system functional (ZS) exhibited a comparable preference only when contact was permitted.

217.12 OLFACTORY ADAPTATION WITHOUT DISCRIMINATION. Thomas Hellman Morton*, Howard Eichenbaum, and Suzanne Corkin (SPON: Stephan L. Chorover). Dept. Chem., Univ. Calif., Riverside, CA 92506; Dept. Biol., Wellesley Coll., Wellesley, MA 02181; and Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139.

The patient H.M. has experienced global anterograde amnesia subsequent to a bilateral resection in the medial temporal zone 28 years ago; his deficits and spared abilities have been well-studied. Eichenbaum, Potter, and Corkin have shown that H.M. has normal olfactory sensitivity but is unable to discriminate among odors. We present here further documentation of H.M.'s inability to distinguish odors from one another, as well as evidence that he exhibited normal olfactory adaptation with the odorants n-butanol (BuOH) and β-phenethyl alcohol (φEtOH).

In signal-detection tasks, H.M. scored significantly above chance in distinguishing 10 mM aqueous BuOH from blank and 3.3 mM φEtOH from blank, when the odorants were presented in equilibrium sniffers; his values of d' lay in the range from 1 to 2, within normal limits. However, he could not discriminate the two odors in a series of triangle tests. In this procedure, a weak sample was matched to either a weak or a strong choice, one of which was the same odor as the sample. Given a weak φEtOH sample, he could match it perfectly to the same stimulus paired with strong BuOH, but he scored at chance in matching to strong φEtOH paired with weak BuOH. He scored at chance in any task that required matching to a weak BuOH sample.

Preadaptation to BuOH significantly impaired H.M.'s detection of BuOH versus blank, but did not affect his detection of φEtOH; similarly, preadaptation to φEtOH impaired his detection of φEtOH versus blank, but did not affect his detection of BuOH. We conclude therefore that:

(1) H.M. adapts to odor quality and not to odor intensity alone.
(2) Odor differentiation is not requisite for olfactory adaptation.
(3) A central olfactory discrimination mechanism is not necessary for adaptation.

217.13 TASTE RESPONSES OF THE GLOSSOPHARYNGEAL AND VAGAL NERVES IN THE CATFISH. Jagmeet S. Kanwal* and John Caprio. (SPON: G.M. Strain). Dept. of Zoology and Physiology, Louisiana State University, Baton Rouge, LA 70803.

Electrophysiological investigation has revealed that the glossopharyngeal (IXth) and vagal (Xth) nerves of the channel catfish, Ictalurus punctatus, contain taste fibers that respond to amino acids and classical taste stimuli. The IXth nerve innervates taste buds on the ventral surface of the oral cavity and first gill arch. Branches of the vagus innervate the 2nd, 3rd and 4th gill arches and the pharynx. Electrophysiological reports of IXth and Xth nerve taste responses in fish are few in number, and recent studies involving amino acid taste sensitivity have involved primarily facial (VII) nerve recordings. The objectives of the present study were to determine the response properties and chemospecificities of the IXth and Xth nerves and to compare these with similar data obtained from the facial taste system in the same species. Taste buds innervated by facial nerves are highly sensitive to amino acids, especially L-alanine and L-arginine.

In vivo glossopharyngeal and vagal nerve recordings were obtained with a monopolar Pt.-Ir. hook electrode from the cut peripheral end of the nerves in the region of the branchial musculature adjacent to the cranium. The nerves responded phasically to mechanical stimulation of the oral and pharyngeal epithelium; tactile stimuli consisted of pulsing water flow and gentle stroking of the epithelium. Additionally, spontaneous, tonically active units with response frequencies dependent upon the position of the gill arches were observed in the majority of nerve bundles teased from the IXth and Xth nerves. Since this activity obscurred the responses to chemical stimuli, taste recordings were obtained from nerve bundles showing little or no tonic activity. Chemical stimuli were injected into a constant flow of water bathing the oral epithelium. Integrated multiunit activity showed L-alanine and L-arginine to be the most stimulatory amino acids tested with thresholds below 10^{-6}M; thresholds for other amino acids tested were higher ($> 10^{-5}$M). Also, L-proline was highly stimulatory at concentrations $\geq$ 1mM. Reciprocal cross-adaptation studies indicate the presence of relatively independent receptor mechanisms for L-arginine, L-alanine and L-proline. Individually identified units responded best to either L-arginine or L-alanine. The integrated phasic taste responses to amino acids were positively accelerating functions of log molar concentration of the stimulus. Thus with respect to amino acids, the facial, glossopharyngeal and vagal taste systems have strikingly similar chemical response profiles.

(Supported in part by NIH Grant NS14819).

217.14 INHIBITION OF IXth NERVE TASTE RESPONSES INVOLVES CHOLINERGIC EFFERENT FIBERS. E. Outwater* and B. Oakley, Dept. of Physiol. Univ. Calif. Sch. Med., San Francisco, CA 94143 and Dept. of Zoology, Neuroscience Lab. Bldg., Univ. of Mich. Ann Arbor, MI 48109.

Summated taste responses to stimulation of the tongue were recorded from the IXth nerve of gerbils (Meriones unguiculatus) anesthetized with ketamine HCl (330 mg/kg bw im). Acute administration of d-Tubocurarine produced a dose-dependent increase in the magnitude of the summated taste responses to 0.3M NH_4Cl (e.g., +25% with 20 mg/kg bw ip, n=9). Within 5 min d-Tubocurarine (dTC) produced a statistically significant enhancement of taste responses which lasted for more than one hour. Treatment with dTC also caused a significant increase in the time from response onset to peak (from 2.6 to 6.6 sec). Intraperitoneal injection of an equal volume of 0.9% NaCl had no effect. The use of other nicotinic anticholinergic agents [alpha bungarotoxin (0.6 mg/kg), succinylcholine (14 mg/kg), and gallamine triethiodide (200 mg/kg)] also enhanced taste responses recorded from the intact IXth nerve. Enhancement of taste responses was prevented by transection of the IXth nerve before injection of dTC. This result argues against systemic pharmacological reactions or general vascular reactions which should have been evident even after IXth nerve transection. It is likely that dTC acted peripherally to reduce efferent inhibition by the IXth nerve, since impulse activity in the proximal stump of the transected IXth nerve was unaffected by dTC.

To test the suggestion that the IXth nerve contains cholinergic efferent fibers which innervate the vallate papilla, histochemical staining for acetylcholinesterase (AChE) was carried out. The vallate papilla contained specific cholinesterase that was eliminated by bilateral section of the IXth nerve. Butyrylcholinesterase (BChE) was only weakly present. The AChE reaction was unaffected by a specific inhibitor of BChE (tetraisopropylpyrophosphoramide). Our working hypothesis is that the IXth nerve contains cholinergic efferents that can tonically inhibit taste fiber responses.

Supported in part by NIH grant NS-07072.

217.15 IONIC EVENTS OF ELECTRIC TASTE. M. Scott Herness*.(SPON: L. M. Beidler). Dept. of Biology, Florida State University, Tallahassee, FLA 32304

The phenomenon of electric taste has been known for almost two hundred years since Volta's early discovery of it during the course of his investigations on electricity. Despite its long and rich history, the mechanism of electric taste has yet to be elucitdated. There are, however, two main hypotheses. The first maintains that electrical taste is the result of a direct action of the current on either the nerve fibers and/or the taste cells. The second, the electrolytic-chemical hypothesis, describes electrical taste as the result of a chemical stimulation of taste receptors by ions (which may include electrolytic products of saliva) iontophoresed to the taste cells.

In the present set of experiments, anodal current (10 - 50 μamps) was delivered through various subthreshold salt solutions (0.001 M) and neural responses recorded from the chorda tympani nerve of the rat. Current passed through any solution may be divided into two fractions, that carried by the cation and that carried by the anion. Salts with a larger less mobile anion will transfer more current through the cationic current than salts with a smaller more mobile anion. A larger cationic current should result in a greater accumulation of cations at the tongue surface and thus elicit a larger neural response. Such responses were measured for sodium and potassium salts with the following series obtained:

Butyrate > Propionate > Acetate > Formate > Chloride.

Moreover, sodium responses were much larger than potassium responses. These observations were interpreted in support of the electrolytic-chemical hypothesis since those salts with a greater cation accumulation elicited larger neural responses and the same transducing ability of cations is reflected in both chemical and electrical stimulation.

217.16 MODELING THE CONVERGENCE OF GUSTATORY NEURONS. Stephen L. Bieber* and David V. Smith. Depts. of Statistics and Psychology, Univ. of Wyoming, Laramie, WY 82071.

Taste-responsive fibers in the hamster chorda tympani (CT) nerve are relatively narrowly tuned, especially those that respond best to sucrose. The breadth of responsiveness of hamster taste neurons to anterior tongue stimulation increases systematically at the levels of the nucleus tractus solitarius (NTS) and parabrachial nuclei (PbN). Response profiles within a best-stimulus class of neurons are relatively homogeneous at each of these levels. Thus, it should be possible to model the nature of the convergence process leading to the increase in breadth of responsiveness at each level.

Responses (impulses/5 sec) to each of the four basic taste stimuli (0.1 M sucrose, 0.03 M NaCl, 0.003 M HCl and 0.001 M quinine hydrochloride) in 78 CT, 57 NTS and 53 PbN neurons were used to classify these cells into S-, N-, H- and Q-best categories, depending upon which of the four stimuli elicited the maximum response in each neuron. The values of the average response profiles of each best-stimulus class of fibers in the CT were used as the independent variables in a multiple regression analysis to predict the values of the average response profiles of each best-stimulus category of cells in the NTS. Similarly, the values of the NTS profiles were used to predict the profiles of cells in each best-stimulus class in the PbN. This approach estimates the convergence from one synaptic level to the next (i.e., it calculates the proportional contribution of each best-stimulus class). For example, reproduction of the average response profile of S-best neurons in the NTS requires a convergence ratio of approximately three S-best CT fibers to each H-best fiber, with the contribution of N-best CT fibers being essentially zero. In this regression, the predicted average response profile of NTS S-best neurons is: 86.98 impulses/5 sec to sucrose, 31.87 to NaCl, 28.79 to HCl and 10.31 to quinine hydrochloride. The actual response profile of this class of neurons in the NTS was: 87.50 impulses/5 sec to sucrose, 29.20 to NaCl, 30.15 to HCl and 10.35 to quinine.

The response profiles of all best-stimulus classes of cells at both the NTS and PbN could be predicted quite well from various combinations of converging input from the preceding level. This analysis suggests a way in which the increased breadth of responsiveness of brainstem taste neurons could occur from converging input from fungiform papillae on the anterior portion of the tongue.

Supported in part by NINCDS Grant NS10211 and Research Career Development Award NS00168 to D.V.S. Chorda tympani (CT) responses were provided by Dr. Marion Frank.

217.17 CONVERGING TASTE RECEPTOR INPUTS TO THE HAMSTER SOLITARY NUCLEUS. Robert D. Sweazey, J. David Dickman* and David V. Smith. Dept. Psychology, Univ. Wyoming, Laramie, WY 82071.

Taste receptors are distributed over various parts of the tongue and intraoral cavity. Only about 15% of the rat's taste buds are located in fungiform papillae on the anterior portion of the tongue (Miller, 1977). Most electrophysiological studies of taste, however, have restricted stimulation to the anterior tongue. Processing of taste information through the hamster brainstem is understood only with respect to this anterior receptor area. In the rat, responses can be elicited in the nucleus tractus solitarius (NTS) by both anterior tongue and posterior oral stimulation, with considerable overlap of multi-unit responsiveness to both fields (Halpern & Nelson, 1965). In the rat pons, many of the same neurons can be driven by both anterior and posterior stimulation (Norgren & Pfaffmann, 1975).

The present investigation examines the overlap in sensitivities to anterior tongue and posterior oral gustatory stimulation in the hamster NTS. Stimuli (0.1 M sucrose, 0.03 M NaCl, 0.003 M HCl and 0.001 M QHCl) were delivered to the anterior area through a glass chamber and to the posterior area through an inserted tube, both at a rate of 3.6 ml/sec.

Multi-unit responses could be recorded from the anterior lateral NTS over a span of about 400-500 μm in the rostral-caudal and about 200-250 μm in the medial-lateral dimension. Although there was some tendency for the most rostral penetrations to respond primarily to stimulation of the anterior portion of the tongue, the majority of sites responded to both anterior tongue and posterior oral stimulation. This overlap suggests, but does not demonstrate, the convergence of single peripheral fibers onto individual medullary neurons. However, of the several neurons isolated thus far, most were driven by both anterior and posterior stimulation. Often the pattern of responsiveness of a neuron was different to stimulation of these two receptor fields. For example, one neuron responded well to sucrose delivered to either the anterior or posterior fields, but to NaCl following only posterior stimulation. Another responded exclusively to HCl on the anterior tongue and to quinine delivered to the posterior oral cavity. Additional cells possessed similar sensitivities to both anterior and posterior stimulation.

Since the response profile of an NTS neuron may differ, depending upon the receptors stimulated, characterization of the sensitivities of these cells may be more complex than when considering anterior tongue input alone. Complete understanding of taste information processing by brainstem neurons depends upon input from divergent receptor areas.

217.18 ELECTROPHYSIOLOGICAL EVIDENCE FOR THE TOPOGRAPHICAL ARRANGEMENT OF TASTE AND TACTILE NEURONS IN THE FACIAL LOBE OF THE CHANNEL CATFISH. T. Marui* and J. Caprio. Department of Zoology and Physiology, Louisiana State University, Baton Rouge, LA 70803.

In some teleosts, Cyprinidae and Ictaluridae, large numbers of taste buds are distributed across the whole body surface. These taste buds are innervated by the facial nerve (VII) which projects to the hindbrain. Behavioral ablation studies have confirmed the importance of the medullary taste centers in the catfish (Atema, 1971). In the present study, responses in the facial lobe of the channel catfish, Ictalurus punctatus, to mechanical and chemical stimulation of the external skin were investigated. Responses were recorded with glass microelectrodes filled with 3M KCl solution (tip diameter, 2-3 μm; impedence, 2-7MΩ). Finger (1976) reported that facial nerve fibers in bullhead catfish (I. nebulosus and I. natalis)which innervate the trunk, nasal barbel and maxillo-mandibular barbets terminate in the lateral, intermediate and medial lobules of the facial lobe, respectively. In the present study, an electrophysiological analysis of neurons in each of the lobules of the channel catfish was performed. Most neurons in the channel catfish facial lobe responded only to mechanical stimulation. Neurons responsive to amino acids which are known to be highly stimulatory to catfish from peripheral recordings (Caprio, 1975, 1978) were located in the tactile sensitive area. Taste neurons were located generally in the superficial layer (between 0.2-1.0 mm below the surface) of the lobe. In the deeper layer (1.0-2.5 mm in depth) of the anteromedial part of the lobe, only tactile responses were obtained. These deeper neurons have large receptive fields (100mm^2-the whole body surface) and some of them showed lateral inhibition. Secondary taste neurons responded best to L-alanine or L-arginine HCl which is similar to the recordings obtained from peripheral neurons in the same species.

The antero-posterior axis of the face including the barbels is represented in the medial and intermediate lobules of the facial lobe in a postero-anterior axis; in addition, regions associated with maxillary and mandibular barbels are greatly enlarged. The antero-posterior axis of the trunk is represented in the lateral lobule of the facial lobe in an antero-posterior axis descending from dorsal to ventral position. This somatotopic arrangement in the facial lobe of the Ictaluridae is markedly different from that found in the Cyprinidae (Peterson, 1972; Marui, 1977). This discrepancy is probably due to a real difference between these two families of fishes.

217.19 LAMINAR AND COLUMNAR ORGANIZATION OF THE VAGAL LOBE IN GOLDFISH: POSSIBLE NEURAL SUBSTRATE FOR SORTING FOOD FROM GRAVEL. T.E. FINGER. Dept. of Anatomy, Univ. Colo. Med. Sch., Denver, CO 80262

Goldfish possess a highly muscular palatal organ located in the roof of their mouth. Scanning electron microscopy of this organ reveals numerous taste buds as well as microscopic "teeth". Sensory and motor innervation to the palatal organ is via palatine branches of the vagus nerve. The central processes of this nerve enter the vagal lobe, a large, laminated structure protruding from the dorsolateral surface of the mid-medulla. The sensory fibers terminate in a distinct laminar pattern within the superficial layers of the lobe. Motor fibers are believed to originate from α-motor neurons lying in the deep, motor layers of the lobe (Herrick, 1905; McGlone, 1977). McGlone's physiological studies suggest that some degree of somatotopy (palatotopy) exists in the organization of the sensory input to the vagal lobe.

In order to test this, 1-5 μl of 30-50% horseradish peroxidase solution (HRP; Sigma Type VI) was injected just below the surface of different areas of the palatal organ in 15 goldfish. Subsequent histological analysis of the palatal organ demonstrated that the enzyme was restricted to relatively small areas of the organ. Retrograde and transganglionic anterograde transport of the HRP labeled only small areas within the vagal lobe. These studies indicate both a motor and sensory mapping exists between the vagal lobe and palatal organ such that the anterior end of the palatal organ is represented in the anterior end of the vagal lobe and vice versa.

In 8 other goldfish, small amounts of HRP were placed in either the sensory (superficial) or motor (deep) layers of the vagal lobe. Sensory layer injections revealed anterogradely labeled fibers extending radially inward from the point of injection to end in the motor layers. Similarly, the motor layer injections of HRP retrogradely labels a column of cells in the sensory layer extending radially outward from the point of injection. Thus the intrinsic connections of the vagal lobe consist of a topographically organized projection from cells in the sensory layer to the underlying motor layers.

The palatotopically arranged connection from taste receptors in the palatal organ, to sensory part of the vagal lobe, to motor layers of the vagal lobe, to intrinsic musculature of the palatal organ is suggestive of an oral gustatory reflex mechanism. The goldfish may use this hypothesized gustatory mechanism to sort food particles from a mouthful of gravel or other bottom substrate by local contraction of muscles in that part of the palatal organ in contact with a "tasty" morsel.

217.20 PREFERENCE BEHAVIOR OF DOGS FOR SUGARS IN A COMPLEX MIXTURE Dawn Brown* (SPON: D.M.Easton) Department of Biological Science, Florida State University, Tallahassee, Florida 32306.

Previously reported research has shown that beagles prefer sugar solutions to plain water (Brown and Ewen, AChemS, 1981). In the present experiment preference behavior of the same dogs was assessed for sugars added to a soft-moist dog food. Dogs were adults (3-5 years) who had a great deal of experience with a variety of sweetners.

The dogs were housed in groups of three to five in indoor-outdoor runs. They had access to water ad lib and were maintained on dry food. At the beginning of each experimental session they had been food deprived for 23 hours. Brief, 2-pan tests were conducted in a rotating pan apparatus.

Tests were conducted using a commercially prepared soft-moist dog food which contained no sugar or other preservative. To this product 3% by weight corn syrup was added. In preference tests this mixture was paired with the same mixture to which a sugar had been added. Sugar was added on a percent by weight basis and concentration curves plotted for each of the four sugars: Maltose, xylose, glucose, and fructose.

At the lowest concentrations, maltose and xylose flavored food was not prefered to the plain food. All othertests, however, a strong preference was shown for the food containing sugar.

In order to compare these data with that obtained in the previous workconcentrations were converted using the formula:

$$\frac{\text{Grams sugar per kg mixture}}{\text{molecular wt. of sugar}}$$

When these data are plotted with the concentration curves obtained for solutions there is no consistent relationship. It is, therefore, not possible to generalize between preferences for a simple sugar solution and a more complex mixture such as dog food.

217.21 EFFECTS OF TEMPERATURE ON THE TASTES OF NACl, CITRIC ACID, QUININE, SUCROSE AND SACCHARIN. L.M.Bartoshuk and J.E.Hooper*. J.B.Pierce Fndn. Lab. and Yale Univ., New Haven, CT 06519.

Early studies of the effects of temperature on the sense of taste have two limitations: taste function was assessed by threshold measurements, and the tongue was often adapted to the temperature of the stimulus to be tasted to remove "troublesome" thermal sensations. In the real world, individuals typically taste substances at concentrations far above threshold and the tongue is at body temperature so that taste substances that are warmer or cooler than the tongue produce taste and thermal sensations simultaneously.

In the present study, we used the psychophysical procedure of magnitude estimation to assess taste function over the whole dynamic range from threshold to very strong taste sensations. In order to maintain a body temperature baseline, we required subjects to rinse with water at approximately body temperature (36°C) before tasting each stimulus. Concentration series of sucrose, NaCl, citric acid, quinine hydrochloride (QHCl), and saccharin were tested at 4, 12, 20, 28, 36, and 44°C. A single session consisted of: several concentrations of one of the taste substances, each concentration presented at each of the 6 temperatures. An additional stimulus, .32 M NaCl at 36°C, was used to normalize data across sessions. An experiment on one taste substance consisted of two sessions run with each of ten subjects. For saccharin the number of subjects was doubled to include 10 tasters and 10 nontasters of phenylthiocarbamide (PTC).

The most dramatic effects of temperature occurred for sucrose (reported at the last meeting of the Society for Neuroscience). The functions showing sweetness of sucrose for different temperatures converged at about .5 M sucrose. Below that concentration, lower temperatures produced less sweetness. High concentrations of NaCl, citric acid, and QHCl, like those of sucrose, were essentially unaffected by temperature. Although there were some effects of temperature at low concentrations (e.g., 44°C QHCl tended to taste less bitter and 4°C citric acid tended to taste less sour), the effects were small compared to those observed with sucrose.

The sweetness of saccharin did not vary with temperature as that of sucrose did. This is important since the sweet theory of Shallenberger maintains that increases in temperature produce conformational changes in sucrose molecules that increase the amount of sweet stimulus present. Saccharin is not affected in this way by temperature.

217.22 PERCEPTION OF TASTE QUALITY AND INTENSITY IN SUBJECTS WITH ANOREXIA NERVOSA. P. Jirik-Babb and Jack L. Katz*. Dept. of Psychiatry, Albert Einstein Col. of Med. at Montefiore Hosp., Bronx, N.Y. 10467.

Previous reports have indicated that poor gustatory sensitivity is associated with loss of appetite and a decrease in food intake (Hambridge et al, 1972 and Henkin et al, 1971). In order to determine whether or not gustatory impairment is associated with abnormal eating behavior characteristic of persons who have anorexia nervosa, 10 subjects diagnosed as having primary anorexia nervosa (ANs), ages 19 to 28 yrs, and 7 normal control women (NCs), ages 16 to 21 yrs, were tested for perception of taste quality and intensity using the method of magnitude estimation. The 4 taste stimuli used were sucrose, hydrochloric acid (HCl), sodium chloride (NaCl) and quinine hydrochloride (QHCl). Four different log molar concentrations of sucrose (-1.5, -1.0, -0.5, 0.0), HCl (-3.0,-2.5, -2.0, -1.5), NaCl (-3.0, -2.0, -1.0, 0.0) and 3 of QHCl (-5.0, -4.0, -3.0) were employed. All solutions were made with distilled water and reagent grade chemicals except for sucrose solutions which were made with commercial grade sucrose. At the time of testing, solutions were at room temperature (~21°C). Each of the concentrations of the 4 qualitatively different solutions was presented 3 times in random order, along with about 10 blanks consisting of distilled water, thereby making a total of about 55 stimuli presentations. Each trial consisted of swishing 15ml of solution over the tongue. (Before each trial, the mouth was thoroughly rinsed with distilled water.) Magnitude standards of the following log molar concentrations were given at the beginning of the test and arbitrarily assigned a magnitude of 10: sucrose,-0.5; HCl, -2.0; NaCl, -1.0; and QHCl, -4.0. Subjects were instructed to mark both the quality and magnitude of each stimulus on a response sheet. The results indicated no significant differences between the ANs and the NCs in the ability to identify taste quality; however, there were significant differences ($p<.05$) in magnitude estimates of the 2 higher concentrations of sucrose, HCl and NaCl solutions and the QHCl solution of the highest concentration. The magnitude estimates of the ANs were consistently lower than those of the NCs. It is possible that poor gustatory sensitivity is an antecedent, concomitant, or consequence of the low food intake characteristic of anorexia nervosa.

218.1 ANATOMICAL AND OPTICAL CHARACTERISTICS OF THE SPECIALIZED PHOTORECEPTORS IN THE DORSAL RIM AREA OF THE BEE'S EYE. Ernst W. Sommer* (SPON: Karl H. Pfenninger). Department of Zoology, University of Zurich, CH-8057 Zurich (Switzerland).

It is a characteristic of the regular type of ommatidia that the rhabdomers are twisted. This structural twist causes a reduction in polarizational sensitivity (PS<2.0) in spite of the assumed high dichroic ratios of the microvilli. On the other hand, a group of ommatidia can be found at the dorsal rim of the eye in which the rhabdomers are not twisted but straight. Here a high polarizational sensitivity can be expected (Wehner et al., J. Comp. Physiol. 104:225, 1975). We have found that the dorsal rim area (DRA) consists, on the average, of 141 specialized ommatidia (or less than 3% of the about 5500 ommatidia in the compound eye). By morphological comparison with the 3 known UV-receptors (UV-R) in the regular ommatidia, we determined by serial section electronmicroscopy which photoreceptors in the specialized ommatidia are the UV-R. By comparing the diameter of the microvilli, the level of the nuclei, and other characteristics, it is postulated that there are also 3 UV-R in the specialized ommatidium: two UV-R (R1, R5) have their microvilli arranged parallel to one another but, unlike that in the regular ommatidium, the third UV-R (R9) has its microvilli oriented perpendicular to those of R1 and R5. As a further specialization in the DRA the microvillar orientation of R1 and R5 is not constant in adjacent ommatidia but changes up to a maximum of 180° in a fan-like way. The antidromically illuminated corneal pseudopupil technique was used to define the directions of view of single ommatidia and the border lines of the binocular visual field and the DRA. The greatest extension of the DRA is through $90^{\circ} \pm 2.2^{\circ}$ (n=7) within the paramedial plane of the head, lying symmetrical about the zenith, and in the plane perpendicular to this, through $22^{\circ} \pm 1.35^{\circ}$ (n=7) in the contralateral portion of the binocular visual field. Microvillar directions of R1, R5, and R9 of DRA are mapped onto the positions in the sky, defined by polar coordinates, at which the receptors are aimed. This allows us to determine the systematic variations in the retinal excitation pattern evoked by rotation of the bee around its vertical body axis during flight. Intracellular electrophysiological recordings confirm that the UV-R in the DRA exhibit high polarizational sensitivities (average PS=6.6); indeed, two populations of UV-R have been found, their directions of maximal sensitivity to the e-vector of linearly polarized light (Φmax values) differing by 90° (Labhart, J. Comp. Physiol. 141:19, 1981). Behavioral experiments show the important role of the DRA for skylight navigation (Wehner, in prep.). Supported by Swiss National Science Found. (grants #3.529-0.75 & 3.313-0.78).

218.2 THE EXACT NUMBERS OF FLY PHOTORECEPTOR SYNAPSE AND SOME FACTORS BY WHICH THESE ARE REGULATED. D. Nicol & I.A. Meinertzhagen, Life Sciences Centre, Dalhousie University, Halifax, N.S., Canada.

When nerve cells establish correct synaptic interconnections, one may ask how many synapses are deployed between any two identified neurons, whether their number is regulated and if so by what determinants. A solution to this problem has been sought in the first optic neuropile (lamina) of the fly's visual system, where a systematic perturbation in the distribution of photoreceptor axons occurs at the equator. This perturbation results in the convergence of 8 and 7 receptor axon terminals to the unit synaptic columns, or cartridges (making 8R and 7R cartridges respectively) instead of the normal 6 elsewhere (making 6R cartridges). This predictable variation has been exploited to examine the effects of altering the number of presynaptic cells innervating a fixed complement of postsynaptic cells in each of the modular cartridges situated adjacent to the equator.

We examined the chief afferent class of synapse, a population of tetrads at which every receptor axon is repeatedly presynaptic to a fixed constellation of four postsynaptic elements (Burkhardt & Braitenberg: Cell. Tiss. Res. 173, 287). Where these four could be clearly identified one each is invariably contributed from two second-order monopolar interneurons L1 and L2, the other two are usually (55-60%) both α elements of amacrine cells or sometimes (17-20%) both glial elements. The number of these synapses was calculated and compared in 6R, 7R and 8R cartridges from counts of their profiles in electron micrographs of transversely sectioned cartridges from a 1 hr. old female fly (Musca domestica). Counts from many cartridges in single sections were confirmed by counts from single cartridges sectioned serially and reveal that each receptor in 6R cartridges has, on average, a remarkably constant number of synapses (168±17). Small variations in synapse number between 6R, 7R and 8R cartridges correlate with variations in presynaptic membrane area, each synapse occupying on average 1.91μm^2 membrane. Thus, a major determinant of the total cartridge synapse complement appears to be presynaptic.

The number of synapses which are serviced by the same postsynaptic cells therefore increases by 25% in 8R cartridges over 6R cartridges. The membrane area of L1 and L2 dendrites, which accommodate about 87% of all receptor synapses, was measured from serial electronmicroscopy of 6R and 8R cartridges. The increase in synapse number 6R:8R was reflected by an equivalent increase in dendritic membrane area, so regulating the average postsynaptic membrane area per synapse. Overall, the results suggest the regulation of membrane area per synapse and the importance of the presynaptic influence in determining total synapse number. Supported by NSERC of Canada

218.3 THE EYES OF THE GIANT CLAM TRIDACNA: PHOTORECEPTOR ELECTROPHYSIOLOGY. Lon A. Wilkens. Department of Neurobiology, Research School of Biological Sciences, Australian National University, Canberra, A.C.T. 2601, AUSTRALIA.

The mantle surfaces in the giant clam Tridacna maxima contain numerous eyes, ca. 400 in a 50 cm-long clam. The eyes were previously referred to as hyaline organs whose sole function, it was hypothesized, was to focus light on the surrounding, densely packed symbiotic zooxanthellae (Yonge, 1936). More recently, Stasek (1966) has described structural features of the eyes consistent with a visual function, including retinal cells and an optic nerve. I now report the electrophysiological response of photoreceptor cells to light.

Tridacna photoreceptors, as recorded from intracellularly, hyperpolarize to a light stimulus. A decrease in illumination produces a rapid membrane depolarization. Although all photoreceptors display this response polarity, two categories of cells have been observed. Type A cells, when fully dark adapted, give large hyperpolarizing light responses (57.2 mV ±11.5 S.D.) which undershoot the light adapted potential level by an average of 25 mV. In Type B cells, hyperpolarizing responses do not undershoot and are equal in amplitude to depolarizing responses (7.0 mV ±4.2 S.D.). Furthermore, the amplitude of the hyperpolarizing response depends on the extent of dark adaptation in Type A cells whereas, in Type B cells, dark adaptation seemingly has no effect. In nine cells held for a period of time sufficient to record both dark- and light-adapted responses, Type A cells (n = 6) had membrane potentials of 13 mV and 38 mV, respectively, in the dark and light; correspondingly, Type B cells (n = 3) were 35 mV and 45 mV. Light adaptation had little effect on the amplitude of the depolarizing response in either cell type.

In half of the cells a short burst of spikes, 3-4 mV in amplitude, accompanied the depolarizing light-off response. Following light adaptation at relatively high intensities (0.04 W/cm^2), spike frequencies were 60-80 Hz, although they followed the onset of membrane depolarization by 60-70 ms. Spikes were never spontaneous and burst durations were typically 100-400 ms for 1 s shadows. For shorter intervals, the onset of light rapidly terminated spiking. Spike output was also markedly decreased by successive shadow stimuli, i.e. by dark adaptation, even though the depolarizing receptor potential was not. The eyes in Tridacna, therefore, contain primary off receptors similar to those in the distal retina of scallops. (Supported in part by a grant from the Whitehall Foundation).

218.4 MECHANISM OF d-TUBOCURARINE BLOCKADE OF MECHANORECEPTOR TRANSDUCTION IN THE PROTOZOAN, STENTOR. D.C. Wood. Psychobiology Program, University of Pittsburgh, Pittsburgh, PA 15260.

The funnel-shaped ciliate protozoan, Stentor coeruleus, contracts in an all-or-none fashion when stimulated by a suprathreshold mechanical, photic or electrical stimulus. Mechanical stimuli elicit receptor potentials of up to 25mV amplitude. Large receptor potentials trigger all-or-none action potentials which are correlated with the onset of the contraction. These mechanoreceptor potentials are produced by a large ($\cong$180 fold) increase in Ca^{++} permeability accompanied by a smaller ($\cong$20 fold) increase in Cl^{-} permeability.

d-Tubocurarine (d-TC) and other curariform drugs depress the probability of eliciting a mechanically stimulated contraction (ED_{50} = 14 uM for d-TC) but do not alter response probabilities for photic or electrical stimuli. d-TC also produces a dose dependent blockade of mechanoreceptor current (ED_{50} = 7.5 uM) while resting potentials, action potentials, electrical thresholds, membrane resistance and mechanoreceptor current reversal potentials are not significantly affected. The behavioral and electrophysiological effects of d-TC are well correlated with the binding of d-TC (^{14}C) to the cell's surface (K = 22 uM). Thus d-TC appears to bind rather specifically to the mechanical stimulus transduction mechanism and block it.

Mechanoreceptor currents are increased by depolarizing the membrane from the -50mV resting potential to -25mV though this procedure reduces the driving force. Conversely hyperpolarizing the membrane reduces receptor currents while increasing the driving force. These changes in mechanoreceptor current occur exponentially with a rate constant which is a function of the direction and magnitude of the voltage step. These data indicate that the unstimulated mechanoreceptor transduction mechanism is voltage dependent and can exist in at least 2 forms; one of which increases its conductance in response to a mechanical stimulus (responsive form) while the other does not increase its conductance upon stimulation (unresponsive form).

d-TC appears to block mechanoreceptor currents by binding to the unresponsive form of the mechanoreceptor. This conclusion is supported by the inhibition of d-TC (^{14}C) binding observed in depolarizing K^{+} solutions, in which the proportion of unresponsive mechanoreceptors should be decreased. Secondly large depolarizing voltage steps (to +20mV or more) relieve the previously induced d-TC blockade of receptor current seen at resting potential. This effect is observable both during and immediately after the voltage step. The relaxation kinetics of this relief suggests that d-TC is dissociated from its binding site when the depolarizing voltage step converts it to the responsive form.

218.5 BEHAVIORAL AND ELECTRICAL RESPONSES TO AMINO ACIDS IN PARAMECIUM. Robert M. Rivera. Dept. of Biology, UCLA, Los Angeles, CA 90024.

Sensory-motor behavior in Paramecium has been shown to be controlled through ionic mechanisms present in the surface membrane. Electrophysiological methods were used to study the bioelectric basis of behavioral responses of P. caudatum to the amino acids glutamate and serine. Observations were made of direction and velocity of locomotion in response to addition of a small volume of amino acid solution (10^{-6}M) to a slide containing a suspension of swimming cells (bath solution: 3.5mM KCl, 0.5mM KOH, 1.0mM $CaCl_2$, 1.0mM HEPES, pH 7.1). Addition of serine produced a slight increase in forward-swimming velocity within the region of the added amino acid. No increase in the occurrence of reversed swimming was observed in reponse to serine. Addition of glutamate, however, resulted in reversed swimming, causing movement away from the stimulus solution.

Membrane potential was measured with intracellular recording methods while each of these amino acids (10^{-2}M) was pressure pulsed from a micropipette (~5μm tip) into the bath solution near the cell surface. A dye, fast green, added to the stimulus solution, served as a visual indicator of delivery of the solution. Fast green alone had no electrophysiological effect. Application of serine with a 1s pressure pulse caused a hyperpolarization of 3-5mV lasting more than 10s. Glutamate, delivered with a 0.5s pressure pulse, caused a 15s depolarization of 10-20mV.

Depolarization of the cell membrane of Paramecium by a variety of stimuli has been found to elicit reversed swimming, while hyperpolarization induces accelerated swimming in the forward direction. The magnitude of the change in membrane potential from rest determines the frequency of ciliary beating in either direction (Machemer, H., J. Exp. Biol., 65:427-448, 1976; Brehm, P., & Eckert, R., J. Physiol., 283:557-568, 1978). The electrical and behavioral responses to amino acids reported here show these same relations. Locomotor responses to chemical agents in the medium are likely to be important to the foraging ciliate in locating food sources, or in avoiding undesirable conditions. Supported by NSF BNS 80 12346.

219.1 DEVELOPMENT OF MULTITERMINAL INNERVATION IN A LOBSTER MUSCLE. C. K. Govind and Joanne Pearce*. (SPON. N. W. Milgram). Scarborough College, University of Toronto, West Hill, Ontario, Canada, M1C 1A4.

The development of multiterminal innervation from a single identifiable excitatory motoneuron to the lobster distal accessory flexor muscle (DAFM) was examined by serial section electron microscopy. Cross-sections of the entire DAFM were obtained in newly hatched, 24 hr old, 1st stage lobsters, in 2 week old 4th stage lobsters and in a year old 12th stage animal. At each of these developmental stages, the number, size, and location of neuromuscular synapses within the peripheral branching pattern of the axon was determined. The mean size of synapses was similar in all three stages though the number of synapses per unit length of fiber increased more than 20 fold from the 1st to the 4th stage and more than five fold from the 4th to the 12th stage. A similar increase was found for the synaptic surface area per fiber length, thus demonstrating a proliferation of multiterminal innervation. Simultaneously the innervation is delineated from supplying the entire muscle in the 1st stage, to groups of fibers in the 4th stage and to individual fibers in the 12th stage.

The amount of innervation provided by the main axon, the primary branches and other branches differed in the three stages. In the 1st stage, the main axon and its branches which make up the entire branching pattern provide almost equal amounts of innervation. In the 4th stage, the main axon provides 20-25%, the primary branches 45% and the other finer branches 30-35% of the total innervation. In the 12th stage, the innervation is provided completely by the fine branches and none from the main axon and its primary offshoots. This shift in innervation to the ever more distal sites of the axonal branching pattern provides synapses to the enlarging target muscle in an uninterrupted fashion and may occur via nerve terminal sprouting. Research supported by NSERC and MDA of Canada.

219.2 NOREPINEPHRINE AFFECTS SYNAPTOGENESIS IN THE VISUAL CORTEX OF THE RAT. M.E. Blue* and J.G. Parnavelas (SPON: E.D. Ross). Dept. of Cell Biology, The Univ. of Texas Health Science Center, Dallas, TX 75235.

The influence of the noradrenergic (NE) system on cortical synaptogenesis was examined in the visual cortex of rats whose NE afferents were selectively eliminated with the neurotoxin 6-hydroxydopamine (6-OHDA). Experimental animals received up to four subcutaneous injections of 6-OHDA (100 µg/g body weight) during the first four days of postnatal life. Control littermates were injected with equal volumes of vehicle containing 1 mg/ ml ascorbic acid in saline. Depletion of the NE projection to the visual cortex was confirmed in adult animals with glyoxylic acid histofluorescence. Using the electron microscope, photographic montages of 50 µm-wide strips of cortex were prepared from experimental and control littermates at 2,4,6,8,14 and 90 days of age. Synapse counts revealed a significantly higher synaptic density in the cortex of 6-OHDA treated rats during the first week of postnatal life (paired-sample t-test; $p<0.025$ at days 2 and 6 and $p<0.05$ at day 4). The difference between experimental and control rats was less apparent during the second postnatal week, and at day 90 synaptic densities were similar for the two groups of animals. The increased synaptic density was primarily the result of an increased number of Gray's type I synapses. The effect was confined to the lower cortical plate at day 2 but became more widespread in the cortex at subsequent stages of development. These results suggest that in the visual cortex, the NE system exerts an inhibitory influence on synapse formation in early postnatal life.

Supported by USPHS Grant EY02964 and by the Alfred P. Sloan Foundation.

219.3 POSTNATAL DEVELOPMENT OF RAT SUPERIOR CERVICAL GANGLION AS MONITORED BY BINDING OF MONOCLONAL ANTIBODIES K.F. Greif, W.D. Matthew* and L.F. Reichardt Dept. Physiol., Sch. Med., Univ. of Calif., San Francisco, CA 94143

Monoclonal antibodies raised against rat forebrain synaptic junctions were used to monitor the appearance of developmental antigens in the rat superior cervical ganglion (SCG). Two antibodies have binding specificity for synaptic vesicles; the other three bind surface proteoglycans. The localization of determinants defined by these antibodies was examined in sections of adult SCG and in ganglia from rats aged one to thirty days postnatal, using PAP and HRP-IgG immunocytochemical staining. Of five antibodies staining adult tissue, only one stained neonatal ganglia. The remaining antibodies stained developing ganglia beginning in the first month after birth. Quantitation of antigen levels by inhibition radioimmune assays indicates that these antigens are present in very low levels at birth and increase during early postnatal life. These antigens are present in very low levels in adult sensory ganglia, suggesting possible association with developing synapses in the SCG. Immunoelectron microscopy will reveal the precise location of these antigens in the SCG.

This research was supported by a postdoctoral fellowship from the Muscular Dystrophy Association, NIH Training Grant, and the NSF.

219.4 SYNAPTOGENESIS OF PYRAMIDAL NEURONS IN RAT VISUAL CORTEX USING THE COMBINED GOLGI-ELECTRON MICROSCOPE METHOD. M. Miller and A. Peters. Dept. of Anat., Boston Univ. Sch. Med., Boston, MA 02118.

The synaptology of maturing pyramidal neurons has been insufficiently studied because of the difficulty of identifying from which type of cell a specific process originates. Hence, the maturation of pyramidal cells in layer V of rat visual cortex has been examined during the first three postnatal weeks by both light and electron microscopy using the correlative gold toning method of Fairén, Peters and Saldanha (1977; J. Neurocytol., 6: 311-337).

Somata of pyramidal cells form only symmetric synapses presumably with multipolar stellate neurons. These synapses are not evident until day 6. Presynaptic processes in immature axosomatic synapses have smaller diameters and contain fewer pleomorphic vesicles than mature ones. On day 12, about four axosomatic synapses are evident in a thin section through the center of the soma, and by day 21 a mean of eight such synapses can be counted. Dendrites, however, form symmetric and asymmetric synapses which are present by day 3 and by day 9, respectively. Each dendritic spine forms a single synapse. In its immature form a spine is a low, broad protrusion of the dendrite which forms a symmetric junction with a small caliber axonal process containing a few clear vesicles. With time, the spine protrudes further and appears as a taller stump. Eventually, a mature spine with a distinct head and neck is produced, and the synapse with the now enlarged axonal bouton becomes asymmetric. Other dendritic appendages, i.e. growth cones and filopodia, form symmetric junctions. These processes are transient pioneer structures and are important in extension and branching of dendrites. Thus, the junctions they form are probably precursors of synapses seen on mature dendrites and spines. Like axosomatic synapses, axoaxonic ones involving the axon hillock and initial segment of pyramidal cell axons synapse with dendritic spines and shafts of other pyramidal cells. Before becoming asymmetric, these synapses pass through a stage during which the junctional densities are symmetric.

The sequence of development of all synapses on pyramidal cells is similar in that a narrow presynaptic process containing a few vesicles matures into an axonal varicosity. During the development of asymmetric synapses, the junctional densities go through a stage when they appear symmetric. The next phase of this study will be to examine the maturation of nonpyramidal neurons to gain a fuller understanding of the synaptogenesis of the rat cortex. Supported by NS 07016 and EY 07054.

219.5 CHOLINESTERASE LOCALIZATION AT SITES OF NERVE CONTACT ON EMBRYONIC XENOPUS MUSCLE CELLS IN CULTURE. F. Moody-Corbett*, P.R. Weldon*, D.F. Davey*, and M.W. Cohen. Dept. Physiology, McGill University, Montreal, Quebec.

Acetylcholine receptors (AChRs) become localized at sites of nerve-muscle contact in cultures of embryonic Xenopus spinal cord and muscle cells. In the present study we have found that cholinesterase (ChE) also becomes localized at these sites.

Cultures were prepared from spinal cord and myotomal muscle cells of 1-day-old embryos. After two or more days, they were stained for AChRs with fluorescent α-bungarotoxin, and then were fixed and stained for ChE so that the staining patterns of both molecules could be examined on the same cells. More than 70% of the nerve-contacted muscle cells had ChE reaction product localized along the path of nerve-muscle contact. In some instances the ChE stain extended along the whole length of the contact but in most cases it was restricted to shorter segments. In a high proportion (more than 80%) of the examples where ChE stain was located along the path of nerve-muscle contact there were also regions of overlapping AChR stain. The localization of ChE (and AChRs) at sites of nerve-muscle contact developed within 2 days in culture and was also observed 1) when muscle cells were derived from younger embryos, prior to any nerve-muscle contact in vivo; 2) when cultures were maintained in 15 μM-curare in order to prevent spontaneous twitching of nerve-contacted muscle cells; and 3) when cultures were maintained in 1.2 μM-tetrodotoxin alone or together with 2 mM-manganese or 2 mM-lanthanum in order to prevent action potentials.

Electron microscopy showed the ChE reaction product at nerve-muscle contacts to be located in the intercellular cleft and often on the sarcolemma beyond the area of contact. At these contacts the neurites frequently contained accumulations of small clear vesicles, the cleft was about 80 nm wide, and in instances where the reaction product was not too dense, basal lamina-like material was apparent in the cleft. By contrast, at contacts which did not exhibit ChE activity the axolemma and sarcolemma were usually closely apposed (less than 10 nm), the cleft did not contain basal lamina-like material, and vesicle accumulations were rarely observed in the neurites.

It is concluded that ChE develops at sites of neuromuscular synaptic specialization in these cultures even in the absence of muscle contraction and nerve and muscle action potentials.

219.7 NERVE-INDUCED DEPOSITION OF BASAL LAMINA DURING THE DEVELOPMENT OF AN AMPHIBIAN NEUROMUSCULAR JUNCTION IN CELL CULTURE. M.J. Anderson* and D.M. Fambrough, Carnegie Institution of Washington, Dept. of Embryology, Baltimore, MD. 21210

Monoclonal antibodies have been generated to components of basal lamina from the amphibian Xenopus laevis. In adult skeletal muscle the antigens are distributed within capillaries and over the entire surface of each muscle fiber, but appear concentrated both at tendons and at the neuromuscular junction. Immunocytochemical experiments using antibody and α-bungarotoxin labelled with contrasting fluorochromes reveal that this junctional concentration of basal lamina antigen extends into the junctional folds and throughout the synaptic cleft.

Similar experiments with cultured embryonic myotomal muscle cells reveal a complex ordered array of basal lamina antigen. This consists of a diffuse background over the entire muscle cell surface, along with a scattering of discrete plaques and fibrils. In such cells, developing in the absence of innervation, dense aggregates of acetylcholine receptors invariably appear associated with correspoinding specializations of the adjacent basal lamina. At these sites the striking homology in the organization of receptor and basal lamina suggests that their distributions are co-ordinately regulated even in the absence of innervation.

When embryonic muscle cells become innervated by cholinergic neurons in vitro there is a progressive nerve-induced accumulation of acetylcholine receptors in the developing post-synaptic membrane. This accumulation of receptors is closely paralleled by a corresponding deposition of new basal lamina associated with the newly-formed acetylcholine receptor clusters. It is concluded that the junctional specialization of basement membrane is induced by the developing motor nerve, and appears virtually concomitantly with the receptor aggregates in the post-synaptic membrane.

219.8 GUANOSINE 3':5'-MONOPHOSPHATE (cGMP) ACCUMULATION BY SPINAL CORD CELLS DURING NEUROMUSCULAR JUNCTION FORMATION IN VITRO AND IN VIVO. C.L.Weill, Department of Neurology, Louisiana State Univ.Med.Ctr. New Orleans, La., 70112

The molecular signals that subserve neuromuscular junction formation have eluded detection. That communication must take place between these cells is evidenced by the anatomical elaborations that result in the functional alignment of pre- and post-synaptic structures of the mature junction.

cAMP and cGMP were measured by radioimmunoassay in cultured and embryonic chick tissue during synapse formation. Dissociated 6 day spinal cord cultures and post fusion muscle cultures contain constant levels of cAMP, 0.130pm/mg and 0.326pm/mg respectively and cGMP, 0.020pm/mg and 0.025pm/mg respectively over 9 days. Spontaneously twitching cocultures display a 5.7±2.7X increase in cGMP over 4 days while cAMP remained constant. cGMP in cocultures continues to rise at variable rates from day 4-10. The increase in cGMP is specific for cocultured spinal cord and muscle. Spinal cord cocultured with muscle derived fibroblasts and muscle co-cultured with 10 day cerebellar cells showed no increase in cGMP over 8 days.

Increases in cGMP in stimulated muscle have been observed (Beam, et al. Nature 267:534, 1977). Cocultures of nerve and muscle treated with curare (50uM) and tetrodotoxin (10^{-7}g/ml) to block action potential and synaptic potential activity showed increases of 4.4 and 5.5X respectively in cGMP over 4 days. Landmesser (J.Physiol.284:391, 1978) has shown that motoraxons invade their target muscle and begin to form functional contacts at St27. cGMP was measured in lumbar spinal cord and dorsal thigh muscle dissected from 5-8 day embryos. cGMP remained nearly constant at 6.93±0.75pm/mg in muscle while in spinal cord there was a 5.4X increase to 35.7pm/mg on day 8. In a correlate culture experiment with 6 day spinal cord explants, cGMP remained nearly constant in muscle over 10 days at 0.075±0.032pm/mg while in cord explants cGMP rose 2.3X to 0.598pm/mg. Mediation of this effect by a secreted factor or cell contact was tested by growing cells in medium conditioned by the counter cell. cGMP in muscle grown in SC/CM showed no change over 4 days and then rose to 0.964pm/mg on day 5. Spinal cord cells grown in M/CM showed a 24X increase in cGMP to 5.94pm/mg on day 5. A 23X increase in the rate of $^{45}Ca^{++}$ influx by spinal cord cells was also induced by M/CM over 4 days in culture.

It is concluded that a specific, synaptic activity independent increase in cGMP is induced in spinal cord cells upon contact with muscle or a muscle derived factor and a muscle factor induced increase in calcium influx in spinal cord cells may be causal.

219.9 QUANTITATIVE STAINING OF SYNAPSES ON FROG CARDIAC GANGLION CELLS USING ZINC-IODIDE AND OSMIUM. Peter B. Sargent and C. Douglas Evans*, Department of Structural Biology, Sherman Fairchild Building, Stanford University School of Medicine, Stanford, CA 94305.

The zinc-iodide osmium (ZIO) staining procedure has been adapted for use in the Xenopus cardiac ganglion to stain synapses on parasympathetic neurons lying within the interatrial septum. The most critical parameters affecting the staining were found to be osmotic strength, pH, osmium concentration, and the duration of staining. We have been able to label synapses consistently from cell to cell and from preparation to preparation by staining for one hour with a hyperosmotic solution that is buffered to pH 4.5 with potassium acetate and that contains 0.28% osmium tetroxide (w/v). Under these conditions all neurons in adult Xenopus cardiac ganglia have stained synaptic boutons and preterminal axons on their surface. Electron microscopy of stained synapses reveals electron-dense deposits within all small "agranular" synaptic vesicles and in the extravesicular cytosol. Such heavy staining was observed in each of 150 synapses examined on 266 cells in 6 cardiac ganglia. Thus the staining procedure consistently and quantitatively labels synapses in this preparation. Light microscopic analyses of ZIO-stained adult Xenopus hearts indicate that ganglion cell bodies receive an average of 11 synaptic boutons, which emanate usually from one or two axons (S.D.=6 boutons, n=200 neurons taken from 4 animals with body lengths of 5.5-6.0 cm). The number of boutons is strongly correlated with cell body surface area ($r=0.78$, $p<0.001$).

The ZIO-staining conditions suited for adult Xenopus did not label boutons in hearts taken from larval or recently metamorphosed individuals. By modifying the staining conditions, we were able to consistently and quantitatively stain boutons in post-metamorphic frogs; the critical modifications entailed raising the pH to 5.1 and lengthening the staining time to 2.5 h. Under these conditions, 99% of 280 vesicle-containing nerve contacts on ganglion cells were heavily stained, with electron-dense deposits within all "agranular" synaptic vesicles and in the extravesicular cytosol (6 hearts examined from young frogs having body lengths of 1.6-1.9 cm; the remaining 1% of the contacts were "lightly" stained, with reaction product within vesicles only). The modified staining conditions label boutons on ganglion cells at all larval stages beginning with Nieuwkoop and Faber stage 46, when ganglion cells generally can first be recognized in the heart. Ganglion cells in larvae and young frogs have fewer synaptic boutons than those in adults; we are presently quantifying the change in bouton number that accompanies development.

220.1 NEUROGENESIS IN CAT RETINA. A STUDY USING ^{3}H-THYMIDINE AUTORADIOGRAPHY. E. H. Polley, C. Walsh* and T. L. Hickey. Depts. of Anatomy, Ophthalmology and Neurosurgery, U. of Illinois School of Medicine, Chicago, IL 60680, Comm. on Neurobiology, U. of Chicago, Chicago, IL 60637, and School of Optometry/The Medical Center, U. of Alabama, Birmingham, AL 35294.

The pattern of neurogenesis of retinal cells has been determined by making single injections of 500μCi of ^{3}H-thymidine in a series of fetal cats 21-30 days of gestation (E21-E30), which were sacrificed 60-250 days after birth. Some of these animals have been used in a different study by Hickey and Cox (Neurosci. Abstr., 5:788, 1979). The retinae were flattened, embedded in methacrylate resin, and sectioned at 2μm either radially or en face. Autoradiographs were prepared using standard techniques.

An injection at E21 led to no detectable retinal label. An E22 injection labelled a few cells near the optic disc. The retinal area containing labelled cells was greatly increased after injections made slightly later. An E23 injection led to labelled ganglion cells up to 3-5 mm from the optic disc, and after an injection at E24 labelled ganglion cells extended more than half the distance from the disc to the ora serrata. In this material (E24) labelled ganglion cells were very common at the area centralis, and all labelled ganglion cells were small- or medium-sized. Label was also seen in the outer nuclear layer adjacent to the pigment epithelium. In the inner nuclear layer, label was limited to a cytologically distinct cell type adjacent to the outer plexiform layer and tentatively identified as horizontal cells.

Injections on E26 led to label which extended further toward the ora serrata, but there were still many labelled ganglion cells at the area centralis. Again, no large ganglion cells were labelled. Later injections (E29, E30) resulted in labelled ganglion cells which extended from disc to ora serrata and which were primarily large or small, with few labelled medium-sized cells. Other cell types in the inner nuclear layer were also labelled, but label in the outer nuclear layer, now quite heavy, was still seen only adjacent to the pigment epithelium.

These preliminary results suggest that cell production may start roughly synchronously in all three retinal layers for at least some retinal elements, but continue later in the receptor and inner nuclear layers. The material shows that at a given gestational age ganglion cells are produced over a very wide area of retina, so that the retina does not seem to demonstrate a simple radial pattern of development. Lastly, we have found that there is no simple linear relation between date of birth and ganglion cell size.

220.2 THE VOLUME OF THE LATERAL GENICULATE NUCLEUS AND STRIATE CORTEX AS A FUNCTION OF POSTNATAL AGE IN MONKEYS. Michael D. Gottlieb, Pedro Pasik and Tauba Pasik, Dept. Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

The volumes of the lateral geniculate nucleus, pars dorsalis (LGNd) and the striate cortex (SCx) were measured in monkeys (M. mulatta) at birth and at 1, 2, 4, 8, 16 and approximately 100 weeks of age. The brains were fixed by perfusion and marked before processing with two needles inserted 5 mm apart perpendicularly to the future plane of sectioning, thus allowing the calculation of a shrinkage factor per individual specimen. Volume estimates for the left LGNd were derived from camera lucida tracings (41.3X) of the cell laminae (the interlaminae were not included) appearing in 7-9 equally spaced Nissl-stained coronal 40 μm sections through the nucleus. Estimates for the left SCx were obtained from microprojection drawings (13.8X) of 11-14 similar sections through the rostrocaudal extent of the structure. The area measurements of the outlines were used to calculate the volumes by Simpson's rule for irregular solids and the resulting values further corrected by the shrinkage factors.

The results show that the total volume of the LGNd cell laminae increases almost twofold from birth (35 mm^3) to the oldest age sampled (68 mm^3). This growth seems to take place in two stages, namely between birth and 2 weeks, and between 8 and 16 weeks, most of the expansion occurring in the latter period. The changes in total laminar volume parallel those shown by the parvocellular laminae whereas those of the magnocellular laminae exhibit a delayed and slow increase that continues beyond 16 weeks. Similarly to the LGNd, the volume of the SCx increases nearly twofold from birth (1856 mm^3) to adolescence (3262 mm^3). These data also indicate two periods of growth, one between birth and 4 weeks, and the other between 8 and 16 weeks. As in the LGNd, the major development occurs between 8 and 16 weeks. The dynamics of the SCx expansion differs, however, from that of the LGNd in that the first growth period peaks two weeks earlier in the latter structure. In addition, the volume of the SCx decreases beyond 16 weeks, whereas that of the LGNd remains constant. A high correlation is found between the volume of the LGNd cell laminae and that of the SCx across all ages sampled ($r = 0.97$, $p < 0.001$). The slope of the line of best fit for this function indicates an approximately constant 1:50 ratio of LGNd:SCx volumes, thus allowing the prediction of one on the basis of the other.

The findings are consistent with previous data indicating a differential development of the parvocellular and magnocellular LGNd laminae, and with the maturation of the LGNd preceding that of the SCx. Aided by USPHS Grants #MH-02261, EY-01926, EY-01867, and F32NS06251.

220.3 ORGANIZATION OF VISUAL PROJECTIONS IN NEONATAL KITTEN. Z. Henderson* (SPON: R.J.W. Mansfield). University Lab. of Physiol., Parks Road, Oxford OX1 3PT, U.K.

The methods of labelled axonal transport, which have proved to be very sensitive for tracing projections in newborn animals (e.g. Innocenti, G.M., et al., Neurosci. Letts. 4: 237-242, 1977), were used to make a detailed study of connections in the visual system of newborn kitten. The main problem is that standard doses of horseradish peroxidase (HRP) and ^{3}H-proline diffuse rather extensively after injection into neonatal brain. Improved results were obtained by using HRP conjugated to wheatgerm agglutinin (HRP-WGA) and by injecting the markers in very small quantities. Unilateral injections of 1-2 μCi ^{3}H-proline and 2-4 μg HRP-WGA in 0.05 μl H_2O were made, through a stereotaxically-placed 32 gauge needle, into lateral geniculate nucleus (LGN) or superior colliculus (SC) of kittens anaesthetized with halothane. Bilateral or unilateral injections into areas 17 or 18 were made by implantation of 1mm^2 pieces of Millipore filter paper containing the same amounts of tracers in dried form. After 24h the brains were fixed by perfusion with glutaraldehyde and paraformaldehyde. Frozen sections were cut and processed either for autoradiography or for HRP activity with cobalt intensification of the diaminobenzidine-H_2O_2 reaction.

The results indicate that all the major trajectories of the visual system are present in newborn kitten and that most of them have the same gross organization as that in adult. There are ipsilateral and contralateral projections from retinal ganglion cells to SC and LGN. The LGN projections to areas 17 and 18 arise from cells in all the major LGN laminae, are topographically arranged and entirely ipsilateral; small injections of HRP-WGA into area 17 label cells in narrow projection columns in the LGN. The LGN terminal axons end mainly in cortical layers I, III and IV. There is a projection, strictly ipsilateral, arising from layer VI cells of visual cortex and terminating in all the major laminae of the LGN; the topography of this projection closely follows that of the geniculo-cortical pathway. Cells in layer V of the visual cortex form an ipsilateral and topographically organized projection to the superficial layers of the SC above the stratum opticum. In conclusion, a careful application of the labelled axonal transport methods shows that in the cat there is a high degree of precision in the organization of the visual pathways, at birth, before the retina becomes fully functional and when synapses are still relatively sparse (Cragg, B.G., J. Comp. Neurol., 160: 147-166, 1975).

220.4 PLASTICITY IN THE RETINOGENICULATE PROJECTION OF THE CHICK: TEMPORAL PARAMETERS. R. H. Granda* and W. J. Crossland, Department of Anatomy, Wayne State University, School of Medicine, Detroit, Michigan 48201.

Recently we have reported a region of increased innervation density in the chick ventral geniculate nucleus (GLv) which is in topographic correspondence with a lesion placed in the ipsilateral optic tectum on the day of hatching. The increase in retinogeniculate projection could be observed 21 to 70 days after the lesion had been made. We have extended these observations by examining two temporal parameters of the plasticity phenomena: 1) the time course of appearance of the augmented GLv projection following lesions at hatching, 2) the period in which the GLv is subject to plasticity.

The time course of appearance of augmented GLv projection was investigated by lesioning chicks on the day of hatching, followed at three-day intervals by labeling the retinofugal projections with an intravitreal injection of 200 μCi of ^{3}H-proline in the eye contralateral to the lesion. Six to eighteen hours later the chicks were perfused with formalin, the brains were embedded in paraffin and sections were prepared for autoradiography. Using brightfield and darkfield light microscopy, we observed a patch of heightened grain density in the GLv corresponding topographically to the ipsilateral tectal lesion by the sixth day after hatching. No qualitative differences were noticed in the appearance of the zone of plasticity between six and twenty-one day post-operative survival periods.

To determine the period of susceptibility to plasticity tectal lesions were made three to ninety-six days after hatching. Six weeks later the animals were injected and sacrificed as described above. We have found that the plasticity phenomena is demonstratable through the 96th day after hatching. The labeling pattern at 96 days appears qualitatively similar to that observed in chicks lesioned at hatching. Whether the chick continues to express the ability to alter the retinogeniculate projection in still older animals is under investigation.

220.5 CATECHOLAMINE DEPLETION, OCULAR DOMINANCE SHIFT AND DIRECTION SELECTIVITY IN KITTEN VISUAL CORTEX. J. D. Daniels, Mary Kay Ellis*, S. A. Bianco*, Mary Garrett*, S. B. Nelson* and Marjory Schwartz*.

If a kitten is dark-reared until about 5-7 weeks of age, one day of normal visual experience through one eye only can cause ocular dominance shift of area 17 neurons to the opened eye, and cause those neurons to develop direction and orientation selectivities. We have used this paradigm in four kittens in which one hemisphere was injected with the selective catecholamine neurotoxin 6-hydroxydopamine (6-OHDA), and the other hemisphere was sham-operated.

The injections (10 micro ℓ. of 2mg/ml fresh 6-OHDA in vehicle of Ringer's solution with 0.4% ascorbic acid) were given three days before the visual experience. We allowed twelve hours for overnight consolidation after the visual experience before beginning single unit recording (nitrous oxide anesthesia). Recording sites were spaced every 75-100 microns in the medial bank of the postlateral gyrus (area 17).

In the control hemispheres 76% (50/66) of the visual units were driven by the opened eye (ocular dom. groups 1-2 or 6-7) and 52% of the units were selective for the stimulus' direction of movement. In the 6-OHDA-treated hemispheres 28% (18/64) of the visual units were dominated by the opened eye and only one unit of the 64 was genuinely direction selective. The two groups didn't differ significantly in percentage of non-visual sites--about 20% of the total in each case.

We recorded from two dark-reared kittens and found the results similar to the drugged hemisphere recordings. Both had similar percentages of binocular (gp 3-5) units, about 55%. The dark-reared actually had more selective units (17%). Twenty-eight percent of the dark-reared recording sites were non-visual.

We confirmed catecholamine depletion by subjecting tissue near each injection site to a high performance liquid chromatography (HPLC) assay. The drugged hemispheres averaged 35% the norepinephrine (NE) context of the control hemispheres. Control values were about 80 ng/gm. One kitten injected with 6-OHDA did not show any depletion and did show ocular dominance shift and selectivity.

We have verified and extended the results of Kasamatsu and Pettigrew (J. Comp. Neurol. 1979); we think both ocular dominance and selectivity can be altered only when proper levels of catecholamines are present in cortex during development. We are continuing to test this idea by studying kittens with NE delivered to cortex via osmotic minipumps.

Supported by ONR N00014-81-K0136.

220.6 EFFECT OF 6-HYDROXYDOPAMINE ON PLASTICITY OF DIRECTION SELECTIVE CELLS IN VISUAL CORTEX. N.W. Daw, R.K. Rader* and T.W. Robertson.* Physiology Dept., Washington Univ. Med. School, St. Louis, MO, 63110.

Plasticity of direction sensitivity in the visual cortex is known to have a different critical period from the plasticity of ocular dominance. Moreover, the synapses responsible for direction sensitivity (inhibitory GABA synapses) are almost certainly different from the synapses that determine ocular dominance. It is therefore important to know whether 6-hydroxydopamine (6-OHDA) has the same effect on direction sensitivity as it does on ocular dominance, in order to test the generality of the effect of 6-OHDA on plasticity in the visual cortex.

Six kittens were reared in the dark. At the age of 3 1/2-4 weeks a minipump containing 1 mg/ml 6-OHDA in 0.4% ascorbate in saline was inserted under the skin, leading to a needle in the left cortex. During the next 1-2 weeks the animals were exposed to an environment continually moving in one direction (left in three cases, right in three) for approximately 50 hours. Shortly after that recordings were made from the cortex and a sample of approximately 40 cells was accumulated from each kitten. The number of cells preferring the direction of movement of the drum was compared to the number of cells preferring the opposite direction. As one control, the opposite cortex was recorded in two animals; as a second control group, four animals were reared similarly with a minipump containing ascorbate but no 6-OHDA; as a third control group, four animals were reared similarly, but no minipump was inserted.

The ratio of cells preferring movement with the drum to cells preferring movement against the drum was 67:33, 70:30 and 65:35 in the three control groups and 41:59 in the experimental group. The ratios from the control groups are not significantly different from each other, but the ratio from the experimental group is significantly different from the control groups ($p < .001$) and is close to the ratio in normal animals (50:50). Therefore 6-OHDA does prevent the plasticity of direction sensitivity in the visual cortex. It appears that the effect of 6-OHDA on plasticity in the visual cortex is a general phenomenon, affecting the connections for direction sensitivity as well as the connections for ocular dominance.

220.7 CHANGES IN THE DORSAL LATERAL GENICULATE INDUCED BY MONOCULAR DEPRIVATION IN HOODED RATS. D. McClearn* and E. Fifková (Spon.: S.K. Sharpless). Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

The dorsal lateral geniculate (GLD) was studied (volume and cell density) in 26 hooded rats in which the right eye was suture shut prior to the physiological eye opening at the 14th postnatal day. Twenty-six controls with both eyes open were kept together with their lid-sutured littermates for varying periods of time prior to the sacrifice. Controls and lid-sutured rats were matched as to their sex, weight and survival time. Volume of the rostral and caudal half of the GLD were calculated separately. While no consistent difference in the volume was found in the rostral part, the caudal part was significantly smaller by 9.8% ($p<0.05$) in deprived animals which survived for 8-14 weeks. In those animals which survived for longer periods of time (15-23 weeks), no significant volume reduction could be observed in either part of the GLD. The cell density was calculated in the caudal half of the GLD in two separate regions. One forms the dorsolateral aspect of the nucleus and receives mostly crossed optic fibers. The other region is located ventromedially and was shown to receive a crossed as well as an uncrossed visual input (Cunningham and Lund, Brain Res., 34:394). In the dorsolateral region, the cell density was significantly decreased by 13.7% ($p<0.01$) in deprived rats which survived for 8-10 weeks, while no systematic variation of the cell density was observed in the ventromedial region. In rats which survived for more than 10 weeks, the cell density in the dorsolateral region of the deprived GLD reached control levels. Monocular deprivation thus seems to retard the development of GLD neurons in hooded rats, however, without halting it. The severity of the postdeprivation change appears to be determined by the length of deprivation period, since the decreased volume and cell density of the deprived GLD were observed only in shorter intervals after the lid-suture. This result agrees with the time curve of postdeprivation changes observed in the rabbit visual system (Chow and Spear, Exp. Neurol., 42:129; Grobstein, et al., Neurosci. Soc. Abstr., IV, 239). (Supported by NIH Grant EY 01500-07.)

220.8 POSTNATAL CHANGES IN THE NUMERICAL DENSITY AND THE TOTAL NUMBER OF NEURONS AND SYNAPSES IN THE DIFFERENT LAMINAE OF THE STRIATE CORTEX OF MACAQUE: A STEREOLOGICAL ANALYSIS. J. O'Kusky* and M. Colonnier, Lab. de Neurobiologie, 1401, 18e Rue, Québec, Qué. G1J 1Z4.

The surface of area 17 and the thickness of its laminae were measured in a series of new-born, 3-month, 6-month and adult macaques. The numerical density (N_v) of neurons was determined by the method of size frequency distribution (Weibel '69, Int. Rev. Biol: 26, 260) for each of the lamina. The N_v of synapses was similarly estimated in the new-born, 6-month and adult specimens. The total number of neurons and synapses were derived from these measures. Except where noted all the described changes are statistically significant.

The thickness of the cortex increases from birth to 6 months and diminishes back to near new-born values in the adult. The 6-month cortex is 19% thicker than that of the adult, and this overshoot is greatest in layers II-III which are 43% thicker at 6 months. The average surface of area 17 in each age group shows a similar trend, being 23% greater at 6 months, but the differences are not statistically significant because of large within group variability.

The N_v of neurons decreases from birth to 6 months and increases back to near new-born values in the adult. The 6-month N_v is 30% smaller than that of adults and again the greatest difference is found in layers II-III where it is 38% smaller. When the total number of neurons in a hemisphere is calculated, however, the undershoot in N_v is compensated by the overshoot in thickness and surface. The pattern of change with age becomes that of a gradual decrease in the number of neurons from new-born to adult (16%) but this overall decrease is not statistically significant. There is a significant decrease, however, in layers I, IVC , V and VI. In layer I the number of neurons in adult is decreased by 73%, while in layer VI the number at 3 months is decreased by 34%.

The N_v of synapses on the other hand undergoes a pattern of change similar to that of cortical thickness, increasing from birth to 6 months and decreasing back to near new-born values in adult. The 6 month overshoot is 35% for the total cortex, and is greatest in layers I-III, at 41%. The total number of synapses in the striate cortex of one hemisphere is 90% greater at 6 months than in the adult. For layers I to III the synapses are 120-155% more numerous (i.e., more than twice as numerous) at 6 months.

These data demonstrate an increase in neuronal connectivity in the striate cortex from new-born to 6-months, especially in layers I, II and III, and a subsequent decrease in connectivity in the adult. It is as if at the time of cortical plasticity an overabundant neuropil develops, capable of adapting to several potential environments, and is later resorbed as the most appropriate circuits are selected.

220.9 PRESERVATION OF STEREOPSIS IN CATS FOLLOWING NEONATAL SECTION OF THE OPTIC CHIASM. Brian Timney and Gordon Lansdown*. Psychology Department, University of Western Ontario, London, CANADA, N6A 5C2.

Section of the optic chiasm (OX) eliminates the descussating pathways from the nasal retinae to the contralateral visual cortex, thus preventing the direct convergence of optic fibres onto binocular cells in the visual cortex. The relatively high proportion of binocular neurones found in the cortices of OX sectioned cats results from an indirect pathway through the corpus callosum (Cynader et al., Neurosci. Abs. 1979, 5, 781). Blakemore (J. Physiol. 1969, 205, 471) has suggested that such a pathway might subserve midline stereopsis, when disparate images of a target lying directly behind or in front of a fixation point fall on opposite hemiretinae and therefore should project to different cortical hemispheres.

We assessed the functional integrity of the indirect pathway by measuring stereoacuity in 2 cats which had undergone OX section at the age of 3 weeks. Control measurements of visual fields and acuity also were taken. Perimetric examination, using the Sherman procedure, revealed the expected losses in the temporal hemifield of each eye. Visual acuity of both cats was low compared to normals, with a maximum of approximately 2 cycles/degree.

Binocular and monocular depth thresholds were measured using the jumping stand technique. Thresholds for the OX cats were somewhat worse than normals, but their respective binocular thresholds were still very much better than when they were tested monocularly, suggesting that these animals were still able to use binocular cues to make depth judgements. These results suggest that the indirect callosal projections, which maintain binocularity in OX section cats, are sufficient also to mediate binocular depth discrimination.

Supported by grant MA 7125 from the Medical Research Council of Canada.

220.10 EFFECTS OF SELECTIVE EXPOSURE TO LINES ON DIFFERENT CELL TYPES IN CAT VISUAL CORTEX. M. McCall*, A.G. Leventhal, D.G. Tieman* and H.V.B. Hirsch. SUNY Albany, Albany, N.Y. 12222.

We have suggested previously that several receptive field properties of a cortical cell help to predict the extent to which development or maintenance of its orientation preferences requires exposure to appropriate patterned stimuli (Leventhal and Hirsch, 1980). To test this further we have now raised cats in controlled visual environments. Three groups of cats were raised wearing masks within which each eye could view lines of a single orientation. Animals in one group viewed the same orientation with both eyes (0 deg or 90 deg); animals in the second group viewed 0 deg lines with one eye and 90 deg lines with the other eye; animals in the third group viewed 45 deg lines with one eye and 135 deg lines with the other eye. When animals were not wearing masks they were housed in a dark room. Once animals received about 150 h of exposure to the patterns, we recorded extracellularly from single units in Area 17.

Exposure to one or two orientations produced a matching bias in the distribution of orientation preferences of cortical cells; the distribution had one peak in cats exposed to a single orientation and two peaks in cats exposed to two orientations. The proportion of non-selective cells was inversely proportional to the number of lines the cats had seen, suggesting there are constraints on the preferred orientation a cell may develop. The bias in the distribution of orientation preferences of cortical cells was greater for cells dominated by the ipsilateral eye than for cells dominated by the contralateral eye. Furthermore, the bias was greater for cells with high cutoff velocity (suggestive of an excitatory input from Y-type cells in the LGNd; Dreher et al., 1980) than for cells with a low cutoff velocity and narrow receptive field (suggestive of an excitatory input from X-type cells in the LGNd; Dreher et al., 1980). The results provide further evidence that there is a class of cortical cells whose members do not require visual stimulation for either development or maintenance of their orientation preferences, while there are other cells which are dependent upon visual stimulation for either the development or maintenance of an orientation preference. 220.11 EVIDENCE FOR A "CONSOLIDATION" EFFECT DURING CHANGES IN THE OCULAR DOMINANCE OF CORTICAL NEURONS IN KITTENS

V. S. Ramachandran and M. Ary, Division of Biology 216-76, California Institute of Technology, Pasadena CA 91125.

In a previous study (Soc. Neurosci. Abstr., 1980), we had compared the effects of massed and distributed sessions of brief visual experience in changing the ocular dominance of cortical neurons and had suggested that a "consolidation"-like effect might be taking place. We now present further evidence for such a process.

Eight kittens, 5-6 weeks of age were used to study the effects of brief monocular visual experience on the ocular dominance of neurons in area 17. They were monocularly deprived for 2½ days and in all of them ocular dominance was found to have shifted almost completely towards the experienced eye. Two of them were recovered from anesthesia and paralysis and the deprived eye was then stimulated for 4 hours with high-contrast rotating gratings. They were then anesthetized and paralysed again to obtain 'Post-Stimulation' ocular dominance histograms - and only a slight change in ocular dominance was observed. In two of the kittens the deprived eye was stimulated for 4 hours as in the previous experiment, but we put the kittens in total darkness for 3-4 days before obtaining a 'Post-Stimulation' histogram. In these 2 animals the two eyes became almost equally effective in driving cortical neurons suggesting that the effects of brief visual experience become more obvious if some time is allowed to elapse after stimulation. As a control we monocularly deprived two kittens for 2½ days and placed them in the dark for 3-4 days without any prior visual stimulation. Only a slight recovery was observed in these animals.

Lastly, two of the monocularly deprived animals had their deprived eye stimulated in 4 one-hour sessions distributed over 4 days instead of a single 4 hour session. (They were kept in total darkness whenever they were not being stimulated.) The observed recovery was even more striking in this experiment suggesting that 'distributed' practice may be more effective than 'massed' practice.

We conclude that a) For reversing the effects of monocular deprivation one needs only 4 hours of visual experience i.e. one doesn't need 3-4 days of on-going stimulation. b) The effects of this brief experience are more obvious after some time has elapsed in the dark. This implies that even after active synaptic stimulation has ceased, some time-dependent process akin to 'consolidation' must continue to occur in the dark.

220.12 BINOCULAR COMPETITION DETERMINES THE SIZE AND SHAPE OF OCULAR DOMINANCE COLUMNS IN CATS. Nina Tumosa* and Suzannah Bliss Tieman. Neurobiology Res. Ctr., SUNY Albany, Albany, NY 12222.

To determine the effect of binocular competition on the development of ocular dominance columns (ODC) in cats, we used the C14-2-deoxyglucose technique to map the ODC in cats reared with different degrees of competitive advantage to one eye. Cats were reared normally, with monocular deprivation (MD), or with unequal alternating exposure (unequal AME). In unequal AME, each eye receives normal patterned vision but on alternate days and for unequal periods (8 h/day vs. 1 h/day). It was previously shown that this imbalance in the duration of stimulation gives a competitive advantage to the 8 h eye (Tumosa et al., Science, 208: 421, 1980). One eye was removed from each of 4 MD cats, 4 AME 8/1 cats, and 2 normal cats under halothane anesthesia when they were 12-16 wks old. One week later, the cat was reanesthetized with halothane, a flexible catheter was inserted into the femoral vein, and the cat was allowed to recover from the anesthetic. A neck ruff prevented the animal from removing the catheter. The next day, 175 µCi C14-2-deoxyglucose was injected intravenously, and the animal was allowed to explore the lighted laboratory for 45 min before it was deeply anesthetized and perfused with buffered saline followed by 3 l of buffered formalin and then by 500 ml of 30% sucrose. The visual cortex was removed, rapidly frozen, and sectioned in the horizontal plane at 30 µm with a cryostat. The sections were picked up onto warm coverslips, dried at 60°C, and exposed with Kodak SB-5 film for 1-3 wks. The size of the resulting ODC varied with the rearing of the cat and with which eye was stimulated: the eyes with the greatest competitive advantage activated the largest ODC. In order of increasing percentage of Area 17 activated by the stimulated eye, they are: deprived eye (DE) of MD cats, 1 h eye of AME 8/1 cats, either eye of normal cats, 8 h eye of AME 8/1 cats, and experienced eye of MD cats. The ODC of the DE of MD cats were widest in layer IV, where they were about the same width as those of the 1 h eye of the AME 8/1 cats; in other layers they were narrower, sometimes disappearing altogether. In contrast, the ODC of the 1 h eye were the same width in all layers. Thus the degree of competitive advantage determines both the size and shape of ODC in the cat. These results suggest that when one eye is placed at a severe disadvantage, as in MD, both geniculocortical connections and intracortical connections may be disrupted, but when the disadvantage is less, as in unequal AME, only the geniculocortical connections are disrupted. (Supported by PHS grants EY02609 to SBT and EY01268 to HVBH).

220.13 MONOCULAR AND BINOCULAR VISUAL FIELD LOSSES IN KITTENS WITH OPTICALLY INDUCED STRABISMUS. A.J. Elberger, E.L. Smith, III* and J.M. White*. Dept. of Neurobiology and Anatomy, The Univ. of Texas Med. Sch. at Houston, Houston, TX 77030, and College of Optometry, Univ. of Houston, Houston, TX 77004.

Optically induced strabismus was produced in 4 kittens by the following procedure: the kittens were reared in the dark, and in addition from 28 days through 14 weeks old, were given 2-3 hours daily light exposure through visual goggles. The right eye covering was a 15 Diopter base in prism and the left eye covering was a zero power lens. A control cat was reared identically except that zero power lenses were placed over both eyes in the goggle exposure; a second control cat was given normal laboratory rearing. All 4 prism-reared cats demonstrated a range of esotropia as a result of the rearing conditions. The direction and magnitude of the deviation was determined using the corneal reflex technique. The resulting fixation pattern was determined from qualitative results of cover testing. The extent of monocular and binocular visual fields was determined using perimetry testing.

The normal and goggle control cats demonstrated normal interocular alignment and normal extents of monocular and binocular visual fields (Elberger, Exp. Brain Res. 36:71-85, 1979). In comparison, all 4 experimental cats demonstrated significant contralateral field shrinkage in monocular tests. In addition, in binocular tests 2 of the 4 cats, those which exhibited constant unilateral esotropia (8^{o} and 16^{o} compared to normals) in cover testing and corneal reflex photography demonstrated a significant shrinkage in the peripheral field (monocular segment) ipsilateral to the deviating eye. However, the other 2 cats, exhibiting an alternating fixation pattern in cover testing, and 4^{o} and 17^{o} esotropia, demonstrated no consistent reduction in the peripheral binocular visual field.

It is interesting to note that both unilateral and alternating fixation patterns were exhibited by the identically reared experimental kittens; these two patterns also occur in human esotropes. Nevertheless, the contralateral field loss under monocular testing of both unilateral and alternating fixators is qualitatively similar to the results of other investigators using surgically induced esotropes. This indicates the field loss is due to anomalous visual experience rather than abnormal eye movement patterns associated with a surgically induced noncomitant squint.

220.14 THE CRITICAL PERIOD FOR FUNCTIONAL COMPENSATION IN LATERAL SUPRASYLVIAN VISUAL AREA FOLLOWING NEONATAL VISUAL CORTEX REMOVAL IN CATS. L. Tong, P.D. Spear, and R.E. Kalil., Depts. of Psychology & Ophthalmology, Univ. of Wisconsin, Madison, WI 53706

Following a unilateral lesion of visual cortex (areas 17 & 18) in adult cats, lateral suprasylvian visual cortex (LS) exhibits a decrease in direction selective cells, an increase in cells responsive to stationary stimuli, and a decrease in percent of cells responsive to the ipsilateral eye. In LS of cats with a lesion on day of birth, however, cells develop normal response properties. Thus, in cats with day 1 lesions, there is functional compensation in LS not found following adult lesions.

In this study we investigated the critical period for the functional compensation. Cats received visual cortex (VC) lesions at 1 day, 2,4,8,12,18, and 26 wks of age or as adults. After a survival of at least 6 months, single cells were recorded in LS. Results for different response properties are as follows.

Direction selectivity: Following a day 1 lesion, the percent of responsive cells that are direction selective appears normal (80%) whereas following an adult lesion 18% are direction selective. The ability to develop direction selectivity following a lesion decreases between 12 and 18 wks of age, and by the age of 26 wks a lesion results in only 22% direction selective, comparable to an adult lesion. The loss in direction selectivity is accompanied by an increase in the percent of cells responsive to stationary stimuli.

Ocular dominance: A day 1 lesion results in a normal ocular dominance distribution while an adult lesion reduces the percent of cells driven by the ipsilateral eye (OD 2-7) from 70% to 40%. Visual cortex lesions at ages up to 18 wks result in normal ocular dominance, but by 26 wks of age a lesion decreases the percent OD 2-7 to that found after an adult lesion.

Orientation selectivity: Orientation selective cells are not found in LS in normal cats. Following a day 1 or an adult VC lesion, less than 4% of LS cells are orientation selective. By contrast, 35% of the responsive cells are orientation selective in cats with a lesion at 2 wks. Increased orientation selectivity also is found following lesions at 4, 8 and 12 wks, but is less than 4% after a lesion at 18 or 26 wks.

In summary, the critical period for functional compensation in LS following visual cortex lesions extends at least to 18 wks of age. In addition the anomalous property of orientation selectivity can develop after VC lesions at some ages. The critical period for this property differs from the critical period for development of direction selectivity and normal ocular dominance.

220.15 REGROWTH OF CENTRAL CATECHOLAMINERGIC FIBERS IN CAT VISUAL CORTEX FOLLOWING LOCALIZED LESION WITH 6-HYDROXYDOPAMINE

K. Nakai*, G. Jonsson* and T. Kasamatsu, Division of Biology, California Institute of Technology, Pasadena, CA 91125, U.S.A. and Department of Histology, Karolinska Institute, Stockholm, Sweden.

We have been studying roles played by the central catecholamine (CA)-containing system in regulating synaptic plasticity in cat visual cortex. In the kitten visual cortex perfused with 6-hydroxydopamine (6-OHDA) to place chemical lesions specific to CA-containing nerve endings, we physiologically demonstrated the prolonged suppression, with a waning trend, of recovery of cortical cells from the effects of monocular lid suture which was followed by reopening the previously closed eye (Kasamatsu et al., 1981a). The CA system is known for its remarkable capability of regrowth of terminal fields or sprouting after partial lesions, provided that the proximal axons and the somatas of CA cells are saved from initial lesions. Thus, we may explain the observed incomplete suppression of recovery in cortical physiology by the quick regrowth of intracortical CA-fibers after localized chemical lesions with 6-OHDA, in conjunction with some biochemical changes such as dennervation supersensitivity.

The visual cortex of 5-week-old kittens, which had priorly been subjected to the bilateral resection of superior cervical ganglia, were locally perfused with 4mM 6-OHDA for a week. With varying the survival time (0, 2 and 4 weeks) after stopping the 6-OHDA perfusion, such cortex was then studied by either glyoxylic acid fluolescence histochemistry or a biochemical assay for endogenous CAs using liquid chromatography. Immediately after the end of the 6-OHDA perfusion no CA terminals were seen within a cortical area whose radius was about 5mm away from the perfusion site (Kasamatsu et al., 1981b). In the vicinity of this primary lesion area, especially in superficial layers, CA terminals and fibers were seen more densely than the normal. Two weeks after stopping the 6-OHDA perfusion, the CA-terminal-depleted area seemed to be shrunken (a radius, 2-3mm). Some of regrowing CA fibers were observed even at the edge of the gliosis caused by the placement of cannulae. By four weeks after stopping the 6-OHDA perfusion, CA fibers with terminals were virtually seen everywhere in the visual cortex including the previous site of cannulation. At the perfusion center, however, the intensity of CA fluolescence did not yet return to the normal level. In an area 3-4mm away from the perfusion site, complexity and intensity of fluolescent fibers were already indistinguishable from those in the normal. Reappearance of moderately bright fluolescent fibers, parallel to the cortical surface, were especially notable in the superficial layers. In corollary with the above results in histofluorescence biochemical assays also revealed the quick recovery of CA contents in a cortical area which had been once depleted of its CA terminals with 6-OHDA. (USpHS EY 03409-01; Swedish MRC 04X-2295)

220.16 POSTNATAL MATURATION OF LATERAL GENICULATE NEURONS IN RELATION TO DEVELOPING RETINAL AFFERENTS IN THE KITTEN. C.A. Mason. Dept. of Pharmacology, New York Univ. Med. Centr., New York 10016.

Dendritic maturation of cells in the lateral geniculate nucleus (LGN) was studied in kittens of 1-8 postnatal weeks in tissue impregnated by the Golgi-Kopsch method. During the first few postnatal days, all impregnated cells display many stubby perikaryal extensions. By 1 week, recognizable dendrites have emerged. Dendrites bear growth cones at their tips and are covered with irregular protrusions. At primary and secondary branch points, sprays of finger-like extensions occur. Cell class distinctions that can be made in the adult (Guillery, J. Comp. Neur. 128: 21, 1966) cannot yet be applied. By 2 weeks, large cells bear much longer dendrites that are shaggy with spines, hairs, and growth cone-like protrusions. Smaller cells have more finely divided dendrites that also bear sprays of finger-like structures at branch points. Assignment to cell classes can more easily be made. At 3-4 weeks, dendrites are longer and characteristic 'grape-like' appendages can be recognized on larger cells. By 5-6 weeks, dendrites of all cell types have thinned out, but they bear many more spines than in the adult. Obvious class I cells have more finely sculpted appendages, and smaller cells bear some immature appendages. By 8 weeks all cell types look virtually mature, although spines are still seen on some peripheral dendrites.

Golgi material was taken from littermates of kittens used to study postnatal development of terminal arbors of retino-geniculate axons. Axon arbors were diffusely labeled with horseraddish peroxidase and analyzed in the light and electron microscopes (Mason, Soc. Neurosci. Abstr. 6:660, 1980). At 1 week postnatal, axon arbors look mature in their extent but terminal swellings are highly immature. During the major phase of dendritic outgrowth at 1-2 weeks, however, axon terminal arbors undergo little change. New ultrastructural findings reveal that broad expansions on axons make proto-glomerular contacts, but the more numerous filopodial structures make frequent simple contacts with dendrites and perikaryal blebs. These latter synaptic patterns are not seen in the adult. From 3-6 weeks, refinement of shape both of axonal terminals and of specialized dendritic appendages at proximal branch points where most retinal input occurs, proceeds in tandem. Since retinal axons have reached the LGN one month prenatal (Shatz and DiBerardino, Soc. Neurosci. Abstr. 6:485, 1980), these results suggest that waiting afferent retinal axons may influence primary dendritic outgrowth and subsequent modeling of appendages of geniculate neurons. (Supported by NIH Grants NS-14283 to R.W. Guillery and NS-16951).

220.17 IRREVERSIBLE DISRUPTION OF CORTICAL BINOCULARITY FOLLOWING EARLY EXPERIENCE WITH 32° OF ROTATIONAL DISPARITY BETWEEN THE LEFT AND RIGHT VISUAL FIELDS. Michael R. Isley*, Diane C. Rogers*, William C. Owen*, and Paul G. Shinkman. Univ. North Carolina, Chapel Hill, NC 27514.

Previously, we reported that when kittens' early visual experience (between the ages of 4-12 wks.) consists of left- and right-eye visual fields optically rotated in opposite directions about the visual axes (16° of disparity between the two eyes), the distribution of interocular differences (IOD) in visual cortical cells' preferred stimulus orientations is found subsequently to be centered about the rotation experienced during early development. In other respects, the organization of visual cortex resembles that found in normally reared kittens.

At last year's Neuroscience meeting, we described experiments designed to assess the parametric limits of this developmental plasticity. Kittens were reared viewing a normal environment through goggles fitted with prisms that introduced 32° of rotational disparity between the two eyes' visual fields. The results differed in three principal ways from the earlier (16°) experiments: (1) the ocular dominance distribution was U-shaped rather than normal; (2) the distribution of preferred interocular orientation disparities was somewhat rectangular, with significantly greater variance than that of normally reared or control kittens; and (3) there was a substantial overrepresentation of cells with preferred stimulus orientations in the dominant eye near horizontal or vertical (± 22.5°).

The present experiment was designed to assess the permanence of this effect, and its susceptibility to modification by subsequent normal visual experience during adulthood. Kittens that had worn 32° prism goggles during early development, with results as described above, were subsequently returned to the main colony without goggles where they experienced a normal visual environment for 4-8 mos. They were then retested to assess the effects of this exposure upon the physiological organization of visual cortex. No changes were found; the pattern of results was the same as in the earlier measurements. We conclude that the disruption of binocularity and also of interocular matching of preferred stimulus orientations produced by early experience with a rotational disparity of 32° between the left and right visual fields is permanent and not subject to modification by subsequent prolonged visual experience without the goggles during adulthood.

220.18 THE EFFECT OF IMPULSE BLOCKAGE ON CYTOCHROME OXIDASE ACTIVITY IN THE CAT VISUAL SYSTEM. M. Wong-Riley and D.A. Riley. Dept. of Anatomy, Univ. of Calif., San Francisco, CA 94143

The use of cytochrome oxidase histochemistry as an indicator of oxidative metabolism in neurons has proven effective in revealing functional changes following sensory deprivation in developing and mature nervous systems (Wong-Riley and Welt, '80). Since sensory deprivation can involve several parameters, such as natural stimuli, action potentials and axoplasmic transport, we wished to know if the cessation of impulse transmission alone could bring about an adjustment of oxidative metabolism in the postsynaptic neurons. We used tetrodotoxin (TTX) in a dosage that blocked action potentials without blocking axoplasmic transport (Ochs and Hollingsworth, '71; Stryker, personal communication). TTX was injected intravitreally into one eye of 8 adult cats every 3 days for total periods of 1,2,4,5½ or 6 weeks respectively. The effect of the drug could be monitored by the disappearance of the pupillary reflex and its return in about 3 days. At the end of the experimental periods, the animals were perfused and their brains were processed for cytochrome oxidase histochemistry. The results indicated that: (1) A decreased level of C.O. activity was observed in the LGN laminae innervated by the TTX-treated eye as well as in area 17 of all animals. (2) Changes were discernable after one week, but became progressively more prominent up to 6 weeks. (3) Within the LGN, the ipsilateral lamina A1 consistently appeared more severely affected than the contralateral lamina A. This pattern was similar to that seen previously in unilaterally lid-sutured cats (Wong-Riley,'79). (4) The monocular segment of the affected lamina A exhibited a high level of enzyme activity, indicating that its oxidative metabolism might be sustained by other factor(s) or synaptic activity. (5) Within the striate cortex, banding pattern of high and low C.O. activity was seen in lamina IV. This was consistent with the pattern observed in monocularly sutured cats. Cortical changes after one week survival appeared milder than that in the LGN, suggesting that alterations in the LGN preceded that of the cortex. Experiments were also initiated to determine whether the histochemical changes were reversible following the termination of drug treatment. Preliminary results in cats TTX-treated for 4 weeks with 6 weeks recovery showed that the enzymatic levels in the affected LGN and cortical laminae were comparable to that of the normal. This indicates that the dosage used apparently did not damage the neural pathways. Thus, impulse blockage alone can cause a decrease in the level of cytochrome oxidase activity in the affected postsynaptic neurons, and the maintenance of functional and enzymatic integrity of postsynaptic neurons in the adult is dependent upon viable presynaptic impulse conduction.

220.19 PATTERN PROCESSING AND SLOW WAVES IN VISUAL CORTEX OF PATTERN DEPRIVED CAT. J. D. Glass and R. W. Hall*. Dept. Pharmacol., Univ. of Pgh., Sch. of Med. and Elec. Eng., Univ. of Pgh., Pgh., PA 15261.

We recently showed that pattern processing mechanisms of cat visual cortex can be studied with the slow-wave response (Glass and Hall, 1981). In the context of the relationship between pattern processing and the slow wave, we have now examined the effects of monocular lid closure upon the slow-wave response.

Kittens received lid closure over one eye prior to the time of the normal opening of the lids. After at least 13 months of closure, bipolar electrodes were implanted under anesthesia into the visual cortex. Recordings were taken with the cats awake and restrained. A diffuse and a checkerboard pattern stimulus were used. In each test condition 15 responses were digitized and peak amplitudes were compared with T tests.

Comparisons between the responses evoked from the non-deprived (ND) eye by the diffuse and patterned stimuli showed significant peak amplitude differences primarily for those components occurring between 50-230 msec. Components before and after this critical interval rarely showed significant differences. However, for the deprived (D) eye, when the responses were recorded immediately after opening the lids, the percentage of significant comparisons in the critical interval was substantially reduced. The response evoked from the D eye was of decreased amplitude and altered waveform compared with the response evoked from the ND eye.

Single-unit studies in cats have shown a visual cortex that is virtually unresponsive to edge stimuli as a result of the deprivation. Our findings with the slow-wave response show that pattern processing abnormalities are present in the visual cortex confirming the single-unit evidence. However, the existence of a reliable and complex slow-wave response within the visual cortex demonstrates that visual stimulation of the deprived eye is indeed activating the visual cortex. The maintained responsiveness of visual cortex following visual deprivation has also been demonstrated with the slow-wave response recorded from humans. The role of this retained cortical activity in visual function is not known. The use of the slow-wave response in the visually deprived cat may provide a useful animal model for studying the retained visual function in humans.

220.20 DARK REARING EFFECTS ON CORTICAL CELLS OF CATS FOLLOWING POSTNATAL MONOCULAR DEPRIVATION. U. Yinon and S. Goshen (SPON: S. YEHUDA). Physiol. Lab., Maurice and Gabriela Goldschleger Eye Inst., Tel Aviv Univ. Sch. of Med., Sheba Med. Ctr., Tel Hashomer 52621, Israel.

The effect of prolonged periods of dark rearing on early visual experience was studied in five age groups of kittens (N=13) subjected postnatally to 0-85 days of normal binocular vision. Following this they were all monocularly deprived for one month and dark reared for 9.5-20.5 months. Unit recording was performed from visual cortex area 17 and compared to kittens (N=2) postnatally monocularly deprived (MD)for 10 months and to normal control adult cats (N=13).

The ocular dominance distribution shows already a minor bias toward the formerly exposed eye in the age group of kittens which has received the earliest monocular visual experience (8-38 days). The highest bias in the ocular dominance was found in the second age group of kittens in which the monocular visual experience has covered the most critical part of the susceptibility (Hubel and Wiesel, J. Physiol. 206: 419, 1970) period (23-53 days postnatally). Accordingly the maximal diminution in the proportion of binocularly driven cells was found in this group age. The smallest bias was obtained in the last age group of kittens which has received the period of monocular deprivation at the latest age (93-124 days postnatally). Of the visually unresponsive and direction and orientation nonselective cells the highest proportion was found in the first group age of kittens while in the other group ages it was similar to that of the MD or the control groups.

It was concluded that the age factor is more important than the duration at which a certain visual experience within the susceptibility period was given. In addition, it was proved that brief periods (several days) of monocular deprivation are ineffective if followed by a complete absence of visual experience; a continuous visual exposure is needed for the effect of the binocular competition to persist.

221.1 HISTOCHEMICAL EVIDENCE THAT HEART CONDITIONED MEDIUM PROMOTES CENTRAL CHOLINERGIC REGENERATION IN VIVO. Amy Rothman Schonfeld and Robert Katzman. Dept. of Neurology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

The ability of central cholinergic neurons to undergo axonal regeneration after injury has been demonstrated both histochemically (Svendgaard et. al., Brain Res. 102:1, 1976) and biochemically (Emson et. al., Brain Res. 135:87, 1977) in adult rats. In these studies, iris tissue implanted into the anterior hippocampus, served as targets for newly regenerating cholinergic septo-hippocampal fibers which had been transected during the implantation procedure. Recently, the activities of several "cholinergic growth factors" have been studied in vitro. One of these, heart conditioned medium (HCM), has been shown to promote both the survival and neuritic outgrowth of chick ciliary ganglion cells in culture (Helfand et. al., Devel. Blo. 50:541, 1976). In a recent report from this laboratory (Schonfeld et. al., submitted for publication, 1981), we observed that daily application of HCM near cholinergic soma in the septum significantly stimulated axonal regeneration, as measured by choline acetyltransferase activity, into iris implants in the anterior hippocampus. Using the same experimental paradigm, the aim of the present study was to examine the effect of HCM on cholinergic regeneration histochemically.

For this, heterologous iris implants were inserted in the anterior hippocampus in female rats previously subjected to ipsilateral superior cervical ganglionectomies. At the same time, a cannula was stereotaxically placed in the medial septum. Animals were administered either HCM (prepared by Dr. R. Johnston of Stanford University according to Helfand et. al., 1976) or saline as control vehicle. Rats received either daily injections for 0 or 8 days post-op or alternate day injections for 16 days. Animals were sacrificed by decapitation. The brains were rapidly removed, frozen, sectioned on a cryostat, stained for acetylcholinesterase by the direct-coloring thiocholine technique (Karnovsky and Roots, J. Histochem. Cytochem. 12:219, 1964) with modifications (Hardy et. al. Neurosci Lett. 3:1, 1976) and analyzed.

Differences between treatments were most evident 16 d post-op. In the saline treated implants, areas of reinnervation were generally limited to those peripheral areas most proximal to the hippocampal fimbria. In contrast, HCM appeared to stimulate both the number of regenerating fibers as well as extend the distribution of these fibers to include central portions of implant and sections in dorsal hippocampus relatively distal to the fimbria. These observations support our earlier neurochemical findings and indicate that HCM stimulates cholinergic regeneration in vivo.

221.2 IN THE SNAIL MELAMPUS EXCISED CEREBRAL GANGLIA INTRODUCED INTO THE HEMOCOEL BECOME INTEGRATED INTO CNS CIRCUITRY. Stacia Moffett, Dept. of Zoology, Washington State University, Pullman, WA 99164.

When a cerebral ganglion is implanted in the hemocoel of a normal adult snail, the ganglion often forms afferent and efferent connections. Extracellular recordings from the implant surface and nerves reveal reflex activity that mimics the host snail's responses to stimulation. Projections from the implanted ganglion to the host snail's CNS are more rare, but occasionally do form. In these cases, stimulation applied to the implanted ganglion is capable of eliciting reflex responses from the host's nervous system. In addition, many of the implanted ganglia induce supernumerary eyes and tentacles (Moffett and Austin, Amer. Zool 20, p. 891, 1980; J. Exp. Zool. 216(2), 1981).

Removal of one cerebral ganglion results in formation of a ganglion bud and some restoration of normal behavior on the operated side (Moffett, Soc. Neurosci. Abs. 5 p. 754, 1979). If, however, the cerebral ganglion has all its nerves and central connections severed and is then replaced in approximately its former position, it is reincorporated into the CNS circuitry. In six of seven animals examined 6-8 mos. postoperative, the restored ganglion had assumed its normal position relative to the other cerebral ganglion. The ganglion bud development was rudimentary and the bud connected directly to the restored ganglion. In the exceptional case, the restored ganglion was displaced and was connected to the contralateral cerebral ganglion via the ganglion bud. Nickel chloride backfilling has confirmed the reestablishment of central tracts and electrophysiological recordings show that the restored ganglion motoneurons effect motor responses on the operated side.

When, in addition to reintroduction of the snail's own excised ganglion, another cerebral ganglion is also inserted, the ganglia fuse or are closely associated and joined by a commissure. In four of the five preparations examined six weeks postoperative, the two united ganglia are incorporated as one into the brain pathways, with varying degrees of redundancy in peripheral nerve connections. For instance, the tentacle nerve in one preparation bifurcated and entered both cerebral ganglia. In two preparations, cerebrobuccal connectives extended from both reintroduced ganglia. Communication from the ring ganglia via the ganglion bud extended to both of the united ganglia and one or two cerebral commissures were formed with the contralateral ganglion. Despite the possibilities for maladaptive responses inherent in these operations, the snails appear quite normal, and preliminary physiological recordings indicate that reflex control is fairly normal.
