CHRONOLOGICAL LIST OF SESSIONS

(See page vii for Thematic Index of Sessions.)

THEMATIC INDEX OF SESSIONS*

Theme A: Development and Plasticity

Session Number	Title	Type	Day	Time
115.	Axonal Growth	Slide	Tu.	1:30 PM
178.	Axonal Growth and Guidance	Poster	W.	2:00 PM
15.	Sprouting and Sprouting Mechanisms I	Slide	M.	10:45 AM
154.	Sprouting and Sprouting Mechanisms II	Poster	W.	9:00 AM
89.	Regeneration I: Central	Slide	Tu.	10:45 AM
153.	Regeneration II: Peripheral	Poster	W.	9:00 AM
221.	Regeneration III:Central	Poster	Th.	9:00 AM
48.	Trophic Factors and Interactions in Development	Slide	M.	2:00 PM
179.	Trophic Agents in Development	Poster	W.	2:00 PM
249.	Trophic Interactions in Development	Poster	Th.	2:00 PM
24.	Competition and Remodeling	Poster	M.	9:00 AM
5.	Synaptogenesis	Slide	M.	9:00 AM
219.	Synapse Formation	Poster	Th.	9:00 AM
60.	Specificity of Synaptic Connections	Poster	M.	2:00 PM
152.	Morphogenesis and Pattern Formation I	Poster	W.	9:00 AM
243.	Morphogenesis and Pattern Formation II	Slide	Th.	3:45 PM
98.	Neuronal Death	Poster	Tu.	9:00 AM
250.	Effects of Activity, Inactivity, and Denervation I	Poster	Th.	2:00 PM
271.	Effects of Activity, Inactivity, and Denervation II	Slide	F.	9:00 AM
23.	Neural Plasticity in Adult Animals I	Poster	M.	9:00 AM
205.	Neural Plasticity in Adult Animals II	Slide	Th.	9:00 AM
61.	Motor Systems II (Motor System I, III, see Theme G)	Poster	M.	2:00 PM
176.	Development of Sensory Systems	Poster	W.	2:00 PM
288.	Limbic System	Poster	F.	9:00 AM
47.	Visual System I: Retino-Geniculo-Cortical Connections	Slide	M.	2:00 PM
132.	Visual System II: Retinotectal Connections	Poster	Tu.	1:30 PM
220.	Visual System III: Retino-Geniculo-Cortical Connections	Poster	Th.	9:00 AM
236.	Visual System IV: Retinotectal Connections	Slide	Th.	2:00 PM
4.	Development in Invertebrates	Slide	M.	9:00 AM
177.	Neurogenetics	Poster	W.	2:00 PM
97.	Endocrine Control of Neural Development	Poster	Tu.	9:00 AM
131.	Biochemical and Pharmacological Correlates of Development	Poster	Tu.	1:30 PM
83.	Development of Excitable Membranes	Slide	Tu.	9:00 AM
273.	Molecular Correlates of Development	Slide	F.	9:00 AM
25.	Nutritional and Prenatal Factors in Development I	Poster	M.	9:00 AM
116.	Nutritional and Prenatal Factors in Development II	Slide	Tu.	1:30 PM
289.	Developmental Disorders	Poster	F.	9:00 AM
62.	Aging I (Aging II, see Theme H)	Poster	M.	2:00 PM
123.	Aging III	Slide	Tu.	3:00 PM
39.	Applications of Recombinant DNA in Neuroscience	Symp.	M.	2:00 PM
73.	CNS Development in Invertebrates	Symp.	Tu.	9:00 AM
145.	Approaches to Studying Gene Expression and Regulation During Neuronal Differentiation and Functioning	Symp.	W.	9:00 AM
265.	Regeneration of Nerve Fibers in Mammalian CNS	Symp.	F.	9:00 AM

*Includes contributed paper sessions, symposia, and workshops only.

Theme B: Cell Biology

Session Number	Title	Type	Day	Time
136.	Morphology of Neurons and Glia	Poster	Tu.	1:30 PM
103.	Identified Cells	Poster	Tu.	9:00 AM
158.	Neuronal Tracing by Marker Transport	Poster	W.	9:00 AM
28.	Comparative Neuroanatomy	Poster	M.	9:00 AM
225.	Functions of Glia	Poster	Th.	9:00 AM
50.	Cell and Tissue Culture I	Slide	M.	2:00 PM
224.	Cell and Tissue Culture II	Poster	Th.	9:00 AM
102.	Membrane Structure and Function	Poster	Tu.	9:00 AM
293.	Lipids and Myelin	Poster	F.	9:00 AM
292.	Proteins and Nucleic Acids	Poster	F.	9:00 AM
40.	Specific Immunological Probes	Slide	M.	2:00 PM
101.	Cell Surface Macromolecules	Poster	Tu.	9:00 AM
157.	Axoplasmic Transport I	Poster	W.	9:00 AM
241.	Axoplasmic Transport II	Slide	Th.	2:00 PM
82.	Metabolic Studies I	Slide	Tu.	9:00 AM
254.	Metabolic Studies II	Poster	Th.	2:00 PM
29.	Blood-Brain Barrier	Poster	M.	9:00 AM
52.	Cellular Aspects of Disease I	Slide	M.	3:45 PM
182.	Cellular Aspects of Disease II	Poster	W.	2:00 PM
3.	Lectins: Cytochemical Markers for Nervous System Carbohydrates	Wkshp.	M.	9:00 AM
110.	Quantitative Microscopy: Theory, Methods, and Applications	Wkshp.	Tu.	1:30 PM
168.	Cytoskeletal Determinants of Neuronal Form and Function	Symp.	W.	2:00 PM

Theme C: Excitable Membranes and Synaptic Transmission

Session Number	Title	Type	Day	Time
227.	Synaptic Structure and Function	Poster	Th.	9:00 AM
167.	Electrical Synapses and Gap Junctions	Poster	W.	9:00 AM
140.	Presynaptic Mechanisms	Poster	Tu.	1:30 PM
141.	Postsynaptic Mechanisms I	Poster	Tu.	1:30 PM
233.	Postsynaptic Mechanisms II	Slide	Th.	2:00 PM
270.	Presynaptic and Postsynaptic Mechanisms	Slide	F.	9:00 AM
41.	Pharmacology of Synaptic Transmission I	Slide	M.	2:00 PM
260.	Pharmacology of Synaptic Transmission II	Poster	Th.	2:00 PM
226.	Acetylcholine and Cholinergic Receptors	Poster	Th.	9:00 AM
262.	Receptor Sensitization and Desensitization	Poster	Th.	2:00 PM
34.	Drug Effects on Receptors	Poster	M.	9:00 AM
259.	Metabolism of Receptors and Transmitters	Poster	Th.	2:00 PM
166.	Membrane Biophysics	Poster	W.	9:00 AM
8.	Action Potentials and Ion Channels I	Slide	M.	9:00 AM
165.	Action Potentials and Ion Channels II	Poster	W.	9:00 AM
291.	Action Potentials and Ion Channels III	Poster	F.	9:00 AM
280.	Oscillators and Rhythmic Discharges	Slide	F.	10:45 AM
187.	Epilepsy I: Kindling	Poster	W.	2:00 PM
188.	Epilepsy II	Poster	W.	2:00 PM
206.	Epilepsy III	Slide	Th.	9:00 AM
261.	Epilepsy IV	Poster	Th.	2:00 PM
234.	Sensory Transduction	Slide	Th.	2:00 PM
190.	Studies of Excitable Cells in Culture	Poster	W.	2:00 PM
76.	Electrobiology and Membrane Properties of CNS Neurons I	Slide	Tu.	9:00 AM

189.	Electrobiology and Membrane Properties of CNS Neurons II	Poster	W.	2:00 PM
36.	Electrobiology of Invertebrates	Poster	M.	9:00 AM
191.	Diseases of Synapses and Axons	Poster	W.	2:00 PM
38.	The Neurobiology of Dendrites	Symp.	M.	2:00 PM
109.	Cellular Mechanisms of Epileptogenesis	Symp.	Tu.	1:30 PM
170.	The Growing Relevance of Gap Junctions and Electrotonic Synapses to Neurobiology	Wkshp.	W.	2:00 PM
195.	Synaptic Regulation of Voltage-gated Channels	Symp.	Th.	9:00 AM
231.	Altered Axons: Is Compulsive Conduction Replaced by Spontaneous Spiking?	Wkshp.	Th.	2:00 PM

Theme D: Neurotransmitters, Modulators, and Receptors

Session Number	Title	Type	Day	Time
159.	Acetylcholine	Poster	W.	9:00 AM
35.	Amino Acids I: Pharmacology and Physiology	Poster	M.	9:00 AM
106.	Amino Acids II: Uptake and Binding	Poster	Tu.	9:00 AM
111.	Amino Acids III	Slide	Tu.	1:30 PM
32.	Peptides I: Anatomical Localization in CNS	Poster	M.	9:00 AM
33.	Peptides II: Peripheral Nervous System	Poster	M.	9:00 AM
138.	Peptides III: Receptors	Poster	Tu.	1:30 PM
162.	Peptides IV: Central Physiologic Effects	Poster	W.	9:00 AM
163.	Peptides V: Distribution and Regulation	Poster	W.	9:00 AM
197.	Peptides VI: Distribution and Regulation	Slide	Th.	9:00 AM
30.	Opioid Peptides I: Characterization	Poster	M.	9:00 AM
31.	Opioid Peptides II: Localization	Poster	M.	9:00 AM
43.	Opioid Peptides III: Receptors	Slide	M.	2:00 PM
139.	Opioid Peptides IV: Receptors	Poster	Tu.	1:30 PM
185.	Opioid Peptides V: Electrophysiology	Poster	W.	2:00 PM
257.	Opioids: Neuronal Interactions I	Poster	Th.	2:00 PM
267.	Opioids: Neuronal Interactions II	Slide	F.	9:00 AM
7.	Dopamine I: Receptors	Slide	M.	9:00 AM
42.	Dopamine II: Receptors	Slide	M.	2:00 PM
184.	Dopamine III: Electrophysiology	Poster	W.	2:00 PM
67.	Catecholamines I: Functional Neurochemistry	Poster	M.	2:00 PM
183.	Catecholamines II: Central Physiology	Poster	W.	2:00 PM
258.	Catecholamines III: Central Neuroanatomy	Poster	Th.	2:00 PM
297.	Catecholamines IV: Functional Neurochemistry	Poster	F.	9:00 AM
278.	Biogenic Amines: Histamine and Phenethylamines	Slide	F.	10:45 AM
6.	Serotonin I: Receptors	Slide	M.	9:00 AM
87.	Serotonin II: Electrophysiology	Slide	Tu.	10:45 AM
186.	Serotonin III: Localization, Physiology, and Pharmacology	Poster	W.	2:00 PM
105.	Transmitters in Invertebrates	Poster	Tu.	9:00 AM
86.	Cardioactive Neuropeptides in Arthropods	Slide	Tu.	10:45 AM
255.	Transmitter Cytochemistry and Immunochemistry I: Biogenic Amines	Poster	Th.	2:00 PM
294.	Transmitter Cytochemistry and Immunochemistry II	Poster	F.	9:00 AM
75.	Cellular Localization of Neuroeffector Substances	Slide	Tu.	9:00 AM
51.	Interactions Between Neurotransmitters I	Slide	M.	3:45 PM
256.	Interactions Between Neurotransmitters II	Poster	Th.	2:00 PM
208.	Modulators I: Benzodiazepine Receptors	Slide	Th.	10:45 AM
298.	Modulators II	Poster	F.	9:00 AM
299.	Metabolism of Transmitters and Modulators	Poster	F.	9:00 AM
114.	Cholinergic Receptors I	Slide	Tu.	1:30 PM
160.	Cholinergic Receptors II	Poster	W.	9:00 AM
137.	Adrenergic Receptors	Poster	Tu.	1:30 PM
239.	Benzodiazepine/GABA Receptor Complex	Slide	Th.	2:00 PM
161.	Regional Localization of Receptors I	Poster	W.	9:00 AM
200.	Regional Localization of Receptors II	Slide	Th.	9:00 AM

295.	Cyclic Nucleotides	Poster	F.	9:00 AM
279.	Alcohol	Slide	F.	10:45 AM
104.	Alcohol and Barbiturates	Poster	Tu.	9:00 AM
164.	Transmitters and Receptors in Disease I	Poster	W.	9:00 AM
228.	Transmitters and Receptors in Disease II	Poster	Th.	9:00 AM
66.	Behavioral Pharmacology I	Poster	M.	2:00 PM
238.	Behavioral Pharmacology II	Slide	Th.	2:00 PM
296.	Behavioral Pharmacology III	Poster	F.	9:00 AM
65.	Uptake, Storage, and Secretion I	Poster	M.	2:00 PM
122.	Uptake, Storage, and Secretion II	Slide	Tu.	3:00 PM
74.	Mechanism of Action of Antidepressants	Symp.	Tu.	9:00 AM
266.	In Vivo Electrochemistry: Principles and Applications	Wkshp.	F.	9:00 AM

Theme E: Endocrine and Autonomic Regulation

Session Number	Title	Type	Day	Time
10.	Anterior Pituitary I: Sex Hormones	Slide	M.	9:00 AM
45.	Anterior Pituitary II: Endorphins and ACTH	Slide	M.	2:00 PM
108.	Anterior Pituitary III: Sex Hormones	Poster	Tu.	9:00 AM
107.	Posterior Pituitary	Poster	Tu.	9:00 AM
229.	Pineal Gland: Biological Rhythms	Poster	Th.	9:00 AM
68.	Adrenal Medulla	Poster	M.	2:00 PM
71.	Neural Control of Immune System	Poster	M.	2:00 PM
37.	Cardiovascular Regulation I: Morphological Aspects	Poster	M.	9:00 AM
121.	Cardiovascular Regulation II: Electrophysiology	Slide	Tu.	1:30 PM
207.	Cardiovascular Regulation III: Arterial Pressure and Hypertension	Slide	Th.	9:00 AM
263.	Cardiovascular Regulation IV: Central Transmitters	Poster	Th.	2:00 PM
264.	Cardiovascular Regulation V: Functional Aspects, Stress, and Cerebral Blood Flow	Poster	Th.	2:00 PM
276.	Temperature Regulation	Slide	F.	9:00 AM
300.	Respiratory Regulation	Poster	F.	9:00 AM
69.	Peripheral Autonomic Nervous System	Poster	M.	2:00 PM
70.	Hormones and Behavior I: Sexual Behavior	Poster	M.	2:00 PM
201.	Hormones and Behavior II: Sexual Behavior	Slide	Th.	9:00 AM
232.	Hormones and Behavior III: Receptors in CNS	Slide	Th.	2:00 PM
209.	Neuropeptides in Invertebrates	Slide	Th.	10:45 AM

Theme F: Sensory Systems

Session Number	Title	Type	Day	Time
94.	Skin, Muscle, and Visceral Receptors	Poster	Tu.	9:00 AM
22.	Transduction in Sensory Systems	Poster	M.	9:00 AM
21.	Sensory System Transmitters	Poster	M.	9:00 AM
173.	Spinal Cord I	Poster	W.	2:00 PM
199.	Spinal Cord II	Slide	Th.	9:00 AM
130.	Subcortical Somatosensory Pathways	Poster	Tu.	1:30 PM
247.	Somatosensory Cortex I	Poster	Th.	2:00 PM
269.	Somatosensory Cortex II	Slide	F.	9:00 AM
14.	Evoked Potentials I	Slide	M.	9:00 AM
96.	Evoked Potentials II	Poster	Tu.	9:00 AM
77.	Pain I	Slide	Tu.	9:00 AM
112.	Pain II	Slide	Tu.	1:30 PM
174.	Pain III	Poster	W.	2:00 PM
237.	Pain IV	Slide	Th.	2:00 PM
286.	Pain V	Poster	F.	9:00 AM
203.	Retina: Intrinsic Organization	Slide	Th.	9:00 AM

95.	Retina and Retinofugal Pathways	Poster	Tu.	9:00 AM
11.	Functional Organization of Subcortical Visual Areas	Slide	M.	9:00 AM
151.	Subcortical Visual Pathways	Poster	W.	9:00 AM
59.	Visual Cortex: Functional Organization	Poster	M.	2:00 PM
118.	Vision I: Functional Organization of Striate Cortex	Slide	Tu.	1:30 PM
248.	Vision II: Cortex and Cortico-Subcortical Relationships	Poster	Th.	2:00 PM
268.	Vision III: Extrastriate Visual Areas	Slide	F.	9:00 AM
175.	Auditory and Vestibular Sense Organs	Poster	W.	2:00 PM
49.	Auditory and Vestibular Systems: The Sensory Periphery	Slide	M.	2:00 PM
20.	Subcortical Auditory Pathways	Poster	M.	9:00 AM
129.	Subcortical Auditory Pathways and Auditory Cortex	Poster	Tu.	1:30 PM
78.	Auditory System: Functional Organization	Slide	Tu.	9:00 AM
217.	Chemical Senses: Olfaction and Taste I	Poster	Th.	9:00 AM
235.	Chemical Senses: Olfaction and Taste II	Slide	Th.	2:00 PM
85.	Invertebrate Sensory Systems I	Slide	Tu.	9:00 AM
218.	Invertebrate Sensory Systems II	Poster	Th.	9:00 AM
283.	Modeling and Theoretical Studies	Poster	F.	9:00 AM
2.	The Dorsal Horn: A Profound and a Superficial Analysis	Symp.	M.	9:00 AM
146.	Thalamic Mechanisms of Pain Sensation	Wkshp.	W.	9:00 AM
169.	Parallel and Serial Processing in Vertebrate Visual Pathways	Symp.	W.	2:00 PM
196.	Representation of Space Within Sensory Systems	Symp.	Th.	9:00 AM

Theme G: Motor Systems

Session Number	Title	Type	Day	Time
9.	Motor Systems I: Cortex	Slide	M.	9:00 AM
181.	Motor Systems III: Cortex	Poster	W.	2:00 PM
26.	Cerebellum I	Poster	M.	9:00 AM
211.	Cerebellum II	Slide	Th.	10:45 AM
64.	Basal Ganglia I	Poster	M.	2:00 PM
252.	Basal Ganglia II	Poster	Th.	2:00 PM
274.	Basal Ganglia III	Slide	F.	9:00 AM
27.	Reticular System	Poster	M.	9:00 AM
16.	Vestibular System I	Slide	M.	10:45 AM
156.	Vestibular System II	Poster	W.	9:00 AM
100.	Oculomotor System I	Poster	Tu.	9:00 AM
204.	Oculomotor System II	Slide	Th.	9:00 AM
251.	Oculomotor System III	Poster	Th.	2:00 PM
44.	Visuomotor Integration	Slide	M.	2:00 PM
63.	Sensorimotor Integration	Poster	M.	2:00 PM
120.	Spinal Cord and Brainstem I	Slide	Tu.	1:30 PM
290.	Spinal Cord and Brainstem II	Poster	F.	9:00 AM
84.	Reflex Function I	Slide	Tu.	9:00 AM
180.	Reflex Function II	Poster	W.	2:00 PM
155.	Control of Posture and Movement I	Poster	W.	9:00 AM
223.	Control of Posture and Movement II	Poster	Th.	9:00 AM
240.	Control of Posture and Movement III	Slide	Th.	2:00 PM
133.	Muscle Afferents	Poster	Tu.	1:30 PM
222.	Muscle	Poster	Th.	9:00 AM
253.	Disorders of Motor Systems	Poster	Th.	2:00 PM
134.	Invertebrate Motor Function I	Poster	Tu.	1:30 PM
242.	Invertebrate Motor Function II	Slide	Th.	2:00 PM
99.	Neural Prostheses	Poster	Tu.	9:00 AM

Theme H: Neural Basis of Behavior

Session Number	Title	Type	Day	Time
81.	Higher Cortical Functions I: Evoked Potentials	Slide	Tu.	9:00 AM
171.	Higher Cortical Functions II	Poster	W.	2:00 PM

127.	Interhemispheric Relations	Poster	Tu.	1:30 PM
284.	Motivation	Poster	F.	9:00 AM
287.	Neuropsychology and Memory	Poster	F.	9:00 AM
216.	Attention and Arousal	Poster	Th.	9:00 AM
79.	Sleep I	Slide	Tu.	9:00 AM
285.	Sleep II	Poster	F.	9:00 AM
148.	Evoked Potentials and EEG	Poster	W.	9:00 AM
46.	Circuitry and Pattern Generation	Slide	M.	2:00 PM
18.	Biological Rhythms	Poster	M.	9:00 AM
277.	Circadian Rhythms	Slide	F.	9:00 AM
246.	Subcortical Structures	Poster	Th.	2:00 PM
244.	Toxic Effects on Behavior	Poster	Th.	2:00 PM
55.	Neuroethology I: Invertebrates	Poster	M.	2:00 PM
93.	Neuroethology II: Vertebrates	Poster	Tu.	9:00 AM
272.	Neuroethology III: Vertebrates	Slide	F.	9:00 AM
80.	Learning, Memory, and Habituation I: Lesion and Ablation Studies	Slide	Tu.	9:00 AM
119.	Learning, Memory, and Habituation II: Electrical and Pharmacological Studies	Slide	Tu.	1:30 PM
172.	Learning, Memory, and Habituation III: Pharmacological Studies	Poster	W.	2:00 PM
214.	Learning, Memory, and Habituation IV: Lesion and Ablation Studies	Poster	Th.	9:00 AM
245.	Learning, Memory, and Habituation V: Electrical Recording Studies	Poster	Th.	2:00 PM

213.	Psychotherapeutic Drugs I: Affective Disorders	Poster	Th.	9:00 AM
281.	Psychotherapeutic Drugs II	Poster	F.	9:00 AM
90.	Drugs of Abuse: Psychopharmacology	Poster	Tu.	9:00 AM
124.	Aging II	Poster	Tu.	1:30 PM
88.	Neuroanatomical Studies I	Slide	Tu.	10:45 AM
135.	Neuroanatomical Studies II	Poster	Tu.	1:30 PM
144.	Memory and Brain Mechanisms	Symp.	W.	9:00 AM
230.	Neural Mechanisms of Attention	Symp.	Th.	2:00 PM

2 SYMPOSIUM

THE DORSAL HORN: A PROFOUND AND A SUPERFICIAL ANALYSIS.
A.I. Basbaum, University of California, San Francisco (Chmn); A.R. Light, University of North Carolina, G.J. Bennett, NIH-NIDR; E.J. Glazer, University of California, San Francisco; M. Yamamoto-Yoshida, Tsukuba University, Japan.

With the advent of combined morphological and physiological methods for studying the circuitry of the dorsal horn, major advances have been made in our understanding of somatosensory, pain, and pain modulatory systems. This symposium will highlight the results derived from in vivo and from in vitro electrophysiological, morphological, and immunohistochemical studies.

Alan Light will describe the properties and central distribution of primary afferent fibers. His studies involve the intracellular injection of HRP into functionally characterized dorsal root axons, including small, myelinated A delta high threshold mechanoreceptors. An ultrastructural analysis of their central synaptic interactions will also be presented. Gary Bennett will extend these observations to second order neurons of the dorsal horn, including the smallest neurons of the substantia gelatinosa (sg). The application of the technique to the organization of the more ventral, nucleus proprius will also be presented. The pharmacological complexity of dorsal horn circuitry will be next addressed by Ellyn Glazer who has combined EM immunohistochemical and autoradiographic methods to dissect out synaptic interactions between amines, peptides, and other putative neurotransmitters. Finally, Miyuki Yamamoto-Yoshida will discuss the in vitro analysis of the dorsal horn. A variety of pharmacological, morphological, and physiological studies have been effectively combined in the in vivo preparation, providing important new insights into dorsal horn function. Taken together these discussions will provide a comprehensive review of the organization of the superficial and the "deep" dorsal horn.

3 WORKSHOP

LECTINS; CYTOCHEMICAL MARKERS FOR NERVOUS SYSTEM CARBOHYDRATES.
J.D. Coulter (Chairman; Univ. Texas Med. Br.), J.W. Gurd* (Univ. of Toronto), N.K. Gonatas* (Univ. of Penn), M.A. Ruda (NIDR, Nat. Inst. Health), J.H. LaVail (Univ. of Calif., San Francisco), K.H. Pfenninger (Columbia Univ.)

Lectins with selective affinities for mono- and oligo-saccharides provide a powerful tool to identify and localize carbohydrate-containing sites on neuronal membranes. Complex carbohydrates, particularly glycoproteins, are important constituents of the cell surface and have been implicated in the mechanisms of receptor binding, endocytosis, axoplasmic transport and cell-cell recognition. J.W. Gurd describes the application of lectins in the biochemical analysis of membrane and synaptic glycoproteins. Uses of labeled lectins and lectin affinity chromatography to identify and characterize lectin receptors associated with synaptic structures are reviewed. N.K. Gonatas describes studies in cultured neuroblastoma cells comparing the binding, endocytosis and subsequent subcellular localization of lectin-peroxidase conjugates, cholera toxin-peroxidase conjugate and free horseradish peroxidase. Axonal transport of these substances in peripheral nerves is also discussed. M.A. Ruda reviews studies using immunocytochemical methods to localize lectins transported anterogradely or retrogradely in sensory and motor nerves. Evidence that axonally transported lectin may migrate transneuronally into postsynaptic cells is described. J.H. LaVail reports on the use of affinity purified, [^{125}I] labeled wheat germ agglutinin to study axonal transport in chick retinal ganglion cells. Various issues including the specificity of uptake of the lectin, the rate of transport and the ultrastructural localization after transport are discussed. K.H. Pfenninger describes studies using lectins conjugated with the electron dense marker, ferritin, to map quantitatively, plasmalemmal glycoconjugates in developing neurons. How this approach can contribute to understanding cell-cell interactions and regional membrane differentiation in neural development is described.

4.1 EMBRYONIC ORIGINS OF IDENTIFIED CELLS IN THE LEECH CNS BY TRACER INJECTION AND BY ABLATION OF IDENTIFIED BLASTOMERES. D.A. Weisblat, S.S. Blair* and A.P. Kramer. Dept. Mol. Biol. UCB, Berkeley, CA 94720.

Glossiphoniid leeches are well-suited for neurodevelopmental study because both the early embryo and the segmental ganglia of the adult contain identifiable cells, accessible to observation and experimental manipulation. The early embryo contains one bilateral pair of mesodermal precursors, (M teloblasts) and four bilateral pairs of ectodermal precursors (N,O,P and Q teloblasts). The teloblasts give rise to columns of much smaller stem cells which proliferate to form the segmental tissues of the animal, including the ventral nerve cord.

By injecting horseradish peroxidase (HRP) into identified teloblasts of embryos of the leech Helobdella triserialis, it has been shown that, in normal development, the N,O,P and Q teloblasts each contribute a stereotyped, topographically distinct neuronal subpopulation to the ipsilateral hemiganglia of the nerve cord. Taken with the stereotyped position of identified neurons within the adult ganglia of other leech species, these results suggest that, in normal development, identified neurons arise from specific teloblasts. Further evidence for this hypothesis will be presented from studies involving use of a fluorescent, rhodamine-conjugated synthetic peptide (RDP) as an in vivo cell lineage tracer, coupled with Lucifer Yellow injections of cells in the embryonic nervous system of a giant glossiphoniid leech species, Haementeria ghilianii.

Although the small size of the Helobdella embryo prevents electrophysiological identification of its embryonic neurons, a pair of morphologically identifiable neuropil glia found in each segmental gnalgion have been found to arise from the N teloblasts. Normally, one cell of the pair arises from each N teloblast. The ablation of one N teloblast by intracellular deoxyribonuclease (DNase) injection in early embryogenesis results in a later embryo with ganglia that appear to lack *one neuropil glia, even when progeny of the surviving N teloblast* have crossed the ventral midline and are distributed bilaterally within the ganglion.

4.2 CELL INTERACTIONS AND THE FORMATION OF NORMAL CELL PATTERNING IN THE EARLY EMBRYO OF THE LEECH. S.S. Blair*. Dept. Mol. Biol. UCB, Berkeley, CA 94720.

The embryo of the glossiphoniid leech Helobdella triserialis has been used for the study of cell lineage in the developing nervous system. At the outset of development a series of stereotyped cleavages produce three macromeres (A,B and C), four bilateral pairs of ectoteloblasts (N,O,P and Q) and one bilateral pair of mesoteloblasts (M). The teloblasts give rise to bandlets of stem cells which merge to form the two germinal bands; these two germinal bands eventually coalesce along the ventral midline of the embryo to form the germinal plate, from which arise segmental structures, such as the ventral nerve cord and its segmental ganglia. Through injection of tracer dyes into identified teloblasts or teloblast precursors, it has been shown that the progeny of each teloblast contribute in a characteristic manner to specific structures within the ipsilateral hemiplate. Thus, the progeny of the N teloblast are found mainly in the ventral nerve cord, where they form a spatially stereotyped fraction of the neurons of each ipsilateral hemiganglion. To determine the extent to which formation of this developmental pattern is dependent upon interactions with other cell types, a series of experiments were carried out in which an N teloblast was filled with a fluorescent tracer (rhodamine peptide) and other teloblasts or teloblast precursors were ablated through the intracellular injection of DNase I.

Preliminary results indicate that the ablation of the ipsilateral OPQ or OP teloblast precursors has no visible effect upon the distribution of N teloblast progeny. If instead the ipsilateral M teloblast is ablated, the N teloblast progeny are profoundly disorganized, failing to form ipsilateral hemiganglia or other segmental structures; a portion of the N teloblast progeny may even cross the midline from the mesoderm-deficient side of the germinal plate, apparently becoming incorporated there into the contralateral hemiganglia. As reported earlier, the ablation of the contralateral N teloblast may also cause ipsilateral N teloblast progeny to cross the midline of the germinal plate. *Thus, N teloblast progeny appear to interact with contralateral* N teloblast progeny and with the underlying mesodermal substrate. Interactions with the adjacent O, P or Q ectoteloblasts appear to be less important for normal patterning of N teloblast progeny in the genesis of the segmental ganglion.

4.3 MONOAMINE NEURONS IN EMBRYONIC AND ADULT LEECH. Duncan K. Stuart, Department of Molecular Biology, University of California, Berkeley, CA 94720.

Serotinergic and dopaminergic neurons have been studied in the giant leech, Haementeria ghilianii. In the segmental ganglia apparent homologs of all the previously described serotinergic neurons of Hirudo are present: the giant Retzius pair, the two lateral pairs, the unpaired, posterior medial cell, and the anterior medial pair located only in the first three segmental ganglia. These neurons all stain with neutral red and with the glyoxylic acid fluorescence technique of Torre & Surgeon (Histochem. 49, 1976). However, the unpaired, posterior medial cell is found only in the first seven segmental ganglia of Haementeria whereas it is present in all the segmental ganglia of Hirudo.

In Haementeria two pairs of presumed dopaminergic neurons have been found in each segment, the larger pair in the medial branch of the anterior segmental nerves and the smaller, more peripheral pair in the anterior branch of the anterior nerves. Each dopaminergic neuron projects a major axon centrally which ends in extensive varicose endings in the neuropile of its own and adjacent segmental ganglia. In Hirudo there exists only one corresponding dopaminergic pair.

In Haementeria embryos the serotinergic and dopaminergic neurons begin to contain enough serotonin and dopamine to stain them with the glyoxylic acid method one day after hatching. At that time the larger of the dopamine neurons already sends its major axon into the ganglion, where it branches and sends processes into the adjacent anterior and posterior segments. By this time the isolated nervous system can also be shown to be capable of synthesizing serotonin and dopamine from their radiolabeled precursors. Over the next 7 days the dopaminergic endings in the neuropile increase dramatically, as does the distance between the dopaminergic cell body and its target ganglion. The diameter of the Retzius cell bodies increase relative to other somata.

For the present purpose, the glyoxylic acid procedure was modified for staining of unsectioned material. The preparation, consisting of a dissected leech nerve cord and attached body wall, was stretched and pinned out above the surface of a Sylgard-coated dish filled with ice cold saline and stained for 1-2 min., followed by drying with cold air from a hair dryer for 30 min., and heating in a 95°C oven for 3-5 min. This procedure clears the connective tissue and permits excellent visualization of the serotinergic (yellow) and dopaminergic (blue) cell bodies, axons, and endings.

4.4 SPECIFIC KILLING OF MONOAMINERGIC NEURONS IN THE LEECH EMBRYO BY CYTOTOXIC NEUROTRANSMITTER ANALOGS. J. Glover* and A. Kramer. Graduate Group in Neurobiology, UC Berkeley, Berkeley, CA. 94720

The segmental ganglia of the leech Haementeria ghilianii contain a small number of putative serotonergic neurons. These neurons were found to be susceptible to the cytotoxic effects of the serotonin analogs 5,6 - and 5,7 - dihydroxytryptamine.

Late stage leech embryos, already containing a morphologically intact nerve cord, were injected with 3-4 µl of solutions of the toxic analogs in millimolar concentrations. Within 8 hours, the serotonergic neurons had acquired an intense abnormal brown pigmentation. By the fourth day after injection, the serotonergic neurons showed morphological and physiological signs of cell death, with marked shrinkage of cellular diameter. The cytoplasm had a granular appearance, often with accumulations of large vesicles, and the nucleus was not evident. Often the plasma membrane was clearly absent, and the cell persisted only as a cluster of vesicles or dispersed cellular debris. Cells with intact membranes, when penetrated with a microelectrode, exhibited little or no resting potential and no sign of active membrane properties. Injection of the cell body remnants with lucifer yellow revealed an absence of neurites. These cytotoxic effects were evidently specific since other, non-serotonergic, including putative dopaminergic, neurons appeared morphologically and physiologically normal.

Injection of similar concentrations of toxic analogs into adult leeches produced an apparent disruption of serotonergic terminals. The large serotonergic Retzius cells exhibited significant decreases in resting potential, spike amplitude and electrical coupling. The analogs also appeared to interfere with the production and coordination of swimming movements, a behavior known to be modulated by serotonin in leeches. This effect could be transiently overcome by injection of serotonin.

4.5 DEVELOPMENT OF IDENTIFIED NEURONS IN THE LEECH CNS, J.Y. Kuwada and W.B. Kristan, Jr. Dept. of Biol., UCSD, La Jolla, CA. 92093.

We are investigating the development of a simple, shortening reflex in the leech Haementaria ghilianii. As a first step the central mechanosensitive pressure or P cells, which innervate the skin and provide strong input for the reflex, are being studied.

Eleven days after eggs are laid the chain of ganglia which make up the leech CNS is distinguishable and the P cells have a growth cone directed towards the midline. Later this central process branches sending axons into both anterior and posterior connectives. Simultaneously, many peripherally directed processes appear from the soma. A day later one main peripheral axon, which will set up the cell's major receptive field, is evident. The "extra" smaller processes will subsequently disappear. P cells attain their basic adult morphologies (3 wks) when, in order, peripheral axons grow out roots of adjacent ganglia to set up minor receptive fields in adjacent segments, central neuropilar processes appear, and secondary peripheral axons grow out the ganglion containing their somata.

During the first 2-3 days of process growth, the central process is covered with lateral filopodia which later disappear followed by the growth of neuropilar processes. Thus neuropilar processes do not arise by the selective retention and enlargement of some filopodia. During this time the anterior processes develop faster than the posterior ones and P cells go from displaying passive membrane properties to delayed rectification to noninvading axon spikes. Subsequently, overshooting action potentials can be recorded. Spontaneous synaptic potentials become evident at the time of neuropilar growth.

The initial, primary peripheral axon, like the early central ones, is covered with filopodia as it grows out but the axons which grow out later exhibit much fewer filopodia. This may reflect the fact that the initial axon grows out when roots have not yet formed while the later axons follow roots.

There are 2 P cells per hemiganglion--one mainly innervates the ventral skin and the other the dorsal skin. In the first 3 weeks of development, little if any overlap has been observed between the major and minor fields of a P cell, the major fields of the ventral and dorsal P cells, or the major fields of P cells from adjacent ganglia. These findings plus those of A. Kramer on older leeches (personal comm.) indicate that P cell receptive fields do not arise from an initial overgrowth followed by contraction of peripheral fields.

Presently being investigated are factors influencing the loss of early "extra" peripheral processes and growth of the main peripheral axon, development of an interneuron and motor neuron involved in the reflex, and formation of reflex synapses.

4.6 AN INSECT INTERNEURON DEPRIVED OF SENSORY INNERVATION DURING ITS EMBRYOGENESIS DOES NOT FORM THE NORMAL COMPLEMENT OF DENDRITIC BRANCHES. Marty Shankland, Corey S. Goodman, & David Bentley. Dept. of Zoology, University of California, Berkeley, Ca. 94720 & Dept. of Biol. Sci., Stanford University, Stanford, Ca. 94305.

The Medial Giant Interneuron (MGI) of the grasshopper receives its primary input from the peripheral sensory neurons of the cercus. This synaptic connection is established during embryogenesis, and we have examined the way in which the initial contacts are made between these cells. Cobalt fills of the embryonic cercal nerve have shown that the first sensory axons enter the CNS at 60/65% of embryonic life, and intracellular Lucifer fills of the differentiating MGI demonstrate that its dendrite has very few subsidiary branches at this time. Numerous growth cones begin to spring forth from the main trunk of the dendrite after the sensory axons arrive, and these branches radiate outward until they come into contact with the sensory axon terminals. The dendritic branches do not grow beyond this point. Thus, the coordinate morphogenesis of the cercal sensory axons and the MGI dendrites suggests that developmental interactions between these cells could be responsible for the formation of dendritic growth cones, and the orientation and cessation of their growth.

We addressed this question experimentally by unilaterally ablating the cercus at 60% of embryonic life, i.e. before the first sensory axons reach the CNS. The operated embryos were cultured in a defined medium for 3-9 days and, judging from external criteria, underwent relatively normal development up to 90%. Cobalt fills showed that the cercal sensory axons on the unoperated side of the embryo grow in their normal fashion without forming abnormal crossing projections. This means that the MGI dendrites on the operated side are in fact deprived of contact with cercal sensory axons during the entire course of embryogenesis. Lucifer and cobalt fills of the MGIs on the two sides of the ganglion revealed that dendrites on the deprived side have many fewer branches and smaller branches than dendrites on the undeprived side. Despite this reduction in number, the branches which do form exhibit the appropriate orientation and do not project beyond the point where they would normally have contacted the missing afferents. These findings demonstrate that sensory axon contacts are necessary for the MGI to form and/or retain its normal complement of dendrites. It also appears that these particular sensory axons are not necessary guidance cues for dendritic growth cones to display the usual pattern of growth once they are formed, but it is not known to what extent guidance depends upon other remaining inputs.

4.7 ABNORMAL NEURAL DEVELOPMENT IN DROSOPHILA EMBRYOS CARRYING MUTATIONS AFFECTING SEGMENTAL IDENTITY OR SEGMENT NUMBERS. Lily Yeh Jan* and Yuh Nung Jan. Dept. of Physiology, Univ. of California, San Francisco, CA 94143.

We found that antibodies to horseradish peroxidase (HRP) bind to neuronal membranes and serve as a general neuronal marker in Drosophila. This immunohistochemical staining marks sensory structures, neuromuscular junctions, nerves and fiber tracks in the central nervous system of embryos, larvae, and adult flies. Preadsorption of these antibodies with HRP eliminated all staining. The same pattern of nerve fibers as revealed by fluorescent antibodies to HRP was also marked by brown HRP reaction products when sections were treated sequentially with antibodies to HRP, HRP, diaminobenzidine and hydrogen peroxide. Using an electron microscope, we found that the HRP reaction products were on neuronal membranes.

With this staining, one sees in the embryonic central nervous system two bundles of fibers running in parallel along the entire length of the ventral ganglion and, within each segment, two major commisures connecting the two bundles of longitudinal fibers. Embryos carrying various mutations, deficiencies or duplications have been examined using this staining method. Evidence will be presented to demonstrate that the bithorax gene complex (E.B. Lewis, Nature 276, 565-570, 1978) affects the embryonic nervous system. Also, mutations affecting segment number (C. Nüsslein-Volhard and E. Wieschaus, Nature 287, 795-801, 1980), such as paired, even-skipped, runt, Krüppel and knirps, have been found to alter segment number and organization of the nervous system in embryos.

4.8 DEVELOPMENT OF SYNAPTIC TRANSMISSION IN THE ANTENNAL LOBES OF MANDUCA SEXTA DURING METAMORPHOSIS. Leslie P. Tolbert, Steven G. Matsumoto, and John G. Hildebrand, Dept. of Neurobiology, Harvard Medical School, Boston, MA and Dept. Biology, Columbia Univ., NY, NY.

During the 18 days of metamorphic adult development, sensory neurons in the antenna are born and send their axons to contact developing second-order olfactory neurons in the antennal lobe (AL) of the brain. The axons reach the brain on about day 3 of adult development, when the AL is small and has a light-microscopically homogeneous neuropil. By day 5 glial cells begin to separate peripheral areas of the neuropil into distinct spheroidal glomeruli, and by day 6 the AL looks histologically mature except for its small size.

At day 6, the earliest day at which we have been able to obtain adequate ultrastructural preservation, a few synapses have already begun to form in the newly defined glomeruli. In cross-section, these synapses resemble mature synapses except that they have many fewer synaptic vesicles. In addition to synapses there are numerous desmosome-like contacts, both between glomerular processes and between neurites in extraglomerular (nonsynaptic) regions of the neuropil. In the glomeruli, the desmosome-like contacts often form at the points where three processes meet; these junctions resemble synapses without synaptic vesicles. While the total packing density of ultrastructural junctions in the glomeruli remains fairly constant through the rest of adult development, the percentage of these that are synapses increases until day 12, when it reaches the adult value. Our observations do not reveal whether the early desmosome-like contacts become synapses or whether they simply perform, for instance, an adhesive role during synaptogenesis.

Although synapses can be detected by electron microscopy as early as day 6, intracellular recordings from AL neurons do not detect synaptic transmission from the antennal nerve until day 9, when the number of synapses per unit area in the AL also dramatically increases. The early synapses observed in the electron microscope could be extrinsic (i.e. from antennal axons) or intrinsic (i.e. between AL neurons) in origin. We are currently determining the time course of the maturation of the antennal-axon synapses by labelling this population with horseradish peroxidase. This should reveal whether our ability to detect synaptic transmission between antennal axons and AL neurons correlates with a maturation of the synapses observable before day 9 or with the onset of ultrastructural synapse formation by the antennal axons.

4.9 DEVELOPMENT OF THE GIANT FIBER SYSTEM IN CRICKETS. G. Jacobs and R.K. Murphey. SUNY Albany, Albany, N.Y. 12222.

Orthopteran insects have a group of giant interneurons located in the abdominal nervous system which have been implicated in escape responses. We are interested in the development of two of these neurons in crickets, the medial giant interneuron and lateral giant interneuron (MGI, LGI). We wanted to determine their segment of origin and whether they were segmentally homologous. We approached this problem by using axonal iontophoresis of cobalt from the mesothoracic ganglion to the terminal ganglion in cricket embryos at different developmental stages (staging is based on Bentley et al., 1980). Neurons in the terminal ganglion whose axons run anteriorly are selectively stained with this method. At 50% of embryonic development the abdominal nervous system consists of 11 primitive segments, the four most posterior ones (7-11) will fuse to form the adult terminal ganglion. The neurons which stain at this stage form bilaterally symmetric clusters whose axons cross in characteristic positions in the anterior and posterior commissures in each of the abdominal segments. (A cluster is defined as a group of neurons whose somata are grouped and whose axons cross in the same position in the commissure.) We have limited the analysis to neurons in the anterior commissure. There are three clusters of neurons with axons in this commissure: cluster 1 is composed of two to four cells with axons in the anterior portion of the commissure, cluster 2 contains four to six neurons whose axons occupy the medial region of the commissure and cluster 3 is limited to a distinctive pair of neurons whose axons are closely apposed just distal to their cell bodies and occupy the most posterior portion of this commissure. At this stage (50%) the neurons are indistinguishable from each other. Between 50% and 70% the abdominal segments undergo fusion to form the terminal ganglion. The clusters are still visible at 70% and certain neurons within each cluster have begun to enlarge with respect to their neighbors. By 90% both MGI and LGI are much larger than any other neurons and by examining successively younger stages we could determine which cluster they were derived from. MGI and LGI come from cluster 2 in the eighth and ninth abdominal segments respectively. If these clusters correspond to the progeny of homologous neuroblasts then it is conceivable that they are serial homologues. In order to confirm this it will be necessary to determine that they come from the same cell division of the same neuroblast in their respective segments. Future experiments will address this question as well as comparisons with other orthopteran insects to discover whether the giant interneurons in those insects have similar lineages to those in crickets.

Supported by NSF grant BNS 78-24939.

4.10 CRICKET CERCAL FILIFORM HAIRS HAVE A SOMATOTOPIC PROJECTION IN THE TERMINAL GANGLION. J.P. Bacon and R.K. Murphey. SUNY Albany, Albany, New York 12222.

The cricket has two kinds of mechanosensitive hairs on its cercus, wind-sensitive filiform hairs which cover the entire cercus and gravity-sensitivity clavate hairs, found only proximally and medially. Cobalt-filling the cercal nerve reveals that most sensory fibres terminate ipsilaterally in the terminal ganglion to form the hollow, club-shaped cercal glomerulus. Identifiable clavate hair afferents project somatotopically into this glomerulus (Murphey et al., 1980). This means that adjacent points on the cercal surface project to adjacent positions in the cercal glomerulus: the cercal surface is represented as a continuum in neuropilar space.

But what of filiform hair afferents, do they also exhibit somatotopy? Their large numbers and the fact that they are not arranged in obvious rows had hitherto hindered their investigation. However, by working with animals from the first to the sixth instar, when there are far fewer hairs, we have been able to demonstrate that each filiform hair is uniquely identifiable, both in terms of its position on the cercus and the position of its afferent arborization within the cercal glomerulus. Filiform hairs on the proximo-medial cercal surface (that region covered by clavate hairs) project to the same regions of neuropile as their clavate neighbors. This supports the notion that the somatotopic maps of the two types of mechanosensitive hairs, concerned with the processing of different sensory modalities, are isomorphic. Clavate hairs occur on only the medial 150° of the cercal surface whereas filiform hairs are equally distributed around the circumference. By cobalt-filling filiform hairs at all circumferential positions, we found that one circumnavigation of the cercus is represented as two trips around the cercal glomerular shell. In other words, opposite sides of the cercus project to approximately the same region of the glomerulus: a clear example of this general principle being provided by medial and lateral hairs both of which project medially in the glomerulus.

This anatomical description provides new insights into the cercal to giant interneurone system. Some of the large interneurons have already been identified. By studying their anatomy we should be able to predict which filiform afferents will or will not connect directly with a given interneuron and thereby explain its response properties. We intend to test this idea by recording simultaneously from identified sensory neurons and the giant neurons. Such an analysis should demonstrate the functional significance of the filiform hair afferent somatotopic organization. Supported by NSF Grant BNS 78 24039 to RKM.

4.11 SYNAPTIC INTERACTIONS BETWEEN THE CLAVATE SENSORY NEURONS OF CRICKETS AND AN IDENTIFIED INTERNEURON. Donald S. Sakaguchi* and R.K. Murphey. Dept. of Biol. Sci., SUNY Albany, Albany, N.Y. 12222.

Club-shaped sensilla, referred to as clavate hairs, have previously been shown to provide the cricket (Acheta domesticus) with equilibrium information regarding its orientation in the gravity field. Each clavate sensillum is innervated by a single sensory neuron which projects to the cercal glomerulus of the last abdominal ganglion (Murphey, Neurosciences Abstract #841, 1979). These sensory neurons form a somatotopic projection in the cercal glomerulus. A major goal of this study was to correlate the dendritic distribution of the identified positional interneuron with the afferent patterning from the clavate sensory receptors. A bilaterally symmetric pair of interneurons in the terminal ganglion was identified and shown to receive their primary afferent input from the clavate sensory cells. We impaled and filled these interneurons with cobalt-chloride. The soma is located ventrally and found at the anterior lateral margin of the terminal ganglion contralateral to its axon and main dendritic processes. The anteriorly projecting axon has been filled to the meso-thoracic ganglion, where it gives off a single collateral within each ganglion. The major dendrites outline the anterior boundaries of the cercal glomerulus and serial reconstructions in transverse section show that the dendritic branches occur in regions of the neuropil corresponding to areas where the clavate afferents terminate.

Physiological characterization of the interneuron was carried out by intracellular recording from the soma. The interneuron response properties were recorded as the cerci were displaced with respect to the animal's body. When the cerci were held in the normal horizontal position there was a low level of baseline spike activity. When the cerci were deflected upwards from this position (analogous to pitch forward) the interneuron was transiently hyperpolarized and no activity was observed invading the soma. With downward deflection of the cerci (analogous to pitch back) a small, tonic depolarization was observed with an increase in frequency of passively invading spikes superimposed on the excitatory postsynaptic potential. During this movement an initial transient dynamic component was observed which decreases to a tonic level of excitation above the baseline level. We are currently examining the connectivity diagram further by selectively deleting various hairs in an attempt to correlate the now well-described afferent projection with the structure and response properties of the postsynaptic neuron. Supported by NIH grant NS 15571 to RKM.

4.12 COMPETITIVE INTERACTIONS AND THE FORMATION OF A SOMATOTOPIC MAP IN AN INSECT. W.W. Walthall and R.K. Murphey. Dept. of Biol. Sci., SUNY Albany, Albany, N.Y. 12222.

Clavate hairs exist in rows which run approximately parallel to the longitudinal axis of the cercus. Each hair is innervated by a single peripheral sensory neuron. All of the axons from cell bodies within a row project to the same general target area in the CNS. Within this target region there exists a gradation in arbor size: the older more distal neurons have arbors which extend into more anterior regions of the target, while younger, more proximal neurons have arbors which are restricted to more posterior areas. Thus, the central projection of a clavate neuron reflects its cell body's position along the proximo-distal axis of the cercus. We have asked whether competitive interactions between neighboring neurons play a role in the construction of this map? To answer this we forced the regeneration of proximal neurons in the absence of their more distal neighbors. Our experimental paradigm was to cut off all of the cercus just distal to the clavate array and then make a notch deletion removing the five most distal clavate hairs in a row. At the same time the cercal nerve was cut at the junction between the cercus and the abdomen, thus forcing axonal regeneration from this point. The result is that proximal neurons regenerate arbors into more anterior regions of the target. They do not normally project to this area, presumably because they are excluded by the presence of their more distal neighbors. Three types of controls were carried out: nerve cut only, to see if regeneration is orderly; notch deletion without nerve cut to see if regeneration is necessary for expansion; and punctate deletions of clavate hairs leaving more distal components intact, to see if smaller deletions provide the necessary impetus for expansion. In these controls no expansion of the arbors was observed. These results demonstrate that expansion of insect sensory neurons into foreign regions of neuropil can occur, but only when the axon is forced to regenerate into a partially deafferented target. We suspect that this expansion is functionally significant, increasing the synaptic efficacy of proximal neurons and intend to test this physiologically.

Supported by NIH grant NS15571 to R.K.M.

5.1 SYNAPSE FORMATION BY REGENERATING PREGANGLIONIC SYMPATHETIC AXONS IN NEONATAL RATS. A. J. Smolen, L. Wright and T. Lindley*
Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

We have reported that section of the cervical sympathetic trunk (CST) in rats on postnatal day 3 results in some regeneration of the cut axons which form synapses in the superior cervical sympathetic ganglion (SCG). Since there was considerable variability in the numbers of synapses in reinnervated ganglia, we hypothesized that there may be a variable amount of regeneration of cut axons which is responsible for this synaptic variability. The present series of experiments was designed to test this hypothesis.

The left CST was cut approximately 1-2mm caudal to the SCG in neonatal rats on either day 0 (the day of birth) or day 3. The proximal and distal stumps were replaced in a position medial to the common carotid artery, but no special effort was made to approximate the cut ends. After a survival of three months (previously shown to be sufficient for regeneration and synapse formation) the left SCG and its CST were removed and processed for electron microscopical observations. Counts were made of total numbers of axons in the CST and synapses in the SCG.

As reported previously, sectioning the CST on postnatal day 3 resulted in the establishment of approximately one-half the normal number of ganglion synapses (2.5×10^6 in operated animals vs. 4.4×10^6 in controls). Counts of axons revealed that about one-half of the normal number of axons were present in the CST (2600 in operated animals vs. 5900 in controls). Sectioning the CST on the day of birth resulted in the establishment of fewer synapses in the SCG (mean of 1.1×10^6). In this group of animals, the number of axons found in the CST was also greatly reduced (to a mean of 800). Within each age group, the number of ganglionic synapses was correlated with the numbers of axons in the CST.

We have shown that sectioning the CST in neonatal animals results in incomplete regeneration of the preganglionic axons which were cut. The later that the nerve is cut, the less severe is the loss of preganglionic axons. This suggests that the preganglionic neurons may be more susceptible to axotomy-induced direct retrograde cell death, and this susceptibility diminishes during maturation. Thus, the number of ganglionic synapses formed appears to be determined by the number of axons which survive to regenerate into the SCG and not by the number of available target postganglionic neurons.
Supported by NIH grants NS 15952 and NS 07061.

5.2 EFFECTS OF NEONATAL TREATMENT WITH TESTOSTERONE ON MATURATION OF PRE- AND POSTGANGLIONIC SYMPATHETIC NEURONS. Linda L. Wright, and Arnold J. Smolen. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA. 19129

Evidence from studies of reinnervation of the superior cervical ganglion (SCG) following section of the preganglionic nerve suggests that there may be a limit to the number of synapses formed by each preganglionic axon (e.g.Ostberg et al. '76). In these studies in the adult rat a loss of preganglionic axons is correlated with a reduction of synapses in the ganglion, and the presence of unoccupied postsynaptic densities. Thus, the reduced numbers of preganglionic axons cannot expand to reinnervate all of the potential postsynaptic sites in the ganglion. Synaptic recovery is also incomplete after neonatal preganglionic section (Smolen, '81). To the extent that reinnervation mimics normal development, these results suggest that the number of preganglionic axons, not the number of ganglion neurons is the limiting factor in the number of synapses formed in the ganglion (see Smolen et al., this volume). We have tested this hypothesis during normal development by determining whether the numbers of synapses are altered when the numbers of ganglion neurons is increased. Testosterone propionate (TP) has been shown to increase neuron numbers in the rat SCG (Dibner and Black,'78), presumably by increasing endogenous levels of Nerve Growth Factor (NGF) and thereby preventing normal cell death. TP (80mg/kg) or vehicle was administered on alternate days from birth to the time of sacrifice on day 15. Neuron and synapse counts revealed that at 15 days, when 85-90% of the adult numbers of synapses have been formed (Smolen and Raisman,'80) the number of synapses in the TP treated ganglia do not differ from controls, even though the number of ganglion neurons is increased by 30%. This result supports the hypothesis that preganglionic axons have a limited synaptic capacity even during the early postnatal period when synaptogenesis normally occurs. The increased numbers of neurons and normal numbers of synapses suggests that either each ganglion cell receives fewer synapses, or that the neurons prevented from dying by the TP treatment are defective in some way and do not receive synaptic input.

5.3 SELECTIVE CHANGES IN BRAIN SYNAPSE NUMBER ESTIMATED WITH ANTIBODIES TO A POSTSYNAPTIC DENSITY COMPONENT. M.Nieto Sampedro*, C.M. Bussineau* and C.W.Cotman. Dept. Psychobiol., Univ. Calif., Irvine, CA 92717.

Antibodies to molecules present only in the synaptic region of the neuron should be extremely valuable tools in the study of developmental and reactive synaptogenesis. Brain postsynaptic densities (PSDs) contain at least one such antigenic junctional marker, a protein of mol.wt. 95000 (antigen PSD-95). Antibodies raised in rabbits against highly purified PSDs react predominantly (85-90 %) with PSD-95 in SDS-gel electrophoregrams of membrane fractions from rodent brain. By electron microscopy, immunoreactivity is restricted to the PSD, whereas by light microscopy, the three-layer peroxidase-antiperoxidase method (PAP) shows specific staining only in those areas known to contain synapses. Antigen PSD-95 is highly conserved during evolution as it is present in synaptic junctions from the brain of all vertebrate species examined from elasmobranchs to mammals.

Antibodies to PSD-95 can be used in the quantitative estimate of loss and recovery of PSDs during reactive synaptogenesis. This was performed either by microdensitometry of brain slices after immunostaining by the PAP method of by determination of radioactivity in select zones of brain slices after treatment with anti-PSD antibody followed by [^{125}I]protein A. Three days after unilateral ablation of the rat entorhinal cortex, 35-50% of the immunoreactivity was lost in the outer molecular layer of the dentate gyrus ipsilateral to the lesion whereas the inner molecular layer was not affected. Lost immunoreactivity was recovered beginning 10 days post-lesion, in agreement with quantitative electron microscopic studies (Matthews et al., Brain Res.115:121, 1976). Fimbria transection, on the other hand, did not reduce the anti-PSD immunoreactivity in the lateral septal nucleus in agreement with the loss of synapses but conservation of PSDs reported by Raisman and Field (Brain Res. 50:241-264,1973).

These results indicate that antibodies to specific synaptic markers can be used in the rapid quantitative study of changes in synapse number following experimental lesions. Similar determinations should be possible during developmental synaptogenesis, degenerative changes during aging or as a consequence of illness and, perhaps, as a correlate of some types of learning and experience. Supported by grants NS08957 from NIH and AG00538 from NIA.

5.4 Evidence For the Innervation of the Rat Pineal Gland During Late Fetal Development. Anthony Altar*, Tom Motroni*, and Loy D. Lytle (SPON: Harry J. Carlisle). Laboratory of Psychopharmacology, University of California, Santa Barbara, CA 93106.

Previous findings (Altar et al, Fed. Proc. 40: 250, 1981; Yuwiler et al, Am. J. Physiol. 233: 141, 1977) have shown that post-synaptic beta-noradrenergic receptors controlling pineal gland n-acetyltransferase activity (NAT) appear relatively early in development and before the gland has received complete innervation by sympathetic nerve terminals. It has yet to be shown, however, at what age these nascent receptors first become innervated by noradrenergic sympathetic fibers. Catecholamine histofluorescence of the rat pineal gland on the day of birth reveal sympathetic nerves which penetrate the pineal capsule but mainly appear to reside on the surface of the gland (Hakanson et al, Life Sci., 6: 2577, 1967). The present study attempted to determine the age at which pineal gland presynaptic nerve terminals first make functional connections with beta-noradrenergic receptors by incubating pineal glands from rats of various ages with d-amphetamine or l-isoproterenol, sympathomimmetic amines which depend upon pre- or post-synaptic components, respectively, to increase pineal NAT enzyme activity.

Pineal glands from fetuses obtained 19 or 20 days post-conception or from rats 0, 2, 10, or 50 days of age were placed into in vitro organ chambers. Glands were stimulated with either the vehicle or with 10^{-5} M (prenatal pineals) or 10^{-6} M (postnatal pineals) d-amphetamine or l-isoproterenol for 4 hr. Following incubation, pineal glands were assayed for NAT activity according to the procedure of Deguchi and Axelrod (Anal. Biochem. 50: 174, 1972). NAT activity was expressed as nmoles of end product, n-acetyltryptamine, formed per pineal gland per hr.

Daytime NAT activity was relatively low late in gestation, increased after birth to attain a maxima by ten days of age, and declined to a low baseline by 50 days of age. L-isoproterenol markedly increased NAT as soon as 19 days post-conception and, with increasing age, produced successively larger NAT increases. In contrast, relatively high concentrations of d-amphetamine failed to increase pineal NAT 19 or 20 days post-conception. By the day of birth and thereafter, however, NAT was markedly elevated by d-amphetamine.

These results show that the post-synaptic beta-receptor agonist l-isoproterenol stimulates pineal NAT at least 2 days before the presynaptically acting drug, d-amphetamine, is capable of increasing NAT. Thus, functional innervation of the pineal gland by sympathetic, noradrenergic nerve terminals appears to occur during the last 2 days of gestation and after the functional development of post-synaptic beta-noradrenergic receptors. Supported by NIMH grant MH-31134 to LDL and by NIDA predoctoral fellowship award DA-05136 to AA.

5.5 INITIAL SYNAPTIC TRANSMISSION AT THE GROWTH CONE IN XENOPUS NERVE-MUSCLE CULTURES. Y. Kidokoro and E. Yeh.* The Salk Institute, P.O. Box 85800, San Diego, Ca. 92138.

Early events in the formation of the neuromuscular junction have been studied in cell cultures where component cells are clearly visible under a light microscope. Synaptic transmission occurs shortly after nerve-muscle contact, even prior to acetylcholine receptor accumulation to the nerve contact area. We have examined initial synaptic transmission at the growth cone-muscle contact in Xenopus nerve-muscle cultures. The approaching growth cone was observed while the membrane potential of its target muscle cell was continuously monitored. Nerve-evoked synaptic potentials were measured shortly after a growth cone contacted the muscle membrane. The interval between the initial contact of growth cone with muscle membrane and the onset of synaptic transmission was estimated as approximately 8 minutes. Fluctuation of the endplate potential amplitude was analysed by using binomial statistics. It seems that transmitter release at the growth cone occurred in a quantal fashion.

5.6 SYNAPTOGENESIS IN THE DENTATE GYRUS OF PRIMATES: QUANTITATIVE EM STUDY IN RHESUS MONKEY. M.F. Eckenhoff and P. Rakic. Sect. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT. 06510.

The dentate gyrus of 13 rhesus monkeys of embryonic (E) days E71, E73, E75, E78, E91, E110, E130, E149, birth (E165) and postnatal (P) days P34, P64, 10 months and adult were prefused by mixed aldehyde fixative and processed for electron microscopy. Quantitative analyses were conducted using 4-8 EM probes/animal. Each probe consisted of 10-25 consecutive overlapping electron micrographs taken across the full width of the molecular layer of the suprapyramidal (SPL) and infrapyramidal (IPL) limbs. The number of synapses/μ^2 within the inner, middle and outer third of the molecular layer and the density of asymmetrical (ASS) and symmetrical synapses (SS) were determined for each age.

No synapses are present at E71. An occasional synapse can be detected at E73 and E75 but their distribution was quantified only by E78 when their density became measureable. In the IPL, the density of synapses increases rapidly during the second half of gestation and reaches a peak of $0.132/\mu^2$ at birth (66X the number at E78). Although the SPL at E78 contains significantly greater numbers of synapses than the IPL, its peak of synaptic density is also achieved by birth ($0.117/\mu^2$ or 26X the number at E78). The synaptic density levels off after birth; we found no significant density differences between the newborn and adult in either limb although the total number of synapses increases after birth since the hippocampal area continues to grow.

Synaptic densities are similar throughout the inner, middle and outer thirds of the molecular layer of the IPL and SPL although each third receives different inputs. Furthermore, both limbs showed no significant differences in the number of ASS and SS between E78 and E110. However, in the IPL the density of ASS increases 84X from E78 ($0.0015/\mu^2$) to birth and thereafter remains constant, whereas the number of SS increases more gradually (24X) from E78 to E149 ($0.012/\mu^2$) and then decreases to relatively low levels in the adult ($0.002/\mu^2$). In the SPL, the density of ASS increases 40X from E78 ($0.0027/\mu^2$) to birth without significant change thereafter. The number of SS increases more gradually (7X) from E78 to E149 ($0.013/\mu^2$) and then decreases to low levels in the adult ($0.002/\mu^2$).

In summary: (a) Synaptogenesis in the primate hippocampus occurs at considerably earlier embryonic ages than in rodents. (b) There is a biphasic progression of synaptogenesis with a rapid increase from E78 to birth, after which the density levels off. (c) ASS and SS terminals have distinct tempos of development. (d) At early stages synaptogenesis is more robust in the SPL than in the IPL. (e) Time of origin of neurons that form afferents to the molecular layer do not correspond to the sequence of synapse formation. (Supported by NS14841).

6.1 MULTIPLE SEROTONIN RECEPTORS DISCRIMINATED BY ANALOGUES OF 5-METHOXYTRYPTAMINE.[1] M.H. Smit*[a,b], R.L. Glennon*[c], H.I. Yamamura [b,2], and D.L. Nelson.[a] [a]Dept. of Pharmacol. Toxicol., Sch. of Pharm., [b]Dept. of Pharmacol., Sch. of Medicine, Univ. of Arizona, Tucson, AZ 85721; and [c]Department of Pharm. Chem., Sch. of Pharm, Med. Col. of Virginia, Virg. Commonwealth Univ Richmond VA 23298

Evidence has accumulated suggesting the functional presence of multiple serotonin(5-HT) receptors. Ligand-binding studies have revealed a group of high-affinity binding sites (Kd=1-4 nM) for (^{3}H)5-HT on rat brain membranes which this laboratory has previously differentiated into two subpopulations, based on their differential affinities for the neuroleptic spiperone. We are now able to report receptor discrimination using specific analogues of 5-HT. The following compounds were analyzed for their ability to inhibit the binding of [^{3}H]5-HT to its high-affinity sites: 5-methoxy-N,N-dimethyltryptamine [5(MeOH)DMT], 5-methoxy-N,N-diethyltryptamine [5(MeOH)DET], and 5-methoxy-N,N-dipropyltryptamine [5(MeOH)DPT]. Radioligand-binding studies were carried out on a washed membrane preparation from the rat cerebral cortex. Membranes from 10 mg of tissue were incubated in buffer (50 mM Tris-HCl, pH 7.4; 4 mM $CaCl_2$; 10 µM pargyline) containing 2 nM [^{3}H]5-HT and varying concentrations of inhibitor. Bound ligand was isolated by vacuum filtration, and nonspecific binding was defined in the presence of 1 µM metergoline or 0.3 µM 5-HT. All three 5-methoxytryptamines displaced (^{3}H)5-HT from its binding sites in a manner consistent with the presence of more than one type of site. The inhibition curves were shallow, extending over more than a 10,000 fold range of concentrations for the inhibitors and displayed Hill coefficients of less than 1.0. Non-linear regression analysis revealed that each compound fit a two-site model. There was a correlation between their discriminatory behavior and the length of the alkyl substitution. The dissociation constants of the compounds for the high- and low-affinity sites were as follows:

	HIGH	LOW
5(MeOH)DMT	10 nM	500 nM
5(MeOH)DET	15 nM	1000 nM
5(MeOH)DPT	10 nM	1750 nM

The difference in affinity between 5(MeOH)DMT and 5(MeOH)DPT was significant ($p<.05$). These results further support the concept of multiple 5-HT receptors. It is hoped that additional characterization of the structural requirements for fit to these different sites will result in the design of more specific 5-HT agonists and antagonists to aid in the elucidation of the physiological significance of multiple serotonin receptors in the brain. ([1]Supported by grants from the PMA Foundation and the Col. Pharmacy, U. Ariz. [2]Recipient of an RSDA Type II #MS-0095.)

6.2 TISSUE AND SPECIES DIFFERENCES IN ^{3}H-5-HYDROXYTRYPTAMINE BINDING SITES. R.G. Schnellmann* and D.L. Nelson (SPON: B. Schneiderman Fish). Dept. of Pharmacol. & Toxicol., Col of Pharmacy, Univ. of Arizona, Tucson, AZ 85721.

Previous studies have identified two populations of high-affinity (Kd=1-4 nM) ^{3}H-serotonin (^{3}H-5-hydroxytryptamine, ^{3}H-5-HT) binding sites in rat brain which can be distinguished on the basis of their affinities for certain neuroleptics.** Thus, one of these subgroups of sites gave a Kd for spiperone of 2-13 nM and the other a Kd of about 35,000 nM. The present report extends these studies by examining spiperone-sensitive ^{3}H-5-HT binding sites in several different species (rabbit, guinea-pig, and cat) and tissues (frontal cortex, hippocampus, and corpus striatum or caudate nucleus). Saturation studies of ^{3}H-5-HT binding revealed no differences in the affinity of this ligand for its binding sites in any of the species or tissues studied. Kd values for rabbit, guinea-pig, cat and rat ranged from 2.4-2.9 nM. Some small differences were noted in the total number of sites present in tissues from the different species. Examination of spiperone inhibition of ^{3}H-5-HT binding revealed large differences between the species and tissues with IC_{50} values ranging from a low of 87 nM in the guinea-pig hippocampus to 8900 nM in the cat corpus striatum. A heterogeneity of sites was suggested from the finding that logit-log plots of the inhibition curves gave slopes of less than 1.0. Nonlinear regression analysis with computerized curve fitting showed that the inhibition curves for most of the tissues fit a two-site binding model significantly better than a one-site model, as had been shown in the rat brain. However, the affinities for these sites differed from those in the rat. For example, in the guinea-pig the ^{3}H-5-HT binding site having high affinity for spiperone gave Kd values for spiperone in the range of 3-30 nM which were comparable to those described for the rat, but the low-affinity sites gave Kd values which ranged from 400-1300 nM, i.e., at least 25 times lower than the values for the low-affinity site in the rat. Of all the brain areas studied in the different species only 2 gave spiperone inhibition curves which resembeled those found in the rat. These were cat frontal cortex and corpus striatum which gave Kd values of 5-21 nM for the high-affinity spiperone site and 52,000 nM for the low-affinity site. In contrast, cat hippocampus gave Kd values for the high-affinity site of 820-1400 nM which agreed with the values found in the guinea-pig and rabbit. Thus, while the current data agree with the concept of multiple ^{3}H-5-HT binding sites, the classification of these sites is more complex than originally determined in the rat and requires further examination. (Supported by grants from the PMA Fnd. and the Col. of Pharmacy, Univ. AZ.) **Pedigo et al, J. Neurochem. 36:220-226, 1981.

6.3 DETAILED LOCALIZATION OF 5-HYDROXYTRYPTAMINE$_2$ RECEPTORS INVESTIGATED WITH ^{3}H-KETANSERIN, A NEW SELECTIVE LIGAND. J.E. Leysen, M. Verwimp*, R. Geerts*, W. Gommeren* and P.M. Laduron*. Department of Biochemical Pharmacology, Janssen Pharmaceutica, B-2340 Beerse, Belgium.

Ketanserin (R 41 468) is a new 5-hydroxytryptamine (5-HT) antagonist which binds primarily to 5-HT$_2$ receptors and completely lacks interaction with 5-HT$_1$ receptors (Leysen *et al.*, 1981 a). In contrast to previously described ^{3}H-5-HT antagonists, ^{3}H-ketanserin exclusively labels 5-HT$_2$ receptors. Its advantageous binding properties (Leysen *et al.*, 1981 b) renders ^{3}H-ketanserin particularly suitable for investigating the localization of 5-HT$_2$ receptors by *in vitro* and *in vivo* binding. The distribution in the brain and the periphery of specific ^{3}H-ketanserin binding sites studied *in vitro* and *in vivo* in various species shows that the highest receptor density occurs in the prefrontal cortex followed by surrounding cortical areas. Other brain areas and peripheral tissues contain only minor amounts of the receptors. Using neuronal lesions and intracerebral injection techniques the cellular localization and functional role of the frontal cortical 5-HT$_2$ receptors were studied. Hemisection of the frontal cortex by a knife cut just before the tuberculum olfactorium caused 20 to 30 % reduction of the 5-HT$_2$ receptors in the prefrontal cortex anterior to the knife cut, receptors in the cortical areas posterior to the cut were not changed. Hence, part of the receptors seemed to be localized on neurones projecting to the prefrontal cortex. The origin of such neurones was examined by applying electrolesions in various brain areas and by injection of ^{3}H-ketanserin in the prefrontal cortex to verify retrograde axonal transport. Injection of kainic acid in the prefrontal cortex had no noticeable effect on the 5-HT$_2$ receptor population. The possibility exists that a number of the prefrontal cortical 5-HT$_2$ receptors are not located on neurones.

J.E. Leysen, M. Verwimp and P. Laduron (1981 b). Receptor binding properties of ^{3}H-R 41 468, a selective ligand for 5-hydroxytryptamine$_2$ receptors. Abstract - Eight International Congress of Pharmacology - July 1981, Tokyo, Japan.

6.4 SOLUBILIZATION AND PARTIAL PURIFICATION OF ^{3}H-MIANSERIN BINDING SITES. Betty CHAN*, Philip SEEMAN, Anne DUMBRILLE-ROSS and Bertha K. MADRAS (SPON: P. Garfinkel). Psychopharmacology Section, Clarke Institute of Psychiatry and Department of Pharmacology, University of Toronto, Toronto, Ontario, Canada.

The atypical antidepressant mianserin has been shown to bind to S_2 serotonin receptors in cortical tissue (Dumbrille-Ross et al.; Peroutka and Snyder, 1981). ^{3}H-Mianserin has high affinity for the S_2 site although ^{3}H-spiperone is currently used to identify S_2 receptors in non-dopaminergic regions. Purification of ^{3}H-mianserin and ^{3}H-spiperone receptive sites may provide further evidence for their co-existence. ^{3}H-Mianserin receptive sites were solubilized from canine frontal cortex, characterized and partially purified. Binding parameters (drug binding profiles, IC_{50}, K_d) of the membrane and solubilized receptor agreed closely.
R41468 was used to define specific binding.

	IC_{50} (nM) Membrane	Soluble
mianserin	1.3 ± 0.2	4 ± 1
R43448	2.4 ± 0.9	8.4 ± 4
R41468	57 ± 15	64 ± 10
metergoline	125 ± 7	--
d-LSD	206 ± 14	2,150 ± 500
l-LSD	--	35,000 ± 5,000
spiperone	315 ± 70	1,150
haloperidol	867 ± 133	5,700 ± 900
serotonin	7,000	24,000 ± 2,000
tryptamine	45,000	45,000 ± 15,000
histamine	>100,000	>300,000
dopamine	>100,000	>300,000
epinephrine	>100,000	>200,000
norepinephrine	>100,000	>100,000
K_d (nM)	1.1 ± 0.4	2.2 ± 0.5
B_{max} (fmoles/mg)	212 ± 12	95 ± 6

The receptor recovery was 45% whilst protein recovery was 41%. The solubilized receptive site, which yielded a single component on Scatchard analysis was prelabeled with ^{3}H-mianserin and partially purified. Bound ^{3}H-mianserin separated from unbound ^{3}H-mianserin as a single peak on both Sephacryl S-300 columns and on isoelectric focusing columns (pI 5.03 ± 0.16). Both peaks are displaceable by R41468 (1 µM). The same techniques are now being applied to ^{3}H-spiperone binding sites in the frontal cortex and a comparison of both purified preparations is in progress.

6.5 N-ACETYLSEROTONIN BINDING IN HUMAN, CALF AND RAT BRAIN. L.P. Niles*, G.M. Brown and R.K. Mishra*. Neuropharmacology Lab., Depts. Psychiatry & Neurosciences, Faculty of Health Sciences, McMaster Univ., Hamilton, Ontario, Canada, L8N 3Z5.

Prompted by the reported presence of N-acetylserotonin (NAS) and its synthesizing enzyme, N-acetyltransferase, in the rat brain we have studied the binding of NAS in the mammalian CNS in order to determine whether specific central receptors for this N-acetylindolealkylamine exist. Specific binding of H-N-acetylserotonin (^{3}H-NAS) defined as total bound radioactivity minus that not displaced by an excess of non-radioactive NAS was found in synaptosomal membrane fractions from various regions of human, calf and rat brain. Scatchard analysis of equilibrium binding data revealed the presence of saturable high affinity binding sites with dissociation constant (K_D) values ranging from 2-7 nM and binding site concentration (B_{max}) of 0.3-1.25 pmol/mg protein.

Localization studies indicate that cerebellar binding of ^{3}H-NAS exceeds that observed in other brain areas including the hypothalamus, hippocampus, striatum and cortex. Specific binding of ^{3}H-NAS has also been detected in the adrenal, testis, eye and Harderian gland. Initial displacement data indicate that NAS is a more potent inhibitor of ^{3}H-NAS binding than the related tryptamines melatonin, serotonin (5-HT) and N-acetyltryptamine. Furthermore, neither the 5-HT antagonist, methysergide, nor the 5-HT agonist, quipazine are potent displacers of ^{3}H-NAS binding.

These findings are the first evidence that specific high affinity binding sites for NAS are present in the mammalian brain and suggest that specific receptors for NAS may exist in the CNS.

(This work was supported by the Ontario Mental Health Foundation)

6.6 THE CHARACTERISTICS OF ^{3}H SEROTONIN BINDING IN RAT SPINAL CORD TISSUE. P.J. Monroe* and D.J. Smith, Depts. of Pharmacology/Toxicology and Anesthesiology, W.V.U.M.C., Morgantown, WV 26506.

Two distinct serotonin (5-HT) receptor subtypes have been reported in the rat frontal cerebral cortex (Peroutka and Snyder, Mol. Pharmacol 16, 1979). One site (5-HT$_1$ receptor) has a high affinity for ^{3}H-5HT while the other site (5-HT$_2$ receptor) binds ^{3}H-spiroperidol preferentially. In the present study the existence of a similar multiple 5-HT receptor system in rat spinal cord tissue was examined.

A membrane fraction was prepared from either rat frontal cortex or spinal cord according to the method of Peroutka & Snyder (see reference). Binding assays for ^{3}H-5HT were carried out with these membranes at 37°C for 20 min, using 800 µl of tissue suspension (20 mg of tissue/tube), 100 µl of ^{3}H-5HT and 100 µl of drug. Tubes for ^{3}H-spiroperidol binding contained 10 mg tissue and were incubated for 15 min. After the incubation, the tissue was collected on Whatman GF/B filters. The filters were then counted in Hydromix after a 5 hour extraction.

A ^{3}H-5HT binding site could be identified in both spinal cord and frontal cortex tissues. The ratio of specific to total binding was higher in the cortex than in the spinal cord. Values were consistently 60-70% and 35-40%, respectively, when the radioligand was purified, prior to its use, by high performance liquid chromatography. Scatchard analysis of the specific ^{3}H-5HT binding in the spinal cord gave a linear plot yielding a K_D of 9.4 nM and a B max of 5.7 p moles/g. Specifically bound ^{3}H-5HT in the spinal cord could be displaced by unlabeled 5-HT in a similar concentration-dependent manner as in the frontal cortex (50% displacement concentration: 5 nM in spinal cord, 8 nM cortex). Spiroperidol also displaced ^{3}H-5HT but only at concentrations exceeding 10 nM with an apparent 50% displacement concentration of 4 µM. These data agree well with the results obtained by Peroutka and Snyder. However, in contrast to their observations in the rat frontal cortex, there appears to be a lack of saturable ^{3}H-spiroperidol binding in rat spinal cord tissue. Total ^{3}H-spiroperidol binding increased linearly with increasing ligand concentration and was not displaced by either unlabeled spiroperidol or 5-HT, suggesting non-specific interactions. The effectiveness of the two drugs and reletive potencies in displacing ^{3}H-spiroperidol from frontal cortex, where a saturable binding site has been shown to exist, was confirmed.

In conclusion, these results suggest the existence of a 5-HT binding site analogus to the 5HT$_1$ receptor in frontal cortex tissue, but an apparent lack of a putative 5HT$_2$ binding site as distinguished by ^{3}H-spiroperidol.

Supported by W.V.U. Anesthesia Research Fund.

6.7 THE ANTIDEPRESSANT RECEPTORS. A. Dumbrille-Ross* and S.W. Tang. Psychopharmacology Section, Clarke Institute of Psychiatry, Toronto, Ontario, Canada M5T 1R8.

In order to examine whether there is a common antidepressant receptor to which antidepressant drugs bind, we examined the binding characteristics of ^{3}H-imipramine (^{3}H-IMI), ^{3}H-desipramine (^{3}H-DMI) and ^{3}H-mianserin (^{3}H-MIAN) to cerebral cortex membranes and platelets of Wistar and Fawn-Hooded (F-H) rats under a number of conditions. [Platelets of F-H rats have a serotonin (5HT) storage pool deficiency and display an abnormally low accumulation of 5HT.]

Binding characteristics are listed below.

1. Binding of ^{3}H-IMI to cortex membranes was potently displaced by serotonin uptake inhibitors like fluoxetine and citalopram (IC_{50} about 20 nM), and displaced by high concentrations (IC_{50} 2-4 µM) of serotonin S_2 antagonists like spiperone and R43 448. Binding of ^{3}H-MIAN was potently displaced by serotonin S_2 antagonists (IC_{50} about 40 nM) and by high concentrations of the uptake inhibitors (IC_{50} 1-2 µM), showing a profile similar to that of ^{3}H-spiperone binding.
2. Antidepressant drugs compete with very different potencies with both ^{3}H-IMI and ^{3}H-MIAN binding.
3. Binding of ^{3}H-IMI but not ^{3}H-MIAN is sodium dependent.
4. Raphé lesions abolished binding of ^{3}H-IMI but did not alter binding of ^{3}H-MIAN to cortex membranes.
5. ^{3}H-IMI but not ^{3}H-MIAN binds to platelet membranes of Wistar rats. But ^{3}H-IMI binds to neither platelet nor cortical tissue of F-H rats. Binding of ^{3}H-MIAN is similar in the cortex of Wistar and F-H rats. (The binding of the two antidepressants to platelets and cortex membranes will be compared with that of other serotonergic ligands.)
6. There is no high affinity binding site demonstrable for ^{3}H-DMI in cortex membrane preparations examined under similar conditions.

The results show that ^{3}H-IMI and ^{3}H-MIAN label different sites while ^{3}H-DMI failed to bind to membrane surface receptors with high affinity. It is unlikely that there is a "common antidepressant receptor" to which all antidepressants bind in the CNS or platelets.

6.8 DENERVATION SUPERSENSITIVITY OF THE BULBOSPINAL SEROTONIN SYSTEM: 5-HT$_1$ RECEPTOR BINDING AND FUNCTIONAL DATA. Fredrick Sautter*, Lee-Ming Kow, Donald W. Pfaff and Frank P. Zemlan. The Rockefeller University, N.Y., N.Y. 10021 and Dept. of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

The present data demonstrate: 1) a functional denervation supersensitivity of the spinal cord serotonin (5-HT) system, indicated by shifts to the left of the 5-HT agonist dose-response curves for facilitation of spinal reflexes and 2) a "supersensitivity" of spinal 5-HT$_1$ receptors, indicated by increased specific high affinity binding of ^{3}H-5-HT after denervation.

The effects of 5-HT and alpha-noradrenaline (NA) receptor agonists on the receptive field (RF) area and response magnitude of spinal reflexes elicted from the lumbar dorsum were examined from 6 hrs to 3 wks after spinal transection (T_{10}) in the rat. A dose-response related increase in reflex RF area and response magnitude was observed after administration of the 5-HT agonists quipazine (0,5,10 & 20 mg/kg) and 5-MeODMT (0,0.1,0.5 & 2.0 mg/kg) for all spinal reflexes examined across the entire postoperative period, while NA agonists were without effect. An observed shift to the left in the 5-HT agonist dose-response curves with time after transection indicated a functional denervation supersensitivity of the spinal 5-HT system which could be demonstrated as soon as 1 to 2 days postoperatively.

The effect of spinal cord transection (T_{10}) or sham operation on specific ^{3}H-5-HT (2nM) binding to membranes prepared from the lumbar enlargement was examined 0, 1, 2 and 7 days postoperatively. Seven days after transection ^{3}H-5-HT binding (64.3 ± 3.7 fmoles/mg protein) was elevated when compared to the sham control group (47.1 ± 2.6 fmoles/mg protein). Scatchard analysis (0.5 to 16 nM ^{3}H-5-HT) revealed that the maximum number of ^{3}H-5-HT binding sites (B_{max}) was significantly greater ($p<0.01$) 7 days after transection while no change in the apparent 5-HT receptor affinity constant (K_D) was found (transected: B_{max} = 199 ± 19 fmoles/mg protein, K_D = 2.2 ± 0.2 nM, sham: B_{max} = 107 ± 15 fmoles/mg protein, K_D = 1.2 ± 0.2 nM for 4 experiments performed in triplicate).

The present data suggest that the functional supersensitivity observed 7 or more days after denervation may have been due to an increase in the number of spinal 5-HT receptors, while the functional supersensitivity found beforehand was probably due to presynaptic mechanisms altered by axotomy.

6.9 EFFECTS OF CHRONIC AMPHETAMINE TREATMENT ON SEROTONIN RECEPTORS. G. Battaglia* and M. Titeler (SPON: J. Khanna). Dept. of Pharmacol. University of Toronto, Toronto, Ontario M5S 1A8.

Recent evidence has shown potent effects of chronic amphetamine treatment on the serotonergic systems of the brain (1). Meanwhile, ^{3}H-serotonin (S_1 receptors) and ^{3}H-spiperone (S_2 receptors) have been found to label distinct serotonergic receptor sites in rat brain (2). We decided to investigate the effects of chronic amphetamine treatment on serotonin receptors in rat brain to see if chronic treatment with this drug results in changes in the number or the pharmacological properties of these receptors.

Treated and untreated (control) rats were housed separately and fed ad libitum. Treated rats were given 5 mg/kg/day amphetamine sulphate in their drinking water. After six weeks the rats were decapitated and their cortices and caudates dissected. The caudates were prepared and assayed for dopamine receptors as previously described (3). The cortices were prepared and assayed for serotonin receptors as previously described (4).

Table 1

	Control		Treated	
	K_D (nM)	B_{max} (fmol/mg)	K_D	B_{max} (fmol/mg)
^{3}H-ser (cortex)	0.91 ± .09	129 ± 10 (n=8)	1.3 ± .18	137 ± 7 (n=11)
^{3}H-spip (cortex)	1.2 ± .12	347 ± 38 (n=8)	1.1 ± .13	238 ± 25 (n=11)
^{3}H-spip (caudate)	0.1 ± .01	411 ± 26 (n=15)	.07 ± .007	327 ± 14 (n=15)

There were no significant differences between ^{3}H-serotonin binding in treated and untreated rat cortices, whereas there was a 31% decrease in ^{3}H-spiperone binding. In the caudate ^{3}H-spiperone binding was reduced by 20%.

These preliminary results are being extended to varying dosages of amphetamine and to examining the reversibility of the neurochemical effects of chronic amphetamine treatment. This work was supported by a grant from the Hospital for Sick Children Foundation.

6.10 SEROTONIN RECEPTOR LOCALIZATION BY AUTORADIOGRAPHY: QUANTITATIVE ANALYSIS AND THE EFFECT OF STEROID HORMONES. A. Biegon*, T.C. Rainbow and B.S. McEwen, Rockefeller University, New York NY 10021

A modification of the method of Young and Kuhar (Eur. J. Pharmacol. 62:237, 1980) was used to obtain a quantitative analysis of the density of 5HT receptors in rat brain nuclei prior to a study of the effects of steroid hormones on these receptors. Coronal cryostat sections were incubated with 2nM ^{3}H-5HT and placed against tritium sensitive LKB film in the dark for 2 months. The resulting images were analyzed by a densitometer (Rainbow et al., J. Neurosci. Methods, in press) and also subjected to color-enhanced computer analysis. The highest concentrations of 5HT receptor (densitometer readings > 10 units) were found in the anterior hippocampus, subiculum and dentate gyrus, dorsal raphe and the substantia nigra. High values (6-9 density units) were found in the globus pallidus, lateral preoptic area, hippocampal field CA1 and the interpeduncular nucleus. Moderate levels (3-5 units) were found in the nucleus accumbens, medial amygdala, cortical amygdala, arcuate nucleus, bed nucleus of the stria terminalis, olfactory tubercle, superior colliculus, central grey, layer 4 of the cortex, ventromedial and dorsomedial hypothalamus, dorsal tegmental nucleus, n. locus ceruleus and thalamic n. parafascicularis. Low levels (1-3 units) were observed in the cingulate cortex, caudate nucleus, medial habenula, medial preoptic n., median raphe and medial septum. Very low levels were found in hippocampal field CA3, cerebellum, most of the thalamus and all white matter. These data mostly confirm and extend previous reports (Meibach et al., Soc. Neurosci. Abst. 6:357, 1980; Young and Kuhar, cited above). It is noteworthy that most of the brain regions known to concentrate steroids have moderate to high levels of 5HT receptors, and this raises the possibility of an interrelationship between these systems. Thus we are studying the effect of corticosterone on hippocampal 5HT receptors in adrenalectomized rats and the effect of estrogen on 5HT receptors in ovariectomized (OVX) rats. Estradiol benzoate (10µg/day) was injected twice and rats were killed 48h after the second injection; OVX controls received sesame oil vehicle. Estrogen treatment produced an increase in 5HT binding in several estrogen concentrating nuclei: e.g., arcuate nucleus (Control: 3.8±0.2 density units; Estrogen:4.9±0.3; lateral preoptic area near bed nucleus of stria terminalis: 6.2 ± 0.4 vs 7.5±0.3; and ventrolateral septum: 6.4±0.4 vs 9.8±0.4). No change was observed in cortex, caudate, or dorsal raphe nucleus. These results are similar to results of in vitro ^{3}H 5HT binding measurements on homogenates (Fischette et al., This Meeting). Grant support: NSO7080 (BMc), Rockefeller Foundation (RF70095); and by NIMH, MH08055 (TCR) and C. Weizmann (AB) postdoctoral fellowships.

6.11 SEROTONIN RECEPTORS IN ESTROGEN CONCENTRATING BRAIN NUCLEI AND THEIR MODULATION BY ESTRADIOL. C.T.Fischette, A.Biegon* and B.S.McEwen. Rockefeller University, New York, New York 10021

Serotonin (5-HT) receptors have been shown to fluctuate over the estrous cycle in the basal forebrain in intact cycling female rats(Biegon et.al., Brain Res.,187:221,1980). In order to localize the effect of estradiol on these receptors, we have developed a microassay for 5-HT receptor binding in individual brain nuclei. For each of 5 experiments 3 ovariectomized rats were given sesame oil and 3 were given 10µg estradiol benzoate (EB)sc. for 2 days; they were sacrificed 48h after the last injection. Nuclei were removed from frozen 300µm thick coronal sections according to the method of Palkovits et. al.(Brain Res., 77;137,1974) and pooled. Previously described assay procedures (Biegon et.al.,1980) were modified for small samples. Following incubation of the homogenates in 50mM Tris buffer at 37°C, 300µl Tris buffer containing pargyline (10^{-4}M) and ascorbate (0.02%) were added to the homogenates and incubated again for 10min; then, 100µl aliquots were assayed in a final volume of 0.3ml containing 2nM ^{3}H-5HT, with 1µM cold 5-HT used to estimate nonspecific binding. Saturation experiments under these conditions exhibited Kd(1.6nM) and Bmax(170fm/mg pro.) values similar to those previously reported. Binding was linearly dependent on protein concentration from 10-100µg protein.

Moderate to high levels of 5-HT receptor binding were found in all of the estrogen concentrating areas sampled. EB treatment produced a significant (35-50%) increase in 5-HT receptor binding in the preoptic area, lateral septum and arcuate nucleus-median eminence. Non-significant increases were observed in the bed nucleus of the stria terminalis and anterior hypothalamic nucleus. No change was observed in the ventromedial nucleus or corticomedial amygdala. Overall levels of 5-HT receptor binding that were insensitive to EB treatment were very high in the dorsal raphe and substantia nigra, and very low in the ventral thalamus and cerebellum.

The distribution of 5-HT receptors is in agreement with the results obtained by autoradiography (Biegon et.al., this meeting; Meibach et.al., Soc. for Neuroscience, 6:357, 1980). We conclude that EB causes an increase in 5-HT receptor binding in some but not all brain regions which contain estrogen receptors. The specific anatomical localization of the effect may be related to the specific roles of these nuclei in the control of ovulation and/or estrogen-mediated behaviors in the female rat. (Supported by PHS NIH AM06122(CF), Weizmann Postdoctoral Fellowship(AB) and NIH NS 07080(BMc). An institutional grant was also obtained from the Rockefeller Foundation, RF 70095.

7.1 BRAIN D_2 DOPAMINE RECEPTORS: PARTIAL PURIFICATION. Leslie LILLY*, Alan DAVIS, Bertha K. MADRAS, Claire M. FRASER, J. Craig VENTER* and Philip SEEMAN (SPON: P. Brawley). Department of Pharmacology, University of Toronto, Toronto, Canada; Psychopharmacology Section, Clarke Institute of Psychiatry, Toronto; and State University New York at Buffalo, New York, U.S.A.

We used gel chromatography and isoelectric focusing to purify the D_2 dopamine receptors from canine brain striatum. The membrane fraction of the tissue was solubilized in 1% digitonin in phosphate buffer, and the receptors labelled with 4 nM ^{3}H-spiperone. The specific binding was defined as that displaced by 1 μM (+)-butaclamol. The purified preparation was characterized (Madras et al., Soc. Neurosci. Abstr., 1981) and used to raise monoclonal antibodies (Davis et al., Soc. Neurosci. Abstr., 1981).

a. Sephacryl S-300 was used to partly purify the D_2 dopamine receptors. Soluble material, incubated in 4 nM ^{3}H-spiperone and added to a column pre-equilibrated in a phosphate-Triton buffer system, eluted at a volume corresponding to a MW of 220,000 daltons and a Stokes radius of 5.8 nm (N=3). Of the specifically bound fmoles spiperone added to the column, 17 ± 3% were recovered in the peak fraction of the effluent. Concentration of this peak, followed by assay, showed that ^{3}H-spiperone binding was 100% specific in that peak.

b. Using preparative column isoelectric focusing, we focused unlabeled material and assayed each fraction for the presence of D_2 receptors using Sephadex G-50 mini-columns or a polyethylene glycol precipitation method (Chan et al., submitted).

c. We also focused material prelabeled with 4 nM ^{3}H-spiperone alone and in the presence of 1 μM (+)-butaclamol. D_2 receptors were detected by radioactivity in the effluent.

Two peaks of bound ^{3}H-spiperone were obtained in the effluent, with isoelectric points (pI) of 4.93 ± 0.11 (N=13) and 7.76 ± 0.11 (N=9). These peaks were stereoselectively displaced by 1 μM (+)-butaclamol. The peak at 4.9 was always associated with the presence of a visible protein precipitate within the column. (Free ^{3}H-spiperone had a pI value of 11.1). The pH 7.8 fraction represented a 40-fold purification of the D_2 receptors. [Supported by The Medical Research Council of Canada (to PS) grants AHA 79688 and HL 21239 (Nat. Inst. of Health; to CMF & JCV), and NATO/SRC U.K. Fellowship (to AD).]

7.2 PARTIALLY PURIFIED DOPAMINE/NEUROLEPTIC RECEPTORS (D_2-TYPE). Bertha K. MADRAS, A. DAVIS, Leslie LILLY, Claire FRASER, Craig VENTER, Philip SEEMAN. Psychopharmacology Section, Clarke Institute of Psychiatry, Department of Pharmacology, University of Toronto, Toronto, Ontario, Canada; and State University New York at Buffalo, New York, U.S.A.

Solubilized dopamine/neuroleptic receptors (D_2) of canine caudate are stable at 0°C and retain the binding properties of the membrane receptor. Prelabelled (^{3}H-spiperone) soluble receptors were separated by isoelectric focusing into a bound ^{3}H-spiperone fraction (displaceable with (+)-butaclamol) and an unbound ^{3}H-spiperone peak (Lilly et al., Soc. Neurosci. Abstr., 1981). This purified preparation was used to raise monoclonal antibodies (Davis et al., Soc. Neurosci. Abstr., 1981).

Pharmacological characterization of the bound ^{3}H-spiperone peak confirmed that this fraction was the neuroleptic receptor.

Prelabeled soluble receptors were eluted from isoelectric focusing columns as a single peak with a pI of 6.4 ± 0.2. The fractions containing radioactivity were dialyzed overnight and re-labeled with ^{3}H-spiperone (4 nM) in the presence or absence of neuroleptic drugs and dopamine agonists. The recovery of specific - but not total - binding was greater than 82%.

	IC_{50} (nM) Soluble	Purified
Spiperone	3.5 ± 2	2.3 ± 1.3
(+)-Butaclamol	4.6 ± 1	8.0 ± 1.7
Fluphenazine	4.2 ± 1.2	10 ± 0.5
Haloperidol	40 ± 8	58 ± 6
Chlorpromazine	145 ± 15	197 ± 36
(-)-Butaclamol	~10,000	~10,000
Dopamine	5,000 ± 1800	100,000*
Apomorphine	1,650 ± 570	3,800 ± 450
ADTN	950 ± 280	--
Norepinephrine	>100,000	>100,000
Serotonin	>100,000	>100,000

*20% inhibition

The affinity, rank order of potencies of neuroleptics, and stereoselectivity of the site were retained during the focusing procedure.

The reduced affinity of the purified receptor for dopamine could be a consequence of (1) dialysis or buffer conditions; (2) conformational change in the binding site; (3) removal of a dopamine binding cofactor; (4) separation of neuroleptic and dopamine binding sites. These possibilities are being explored.

7.3 MONOCLONAL ANTIBODIES TO PARTIALLY PURIFIED D_2 DOPAMINE RECEPTORS. Alan DAVIS, Claire M. FRASER*, Leslie LILLY*, Bertha K. MADRAS, J. Craig VENTER* and Philip SEEMAN. Department of Pharmacology, University of Toronto, Canada M5S 1A8; Psychopharmacology Section, Clarke Institute of Psychiatry, Toronto; and State University New York at Buffalo, New York, U.S.A.

D_2 dopamine receptors were partially purified and characterized from canine brain striatum by isoelectric focusing (Lilly et al., Madras et al., Neurosci. Abstr., 1981) and used to raise antibodies in mice. Balb/C mice were immunized with a solubilized fraction which was 40-fold enriched in D_2 receptors and which had an isoelectric point of 7.76. After a booster injection, splenic cells from the immunized mice were fused with mouse myeloma SP/O-Ag14 cells, using the method of Fraser and Venter (Proc. Nat. Acad. Sci. 77, 7034-7038, 1980). Spleen and myeloma cells were fused using warm polyethylene glycol 1000. Unfused cells were eliminated by means of selective media, and the fused cells (hybridomas) were grown in 96-well plates. The culture media of active hybridomas were then screened for the presence of antibody to the D_2 dopamine receptor. Membrane preparations of the D_2 receptor were incubated with the culture medium for 18 hr, followed by the addition of 4 nM ^{3}H-spiperone. Specific binding of ^{3}H-spiperone was defined as that displaced by excess (+)-butaclamol. The medium of one hybridoma (D2D3) markedly inhibited specific binding in a concentration-dependent manner.

The hybridoma medium was also screened for its ability to precipitate soluble receptors, using an indirect immunoprecipitation assay. Samples of culture media were incubated with aliquots of digitonin-solubilized receptors for 18 hr, and the receptor-antibody complexes were then precipitated with an excess of rabbit anti-mouse IgG. The supernatant was then assayed for remaining soluble D_2 dopamine receptors, using 4 nM ^{3}H-spiperone and Sephadex G-50 mini-columns. The culture medium from one hybridoma (designated D1D3) effectively precipitated soluble D_2 receptors in a concentration-dependent fashion. At a 1:4 dilution of the D1D3 culture medium, 18.0 ± 3.2 fmoles (N=3) of D_2 dopamine receptors were specifically precipitated. [Supported by The Medical Research Council of Canada (to PS), grant AHA 79688 and HL 21239 (Nat. Inst. of Health; to CMF & JCV), and NATO/SRC U.K. Fellowship (to AD).]

7.4 D_3 AND D_4 DOPAMINERGIC BINDING SITES DETECTED BY ^{3}H-ADTN. Stephen J. LIST and Philip SEEMAN (SPON: Y. Israel). Dept. of Pharmacology, Univ. of Toronto, Toronto, Canada M5S 1A8.

The D_3 binding site is characterized by its high-affinity for ^{3}H-dopamine (K_D = 2 nM) and its low-affinity (200-50,000 nM) for neuroleptics. The D_3 site is also detected by ^{3}H-apomorphine, but less selectively. We now report that ^{3}H-ADTN detects both the D_3 site and another site which we call D_4.

The specific binding to rat striatum of 0.8 nM ^{3}H-ADTN (defined as that inhibited by 1 μM apomorphine) was approximately 60% of total binding. ADTN, apomorphine and dopamine showed monophasic competition curves with IC_{50} values of 3.5 nM, 4.0 nM and 10 nM, respectively. Neuroleptics competed for ^{3}H-ADTN binding with both high- and low-affinity components: spiperone competed for 50% of the specific binding between 0.01 nM and 5.0 nM, and competed for the remaining specific binding between 100 nM and 10,000 nM. Thus, ^{3}H-ADTN detected two sites, one with high-affinity and the other with low-affinity for neuroleptics. The high-affinity neuroleptic site was defined as that displaceable by 30 nM spiperone: the low-affinity site (measured in the presence of 30 nM spiperone) was defined as that displaceable by 1 μM apomorphine.

The density (B_{max}) of the D_3 site (low-affinity for neuroleptics) was 70 fmoles/mg protein, and that for the D_4 sites (high-affinity for neuroleptics) was 90 fmoles/mg protein; the K_D values were both 2 nM.

	IC_{50} (nM) D_3 Site ^{3}H-dopamine	D_3 Site ^{3}H-ADTN	D_4 Site ^{3}H-ADTN
ADTN	1.5	-	4.0
Apomorphine	3.5	3.0	5.0
Dopamine	5.0	3.0	17.0
Haloperidol	200	250	15
Bromocryptine	400	200	10
Chlorpromazine	700	1,600	40
Spiperone	1,500	4,000	0.15
Sulpiride	50,000	-	5.0

The table indicates that the D_3 ^{3}H-ADTN binding site is the same as that detected by ^{3}H-dopamine. The D_4 site detected by ^{3}H-ADTN has a distinct pharmacology characterized by its high affinity for both dopamine agonists and neuroleptics. (Supported by the Medical Research Council of Canada and the Ontario Mental Health Foundation.)

7.5 ^{3}H-NPA LABELS A SUBSET OF D_2-DOPAMINE RECEPTORS IN CALF AND RAT BRAIN. M. Titeler and G. Battaglia*, Department of Pharmacology, University of Toronto, Toronto, Ontario M5S 1A8.

In using ^{3}H-spiperone to label D_2-dopamine receptors evidence has accumulated for the existence of the labelling of multiple dopaminergic sites (1,2). Most notably, catecholamines compete for specific ^{3}H-spiperone binding in caudate homogenates with very shallow slopes, while ergots and neuroleptics compete for this binding with steep slopes (1,2). N-propyl-apomorphine shows a very high affinity and a low-affinity component of competition for specific ^{3}H-spiperone binding. When ^{3}H-NPA is used to label sites in caudate tissue at very low concentrations (10^{-10}M) it clearly labels a site for which neuroleptics and catecholamines can compete with high affinity and steep slopes (see table 1). Scatchard analysis in calf tissue indicates that the ^{3}H-NPA binding to high affinity neuroleptic sites has a B_{max} of 120 fmol/mg, while the B_{max} of ^{3}H-spiperone binding in the same tissue was 380 fmol/mg. Thus ^{3}H-NPA labels a sub-set of high affinity neuroleptic-dopamine receptors, while ^{3}H-spiperone labels two sites, both of which have high affinity for neuroleptics and one of which has a high affinity for catecholamines and one of which has a low affinity for catecholamines. We are currently pursuing investigations designed to determine whether these are two distinct dopamine receptors or two states of a single receptor. Sibley and Creese have recently reached similar conclusions about D_2 dopamine receptors in the pituitary (3).

IC_{50} vs. 10^{-10} ^{3}H-NPA

Drug	Calf (M)	Rat (M)
(+)-Butaclamol	4.1×10^{-9}	
Spiperone	1.6×10^{-10}	4×10^{-11}
Haloperidol	1.8×10^{-9}	
Sulpiride	9.5×10^{-8}	
Dopamine	3×10^{-10}	1.6×10^{-9}
NPA	3×10^{-10}	4.8×10^{-10}
ADTN	1.9×10^{-9}	2.5×10^{-10}
Apomorphine	1.4×10^{-9}

7.6 CHARACTERIZATION OF DOPAMINERGIC BINDING SITES IN THE CYTOSOL FRACTION OF THE STEER ANTERIOR PITUITARY. Andrea S. Weisman*, Robert W. Kuhn* and Richard I. Weiner. Reproductive Endocrinology Center, Univ. of CA School of Medicine, San Francisco, CA 94143.

We have recently shown the presence of high affinity, stereoselective dopamine (DA) binding sites in the cytosol fraction of steer anterior pituitary (AP) homogenates (Kerdelhue et al, Endocrinology, 109, in press). We have further characterized these sites by sucrose density sedimentation, gel filtration, salt precipitation, reaction with N-ethylmaleimide (NEM) and enzymatic digestion. Cytosol was prepared for binding studies by homogenizing steer AP in buffer (15 mM Tris, 1 mM EDTA, 0.01 mM Bacitracin, pH 7.4) containing 304 mM sucrose and centrifuging for 1 hr at 145,000 x g and 4°C. Specific ^{3}H-Spiperone (^{3}H-SPIP) binding was defined as the counts displaced by 10^{-6} M d-butaclamol. Initial experiments showed that the separation of bound from free ligand by gel filtration on Sephadex G-25 or by charcoal adsorption, gave essentially identical values for the K_d (0.26 vs 0.29 nM) and Bmax (9.1 and 11.9 fmole/mg protein). Because of its rapidity and accuracy, the charcoal assay was used in subsequent studies. The ^{3}H-SPIP binding site was found to be precipitable by 40% saturation with ammonium sulfate. Following this partial purification and concentration, the binding sites were analyzed by sucrose density sedimentation and gel filtration. The binding site sedimented as a 6 S molecule and was slightly retained by a Sephacryl S-200 column. These results are consistent with a soluble molecule having a molecular weight in excess of 200,000 daltons. The requirement for a free sulfhydryl group for ligand binding was shown by sensitivity to treatment with NEM: 20 mM NEM eliminated 74% of specific binding while 100 mM completely eliminated specific binding. Incubation for 1 hr at 37°C with Viokase (0.5 mg/ml), Pronase (0.5 mg/ml), or trypsin (0.3 mg/ml) decreased specific binding by 94%, 58%, and 27% respectively, while incubation with DNAse (1 mg/ml) and RNAse (1 mg/ml) were without effect. It thus appears that the DA binding site is a large protein which requires a free sulfhydryl group for binding. The presence of the cytosol receptor does not appear to be due to mechanical disruption of membrane receptors since it is not present in the cytosol fraction from caudate nucleus homogenates, and rehomogenization of the microsomal fractions of the AP does not result in the extraction of additional soluble sites. These sites could result from internalization of membrane receptors, de novo synthesis prior to incorporation into the membrane, or an additional class of sites involved in an intracellular site of action of DA.

This work is supported by NIH HD 08924 and the Mellon Foundation.

7.7 ^{3}H-SPIROPERIDOL BINDING TO HUMAN CAUDATE: SPECIES VARIATION IN SITE NUMBER, AFFINITY, DENSITY AND SELECTIVITY. L.H. Matt*, J.D. Reimnitz*, M.E. Maguire, A.C. Andorn*. Depts. of Psychiat. and Pharmacol. Case Western Reserve Univ. Schl. of Med., Cleve. OH 44106.

^{3}H-Spiroperidol binds specifically to homogenates of human caudate, obtained from normal brains less than 16 hours postmortem, and prepared according to published methods (Andorn and Maguire, J. Neurochem., 35, 1105-1113, 1980). This high affinity binding is saturable, reversible, stereoselective with regard to (+) and (-) butaclamol, linear with regard to defined protein concentrations, and apparently occurs at multiple sites of limited density. Association is biphasic and rapid, with rates consistent with sites of $K_D \leq$ nM. Equilibrium is achieved by 20 min. Dissociation initiated at 30 min. by excess haloperidol is biphasic; approximate $t_{1/2}$ are 2.0 and 17 min. These rates are again consistent with sites of $K_D \leq$ nM. Equilibrium saturation analyses show at least two sets of sites. The K_{Dapp} are 20 +/- 10 pM and 260 +/- 80 pM, while the respective B_{max} are 90 +/- 10 and 100 +/- 10 fmol/mg protein. The K_D 20 pM sites are selective for monoaminergic agonists with serotonin (5HT) $\geq$ dopamine (DA) > (-)-norepinephrine (NE). The K_D 260 pM sites are also selective for these agents but with DA>>5HT$\geq$(-)NE. This selectivity is consistent with a dopamine receptor. In fact, the selectivity of these K_D 260 pM sites is the same as we have observed at rat striatal sites having K_D 20 pM. These findings contrast with previous reports of ^{3}H-Spiroperidol binding in caudate of other mammals. Whether site homogeneity or multiplicity has been shown, the highest affinity site demonstrated has had a selectivity consistent with a dopaminergic receptor, unlike these present observation sin human caudate. These findings suggest that antipsychotic ligand binding site properties may vary between species of the same phylogenetic class.

7.8 EVIDENCE FOR DIRECT DOPAMINE RECEPTOR EFFECTS BY AMANTADINE. R.M. Allen. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Amantadine has been shown to prevent haloperidol-induced dopamine (DA) receptor hypersensitivity in the rat striatum using a stereotyped behavior model (Allen, et al, Biol. Psychiatry 14:541), direct receptor binding techniques (Allen, et al, Eur. J. Pharmacol. 65:313), without apparent effect in the mesolimbic DA system (Allen, et al, Soc. for Neurosci. Abstracts 6). Previous behavioral work has demonstrated that amantadine blocks amphetamine-induced excitability (Clark, et al, Proc. Soc. for Exp. Biol. and Medicine 151:434), blocks amphetamine or apomorphine-induced stereotypy (Schneiden, et al, Eur. J. Pharmacol. 39:133), and inhibits neuroleptic-induced catalepsy (Maj, et al, Psychopharmacologia 24:296). It has been shown to depress cortical DA neuron firing when applied microiontophoretically (Stone, Br. J. Pharmacology 56:101). These results indicate a direct receptor effect. In this study, direct displacing effects on [^{3}H]-spiroperidol and ADTN were examined. Pooled rat striatum crude membrane preparation was used as the study substrate. The radioreceptor assays were performed in a Tris-salt-EDTA buffer system as described by Leysen, et al (J. Neurochem. 36:201). Scatchard analysis of [^{3}H]-spiroperidol was performed using 10^{-5} (+) butaclamol (But) or 10^{-5} amantadine (AM) as displacing agents. Amantadine displaced 32% of specifically bound spiroperidol (Bmax = 90 fmol/mg protein) compared to (+) But (Bmax = 281 fmol/mg protein) with only slighly differing affinity (K_D with AM 111 pM, (+) But 188 pM). Hill plot analysis revealed a Hill coefficient of 0.95 for AM and 1.01 for (+) But. The IC_{50} for (+) But using 300 pM [^{3}H]-spiroperidol was 5 nM, for AM, 10 nM. Using similar conditions except for incubation temperature and time (25°C, 20 min), Scatchard analysis of [^{3}H]-ADTN was performed with apomorphine and amantadine. 10^{-5} amantadine displaced 1.4 times as much [^{3}H]-ADTN (Bmax = 1276 fmol/mg) as 10^{-5} apomorphine (Bmax = 743 fmol/mg) but with almost half the affinity (K_D AM = 4.8 nM, K_D APO = 2.6). Both AM and APO had Hill coefficient of 0.9. These preliminary results indicate that amantadine has direct receptor effects on both antagonist and agonist receptor sites which may explain its effects on neuroleptic-induced behavioral effects and its greater usefulness in neuroleptic-induced extrapyramidal side effects than idiopathic Parkison's disease. Further studies on agonist binding effects and speculation about its possible mechanism of action will be presented.

7.9 CHARACTERIZATION OF ^{3}H-ADTN BINDING SITES IN DOG RENAL CORTEX AND THEIR SENSITIVITY TO REDUCING AGENTS. C.K. Scott*, and C. VanderWende (SPON: A. Feldstein). College of Pharmacy, Rutgers, The State University, Box 789, Piscataway, New Jersey 08854

There has been much evidence to support the existence of a peripheral dopamine receptor located in the kidney which is responsible for renal vasodilation and subsequent increase in renal blood flow. We have identified this receptor utilizing the dopamine agonist ^{3}H-ADTN, in membrane preparations of canine renal cortex. ^{3}H-ADTN binding displays all of the necessary criteria for specific receptor interaction in that it is linear over a given protein concentration, is saturable, and displays appropriate kinetics, (Kd ∿5nM). The receptor displays the appropriate pharmacological specificity for the dopamine agonists: dopamine, 6,7-ADTN, apomorphine and epinine. In addition, the receptor shows a marked sensitivity to a number of reducing agents such as ascorbic acid, sodium metabisulfite and dithiothreitol. Evaluation of saturation kinetics and subsequent scatchard analysis in the presence of 0.1% ascorbic acid, a concentration routinely used in dopamine binding assays, demonstrates a marked reduction in the number of binding sites with no effect on the dissociation constant.

These data indicate that the ^{3}H-ADTN binding site in canine cortex membranes may represent the proposed peripheral dopamine receptor and that this receptor may be similar to the receptor in the brain in regard to the kinetics of ^{3}H-ADTN binding and sensitivity to reducing agents.

7.10 DOPAMINE RECEPTORS, AMPHETAMINE RESPONSE, AND HYPERKINETIC SYNDROME. Daiga Helmeste and Philip Seeman. Dept. of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

In order to examine the potential relation between the density of dopamine receptors (D_2 type) and the behavioural response to amphetamine, the densities (B_{max}) of brain region dopamine receptors in eight strains of mice were measured using ^{3}H-spiperone (0.05 to 2 nM).

The mice with high densities of D_2 receptors in the striatum and olfactory tubercle (C3H/HeJ, CD-1, BALB/cJ and A/J) had B_{max} values 15 to 25% higher than the low-density mice (CBA/J, C57BL/6J, SEC/IReJ and DBA/2J). The K_D values were not significantly different between the two groups.

Locomotor activity after 0.5, 1.0 or 5.0 mg/kg i.p. d-amphetamine - sulphate was qualitatively different depending on whether the strain had high or low D_2 receptor density. The inbred strains (C3H/HeJ, BALB/cJ, A/J) with high D_2 density decreased their activity after 0.5 to 1.0 mg/kg amphetamine. The low-density mice either increased or showed no change in locomotor activity after 0.5 to 1.0 mg/kg amphetamine. All strains showed increased locomotion after 5.0 mg/kg amphetamine (compared to vehicle-injected controls).

The high density of D_2 receptors may reflect a functionally overactive dopamine system in those mice who responded to amphetamine with hypolocomotion. This qualitative difference in behavioural response to amphetamine is similar to that found in hyperkinetic children, with some children being good responders and others being non-responders to equivalent doses of amphetamine.

7.11 INCREASED STEREOSPECIFIC DOPAMINE RECEPTOR BINDING AFTER REMOVAL OF ENDOGENOUS DOPAMINE FROM RAT BRAIN REGIONS. N.G. Bacopoulos, T.L. Miller * and P.L. Ware *. Departments of Pharmacology and Psychiatry, Dartmouth Medical School, Hanover, NH, 03755.

Endogenous dopamine contaminating radioreceptor binding assays can seriously interfere with the measurement of stereospecific 3H-dopamine (3H-DA) and 3H-apomorphine (3H-APO) binding sites in particulate fractions of rat caudate nucleus (CN) or mesolimbic brain regions. Binding was measured with 0.2-15.0 nM 3H-DA or 3H-APO (40-41 Ci/mmole, New England Nuclear) and 0.2 mg tissue protein in a final volume of 1.0 ml containing 20 mM Tris-HCl buffer, pH 7.4, 1.1 mM ascorbic acid 5.0 mM EDTA-4Na, 1.1 mM ascorbic acid and 15 uM pargyline. After a 30 min incubation at 23° C, samples were passed through GF/B filters under suction. Radioactivity on the filters was measured with 10 ml 3% Protosol-Econofluor (New England Nuclear) 24 hr later. Nonspecific binding was measured with 10 uM d-butaclamol. Endogenous dopamine was measured radioenzymatically in perchloric acid extracts of tissue suspensions used in the binding assay. The method of tissue preparation had significant effects on residual dopamine content and on the stereospecific binding sites of 3H-DA or 3H-APO. Successive "washes" (centrifugations and resuspensions of the 20,000 X g total particulate pellet in 20 mM Tris-HCl buffer, pH 7.4) of the crude homogenate reduced dopamine content and increased the number of binding sites of both radioligands proportionately. Preincubation of the tissue suspension at 37° C for 15 min resulted in an additional reduction in endogenous dopamine content and a 2-3 fold increase in stereospecific binding. This was due to an increase in the total binding rather than a reduction in the nonspecific binding. In preincubated tissue suspensions, the stereospecific binding sites of 3H-DA or 3H-APO were saturable, with a Bmax of 250-300 fmoles/mg protein in the CN and 2/3 that value in the mesolimbic region. The Kd of 3H-APO in the CN was 1.1-1.6 nM and of 3H-DA 0.8-1.3 nM. Values shown are the range of 4 experiments. Subfractionation studies revealed that the crude synaptosomal pellet contained most of the saturable stereospecific sites of the two radioligands, but in this tissue preparation preincubation was again necessary for the removal of the majority of endogenous dopamine. It appears that the portion of endogenous dopamine that is removed by preincubation at 37° C may be bound to dopamine receptors, therefore its removal is essential for the accurate measurement of dopamine receptors with 3H-agonists. Supported by PHS research grant MH33958-01.

7.12 THE DOPAMINE RECEPTOR IN THE INTERMEDIATE LOBE OF THE RAT PITUITARY GLAND IS NEGATIVELY COUPLED TO ADENYLATE CYCLASE. H. Meunier* and F. Labrie* (SPON: C. Radouco-Thomas), MRC Group in Molecular Endocrinology, CHUL, Québec, Canada G1V 4G2.

The predominant role of dopamine (DA) in normal brain function, as well as in diseases such as schizophrenia and Parkinson's disease, has been strong stimulus for research on the DA receptor and its mechanism of action. Functionally, the best known action of the DA receptor is its stimulatory effect on adenylate cyclase activity. However, the heterogeneity of brain tissue complicates the analysis of DA action in central nervous system. The intermediate lobe of the rat pituitary gland is a pure population of cells specialized in the secretion of peptides derived from proopiocortin. We have taken advantage of this system to study the interactions of the DA receptor with adenylate cyclase using a series of agonists and antagonists of known pharmacological activity in pars intermedia cells in primary culture. DA agents inhibit cyclic AMP (cAMP) accumulation with the following order of potency (K_d): 2-bromo-α-ergocryptine (0.20 nM) ≥ pergolide (0.27 nM) ≥ dihydroergocryptine (0.5 nM) > apomorphine (1.5 nM) > DA (5.0 nM) > (-)norepinephrine (30 nM) ≥ (-) epinephrine (50 nM). Propranolol (100 nM) was present during incubations with (-)epinephrine and (-)norepinephrine in order to block their interaction with the β-adrenergic receptor which is stimulatory on cAMP accumulation in pars intermedia cells. That changes in cAMP levels in pars intermedia are involved in the control of α-MSH secretion is strongly suggested by the finding that 25 to 35% inhibition by the DA agonist 2-bromo-α-ergocryptine of basal and 100 nM (-)isoproterenol-stimulated cAMP levels is accompanied by 50 to 70% inhibition of α-MSH release respectively. DA antagonists reverse the inhibition of cyclic nucleotide levels induced by 10 nM DA with the following order of potency: spiperone (0.02 nM) ≥ thioproperazine (0.04 nM) > haloperidol (0.5 nM) ≥ fluphenazine (0.6 nM) ≥ pimozide (0.8 nM). The potent neuroleptic (+)butaclamol reverses the inhibitory action of DA (K_d = 1.5 nM) while its pharmacologically weak enantiomer, (-)butaclamol, is 80 times less potent. The serotonergic antagonists cyproheptadine and methysergide can also act as weak DA antagonists while serotonin has no effect on cAMP accumulation or α-MSH secretion. The intermediate lobe of the rat pituitary gland offers a unique model of a dopaminergic receptor which inhibits adenylate cyclase activity in parallel with α-MSH secretion, thus indicating the presence of DA_- receptor. It is expected that the knowledge gained with this relatively simple model will yield useful information for the less accessible dopaminergic systems of the brain.

7.13 THE REGULATION OF OLFACTORY BULB ADENYLATE CYCLASE: INTERACTIONS BETWEEN DOPAMINE AND INSULIN. M. L. Barbaccia*, D. M. Chuang* and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Havrankova and her collegues (Nature 272:827, 1978) reported that different rat brain areas contain various densities of saturable, specific, high affinity, recognition sites for insulin. Moreover, the brain areas that contain the highest density of recognition sites also contain the highest density of insulin-like immunoreactivity (PNAS 75:5737, 1978). Olfactory bulb which has one of the highest contents of insulin and insulin binding sites was used to elucidate the location and role of brain insulin. Since rat olfactory bulbs contain dopaminergic cell bodies we investigated whether they also contain a dopamine dependent adenylate cyclase. Using 300μ slices of olfactory bulb we measured basal cAMP content at 10 minutes after a 30 minute period of preincubation. Dopamine in 3×10^{-5}M or greater increased cAMP content in olfactory bulb slices. Monolateral bulbectomy increased the responsiveness of the contralateral olfactory bulb adenylate cyclase to dopamine stimulation. The increase of cAMP caused by dopamine was partially inhibited by haloperidol (5×10^{-6} M) and facilitated bysulpiride (5×10^{-6}M) and IBMX (5×10^{-6}M). Insulin failed to cause an accumulation of cAMP in striatum and frontal cortex slices. We then tested the action of insulin (3 to 9×10^{-7}M) on the cAMP content of olfactory bulb. We found that also insulin increased the cAMP content in a concentration dependent manner. This action of insulin was unaffected by (5×10^{-6} M) haloperidol and increased by (5×10^{-6}M) sulpiride and IBMX (5×10^{-6}M). The data obtained are compatible with the view that activation of receptors for insulin and dopamine can increase the adenylate cyclase activity. Moreover, monolateral bulbectomy facilitated the accumulation of cAMP in the contralateral bulb elicited by insulin and dopamine. Hence the two neuromodulators appear to interact as if insulin receptors regulating cAMP content were modulated by D-2 receptors. Moreover, our data suggest that the contralateral bulb can modulate the dopamine activation of the adenylate cyclase of an olfactory bulb.

8.1 RUTHENIUM RED INDUCES A NONINACTIVATING NA CURRENT IN PERFUSED SNAIL NEURONS. W. L. Byerly & J. R. Stimers. Dept. Biological Sciences, University of Southern California, Los Angeles, CA 90007.

Ruthenium Red (RuR) blocks Ca binding and/or uptake in a variety of systems. Also, evolked and spontaneous release from synaptosomes and the frog neuromuscular junction is blocked by RuR. Since this later effect is dependent upon Ca current in the membrane, we chose to study its effects on the currents of a voltage clamped membrane. Using isolated, perfused, Limnea neurons, RuR was found to block the Ca current and induce a noninactivating Na current.

The methods are those of Byerly and Hagiwara (in press). Limnea neurons are perfused both intracellularly and extracellularly. All experiments are done using a suction electrode voltage clamp. All external solutions contain Ca^{2+} and Mg^{2+}.

When a cell is intracellularly perfused with CsAsp and bathed in a solution with Ca^{2+} as the only permeant cation, a prominent Ca current is seen. Within 5 minutes of adding RuR to the bath, 95% or more of the Ca current disappears. This indicates that RuR does block the Ca current in this preparation. As with other Ca blockers, the effect is not completely specific. RuR also blocks nearly 50% of the outward currents (with either K^+ or Cs^+ inside the cell). The presence of 5mM EGTA inside precludes this being a secondary loss of the Ca-dependent K current.

RuR has another effect, in that it induces a noninactivating Na current. The normal Na current seen in this preparation inactivates very fast, decaying to near zero within 10ms. However, in the presence of RuR a Na conductance turns on when the membrane potential is stepped above -30mV, fully activating above +10mV. The conductance decays less than 40% during a 60ms pulse. This is very similar to the kinetics and voltage dependence seen for the Ca current. However, when Na^+ is replaced by Tris in the bathing solution, no inward current is seen. The reversal potential of this current agrees with the Nernst potential for Na^+. It is selective for Na^+, in that neither K^+, Cs^+, Ca^{2+} nor Mg^{2+} contribute significantly to this current. Experiments are in progress to determine if this Na current passes through the normal Na channels, Ca channels or by some other mechanism.

8.2 CALCIUM-DEPENDENT SODIUM CONDUCTANCE IN MAMMALIAN DORSAL ROOT GANGLION NEURONS IN PRIMARY DISSOCIATED CELL CULTURE. E.J. Heyer, R.L. Macdonald. Dept. Neurology, Univ. of Michigan, Ann Arbor, MI 48109. Present address (EJH): Dept. Neurology, Mt. Sinai School of Medicine, New York, N.Y. 10029.

Action potentials (APs) dependent on sodium, calcium and potassium conductances can be elicited from mouse dorsal root ganglion (DRG) neurons in primary dissociated cell (PDC) culture. The rising phase of the action potential depends on activation of sodium conductance; its maximum rate of rise ($\dot{V}_{max}$) is directly proportional to peak sodium conductance. In addition, at resting membrane potential (RMP) neuronal input resistance (R_{in}) is due in part to sodium conductance. We have demonstrated that intracellular calcium reduced $\dot{V}_{max}$ and increased R_{in} suggesting that at least a portion of membrane sodium conductance was blocked by intracellular calcium. Tetrodotoxin (TTX), a sodium conductance blocker, also only partially blocked $\dot{V}_{max}$. Its action was probably on that part of the sodium conductance that was calcium sensitive.

PDC cultures of spinal cord dissected from 12-14 day old fetal mice were grown by conventional techniques. After 4-6 weeks in culture, intracellular recordings with 4M KAc-filled microelectrodes were made in neurons bathed in Tris buffered saline containing 5 mM calcium (TBS).

In calcium-free TBS, $\dot{V}_{max}$, AP duration and R_{in} were 231.6 V/sec, 1.0 msec and 26.0 MΩ. In bathing solutions containing calcium (2.5 or 5.0 mM) $\dot{V}_{max}$ was decreased, and AP duration and R_{in} were increased. Since DRG neurons contain a large voltage-dependent calcium conductance, it was possible that this effect was due to calcium entry into the neuron. Therefore, we performed two experiments. First, we blocked extracellular calcium entry by adding manganese (5.0 mM), a calcium conductance blocker, to TBS. $\dot{V}_{max}$, AP duration and R_{in} became 242.0 V/sec, 0.8 msec and 34.8 MΩ which were similar to values obtained in calcium-free TBS. Second, in manganese-containing TBS we restored the effect of calcium on $\dot{V}_{max}$ by injecting calcium intracellularly with a second micropipette containing 0.5 M $CaCl_2$ and 0.5 M KCl. No restoration was possible by injecting manganese intracellularly. Other divalent cations were studied to see if they would substitute for calcium. Barium and strontium substituted for calcium to permit long duration APs to be evoked in DRG neurons. However, only barium substituted for calcium to block $\dot{V}_{max}$ and therefore reduced sodium conductance. Addition of TTX to calcium-, manganese-, barium- and strontium-containing TBS reduced $\dot{V}_{max}$ to the same values, implying that TTX blocked that portion of sodium conductance blocked by some divalent cations. Supported by the Grass Foundation (Morison Fellowship) (E.J.H.),and NINCDS (NS 15225) and RCDA (NS 00408) (R.L.M.).

8.3 Ca^{2+} ACTIVATED K^+CURRENT NOISE AND RELAXATION MEASUREMENTS IN HELIX NEURONES. A. Hermann+ and K. Hartung+ (SPON: A.L.F.Gorman) Fakultät für Biologie, Universität Konstanz, D-7750 Konstanz, FRG.

Ionophoretic injection of Ca^{2+} ions into voltage clamped Helix neurones causes an increase of K^+ current which is associated with an increase of membrane current fluctuations. Membrane current noise generated by the Ca^{2+} injections disappears at the K^+ equilibrium potential and current relaxation reverses at a similar potential. For small outward currents the relationship between the variance of current fluctuations and the mean current is linear. The single channel conductance calculated from the current variance measurements is 3.4+0.4 pS (S.E.M., n=15). Relaxation measurements revealed that with small doses of Ca^{2+} injections the relaxation current can be fitted by a single exponential. At higher doses of Ca^{2+} injections two or more time constants were needed for a fit. The relaxation measurements further showed that the instantaneous current-voltage relation of the Ca^{2+} activated K^+ current is almost linear whereas in the steady state there is strong outward rectification. Relaxation time constants were in the range of 20-60 msec at potentials between -100 mV and +10 mV and increased in a voltage dependent manner with membrane depolarization. The Ca^{2+} activated current relaxation is also voltage dependent and changes e-fold per 28 mV change in membrane potential.

Prolonged injections of high amounts of Ca^{2+} depresses the outward current and the current fluctuations. Subsequent injection of Ca^{2+} into the cell could not activate the outward current again.

Extracellular TEA (tetraethylammonium) effectively blocks the Ca^{2+} activated K^+ current within seconds after application with a half-maximum blockade achieved at 0.7 mM. 4-AP (4-aminopyridine) had no blocking effect at these cells.

It is concluded that ionophoretic injection of Ca^{2+} ions into Helix neurones activates a K^+ conductance specific to K^+ ions and that opening and closing of K^+ channels is voltage- and time dependent. High amounts of intracellular Ca^{2+} or extracellular TEA block the Ca^{2+} activated K^+ conductance.

Supported by DFG Grant SFB 138.

8.4 CALCIUM ACTIVATED OUTWARD CURRENTS (I_c) IN VOLTAGE-CLAMPED BULLFROG SYMPATHETIC NEURONES. A. Constanti*, P.R. Adams and D.A. Brown* (SPON: D. Kunze). Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

I_c's were studied in 2 ways: (1) from clamp-currents generated by depolarizing voltage-commands before and after suppressing inward Ca-currents; and (2) as outward currents induced by intracellular Ca-iontophoresis.

(1) Steady-state I/V curves following 40-100 ms depolarizing commands from a holding potential (V_H) of -30 mV frequently showed an "N"-shape, peaking at between +20 and +50 mV. The "N"-peak was reduced or abolished by omitting external Ca or by adding Cd (0.1 mM), Co (1 mM) or Mn (1 mM). Outward current trajectories at command potentials equal to or more positive than -10 mV showed an early phase, peaking in 5-10 ms, suppressible in Ca-free solution and/or 0.1 -0.5 mM Cd. Additionally a Ca-sensitive transient outward current was sometimes detected on depolarizing to $\geq$ -35 mV from -100 mV. This peaked in $<$ 5 ms and decayed within 20 ms. Both early outward and transient currents were inhibited by 1 mM TEA but not by 4-AP.

(2) Outward I_c- currents following iontophoretic injection of $CaCl_2$ were recorded using a single electrode voltage-clamp. During steady injection I_c peaked within 2-5 sec. Currents declined slowly thereafter but recovered rapidly on stopping injection. Brief (0.2-1 s) injections generated non-desensitizing responses offsetting in 0.5-5 s. Such responses increased linearly with iontophoretic dose up to 6 nC. For constant calcium doses, I_c increased steeply as V_H was made more positive from -60 mV, corresponding to a 12.5 mV increase in conductance (G_c) per e-fold depolarization up to -10 mV. In 25 mM [K], currents reversed in direction at -35 $\pm$ 5 mV (mean $\pm$ S.D., n = 8). V_{rev} shifted by 41 $\pm$ 15 mV (mean $\pm$ S.D., n = 6) on raising [K] from 2.5 to 25 mM. I_c evoked by intracellular Ca-injection was insensitive to external Ca, Cd or 4-AP but was inhibited 50% by 1 mM TEA.

These experiments show that many (though not all) bullfrog sympathetic neurones possess Ca-sensitive K-channels which are also voltage-sensitive, are blocked by low concentrations of TEA, and are activated sufficiently rapidly to aid spike repolarization.

Supported by NS 14986, MRC and the Wellcome Trust.

8.5 SINGLE CHANNEL AND NOISE ANALYSIS OF OUTWARD CURRENTS IN BULLFROG GANGLION CELLS. P.R. Adams, A. Constanti*, R.B. Clark*, C.E.Y. Adams* and D.A. Brown*. (SPON: O.S. Steinsland). Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Fragments of adult bullfrog ganglia maintained in culture for several weeks developed very smooth and round protruding neurons upon which it was routinely possible to establish gigohm seals. Both fresh and cultured neurons were used to perform noise analysis of maintained outward currents. After about 30 sec depolarization to between -10 and +20 mV, a small residual and noisy outward current was observed. The power spectrum of the current noise was approximately Lorentzian with a 1/f admixture. In 8 tests near 0 mV, the mean corner frequency was 8 Hz. The mean single channel conductance in 17 tests was 101 pS (80 mV driving force assumed). Both the residual outward current and the associated extra variance were abolished by perfusing cadmium (100 μM), TEA (10 mM) or calcium-free Ringer. Thus this highly conducting channel is assumed to be a calcium activated K-channel. In one test intracellular calcium injection yielded a sustained outward current with an elementary conductance of 97 pS, and a similar spectral shape.

Depolarized patches exhibited 2 main types of outward event. The large type exhibited a single channel conductance close to 100 pS, and was thus identified as a Ca-activated K-channel. The current through this channel at first ohmically increased with potential, and then decreased with further depolarization. At around +80 with respect to rest the open channel showed glitchy, rapid closings; at more positive potentials these became shorter and more frequent, so that the open channel was very noisy.

At very positive potentials ($\sim$ +200 mV) relative to rest, upward and downward glitches, though very short, seemed to be equally present. The rapid vibration of the channel in a partially open state may expain the apparent decrease in conductance at very positive potentials. The open times of these putative Ca-activated K-channnels was very variable from patch to patch, and could spontaneously increase at a given patch. The open time increased strongly with depolarization (e-fold for 22 mV). Since these channels could be recorded using Ca-free pipettes, they are probably activated by spontaneous internal calcium release.

Patches also usually showed a smaller (2-3x) shorter lived channel whose opening frequency increased strongly with depolarization, and may be a delayed rectifier.

Supported by NS 14986 and NS 14920.

8.6 INTRACELLULAR CALCIUM TRANSIENTS ELICITED BY SYNAPTIC AND ELECTRICAL MEMBRANE ACTIVATION AND BY THEOPHYLLINE MEASURED IN BULLFROG NEURONS USING ARSENAZO III. S.J Smith*, A.B. MacDermott F.F. Weight. Lab. Preclin. Studies, NIAAA, Rockville, MD 20852

We have used the indicator dye arsenazo III to measure three different kinds of intracellular calcium transients in neuronal cell bodies of isolated bullfrog sympathetic ganglia. B-cells were loaded with the dye by microiontophoresis, and their optical absorbance was measured simultaneously at four wavelength bands centered at 570, 610, 660, and 700 nm. Absorbance changes were identified as calcium signals on the basis of spectral characteristics. We found the following. (1) Voltage clamp depolarizations to potentials between -30 and +50 mV and trains of antidromic action potentials produced calcium signals which increased progressively during stimuli up to several seconds in duration. These signals are presumed to result from calcium entry through voltage-dependent channels. Upon return to resting membrane potential, the calcium signals returned to baseline over a monotonic time course lasting approximately one minute. The time course of calcium signal recovery resembles that of the post-tetanic hyperpolarization (PTH) observed in these neurons. It has been suggested that the slow potassium conductance underlying the PTH is activated by intracellular calcium ions (Minota, S., Jap. J. Physiol., 24:501, 1974). Our observations suggest that the accumulation and removal of cytoplasmic calcium ions may directly determine the time-dependence of that slow potassium conductance. (2) Trains of orthodromic synaptic stimuli produce a calcium signal even when the postsynaptic membrane potential is held constant by a voltage clamp. This calcium transient is presumed to result from the opening of transmitter-controlled channels. The amplitudes and kinetics of calcium signals elicited synaptically are roughly similar to those of the signals elicited by comparable trains of antidromic spikes. (3) In the presence of the methylxanthines caffeine or theophylline, rhythmic hyperpolarizations lasting 10-30 seconds occur spontaneously at intervals of a few minutes (Kuba, K., J. Physiol. 298:251, 1980; McCort, S.M. and Weight, F.F., Neurosci. Abstr. 5:47, 1979). In dye-loaded neurons treated with theophylline (5 mM), we observed increases in cytoplasmic calcium coincident with such spontaneous hyperpolarizations. This observation supports earlier suggestions that these hyperpolarizations result from cytoplasmic calcium increases acting by way of the calcium-activated potassium conductance mechanism. There are indications that methylxanthine-induced calcium oscillations may involve calcium movement between cytosol and another intracellular store. (This work partially supported by PHS NS 16671-01).

8.7 DIFFUSION OF Ca^{2+}, Ba^{2+}, H^+ AND ARSENAZO III IN NEURAL CYTOPLASM. J. A. Connor, Z. Ahmed and G. Ebert*. Univ. of IL, Dept. of Physiol. & Biophys. Urbana, IL 61801.

Experiments have been run to compare the movement rates of several small cations in nerve cell cytoplasm to their movement rates in saline solution. The relative diffusional rates of the indicator dye, arsenazo III, have also been examined. The purpose of the study has been to assess the effect of molluscan nerve cytoplasm on the diffusion coefficient of Ca^{2+} and H^+. Neural somata (300-600 µm diameter) from Archidoris monterreyensis were injected with indicator dyes, either arsenazo III (for divalent ions) or phenol red (for H^+) to concentrations of approximately 0.3 mM and 0.5 mM respectively. Following injection the electrode was removed from the cell and a second electrode containing either $CaCl_2$, $BaCl_2$ or HCl inserted for iontophoretic injection. Current pulses of 1 to 2 sec were used and the quantity of injected cations was in the neighborhood of 1 to 5 pmoles. The transient, local concentration changes of indicator-cation complex resulting from injections were monitored by measuring transcellular absorbance changes with two independent light collecting fibers (50 µm diameter). One optic fiber was centered directly over the injection site while the other was positioned at different locations about the cell surface. The injected quantities of ions were too small to cause appreciable steady baseline changes. Identical experiments were carried out using saline droplets of comparable size to the neurons. The droplets were formed under mineral oil and saline contained (in mM) 50 NaCl, 350 KCl, 3 $MgCl_2$, 10 mM Mops buffer at pH 7.4, plus the indicator dye.

The most striking differences between cell and saline droplet experiments occurred for injections of Ba^{2+}, an ion which is apparently poorly buffered by cytoplasm, and H^+. The time course of both signals was slowed by around an order of magnitude. For Ba^{2+} it required between 10 and 20 sec for the absorbance change to decay e-fold at the injection site in the neurons while in saline the corresponding period was about 1 second. The decay of the cellular signal for Ca^{2+} injection was much faster, probably due to high affinity buffering of this ion by cytoplasm. Also in the neurons the second optic fiber detected appreciable absorbance changes for Ba^{2+} injections even when separated from the injection site by 50 to 100 µm. For similar Ca^{2+} injections there was almost no signal. The time course of arsenazo III spread was also slower in the cytoplasm and a fraction of the injected dye appears to be bound and relatively immobile. Simulation studies are being run in an attempt to assess the relative importance of binding to other factors which might also slow diffusion. Supported by NS 15186 from NINCDS.

8.8 CHARACTERIZATION AND PARTIAL PURIFICATION OF FACTORS CONTROLLING THE GENERATION OF ACTION POTENTIALS IN PARAMECIUM. N. Haga,* M. A. Forte, Y. Saimi* and C. Kung,* Laboratory of Molecular Biology, University of Wisconsin, Madison, WI 53706.

The ciliated protozoan, Paramecium tetraurelia, offers a unique opportunity to utilize the combined techniques of genetics, biochemistry and electrophysiology in the analysis of the molecular interaction necessary for the generation of action potentials. Mutants unable to generate action potentials have been isolated as cells which show no backward swimming in response to ionic stimulation. Standard genetic crosses of these recessive mutants called pawns separate them into at least three complementation groups designated pwA, pwB and pwC. We have found that microinjection of cytoplasm from a donor wild-type cell into a recipient pawn of any of the three complementation groups restores the ability of the pawn cell to swim backward when stimulated with 20 mM K+ and hence restores the ability to generate action potentials in these cells. The restoration is not due to a simple addition of ions in the cytoplasm but represents a profound change in the excitable membrane of the recipient pawn cells as demonstrated by electrophysiological analysis under a voltage clamp. Restoration is maximal by eight hours and lasts up to 3 days. The factors from wild-type cytoplasm which restores backward swimming in the pawn mutants have been further characterized and purified. A cell homogenate is centrifuged at 27,000 xg and the supernatant (S_1) further centrifuged at 100,000 xg. The pellet from the 100,000 xg spin (P_2), the original supernatant (S_1) and the cell homogenate from the wild type cells were all active in curing pwA, pwB or pwC cells when injected. The restoration of backward swimming by these fractions can occur in the absence of protein synthesis. The activity for pwC is apparently not sensitive to endogenous or exogenous RNase's, is destroyed by trypsin and is inhibited slightly by divalent cations. P_2 has been further fractionated on sucrose gradients. The activity for pwC is associated predominantly with a membrane vessicle band at 45% sucrose. This final fraction represents about a 30 fold purification from the original cell homogenate. Further fractionation is in progress. 8.9 A DROSOPHILA MUTANT AFFECTS SODIUM CHANNEL LEVELS. L.M. Hall, S.D. Wilson*, J. Gitschier and G.R. Strichartz. Dept. of Genetics, Albert Einstein Coll. of Med., Bronx, NY 10461 and Department of Physiology and Biophysics, SUNY at Stony Brook, NY 11794.

We have used ^{3}H-saxitoxin as a probe in binding studies of the voltage-sensitive sodium channel in mutant and wild-type strains of Drosophila melanogaster. Of particular interest is the mutant nap^{ts} (no action potential, temperature-sensitive) in which nerve conduction is blocked at elevated temperatures (34°C) but recovers rapidly when the temperature is decreased. Both larvae and adults show a corresponding temperature-induced paralysis which is rapidly reversed at lower temperatures (Wu, C. F., B. Ganetzky, L.Y. Jan, Y.-N. Jan, and S. Benzer, Proc. Natl. Acad. Sci. U.S.A., 75: 4047, 1978). Our ^{3}H-saxitoxin binding studies have revealed that this mutant has a reduced number of saturable saxitoxin-binding sites compared to wild-type controls. When binding assays are conducted on Drosophila head extracts at 4°C, the nap^{ts} mutant has 69.7 ± 3.2 fmoles of toxin-binding sites per mg protein while the wild-type has 114.8 ± 24.3 fmoles/mg protein. This same difference persists if the assays are conducted at 30°C. There are no differences between nap^{ts} and the wild-type with respect to K_D, pH sensitivity, thermal inactivation, ion sensitivity, and tetrodotoxin inhibition of the saxitoxin-binding receptor. From these results we suggest that there are no structural differences between sodium channels in the mutant and wild-type. The nap^{ts} gene appears to affect regulation of sodium channel levels.

As one test of this suggestion, we have pharmacologically reduced the number of functional sodium channels in the wild-type strain by feeding flies sublethal doses of tetrodotoxin. After this treatment wild-type flies resemble the nap^{ts} mutant in that they can be paralyzed at temperatures which normally have no effect on wild-type locomotion. We will discuss how all of the nap^{ts} characteristics (temperature-induced paralysis, temperature-induced blockade of action potentials, altered refractory period, and enhanced sensitivity to tetrodotoxin) can be explained on the basis of reduced numbers of sodium channels. (Supported by N.I.H. grant NS 16204 to L.M.H. and NS 12828 to G.R.S.)

8.10 GENETIC MANIPULATION OF POTASSIUM CHANNEL KINETICS AND MATURATION TIME IN DROSOPHILA: A VOLTAGE CLAMP STUDY. Lawrence Salkoff* (SPON: J.L. Rosenbaum). Dept. of Biology, Yale Univ., Box 6666, New Haven, CT. 06511.

Mutations mapping at the X-linked Shaker locus of Drosophila melanogaster alter different properties of the potassium channels that carry the fast, transient, outward current (the A-current) in the dorsal longitudinal flight muscles (DLM). One mutation Sh^5, alters the biophysical properties of the A-current channels. Two other mutations, Sh^{rK0120} and Sh^{KS133}, suppress the normal developmental appearance of the channels during the pupal period. The Sh^5 mutation affects only inactivation: it causes the channels to inactivate (close) twice as fast as wild-type channels, and it accelerates recovery from inactivation. The channels of heterozygote (Sh^5/wild-type) animals close at a rate intermediate to mutant and wild-type channels. Heterozygotes also recover from inactivation at a rate intermediate between wild-type and mutant. Other active and passive membrane properties are not apparently altered by this mutation. Thus, the Sh^5 A-current activation curve and steady-state inactivation curve are indistinguishable from wild-type. Membrane input resistance is also unaffected.

The Sh^{rK0120} and Sh^{KS133} mutations suppress the normal maturation of the A-current channels during pupal development. The pupal period in D. melanogaster lasts for approximately 96 hrs. During this time the DLM fibers are formed. The DLM contains two distinct sets of potassium channels, the A-current channels, and the delayed rectification channels that carry a slower activating, noninactivating current. These channels appear in the membrane at different times. The A-current channels appear in the normal membrane after 55 hrs of pupal development and reach their final density by 72 hrs. Delayed rectification channels are sparse or absent at 72 hrs (Salkoff & Wyman, 1981, Science: 212:461-463). Delayed rectification then develops and is mature at 96 hrs, the time of adult eclosion. Sh^{rK0120}/Sh^{rK0120} or Sh^{KS133}/Sh^{KS133} muscle cells have no A-current response even at 96 hrs. At this stage these mutant cells have only delayed rectification. Heterozygous (Sh^{rK0120}/+ or Sh^{KS133}/+) animals have half the normal A-current response at all pupal stages. In the homozygous mutants the A-current finally appears 24 hrs after eclosion in the majority of adult muscle cells. The expression of these mutant genes may be "leaky" or a different gene may be active in the adults.

8.11 BLOCKADE OF INWARD RECTIFICATION IN IMMATURE STARFISH OOCYTES BY INTRACELLULAR H^+. W.J. Moody and S. Hagiwara. Jerry Lewis Research Center & Dept. of Physiology, UCLA, Los Angeles, CA 90024 and Dept. of Biological Sciences, USC, Los Angeles, CA 90007.

The sensitivity of inwardly rectifying K currents to decreases in intracellular pH (pH_i) was studied in immature oocytes of the starfish, M. aequalis. K currents were measured under voltage-clamp and pH_i was recorded with recessed-tip pH microelectrodes. Average values for pH_i and V_m in normal Ringer were 7.09 ± 0.08 and -71.2 ± 1.6 mV, respectively (n=14). When the external pH was decreased from 7.8 to 5.0 using the membrane-impermeant buffer biphthalate (20mM), pH_i decreased only slightly or not at all (0-0.12 unit), and the inward rectifier currents were affected only slightly or were unaffected (0-12% block). In pH 5 biphthalate solutions, the greatest blocking effects did not correlate with the largest pH_i changes. When the external pH was decreased from 7.8 to 5.0 using the membrane-permeant buffer acetate (10mM), pH_i decreased rapidly to 5.84-6.0, and the inward rectifier currents were virtually eliminated (90-98% block). Since the buffer strength of 20mM biphthalate is 60% greater than 10mM acetate at pH 5.0, it is unlikely that these results are explained by differing abilities of the two solutions to change the pH in a highly buffered extracellular space. Titration curves of inward rectifier currents vs. pH_i were obtained by exposing single cells to a series of acetate-buffered solutions with pH values between 7.8 and 5.0. pH_i was recorded continuously and voltage-clamp pulses delivered after pH_i had attained a steady-state in each solution. The titration curves were very consistent among cells. The pooled data could be described adequately by assuming that three H^+ ions bind to a single site to block the channel. The apparent pK of the site is 6.27. We examined the possibility that the internal H^+ block could be explained by a decrease in internal Na^+ activity ($[Na^+]_i$), since the channel is known to be blocked by low $[Na^+]_i$ (Hagiwara and Yoshii, J. Physiol. 292:251). $[Na^+]_i$ was recorded with Na-sensitive microelectrodes during exposure to low pH acetate solutions. Rather than a decrease, and increase in $[Na^+]_i$ was recorded when pH_i was decreased. This suggests that the inward rectification channel may be even more sensitive to changes in intracellular pH than our titration curves indicate.

8.12 PARTIAL DEMYELINATION AS A TEST FOR LATERAL DIFFUSION OF SURFACE CHARGES IN THE FROG NODE OF RANVIER. P.A. Pappone* and M.D. Cahalan. Dept. of Physiology and Biophysics, Univ. of Calif., Irvine, CA 92717.

We have examined the effects of the amino group reagent trinitrobenzene sulfonic acid (TNBS) on the sodium currents of voltage clamped frog myelinated nerve and skeletal muscle fibers. TNBS is membrane impermeant and converts normally positively charged amino groups into neutral trinitrophenylated derivatives. In both fiber types externally applied TNBS caused a rapid shift in the voltage dependence of steady state sodium current inactivation and in the time constants for development of and recovery from inactivation to more hyperpolarized potentials. Sodium current activation was shifted in the same direction, but to a lesser extent. These effects suggest that TNBS treatment results in an increase in the negative surface potential of the membrane. The effects of TNBS are largely irreversible in muscle fibers, but reverse rapidly (within 1-3 min) in nerve fibers following short exposures (<1-2 min) to TNBS. Nerve fibers recover more slowly from the TNBS-induced shift following longer exposures. Since the reaction of TNBS with amines results in a stable product, we suggest that the reversibility of the TNBS effect in the nerve may be due to diffusion of the modified membrane components laterally into the internodal membrane. In the nerve fibers only the 0.5-1μ node of Ranvier is exposed to the reagent, and diffusion of membrane components with mobility like that of lipids in bilayers would be quite rapid over this distance. To test this hypothesis we examined the effects of TNBS on partially demyelinated nerves. Normal nerve fibers were exposed to 0.5M urea in Ringers for 2-5 min. Following washout of the urea there was a 2-16x increase in the membrane capacity and a 1.5-6x increase in voltage-dependent potassium current, indicating that extranodal nerve membrane was exposed by the treatment. In the demyelinated nerve fibers recovery from the TNBS-induced shift was slow or absent following short (~1 min) exposure to the reagent, supporting the hypothesis that the TNBS-modified membrane components are free to diffuse laterally in the nerve membrane. This result suggests that TNBS may be modifying membrane lipids. If so these results indicate that the charge on membrane lipids can influence the gating of sodium channels. (Supported by a postdoctoral fellowship to P.A.P. from the Muscular Dystrophy Association of America and NIH Grant NS14609).

8.13 ACTION POTENTIAL MECHANISM OF RAT CORTICAL NEURONS IN CELL CULTURE, Marc A. Dichter and James Lisak*, Dept. of Neurology, Harvard Medical School, Children's Hospital, Boston, MA 02115.

Rat cortical neurons maintained in dissociated cell culture have thin, rapidly rising, overshooting action potentials (APs) (Dichter, Brain Res. 149:279-293, 1978). Removal of Ca or application of the Ca channel blocking agent, Co, has minimal effects on AP morphology, but these APs disappear in the presence of tetrodotoxin (TTX) at 10^{-7} g/ml. Thus, these thin APs appear to be generated by a Na-dependent mechanism. In the presence of TTX, many neurons have small to moderate sized, somewhat wider, action potentials which are eliminated by Co. If the voltage sensitive K conductance in these cells is blocked by TEA (25 mM), or if Ba is substituted for Ca, wide and less rapidly rising, overshooting APs appear in all the neurons. These APs appear to be generated by voltage sensitive Ca channels in that they are unaffected by tetrodotoxin, are blocked by Co and verapamil, and their overshoots are a function of the extracellular Ca or Ba concentrations (with slopes of overshoot vs log Ca or log Ba being close to 30 mV/decade change). We conclude that the cortical neurons in culture have voltage sensitive Ca channels which under normal conditions contribute relatively little to the soma action potential. When K channels are blocked or when Ca currents are enhanced, Ca dependent APs can be expressed by essentially all the neurons.

In studies using intermediate concentrations of TEA (10 mM) where Ca APs are more variably present, low threshold APs and APs elicited with short current pulses appear to be Na-dependent APs, whereas spontaneous, synaptically driven APs (possibly arising from EPSPs in dendrites) and APs triggered by larger, longer current pulses are Ca-dependent APs. These data suggest that the Ca-dependent APs are generated in dendrites and the Na-dependent APs are generated in the soma or axon hillock.

9.1 ORGANIZATION OF CORTICOSPINAL PROJECTIONS AS DEMONSTRATED BY THE COMBINED TECHNIQUES OF MICROSTIMULATION AND METABOLIC LABELING. E. Kosar*, and H. Asanuma (SPON: V.J. Wilson). The Rockefeller University, New York, N.Y. 10021.

Activation of restricted portions of the ventrolateral horn of the spinal cord by microstimulation of the motor cortex in both the rat and the monkey could be demonstrated using the [^{14}C] 2-deoxyglucose technique. Under halothane anesthesia, the motor cortex was exposed and a closed chamber installed. Anesthesia was then discontinued. Microstimulation (6-20μamp x 10-13 pulses of 0.2msec duration, 300Hz) was applied to a cortical focus via a tungsten-in-glass microelectrode to elicit movement of individual muscles of the distal forelimb or digits. [^{14}C] 2-DG was injected intravenously (100μCi/1kg of body weight) while microstimulation was continued for 45 minutes. The elicited movement remained stable throughout the full experimental period. The animal was subsequently overdosed with barbiturate and perfused intracardially with 5% glutaraldehyde-0.5% paraformaldehyde. The brain and spinal cord were removed immediately, frozen in Freon XXII, sectioned on a cryostat (20μm) and processed according to the procedure of Sokoloff et al. (J. Neurochem. 28: 1977). Following the appropriate exposure period, alternate sections of the brain and spinal cord were examined by projecting the autoradiograms onto a television screen. Sections were traced from the screen and labeling was reconstructed 3-dimensionally. Metabolic labeling at the stimulation site extended approximately 1.5mm rostro-caudally in motor cortex. Unilateral and bilateral labeling was observed in the spinal cord. Unilateral labeling was located contralaterally in only a restricted portion of the ventrolateral cervical cord in all animals and was localized to the lateral portion of the motoneuron pools. This labeling extended rostro-caudally in the cervical cord approximately 4mm in the rat and 7mm in the monkey, maintaining the same medio-lateral position throughout its full extent. The bilateral labeling was located in the position of the ventromedial motoneurons related to axial musculature. Metabolic labeling was also observed at other levels of the spinal cord but the density of labeling appeared equal on both sides. This is in contrast to the restricted unilateral labeling in the cervical cord described above. The combination of these two techniques has thus far proven useful in analyzing the pattern of activity within the CNS originating from a small restricted area of the cortex.

9.2 INPUT TO CAT'S PERICRUCIATE MOTOR CORTEX (AREA 4γ) FROM PARIETAL CORTEX (AREA 5b AND AREA 7). R. S. Waters, A. Mori*, E. Kosar, R. S. Babb and H. Asanuma. The Rockefeller University, New York, N.Y. 10021.

We have reported (Babb et al. Neurosci. Abstr. 6: 159, 1980) that horseradish peroxidase (HRP) injected into the forelimb region of the motor cortex (area 4γ) labelled cell bodies within the suprasylvian gyrus (areas 5b and 7). The present study was undertaken to examine the physiological properties of these neurons and to determine the caudal extent of the neurons that project to area 4γ. Under halothane anesthesia a double-barreled chamber was installed over the motor and parietal cortices. An array of 8 stimulating microelectrodes was inserted into area 4γ. The receptive field of neurons around each electrode was examined first and then threshold current for muscle contraction was determined. A single recording microelectrode was driven systematically into areas 5b, 7 or 19 while ICMS was delivered simultaneously through the 8 stimulating electrodes. Whenever an antidromically activated neuron was encountered, the effective stimulating electrode was determined and an examination of the receptive field of the neuron was made using natural stimulation by air puffs, brush stroke, pressure to deep structures, and passive movement of joints. Receptive fields of neurons were also examined in penetrations where antidromically activated neurons were not encountered. At the conclusion of an experiment HRP was injected through the recording electrode, at the site where an area 7 neuron was activated antidromically from area 4γ. After a survival time between 44-48 hrs., the subject was sacrificed, the brain perfused, and the tissue processed using the tetramethyl benzidine method.

The following results were obtained: (1) Neurons in area 5b and area 7 could be activated antidromically from electrodes in 4γ. (2) Neurons in caudal 5b and area 7 did not respond to peripheral stimulation nor to auditory or visual stimuli. (3) The majority of the 5b and area 7 neurons projected to the precruciate region of area 4γ. The highly organized projections to motor cortex we reported for neurons in the anterior and posterior ansate area (Waters et al., Neurosci. Abstr. 6: 124, 1980) were not found for areas 5b and 7. (4) Following injection of HRP into the region of antidromically activated neurons in area 7, labelled neurons were found in area 19. Since area 19 is known to receive higher order visual information it is likely that some complex visual information may reach the motor cortex through areas 5b and 7.

9.3 THE MONKEY'S PREMOTOR CORTEX. S. P. Wise and M. Weinrich, Laboratory of Neurophysiology, NIMH, Bethesda, MD.

The definition of a premotor cortex (PM), as distinguished from the precentral motor cortex (MI) or any other motor representation, remains uncertain. Investigations employing microelectrode methods should improve the understanding of PM, but previously neither the location of isolated neurons nor the cytoarchitectural characteristics of the region have been clearly described. Therefore, we have initiated a re-investigation of PM.

A rhesus monkey was operantly conditioned to depress one of four keys located in a perimeter at arms length. While the monkey pressed one key, another of the four keys, selected randomly, was illuminated after a randomly varied delay. This key thereby became the next target. A barely discernible visual cue near the target key, appearing after another variable delay, signaled the monkey to move and depress the target. The monkey was required to make the movement within a short period of time, near the limit of reaction time. Reaction time was typically 350 msec; movement time, an additional 250 msec. EMG of selected muscles and EOG were monitored periodically during the recording sessions.

(1) Many (149/221) neurons in PM show changes in activity markedly (90-190 msec) before the onset of a voluntary movement (20-120 msec before the onset of EMG change) and usually continue their altered discharge rate throughout the movement and for 50-350 msec after the termination of movement. Their activity is often (57/149) specific for the direction of arm movement. (2) These neurons are located within the frontal agranular cortex, corresponding to a part of area 6 as defined by the absence of a large population of giant, layer V pyramidal cells in addition to the lack of an internal granular layer. (3) PM can be distinguished from the MI representation by its markedly increased threshold for intracortical microstimulation effects (constant current, 30 msec trains, 0.2 msec pulses at 333 Hz). The threshold exceeds 90 μA in 37/40 penetrations. Conversely, MI can be defined by the consistently low microstimulation thresholds (28/30 penetrations at <50 μA). And (4) a substantial population of neurons (102/221) change their activity in relation to motor set and/or signals which indicate the location of motor targets.

These features are consistent with a role of this part of area 6 in the control of movement, especially the dynamic phase of a voluntary movement, and with the concept of a distinct premotor cortical field which constitutes part of a belt of somatic sensorimotor cortex surrounding the "primary" motor (MI) and somatic sensory (SI) cortex.

9.4 THE MOTOR CORTEX OF THE RAT: DEFINITION BY MICROSTIMULATION AND CYTOARCHITECTONICS. J. P. Donoghue and S. P. Wise, Laboratory of Neurophysiology, NIMH, Bethesda, MD. 20205

The somatic sensorimotor cortex of the rat contains several distinct cytoarchitectonic fields. Welker (Brain Res., 26:259, 1971) showed that the first somatic sensory (SI) cortex, as defined by cells sensitive to cutaneous inputs, corresponds to the most densely granular part of the cortex. But there is not, as yet, a clear cytoarchitectural definition of the rat's motor cortex. We have used intracortical microstimulation and standard neuroanatomical methods to define the first motor (MI) cortex in the albino rat.

Retrograde axonal transport experiments demonstrate that the corticospinal projection originates, in part, from two cytoarchitecturally distinct fields of the frontal agranular cortex (FAC). Anterograde transport experiments show that fibers from FAC project to the ventral horn of the spinal cord, in addition to a denser projection to the intermediate spinal laminae. These findings suggest that both of these FAC fields are part of the somatic sensorimotor cortex. Under ketamine anesthesia, relatively low threshold microstimulation (10-65 uA, 30 msec trains, 0.2 msec pulses, 333 Hz) elicits movements of the contralateral head, trunk, or forelimb from only one of these FAC fields. In the other field, stimulation thresholds generally exceed 100 uA. The low threshold field can be characterized by the relative homogeneity of its superficial laminae This appearance contrasts, in thionin stained sections, with the less densely staining layer III of the adjacent higher threshold FAC field. We therefore conclude that the low threshold FAC field corresponds to MI, while the higher threshold, spinally projecting part of the FAC is a distinct cortical field within the somatic sensorimotor cortex.

Caudolateral to the low threshold FAC, we observed a continuation of the low threshold (hindlimb and forelimb) microstimulation responses into the granular cortex. Such an overlap between the SI and MI representations was originally described by Hall and Lindholm (Brain Res., 66:23, 1974). Microstimulation of other parts of the granular cortex at <65 uA does not evoke movement.

These experiments demonstrate that a cytoarchitecturally distinct cortical field can be identified as a major part of MI in the rat. The rat's MI representation apparently differs from that of certain primates in that it includes granular cortex which is also part of the SI cortex.

9.5 CLASSIFICATION OF HINDLIMB AREA 4 UNITS AS RELATED TO FORCE DURATION AND DIRECTION IN THE CONDITIONED MONKEY. S. A. Sahrmann, M.H. Clare, E. B. Montgomery Jr.*, and W. M. Landau. Dept. Neurol., School. Med., Washington U., St. Louis, MO 63110.

Rhesus monkeys were conditioned with light signals to perform four randomly selected tasks with the hindfeet. Force was exerted bilaterally on fixed bars with attached strain gauges. The tasks were: (1) to exert a strong plantarflexion force, hold it a random time, on cue exert a strong, brief, rapid dorsiflexion force and return to rest (rapid-relax); (2) to do the converse; (3) to plantarflex into a small force window, holding until signalled to return to rest; and (4) to perform the converse of (3).

A preliminary report (Sahrmann, S.A., et al. Soc. Neurosci. Abstr., Vol. 5, p. 384, 1979) designated units as phasic if their firing rate did not remain increased for the 200 msec. after achievement of force criterion for hold tasks. The tonic units showed sustained activity during hold. Present analysis of 228 units recorded from 3 rhesus monkeys indicated that 65% were phasic and 17% were tonic (sustained increased activity for at least 500 msec. after force criterion).

Units were further classified as Directional if increased activity was consistently related to development of either plantarflexion or dorsiflexion force (103/228, 45%). Bi-directional units were those with increased activity during both plantarflexion and dorsiflexion force (99/228, 43%). Inhibitory units were those with decreased activity during plantar and/or dorsiflexion (26/228, 11%).

Directional units were further subgrouped according to the presence or absence of additional phases of increased activity other than that with primary agonist contraction. Some units were similar to spinal motoneurons since increased activity exclusively paralleled initiation of agonist contraction (26/103, 25%). Others, those with high resting frequencies, were inhibited during antagonistic contraction (37/103, 36%). A third group showed increased activity during antagonistic relaxation as well as during agonist contraction (40/103, 39%).

Bi-directional units were designated as symmetric if activity during both plantar and dorsiflexion was similar (17/99, 83%). Asymmetric units were more strongly associated with force development in one direction than in the other (82/99, 83%).

9.6 RELATIONSHIP OF CLASSIFIED HINDLIMB AREA 4 UNITS TO FORCE MAGNITUDE IN THE CONDITIONED MONKEY . M.H. Clare, S.A. Sahrmann, E.B. Mongtomery Jr.* and W. M. Landau. Dept. Neurol., School. Med., Washington U., St. Louis, MO 63110.

Rhesus monkeys were conditioned with light signals to perform four randomly selected tasks with the hind feet. Force was exerted bilaterally on fixed bars with attached strain gauges. The tasks required either a large (1 kg) plantar or a large dorsiflexion force maintained for a random period, and at a light cue, a large rapid force in the opposite direction (rapid reversal) followed by relaxation. A small plantar or dorsiflexion force (200 gm) held for a random period, with relaxation on light cue was also required. Thus the activity of each cortical unit was recorded during large maintained, large rapid-reversal and small maintained forces in both plantar and dorsiflexion.

The large rapid-reversal force was associated with the peak discharge frequency of 56% of the phasic units (as classified in Sahrmann, S.A., et al., Soc. Neurosci. Abstr., vol. 7, 1981) but with only 24% of the tonic units.

Few units were found with frequency changes proportional to small and large forces (Directional 12% and Bi-directional 8%). Peak frequency was associated with either or both large forces for 27% of the Directional and 46% of the Bi-directional. The asymmetric units usually had greater frequency changes for both large forces than for the small forces.

The Directional units had the highest incidence of the peak frequency during the small force equalling or exceeding that of the large force, (35% Directional; 20% Bi-directional). Twenty-five percent of the Directional and 8% of the Bi-directional units increased their firing rate with large forces exclusively.

Most Inhibitory units showed decreased discharge during force in both directions. The magnitude of the decrease in firing frequency was not related to the magnitude of the force but did vary for plantar and dorsiflexion.

10.1 EVIDENCE THAT ENDOPEPTIDASE-CATALYZED LHRH CLEAVAGE CONTRIBUTES TO THE REGULATION OF MEDIAN EMINENCE LHRH LEVELS DURING POSITIVE FEEDBACK. J.P. Advis*, J.E. Krause* and J.F. McKelvy, Department of Neurobiology and Behavior, SUNY Stony Brook, New York 11796.

In order to examine the possible physiological relevance of peptidases acting on LHRH, we have studied the degradation of LHRH by homogenates of median eminence from ovariectomized, estradiol-progesterone treated rats, decapitated at three hour intervals after progesterone administration (10.00 h). It is known that under these conditions an increase in median eminence LHRH content (13.00 h) precedes the release of LHRH into the portal vessels, which subsequently gives rise to a surge-like release of pituitary LH (16.00 h). Furthermore, both the increase in LHRH content and of serum LH can be prevented by prior administration of the noradrenergic synthesis inhibitor diethyldithiocarbamate (DDC).

Total LHRH peptidase activity was assessed by HPLC estimation of the loss of synthetic LHRH incurred when aliquots of supernatant (5'/10,000g) were incubated (37°/30 min.) with LHRH under optimal conditions. LHRH degradation was measured as initial velocities using saturating substrate concentrations. Characterization of degradation products by HPLC and amino acid analysis revealed a rate limiting step to TYR^5-GLY^6 bond scission. Other studies showed that the responsible activity is a metalloendopeptidase. LHRH content and serum levels of gonadotropins were estimated by RIA.

LHRH degradation was decreased ($p<0.01$) three hours after progesterone administration, at a time when LHRH content is increased ($p<0.01$), and serum LH remained at basal levels (13.00 h). At the time of the LH surge (16.00 h) LHRH degradation was still low and LHRH content had returned to basal levels. LHRH degradation in animals which received a single dose of DDC, one hour before progesterone administration was higher ($p<0.01$) than in saline treated controls at 13.00 h and 16.00 h.

We conclude that the degradation of LHRH by a metalloendopeptidase may contribute to the regulation of LHRH levels appropriate for gonadotropin release.

Supported by NSF BNS 7684506 and NIH RCDA AM 00751 (JFM).

10.2 IN VIVO LHRH RELEASE ESTIMATED WITH PUSH-PULL CANNULAE AND SIMULTANEOUS SERUM LH MEASUREMENT IN OVARIECTOMIZED EWES. J.E. Levine, F. Pau*, V.D. Ramirez, and G.L. Jackson*. Dept. of Physiology and Biophysics, and Dept. of Veterinary Biosciences, University of Illinois, Urbana, IL 61801

A neural oscillator may regulate pulsatile release of LH. This regulation likely is achieved through rhythmic discharge of LHRH from axon terminals in the median eminence (ME). Recently we showed that release of LHRH can be estimated in unanesthetized animals using the push-pull cannula (PPC) (Endo 107:1782). Combining this technique with measurement of serum LH, we attempted to determine the: 1) pattern of spontaneous LHRH output from the ME of the ovariectomized (OVX) sheep, and 2) temporal relationship between LHRH and LH release. Thirty days after ovariectomy, ewes received a permanently implanted PPC (20g). The tip of the PCC was directed into the lateral ME. Post-implantation recovery was at least 6d. Before perfusion, a stylette was removed from the outer PPC and an inner cannula assembly (28g) inserted. Artificial CSF was pumped through the inner cannula and pulled between the cannulae at 18ul/min. Continuous 10min fractions were collected, acidified, and stored for LHRH RIA. Blood samples were obtained every 10min via jugular catheter, each being drawn 5min after the start of a perfusate collection interval. Duration of sampling was 5-7h. Plasma LH levels were determined by RIA.

LHRH output was distinctly pulsatile, occurring at a frequency of about 1 pulse/40min. Peak values were consistently within 1.0-1.6pg/10min, while trough values were ≤0.6pg/10min. The pattern of LHRH output remained unchanged throughout all perfusions (5-7h). Plasma LH values also were pulsatile, and LH peaks occurred either during the same interval or interval after an LHRH pulse. LH pulses always were preceded by LHRH pulses, but LHRH pulses were not always followed by LH pulses. Data from one sheep were subjected to spectral analysis. Peak frequencies for LHRH and LH were identical (1.5cycles/h) and the squared coherence was .77. Histological examination revealed that each cannula tip was placed in the lateral ME. These experiments demonstrate for the first time that hypothalamic LHRH release in the OVX ewe occurs in discrete pulses, and that LH pulses appear to be preceded by LHRH pulses. Furthermore, this study establishes the push-pull perfusion technique as a direct method by which the output of releasing factors can be measured and correlated with circulating pituitary hormone levels. 10.3 IDENTIFICATION OF LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) NEURONS IN THE ARCUATE NUCLEUS OF HYPOTHALAMIC SLICES. M.J. Kelly, O.K. Ronnekleiv Dept. of Physiology (MJK), and Dept. of Psychiatry (OKR), Univeristy of Pittsburgh School of Medicine, Pittsburgh, PA 15208.

Arcuate (ARC) neurons have been found to be acutely sensitive to 10^{-10} M 17β-estradiol when applied to the medium bathing hypothalamic slices (Kelly et al., Exp. Brain Res. 40:440 (1980). We have labeled these neurons with procion yellow and have found that these estrogen-responsive neurons are small fusiform cells with little branching of the dendrites and little or no spine-like appendages. In order to identify these neurons, it was necessary to develope an immunocytochemical technique which was compatible with the procion yellow fluorescence. Cycling female rats were killed and sagittal hypothalamic slices were prepared as previously described (Kelly et al., 1980). The 400 μm thick slices were then immediately immersed in cold 4% Paraformaldehyde in .1 M phosphate buffer (pH 7.2) for 1-1/4 hrs. Then the slices were transfered to phosphate buffered saline (10% sucrose, pH 7.2) and refrigerated until cutting. The slices then were taken, frozen rapidly in isopentane cooled to -75°C in a dry ice/ethanol mixture, and 16 μm sections were cut at -17°C on a cryostat. The sections were kept frozen until the PAP immunochemical procedure (Sternberger, 1974) was done using the WP-1 antiserum (courtesy of Dr. R.L. Eskay) for LHRH. LHRH-immunoreactive neurons were identified scattered throughout the ARC region. This staining was abolished by pre-incubation of the antiserum with synthetic LHRH. The LHRH-immunoreactive neurons have a similar morphology as the identified estrogen-sensitive neurons previously described. We cannot say at this point that these are the same cells, but the compatibility of this staining procedure with the procion yellow fluorescence will allow us to correlate the electrophysiological response to estrogen with the peptide content of the cell.

10.4 IMMUNOCYTOCHEMICAL LOCALIZATION OF LHRH IN MALE AND FEMALE RAT BRAIN: A QUANTITATIVE COMPARISON. B.D. Shivers, R.E. Harlan*, J.I. Morrell and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

Luteinizing hormone releasing hormone (LHRH) regulates functions which are sexually dimorphic and steroid dependent. In this study LHRH was immunocytochemically localized in the brains of adult rats of both sexes, using Sternberger's peroxidase-antiperoxidase method and Silverman Rb III primary antiserum. Four groups of rats were used: intact males, gonadectomized (gdx) males, gdx females and gdx females with estradiol (E2) capsules. Each brain was examined from midseptal through midbrain intercollicular levels inclusive.

	intact ♂	gdx ♂	gdx ♀ + E2	gdx ♀
Total number LHRH cells ($\bar{x}$ + SE, N=4)	507±52*	130±58	146±41	82±30
% LHRH cells dark	81.9*	54.5	51.2	47.1
% LHRH cells in DBB+POA	75.1#	55.4	63.7	65.8

* $p < .01$ vs. three other groups
\# $p < .005$ vs. gdx male and gdx female with E2.

Intact male rats had a significantly greater number of visualized LHRH cell bodies than did the three other groups. Cells were classified as dark or light based on the amount of immunoreactive cytoplasmic material. Intact males showed a significantly greater percentage of dark cells than did the three other groups. No differences in either cell number or percentage of dark cells were found among the three other groups. The majority of LHRH cells was seen in the diagonal bands of Broca (DBB) and preoptic area (POA). Intact males had a significantly higher percentage of LHRH cells in the DBB+POA than did gdx males or gdx females with E2.

The results suggest that LHRH content in cell bodies is greater in intact males than in the three other groups. One interpretation of the decrease in the percentage of LHRH cells in the DBB+POA following gonadectomy in the male is that some LHRH cells are more responsive to testicular steroids than are others.

10.5 EFFECTS OF ELEVATED LEVELS OF PROLACTIN ON LORDOSIS BEHAVIOR AND LHRH-STAINED CELLS IN THE FEMALE RAT. C.A. Dudley, S. Jamison and R.L. Moss. Dept. of Physiology, University of Texas Health Science Center, Dallas, Texas 75235.

Elevated plasma levels of prolactin (PRL) induced either by pituitary transplants under the renal capsule or by direct peripheral administration have been shown to suppress reproductive behavior in the male rat and to interfere with vaginal cyclicity in the female rat. The purpose of the present study was to investigate the effects of persistent, elevated levels of PRL on lordosis behavior and on brain LHRH-staining in the intact, normal cyclic female rat. Hyperprolactinemia was induced in 11 female rats by grafting whole pituitaries under the kidney capsule, while sham surgery was completed on 12 control female rats. Serum PRL levels were measured via radioimmunoassay and levels of sexual receptivity were determined in the grafted and control animals at one and three months after transplantation. At the fourth month, the grafted and control animals were sacrificed and the extent of brain LHRH staining determined immunocytochemically. Serum PRL levels were found to be 2 to 3 times higher in the grafted than the control animals at both times of assay. On the other hand, high levels of mating behavior were successfully induced in both groups of animals at one month by exogenous administration of estradiol benzoate (E) and progesterone (P). The lordosis to mount ratio (L/M) for the grafted animals was 1.00± .00 whereas that for the sham group was .95±.01. However, at three months, E-P induced mating behavior could not be obtained in the grafted animals (L/M=0.0) whereas the control group still exhibited good lordotic responsiveness (L/M=.62). The animals were then sacrificed (at four months) via perfusion with a mixture of paraformaldehyde and glutaraldehyde. The brains were removed and 50 μ sections were cut on a Vibratome from the septal area through the median eminence. The sections were then processed immunocytochemically according to standard peroxidase anti-peroxidase techniques using a specific antibody to LHRH provided by W. Vale. The number of LHRH stained cell bodies in each section was counted and a mean per animal was then obtained without knowledge as to the condition of the animal. Subsequently, a mean for the grafted and control animals was calculated. The number of LHRH stained cell bodies was dramatically lower in hyperprolactinemic animals than in the control animals. The mean number of LHRH stained cell bodies per tissue section was 1.8± .58 for the grafted animals and 3.1±.77 for the sham controls.

The absence of mating behavior in the hyperprolactinemic animals may be due to decreased LHRH synthesis as reflected by a reduction in the number of stained cell bodies in these animals.

10.6 ACTIONS OF OVARIAN HORMONES AND MICROELECTROPHORETICALLY APPLIED PROLACTIN ON LHRH-SENSITIVE NEURONS IN THE NUCLEUS VENTROMEDIALIS HYPOTHALAMI. A. Chan*, C.A. Dudley* and R.L. Moss (SPON: J. Schadt). Dept. Physiol., Univ. Tx. Hlth. Sci. Ctr., Dallas, TX.

Previous reports have demonstrated that luteinizing hormone-releasing hormone (LHRH) exerts a facilitatory effect on mating behavior in the female rat. Prolactin (PRL), administered intraventricularly, has been shown to suppress mating behavior in the estrogen-progesterone (E-P) primed ovariectomized rat. The inhibitory effect of PRL on mating has been suggested to be mediated through LHRH. Since the ventromedial nucleus (VMH) has been implicated in the control of mating behavior, the present experiment was designed to study the actions of ovarian hormones and microelectrophoretically applied PRL on the LHRH-sensitive units in the VMH. Extracellular potentials were recorded via 4 M NaCl-filled central barrel (4-8 MΩ) of a seven-barreled micropipette (composite tip diameter of 1.5-3 μm). Each of the outer barrels contained one of the following solutions: 0.1 M norepinephrine (NE); 0.5 M dopamine (DA); 0.5 M sodium glutamate (GLUT); 0.1 mM PRL; 1 mM LHRH; 1 mM D-Pro, D-Phe^2, D-Trp^{3,6}-LHRH (LHRH$^-$, LHRH antagonist which inhibits the release of LH from the pituitary gland in a concentration ratio of 0.5:1).

Summary of pharmacological responses of VMH neurons

Agents	Untreated OVX rats				E-P treated OVX rats			
	n	↑	↓	→	n	↑	↓	→
LHRH	39	13%	18%	69%	80	16%	31%	53%
LHRH$^-$	26	8%	27%	65%	59	17%	41%	42%
DA	47	11%	72%	17%	37	8%	73%	19%
GLUT	21	62%	5%	33%	52	69%	8%	23%
PRL	77	68%	13%	19%				

The results tabled above indicate that more nerve cells are inhibited by LHRH and LHRH$^-$ in E-P treated than untreated OVX rats. No such hormonally dependent differences were observed with DA or GLUT. The stimulatory effect of PRL appeared to be dose-dependent (0-30 nA). Of all the LHRH-inhibited units, PRL excited 65%, inhibited 13% and had no effect on 22% of neurons tested (n=23). Of all PRL-activated units, LHRH excited 23%, inhibited 32%, and had no effect on 45% of these units tested (n=47). This result indicates that the LHRH-inhibited units are predominantly excited by PRL, but the stimulatory action of PRL is not specific for the LHRH-inhibited units. The above findings can be interpreted to suggest that the inhibitory response of LHRH in the VMH, which is dependent on ovarian hormones, may be related to mating behavior. The mechanism by which PRL suppresses mating behavior could be mediated by stimulating the LHRH-inhibited units and thus exerting an opposite effect to LHRH in the VMH. Research supported by NIH grant NS 10434 to RLM.

10.7 EFFECTS OF LHRH ON MULTIUNIT ELECTRICAL ACTIVITY OF THE PREOPTIC-ANTERIOR HYPOTHALAMUS IN THE OVARIECTOMIZED RAT. David I. Whitmoyer, Peter C.K. Leung and Charles H. Sawyer. Department of Anatomy and Laboratory of Neuroendocrinology, Brain Research Institute, UCLA, Los Angeles, CA 90024.

Luteinizing hormone-releasing hormone (LHRH) has been implicated as a possible mediator of "ultrashort-loop feedback" in the control of LH release. In the rat, perikarya of LHRH neurons have been located primarily rostral to and within the preoptic-anterior hypothalamic region. In the present study, effects of intraventricular infusions of LHRH on the multiunit activity (MUA) of this rostral brain region were investigated in long-term ovariectomized rats.

Adult female Sprague-Dawley rats were chronically implanted with third-ventricle cannulas and electrode arrays for recording MUA and cortical EEG. All animals were ovariectomized 2 weeks prior to implantation and recordings were taken from the unanesthetized freely-moving animals 2 weeks post-implantation. MUA records were obtained from 25 electrode sites in the preoptic-anterior hypothalamus. Intraventricular infusion of saline (2 μl, pH 5.5) had no effect on MUA. On the other hand, infusion of LHRH (0.5 μg in 2 μl saline, pH 5.5) led to changes in MUA in 11 of 25 trials. Of these 11 responses, 5 were increases; i.e., MUA rose by 40-50% by 40 min post-infusion. The inhibitory effects were striking, with 5 sites showing 50% decreases by 50 min post-infusion and lasting through the end of the 90-min recording period.

In ovariectomized rats, norepinephrine (NE) has been shown to inhibit LH release. The effects of NE (10 μg in 2 μl saline, pH 5.5) were assessed for 17 of the 25 sites. NE infusions were separated from the LHRH tests, either 2 days before or 2 days after. In 15 of the 17 cases, NE led to dramatic decreases in MUA within 10 min. Thus, in rostral brain sites some populations of neurons were responsive to both NE and LHRH. However, although the time course of MUA changes following LHRH infusion may be a direct result of LHRH exposure, the possible involvement of secondary effects such as a change in plasma LH cannot be excluded.

Previous MUA studies from our laboratory have employed several different techniques for deriving an "integrated" record from the raw MUA activity. The present system employs analog elements which continuously compute the root-mean-square (RMS) value of the MUA signal (RMS-MUA). This is the preferred approach to integration because it yields a calibrated output signal, the technique can be reproduced easily by other investigators, and it conforms to the standard electrical engineering approach to the measurement of non-sinusoidal signals.

10.8 PITUITARY IMMUNOCYTOCHEMISTRY OF LHRH AND cAMP AFTER SYSTEMIC LHRH ADMINISTRATION. Jorge Pecci-Saavedra, J. Yuan Li*, Joan L. Greenwald* and Ludwig A. Sternberger. Center for Brain Research, University of Rochester School of Medicine, Rochester, NY 14642.

Male rats were injected I.V. with doses of LHRH ranging from 0.1 to 100μg and sacrificed by perfusion after 2-30 min. Vibratome sections of the pituitaries were processed for light and electron microscopy with the PAP technique using antibodies to cAMP, LHRH and LH. After injections of 1, 10, and 100μg of LHRH, cytoplasmic cAMP was visualized in large and small gonadotrophs with increasing intensities. Uninjected controls were unstained. A proportion of gonadotrophs, identified morphologically and immunocytochemically with anti-LH exhibited granular cytoplasmic staining for LHRH. Results allow for the identification of the gonadotrophs as responsible for the previously reported controversial increase of cAMP in whole pituitaries after stimulation by LHRH. The finding of intracytoplasmic LHRH in the present experiments gives further support to previous studies on intracellular LHRH receptors. These findings could suggest a biphasic action of LHRH on gonadotrophs: a) a releasing effect mediated through granule LHRH receptors; and b) a rapid, secondary activation of adenyl cyclase, that follows exocytosis and fusion of the LHRH-granule receptor complex with the plasma membrane. Results of this secondary effect may be up-regulation of LHRH receptors, gonadotropin replenishment and LHRH-receptor transport to GERL or Golgi regions.

Anti-cAMP antibodies were kindly supplied by A.L. Steiner. Supported by NIH grants HD 12932, NS 15843 and NS 15809 and by Conicet, Argentina.

10.9 HYPER-RESPONSIVENESS OF MEDIAN EMINENCE LHRH TERMINALS INDUCED BY NEONATAL MONOSODIUM GLUTAMATE TREATMENT. L.V. DePaolo* and A. Negro-Vilar. Department of Physiology, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

Monosodium glutamate (MSG) treated rats present atrophic gonads and pituitaries, low to normal gonadotropin levels, normal pituitary responsiveness to exogenous LHRH, but decreased responses to the negative and positive feedback effects of gonadal steroids. These disturbances, combined with the known neurotoxic effects of MSG on the arcuate nucleus (ARC) neurons, suggest a derangement in the LHRH releasing mechanism. The present experiments were designed to test this hypothesis. Neonatally MSG-treated male rats and their controls were sacrificed at 5 months of age. MSG-treated rats presented reduced body, anterior pituitary and ventral prostate weight. Interestingly, weights as well as protein content of the median eminence (ME) were also significantly reduced ($p<.01$) in MSG-rats. As reported by others, dopamine (DA) levels in the ARC were reduced by about 50% in MSG rats, whereas levels of the amine in other areas were not affected. LHRH concentrations (pg/μg protein) were slightly but significantly decreased in the ARC of MSG-rats, whereas LHRH in the ME in the same animals was two fold higher than control values. Release of LHRH from median eminence fragments was evaluated in vitro using a perifusion system. ME's from MSG-treated or control male rats were incubated in Krebs-Ringer medium for a control period of 50 min, after which the tissues were incubated for 50 min in a high K^+ medium at a concentration (30 mM) which induced half-maximal stimulation of LHRH release. This was followed by another 50 min period during which prostaglandin E_2 (PGE_2, 10 μg/chamber) an effective releaser of LHRH, was injected as a pulse superimposed on the high K^+ medium. Minor differences were seen in basal LHRH release between MSG and control rats. However, in response to K^+ stimulation, ME's from MSG rats released more LHRH ($p<.01$) than control rats. Similarly, after combined PGE_2 and high K^+ treatment, LHRH release in MSG rats was 2.5 fold higher ($p<.01$) than in controls. These results suggest that the hyper-responsiveness of the median eminence LHRH terminals in vitro may result from denervation of the LHRH neurons due, at least in part, to the loss of DA neurons in the ARC. Further, they indicate that the mechanism(s) that normally triggers LHRH release is defective in the MSG rat. Therefore, a reduced in vivo release of LHRH in MSG rats may be the primary defect causing the alterations in the hypothalamic-pituitary-gonadal axis of these animals. Supported by NIH Grants HD-09988-05-3 and HD-05776.

10.10 ROLE OF TUBEROINFUNDIBULAR DOPAMINE NEURONS IN THE BIPHASIC EFFECT OF 5-METHOXY-N,N-DIMETHYLTRYPTAMINE ON RAT PROLACTIN SECRETION, M. Simonovic, G.A.Gudelsky and H.Y. Meltzer, Dept. of Psychiatry, University of Chicago Pritzker School of Medicine,Chicago,IL 60637

The two best described influences on rat prolactin (PRL) secretion are an inhibitory effect of dopamine (DA) released by the tuberoinfundibular dopaminergic (TIDA) neurons and a stimulatory effect of serotonin (5HT) and 5HT agonists. Midbrain raphe nuclei are the major source of the hypothalamic 5HT input. Little is known about the interaction, if any, between the ascending 5HT neurons and TIDA neurons. We have investigated the effect of 5-methoxy-N,N-dimethyltryptamine (5MeODMT), a 5HT receptor agonist which inhibits raphe neurons, on the turnover of DA in the median eminence and on the increase in PRL produced by variety of drugs which affect the dopaminergic inhibition of PRL secretion.

5MeODMT (2.5 - 10 mg/kg,ip) produced a marked, dose-related but short-lasting (less than 30 min) stimulation of rat PRL secretion. Thirty minutes after 5MeODMT (10 mg/kg,ip) serum PRL concentration was not significantly different from those in vehicle-treated controls. The elevations in serum PRL concentration induced by a low dose of alpha-methylparatyrosine (AMPT, 50 mg/kg,ip), an inhibitor of DA synthesis, or haloperidol (0.15 mg/kg,ip),a potent DA receptor blocker, were significantly reduced in rats which received 5MeODMT (10 mg/kg,ip) 30 min before either of the two drugs. However, 5MeODMT pretreatment did not significantly alter the increase in serum PRL concentrations induced by a higher dose of AMPT (250 mg/kg,ip) or haloperidol (1.0 mg/kg,ip). 5MeODMT also failed to alter the increase in serum PRL following morphine (5, 10 or 20 mg/kg,sc) or gamma-butyrolactone (500 mg/kg,ip), two drugs which decrease the activity of TIDA neurons. In order to test the hypothesis that inhibition of raphe firing by 5MeODMT results in increased activity of TIDA neurons, the turnover of DA in the median eminence was estimated using AMPT-induced decline of DA concentration. Steady-state concentration of DA in the median eminence was not significantly altered by 5MeODMT (10 mg/kg,ip).However, 5MeODMT significantly enhanced AMPT-induced DA decline in this region.

These results demonstrate that 5MeODMT exerts a biphasic effect on rat PRL secretion.The initial stimulation of PRL release is probably due to its ability to activate postsynaptic 5HT receptors. The subsequent inhibitory effect of 5MeODMT appears to be due to increased activity of TIDA neurons. If the inhibitory effect of 5MeODMT on PRL secretion reflects its ability to inhibit the spontaneous firing of ascending 5HT neurons, then these results suggest that decreased 5HT transmission leads to increased activity of TIDA neurons.This research was supported by USPHS MH 30,938 and MH 29,206.

10.11 EFFECTS OF AGING ON THE RELEASE OF LUTEINIZING HORMONE IN FEMALE GOLDEN HAMSTERS. H.J. Chen. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Release of luteinizing hormone (LH) as affected by aging, estrous cycle, luteinizing hormone releasing hormone (LHRH), castration and oestridiol benzoate, was studied in the female golden hamster (Mesocricetus auratus). About 80% of female golden hamsters cycled regularly when reaching 17-22 months of age until a terminal disease intervened. Age-induced irregularity of the estrous cycle included an absence of or a delay in proestrous vaginal discharge. Young female hamsters (3-5 months) had significantly (p 0.01) higher basal LH concentrations than old animals (17-22 months) in the morning of each stage of the oestrous cycle. LHRH elicited about 20-30 fold increase in serum LH concentrations in both young and old hamsters. No significant difference or definite pattern of LH release was observed between young and old hamsters in response to LHRH. However, in old hamsters that were not cycling, the peak of LH release in response to LHRH was delayed. The release of LH in response to exogenous LHRH was greater in the morning of proestrus than during other stages of the estrous cycle in both young and old hamsters. The rise in LH was significantly higher in the young than in old hamsters on the 13th and 15th days after castration. However,positive feedback stimulation of LH release by estridiol benzoate resulted in the same magnitude of LH release in both young and old hamsters.These results indicate that in the female hamster, LH release from the pituitary in response to acute stimuli such as LHRH and estrogens is the same in the young as in the old animals if they are cycling. The peak of LH release in response to LHRH was delayed in old hamsters with irregular estrous cycles. Basal LH concentrations as well as LH concentrations on the 13th and 15th days after ovariectomy were significantly higher in the young than in the old hamster,.suggesting that chronic release of LH may decrease or its degradation or clearance may increase during the aging process in female golden hamsters.

11.1 RESPONSES OF SENSORY RELAY NEURONS AND EXTRAOCULAR MOTONEURONS TO OPTOKINETIC STIMULATION IN THE FROG. S.L. Cochran, W. Precht* and N. Dieringer*. Brain Research Institute, Univ. of Zürich, CH-8029 Zürich, Switzerland.

Movement of the visual surround around an animal results in a compensatory following of the head and eyes. We have been attempting to determine the neuronal circuitry responsible for mediating this behavior in the frog, Rana temporaria. Neurons within two midbrain nuclei, innervated by the retina, are responsive to optokinetic stimulation of the contralateral eye. The basal optic nucleus (BON) contains neurons predominantly sensitive to vertically-moved patterns, while the pretectal (PT) neurons are sensitive to horizontally-moved patterns (Cochran et al., 1980). Additional recordings have been made from antidromically identified motoneurons within the oculomotor nucleus (innervating the ipsilateral, visually-stimulated eye) and the contralateral abducens nucleus. Oculomotor neurons have response properties identical to those found in the BON, both in terms of their direction specificity as well as their velocity sensitivity. In addition, some oculomotor neurons, presumably innervating the medial rectus musculature, and contralateral abducens neurons have response properties identical to PT neurons. These similarities in response properties suggests that a close relation exists between the sensory nuclei, the BON and PT nucleus, and the extraocular motoneurons. Indeed, in the frog the BON has been reported to project to the oculomotor nucleus in a monosynaptic fashion (Montgomery et al., 1979). One is thus led to the hypothesis that optokinetic reflexes of the ocular system are mediated by a three-neuronal chain from retina to midbrain sensory system to ocular motoneuron. Two findings are compatible with this hypothesis. First, the shortest EPSP latencies of BON, PT neurons, oculomotor neurons, and abducens neurons (3 msec; range 3-7 msec from optic nerve stimulation) are compatible with the proposed disynaptic innervation from the retina. However, sources other than BON or PT (e.g. the optic tectum) may also contribute to the excitation of the motoneurons. Second, PT neurons sensitive to horizontal optokinetic stimulation of the contralateral eye, can be activated at a short, fixed latency (approx. 1 msec) with electrical stimulation of the abducens nucleus. This presumed antidromic activation might indicate that PT cells terminate in the abducens. Further attempts are currently being undertaken to verify or nullify this hypothesis.

11.2 METABOLIC MAPPING OF POSTNATAL DEVELOPMENT OF AVIAN BRAIN REGIONS RESPONSIVE TO RETINAL SLIP. Olivia C. McKenna and Josh Wallman. Dept. of Biology, City College of the City University of New York, New York, N.Y. 10031

Detection of retinal slip, movement of the visual world on the retina, is necessary for stabilizing eye movements. A previous metabolic mapping study demonstrated that in birds information regarding vertical retinal slip is transmitted to the nucleus of the basal optic root (nBOR), a portion of the accessory optic system, while information regarding horizontal retinal slip is transmitted to the lentiform nucleus of the mesencephalon (LM), a pretectal nucleus. We report here developmental differences between the two nuclei.

After injection of ^{14}C-2-deoxyglucose, chicks were placed in a striped drum rotating either vertically or horizontally at 2-4°/sec. for 45 min. Alternate brain sections were stained or placed against x-ray film to produce autoradiograms. Since the visual pathways in chicks are crossed, differential stimulation of the two eyes results in differential stimulation of the two sides of the brain. In all situations tested if the eye was covered, no label was seen in the contralateral brain. Results from 3 to 7 day old chicks were compared to those of 3 to 5 week old chicks.

We found that in the nBOR of older chicks upward moving stimuli resulted in labeling of the dorsal nBOR whereas downward moving stimuli resulted in labeling of the ventral nBOR. This functional separation was not detected in the nBOR of younger chicks. These results suggest the possibility of a postnatal reorganization of the synaptic afferents within the nBOR.

In the LM, postnatal changes were different. In young chicks labeling was produced only in the LM contralateral to the eye viewing temporal to nasal stimulus movement; in older birds both temporal to nasal and nasal to temporal movement produced labeling throughout the contralateral LM. These results suggest that the LM becomes responsive to nasal to temporal movement after the first postnatal week and that, unlike the nBOR, units responding to opposite directions are not separated anatomically, although we cannot exclude the possibility that developmental changes in oculomotor responses may account for these results as well.

11.3 CELL TYPES IN THE CAT'S PARABIGEMINAL NUCLEUS. H. Sherk* (SPON: K. Fukada). Dept. of Neurobiology, Harvard Med. Sch., Boston, MA

The cat's parabigeminal nucleus has very limited connections with other parts of the brain. It receives input from the ipsilateral superior colliculus (SC), and projects to the ipsilateral and contralateral SC, and weakly to the ventral C laminae of the lateral geniculate nuclei (LGN) (A.M. Graybiel, Brain Res. 145: 365, 1978; H. Sherk, J. Neurophysiol. 42:1656, 1979). I have investigated whether all parabigeminal neurons have similar connections, or whether they form distinct subpopulations.

First, the possibility that there are interneurons in the nucleus was explored in 2 cats by making massive injections of horseradish peroxidase (HRP) into the left LGN and both SC's, with the intent of labeling all parabigeminal projection neurons. Coronal sections 2 μ thick were searched for unlabeled neurons. A few of these were present in every section, and made up 9% of the total population. They were small cells, averaging about 13 μ in diameter, compared to 19 μ for the labeled projection cells. In another experiment, scattered neurons throughout the nucleus that were similar in size to these unlabeled cells were heavily labeled autoradiographically by a local injection of 3H-GABA. At least some small parabigeminal neurons thus appear to take up GABA selectively.

Since parabigeminal cells send major outputs to both SC's, an obvious question is whether they do so by way of branching axons. To answer this, 125I-wheatgerm agglutinin (WGA) was injected in the right SC, and HRP was injected in the left SC. Many parabigeminal cells were labeled either with peroxidase or autoradiographically, but none contained both labels. WGA-tagged cells were larger than those labeled by peroxidase. It thus appears that in addition to a modest number of interneurons, the parabigeminal n. contains a population of large contralaterally-projecting cells, and a population of smaller, ipsilaterally-projecting neurons.

Observations on connectivity within the nucleus were made using the EM. The presence of Type II as well as Type I synapses gives some support to the hypothesis that the parabigeminal n. contains inhibitory interneurons. Of the terminals making Type I contacts, at least some appear to come from the SC, since they can be labeled by anterograde transport of HRP after tectal injections. Such labeled terminals are sometimes found as the first elements in axoaxonal synapses, which are fairly common in the nucleus. An unusual structure also present here is the crest synapse, and again a labeled tectal afferent sometimes forms the presynaptic element.

11.4 NASO-TEMPORAL VERSUS TEMPORO-NASAL OKN IN THE CAT. K.P. HOFFMANN, BIO IV, UNIVERSITÄT ULM, D-79 ULM, GFR.

A model based on our anatomical and neurophysiolocical data from cells in the nucleus of the optic tract (NOT) is proposed to explain the difference in gain for optokinetic nystagmus (OKN) with temporo-nasal (nasal) or naso-temporal (temporal) stimulus movement in cats. The basic assumption in this model is that stimulus direction in visual space is coded by the activity in one NOT minus the activity in the other NOT. This signal, called the NOT-output, is then used to control OKN. Testing OKN of normal adult cats monocularly shows that the gain is higher with nasal stimulus movement than with temporal movement. With nasal stimulus movement each eye strongly activates all units in the contralateral NOT in two ways, via the direct retino-pretectal fibers and via the binocular cortico-pretectal axons. With temporal stimulus movement about 40 % of the units in the ipsilateral NOT are activated, because each eye reaches the ipsilateral NOT only via binocular cells in visual cortex. As a consequence of these pathways 60 % of the cells in NOT are monocularly driven by the contralateral eye and 40 % are binocular. This ratio of .6 : .4 is taken as the relative strength of retinal vs. cortical influence on NOT cells. The maximal output value which is reached with horizontal movement and binocular stimulation is set to 1. 0.8 of the NOT-output is supplied by the activation of one nucleus and .2 by the suppression of spontaneous activity in the other nucleus. The contribution to the NOT-output made up by activation is .8 x .6 from the retinal and .8 x .4 from the cortical input, the contribution from suppression is .2 x .6 retinal and .2 x .4 cortical. With monocular stimulation the NOT-output is dependent on the stimulus direction and becomes asymmetric. With nasal stimulus direction, the contralateral NOT is fully activated (.8), the ipsilateral NOT inhibited only via the cortex (.1). With temporal stimulus direction the contralateral NOT is fully inhibited (.2) and the ipsilateral NOT activated only via the cortex (.3). These output values of .9 in nasal direction and .5 in temporal direction are matched qualitatively by the gain of OKN in the same stimulus condition. Following from this model, cortical lesions in the adult or developmental manipulation in young kittens must increase the asymmetry between nasal and temporal OKN.

11.5 FROM LOCAL DIRECTION PREFERENCES TO GLOBAL ROTATION PREFERENCES IN THE ACCESSORY OPTIC SYSTEM. C. S. Leonard*, J.I. Simpson and R.E. Soodak*, Dept. Physiol. & Biophys., New York Univ. Med. Ctr. 550 First Avenue, New York, N.Y. 10016

Previous studies from this laboratory have shown that neurons of the medial terminal nucleus (MTN) of the rabbit accessory optic system respond preferentially to large, textured visual stimuli slowly moving in near vertical directions. In this study we have focused on the spatial distribution of preferred directions within the receptive field (RF) of MTN neurons and of neurons neighboring the MTN. Neurons from the latter group project to the dorsal cap (DC) of the inferior olive. Extracellular recordings were made in anesthetized, pigmented rabbits presented with stimuli provided either by rear projection onto a tangent screen or by a planetarium projector. Latencies of orthodromic and antidromic activation were obtained with electrical stimulation of the optic chiasm and the ipsilateral DC. Most neurons recorded within the MTN can be characterized by a single preferred direction (PD), either up and somewhat backward or down and somewhat backward, and have their RF in and above the visual streak. These neurons responded only to stimuli presented to the contralateral eye and were activated at short, presumably monosynaptic latencies (1.5-2.5msec) from the chiasm. Other neurons recorded within the MTN had two distinctly different PD's in separate regions of their monocular, contralateral RF. That is, in one part of the RF the preferred direction was up and somewhat backward whereas in the other part of the RF the preferred direction was down and somewhat backward. Neurons located outside the MTN, including those antidromically activated from the DC, were typically binocular, with one or the other eye dominant. Monocular neurons with one or two PD's, as well as most contralateral dominant binocular neurons were activated from the chiasm at latencies in the monosynaptic range, thus excluding a purely serial development of RF organization in which retinal fibers synapse only with neurons having a single PD. The direction selectivity of neurons with more than one PD can be characterized by a preferred axis of rotation. For example, if the PD in the RF region extending from 0° (the nose) to 45° posterior is up and backward, the PD in the region from 45° to > 160° posterior is down and backward, resulting in a preferred axis of rotation at approximately 45° to the midline. In short, transformations occurring in the accessory optic system put retinal signals of local direction preference into a global form compatible with semicircular canal signals of rotational self-motion. Supported by USPHS Grant #NS13742.

11.6 RESPONSES OF CELLS IN THE MONKEY LATERAL GENICULATE NUCLEUS (LGN) TO LUMINANCE AND CHROMATICALLY-MODULATED GRATINGS. B.B. Lee, T.R. Vidyasagar* and T.P. Hicks. Max Planck Institute for biophysical Chemistry, D-3400 Göttingen, FRG.

The activity of cells in the parvocellular layers (PCL) of the LGN may be increased or suppressed according to the colour of a stimulus. They might thus be expected to respond to both luminance and chromatic gratings. Responses to such gratings have been recorded from the LGN of the anaesthetised macaque. Sinusoidal grating stimuli were displayed on a tangent screen, colours being generated with interference filters in the light beams of the projector system.

PCL cells showed no low spatial frequency attenuation in their responses to either luminance- or chromatically-modulated gratings. For most chromatic gratings, responses of wide-band cells (WS,+G-R; WL,+Y-B; Creutzfeldt, O.D. et al., Exptl. Brain Res., 35: 527-545, 1979) were less vigorous and such cells resolved fine gratings less well. With narrow-band cells (NL,+R-G; NS,+B-Y) responses were enhanced and gratings better resolved. Magnocellular layer (MCL) cells responded scarcely or not at all to chromatic gratings. These results may be explained with reference to the cells' spectral response characteristics. When gratings of two wavelengths which both caused neuronal excitation were alternated in a grating, the cell's responses moved between two excitatory points on the spectral response curve and modulation of discharge was less than in the luminance-modulated case. If one of the colours used suppressed the cell's activity, responses were enhanced in comparison with the luminance-modulated case.

Wide-band and MCL cells resolved much finer gratings than narrow-band cells and it was the resolution of these cell types which was impaired with chromatic gratings. The decrease in acuity with chromatic gratings in human psychophysics thus acquires a physiological basis. The results are also of interest in relation to colour contrast phenomena.

11.7 INFLUENCE OF STIMULUS VELOCITY ON LGN NEURONS. G.A. Orban, K.-P. Hoffmann and J. Duysens, Lab. Neuroen Psychofysiologie, KULeuven, Campus Gasthuisberg, Herestraat, B-3000 Leuven, Belgium and Universität Ulm, Abt. Vergleichende Neurobiologie, Oberer Eselsberg M25, D-79 Ulm (Donau), West Germany.

Neurons in the dorsal lateral geniculate nucleus (LGN) were recorded in paralyzed and anesthetized (N_2O/O_2) cats. The influence of stimulus (light or dark bars) velocity (.18° to 900°/sec) was tested quantitatively with a multihistogram technique. Geniculate cells were classified into X and Y types according to their conduction velocity, center size, grating resolution and upper cut-off velocity for stimuli appropriate for center and surround. Velocity-response (VR) curves were compared to VR curves obtained under similar circumstances for cortical cells (Orban et al., J. Neurophysiol., in press and Duysens et al., Neurosci. Abstr., this volume). When tested with the center stimulus (i.e. a light slit for ON center cells) geniculate neurons responded over a wider range of velocities than cortical cells. More LGN cells responded to the fastest movement tested (900°/sec) while less responded to the slowest movement (.18°/sec) which in many cortical cells elicits nearly maximal response. Consequently hardly any geniculate cell showed a low pass VR curve, characterized by a general preference for slow movement. Comparison of X and Y cells showed that on average X cells responded to slower movements than Y cells. In particular all velocity high pass curves belonged to Y cells. Many X cells had a tuned curve with optimum between 40 and 70°/sec.

In order to evaluate the latency of responses, spatial lag velocity curves were prepared. These curves often showed a nonlinearity in Y cells. Such nonlinearities are also seen in many area 18 cells and in some cells of areas 17 & 19 subserving peripheral vision. Center stimuli evoked two responses : a main response with short latency (37-76 msec) and a second with long latency (80-178 msec). Surround stimuli (i.e. a dark bar in ON center cell) usually evoked two responses as well but these had longer latencies and a different origin than the responses to center stimuli. The differentiation between X and Y cells on the basis of velocity characteristics was enhanced when only the short latency center response was considered.

11.8 EFFECT OF BLOCKING RETINAL ON-CHANNELS WITH AMINOPHOSPHONOBUTYRIC ACID (APB) ON THE CAT VISUAL SYSTEM. J.C. Horton*(SPON:E.T. Hedley-Whyte) Dept. Neurobiology, Harvard Medical School, Boston, Mass.

Several months ago Slaughter and Miller reported that APB selectively blocks the on-channel in the perfused retina-eyecup preparation from the mudpuppy (Science, 211:182-85, 1981). I have tested the effect of this drug in the cat by injecting it into the eye, in the hope of studying the contributions of separate on and off channels to receptive field properties of cells in central visual nuclei.

Physiological recordings were made in 6 anesthetized, paralyzed cats. After the lateral geniculate body was located with a tungsten electrode, APB was injected into the vitreous of the contralateral eye and response properties in lamina A and A1 were compared every 10 minutes for any effect produced by the drug. Within a few hours a striking change in geniculate properties was observed. The on-response in lamina A was completely abolished: only off-center cells could be driven by visual stimulation; cells and multiunit activity responded to a stationary flashing spot only at light off. Center-surround receptive field organization of the remaining off-center cells was preserved, in the sense that a small spot of light evoked a more vigorous response than a large spot. More subtle changes in response properties may have been present. In two cats, after onset of the drug's action in the geniculate body, penetrations were made through the optic tract and recordings obtained from 27 retinal ganglion cell axons; no obvious abnormalities in receptive field properties were found. Of the 19 fibers from the normal eye, 7 were on-center and 12 were off-center; all 8 fibers from the APB-injected eye were off-center. This result was not unexpected since on-center geniculate cells receive their main excitatory input from on-center retinal ganglion cells (Hubel & Wiesel, J. Physiol., 155:385-98, 1961 and Cleland, Dubin, & Levick, J. Physiol., 217:473-96, 1971)

In a preliminary experiment the effect of APB on the striate cortex has been tested. Cells were less responsive to stimulation through the APB-injected eye; orientation selectivity did not seem to be affected. Some changes were noted in organization of receptive fields. In another cat APB was injected into both eyes and the animal observed closely for the next 14 hours. No obvious changes in visually guided behavior were apparent; careful testing will be necessary to reveal any possible deficit.

11.9 TERMINAL MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED X AND Y OPTIC TRACT AXONS WITHIN THE LATERAL GENICULATE NUCLEUS OF THE CAT. L.R. Stanford, M. Sur* and S.M. Sherman. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

We have correlated the physiological properties of retinal ganglion cells in the cat with their morphological pattern of projection into the lateral geniculate nucleus (LGN). Ganglion cell axons were recorded within the LGN and in the portion of the optic tract lying ventral to the LGN. Axons were classified as X or Y according to standard criteria, including conduction velocity and spatial summation properties. Physiologically characterized axons were impaled and iontophoretically injected with horseradish peroxidase. Brain sections were reacted with diaminobenzidine, using cobalt chloride intensification, permitting clear visualization of anterogradely-filled terminal processes and retrogradely-filled axon trunks.

To date, 10 X and 12 Y axons have been filled and recovered. Within the optic tract, each X and Y axon has a parent trunk that issues one or more major branches terminating within the LGN. Individual Y axons terminate in the main laminae and the medial interlaminar nucleus (MIN) of the LGN. They then continue medially and posteriorally to the superior colliculus, in accordance with a previous description (Bowling and Michael, Nature, 286:899, 1980). Within the LGN, contralateral Y axons terminate in lamina A and in the C laminae.

There are several morphological differences between X and Y axons. Within the optic tract ventral to the LGN, X axons are thinner and tend to occupy a more dorsal position than Y axons. X axons have relatively narrow terminal fields. Many X axons have long cylindrical fields, 100-150 μm in width, oriented perpendicular to the lamination. These lie centrally within one of the A laminae. Other X axons have shorter terminal fields that lie predominantly dorsally within a lamina. Y axons have broader terminal fields. Some Y axon terminations in lamina A or A1 are relatively wide (≤400 μm) at the base of the lamina. Other Y axons have terminal fields that are more cylindrical in shape and are oriented perpendicular to the geniculate laminar borders. Within the MIN, Y axon terminations spread predominantly in a dorsoventral direction. In the terminal field, both X and Y axons become extremely thin, and there is no clear difference in their width.

Both X and Y axons have small, medium, and large (crenulated) terminal boutons (Mason and Robson, Neuroscience, 4:79, 1979). Terminal boutons of X axons tend to occur in clusters more often than do those of Y axons.

11.10 TERMINATION PATTERNS OF SINGLE OPTIC TRACT AXONS OF DIFFERENT PHYSIOLOGICAL TYPES. Douglas B. Bowling* and Charles R. Michael. Dept. of Physiology, Yale Univ. Sch. of Med., New Haven, CT 06510.

By recording from single axons in the optic tract of the cat and injecting them with the marker enzyme horseradish peroxidase, we have examined their physiological responses and central structure. Serial reconstructions reveal the courses and destinations of the axons' collaterals, their patterns of arborization and the three-dimensional distributions of their synaptic boutons. The projection sites and terminal distributions show consistent patterns that are related to three factors: 1) eye of origin (ipsilateral vs. contralateral), 2) physiological classification as Y or X (based primarily on differences in latency to electrical stimulation) and 3) sign of response to changing contrast (ON vs. OFF).

The Y axons send collaterals to LGNd (dorsal lateral geniculate nucleus), MIN (medial interlaminar nucleus) and SC (superior colliculus). Those from the ipsilateral eye terminate in lamina A_1 of the LGNd and in a single layer in the MIN. Those from the contralateral eye terminate in both laminae A and C of the LGNd and in two areas of the MIN (medially and laterally). In A and A_1 the terminal boutons are distributed across the full width of a lamina with about 75% of them in the lower half. The distributions, which contain from 600 to 2,000 boutons, tend to be conical in shape (base at the bottom of the lamina, apex at the top) for the OFF axons and hourglass shaped for the ON axons. The boutons are distributed laterally (in the plane of the retinotopic map) over 200 to 400 μm.

The X axons project to the LGNd and may or may not send a collateral into the MIN. Those from the ipsilateral eye terminate in lamina A_1 and those from the contralateral eye, in A. The terminal distributions, which span the width of a lamina, contain from 300 to 1,000 boutons, about 65% of which are in the upper half. In A the distributions tend to be conical (base at the top of the lamina, apex at the bottom). In A_1 the distributions are basically cylindrical in shape. The lateral spread of the terminals is 100 to 150 μm.

In some experiments injection of an axon results in stained cell bodies in the LGNd. The axons' terminal boutons are closely apposed to the proximal dendrites of the stained cells, suggesting that the staining is transsynaptic and specific for target cells of the injected axons. We have seen up to eleven geniculate cells contacted in this way by a single Y afferent.

11.11 W-CELLS IN THE C LAMINAE OF THE CAT'S LATERAL GENICULATE NUCLEUS: CONTRAST SENSITIVITY AND OTHER RESPONSE MEASURES. M. Sur*, L.R. Stanford and S.M. Sherman. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794

W-cells were recorded in the C laminae of the lateral geniculate nucleus of cats. Parameters studied were: the latency to optic chiasm, cortical and visual stimulation; response rate; variability in response; and contrast sensitivity as a function of spatial and temporal frequency. All cells have latencies to optic chiasm stimulation >2.0 msec, and most have latencies >2.5 msec. Some cells can be driven antidromically from visual cortex with latencies ≥2.0 msec. About a third of the neurons cannot be reliably driven by any form of visual stimulation, but they respond to chiasm shock. Those that can be visually driven have receptive fields larger than X- or many Y-cell fields at similar eccentricities. Contrast sensitivity functions were derived using phase-reversing sinusoidal gratings. W-cells show either linear or non-linear spatial summation. Linear and non-linear W-cells are found in roughly equal numbers. Linear W-cells respond only to the fundamental temporal frequency of stimulus, have well-defined "null" positions, and display an approximately sinusoidal dependence of sensitivity on spatial phase. Non-linear W-cells show phase-independent second harmonic responses. A major characteristic of W-cells is their very poor contrast sensitivity compared to that of X- or Y-cells. For most visually responsive W-cells, at 0.85 contrast, spatial resolution is 0.5-1.5 cycles/degree, and temporal resolution is 8-24 Hz. For non-linear cells, the spatial resolution of the fundamental component is lower and the temporal resolution higher than the second harmonic component of response. Our sample of linear W-cells includes both "sustained" and "transient" neurons, while the non-linear W-cells are "transient". Otherwise, there are no obvious differences between linear and non-linear cells in receptive field size, latency to optic chiasm stimulation, response rate, spatial and temporal resolution, and peak sensitivity. Cells unresponsive to visual stimulation tend to have longer latencies to optic chiasm stimulation than do visually responsive cells.

11.12 RETINAL Y-CELL INPUTS TO THE DEEP LAYERS OF THE CAT'S SUPERIOR COLLICULUS. David M. Berson* and James T. McIlwain, Division of Biology and Medicine, Brown University, Providence, RI, 02912.

In the cat, retinal W-cell axons terminate near the surface of the superior colliculus (SC), whereas axons of Y-cells terminate more deeply in the superficial layers. Both of these direct retinal pathways, as well as a polysynaptic "Y-indirect" pathway (Hoffmann, '73), have been shown to make excitatory contact with cells in the upper tectal layers. We now present evidence that retinal Y-cell pathways also contribute substantial excitatory inputs to the deep collicular strata.

In ketamine anesthetized cats, bipolar stimulating electrodes were placed in the left optic disc (OD), right optic tract (OT) and left predorsal bundle. Extracellular activity was recorded from 163 deep layer cells in the right SC. In most cells (85%), single shocks to the OD or OT (50 μsec, 1-5 mA) elicited a burst of 1-3 spikes beginning 3-10 msec ($\bar{X}$=6.6) after OD and 2-9 msec ($\bar{X}$=5.7) after OT shock. The small latency difference appears to reflect mediation by rapidly-conducting Y-cell axons ($\bar{X}$=42 m/sec), but the absolute latencies indicate that these axons do not synapse directly upon the recorded cells (Y-indirect pathway). In a smaller number of deep cells (27%), there appeared, in addition, a single "early" spike, evoked intermittently but at a stable latency following OD shock (1.1-3.9 msec, $\bar{X}$=2.1) and OT shock (0.9-2.1 msec, $\bar{X}$=1.4). These latencies imply the existence of a sparse "Y-direct" input (mean conduction velocity 54 m/sec) making monosynaptic contact with the recorded cells. This short-latency excitation of deep tectal cells survived transection of the IIIrd, IVth, ophthalmic Vth and VIth cranial nerves as well as midpontine pretrigeminal brainstem transection. Hence, it is unlikely that the occurrence of the early spike following OD stimulation resulted from inadvertent activation of non-visual fibers in the orbit.

Cells with apparent Y-direct and Y-indirect input were found throughout the deep layers (laminae IV-VII of Kanaseki and Sprague, '74). Most of these cells could also be antidromically driven from the predorsal bundle. Thus, the present findings demonstrate a major retinal Y-cell influence on output cells in the deep layers of the cat's superior colliculus. Part of this influence may be mediated by a direct, monosynaptic projection from the retina.

11.13 TRACING RETINOFUGAL FIBERS IN MAN: PARAPHENYLENE DIAMINE (PPD) AS A FIBER DEGENERATING STAIN. Alfredo A. Sadun, Lois E. Smith*, and Kenneth R. Kenyon*. Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA 02114.

Previous investigations of the human visual pathways have been largely limited by the infeasibility of certain techniques in man. Single unit electrophysiology and neuron tracer studies are clearly inapplicable. Most significantly, silver impregnation of degenerating fibers has, for technical reasons, not been fruitful in man. Compounding the problem has been the lack of clinically supported autopsy material, poor fixation techniques, and the prolonged survival times inherent in human studies. Accordingly, the present view of the neuroanatomy of the human visual system has been formulated from classical observations of gross pathology, clinical deduction, and inference from animal studies.

We here demonstrate the use of paraphenylene diamine (PPD) in conjunction with standard transmission electron microscope (EM) tissue preparation methods. Osmium precipitates on degenerating neural processes resulting in their dark profile when examined by EM. PPD chelates osmium and thus becomes a light opaque marker of degenerating neural processes. Semi-thin epon embedded sections stained with PPD provide sufficient resolution, at the light microscope level, for the identification of degenerating axons and axon terminals (Sadun, Brain Res. 1975). The stain identifies degenerating axons even after survival times in excess of one year.

Post-mortem case studies are presented of patients with documented optic nerve lesions. Included is a specimen from a young woman who died one year after complete transsection of her left optic nerve. The degenerating ganglion nerve fibers are followed with PPD and confirmed with EM. Previously proposed primary visual projections are confirmed and new retinofugal pathways (Smith et al., Soc. Neurosci. 1981) are demonstrated with this method. It is now possible to study, in man, the many retinofugal projections and visual nuclei described in animal models.

12.1 CHEMORECEPTOR CHANNEL KINETICS INVESTIGATED IN FEEDING.
J. Zabara and E. Omand. Depts. of Physiology and Biophysics and Physiology, Temple University Health Science Center, Philadelphia, PA 19140

A method of channel analysis in chemoreceptor activation is presented, and is associated with behavioral regulation in feeding. The analysis is based on the recording of membrane noise which may give information about chemoreceptor action at a molecular level. In this chemoreceptor preparation (fly, Musca), the specific action of a stimulant molecular species (sugar, salt or water) may be elucidated as a temporary opening of specific channel populations. A microcapillary (100μ tip diameter) containing the stimulus solution, also records the receptor response which is viewed on an oscillograph. The recorded response consists of the receptor potential, spike discharge and potential oscillations. We observed oscillations in non-spiking potentials which apparently correspond to the phenomenon of membrane or synaptic noise as observed in end-plate recordings such as the locust flight muscle. These oscillations in chemoreceptor nerves had a direct relationship with exposure to food deprivation or a normal light cycle. For instance, the oscillations increased with food deprivation, and they were diminished in darkness. By recording simultaneously DC at low gain and AC (TC = 1 sec.) at high gain we could visualize the corresponding DC correlate of these oscillations. In correspondence with membrane noise, we might expect these oscillations to represent step-function potential changes corresponding to opening or closing of channels. This is supported by our observations relating AC and DC recordings. Further, the step-like potentials are directly proportional to the rise-time and magnitude of the oscillations. Also, the oscillations exhibit both positive and negative polarities which reflect the polarity of the step-like potential change. In the course of long term stimulation, periods of oscillation alternate with those periods which are oscillation free. So that the oscillations appear to represent fluctuations in the number of open channels involved in the generation of the receptor potential. Thus, in the presence of a stimulant molecule, channels continue to be transiently opened, and a steady membrane potential change obtains. The receptor potential changes due to fluctuations in the number of open channels which appear to represent a rectangular conductance pulse. A model is described linking receptor activation (A) and channel dynamics: $A = \int_{1}^{n} \frac{dE}{dZ} \cdot \left[(Z_1) \oplus (Z_2) \oplus \ldots \oplus (Z_n)\right] dZ$

Where: E = the excitability state as measured as a function of the receptor potential; Z = receptor-channel equivalence; and ⊕ is an equivalence operator. Supported by NIH Grant NS14209

12.2 INCREASED BRAIN SEROTONERGIC ACTIVITY ASSOCIATED WITH CANCER ANOREXIA.
W. T. Chance, M. von Meyenfeldt and J. E. Fischer*. Dept. of Surg., Univ. of Cinti. Med. Ctr., Cincinnati, OH 45267.

Since increased brain serotonergic (5-HT) activity has been associated with reduced eating, the role of 5-HT in cancer anorexia was investigated. Previously, we observed elevated brain tryptophan (Trp) and 5-hydroxyindoleacetic acid (5-HIAA) in immature female rats that became anorectic 6 days after the injection (im.) of 5×10^4 Walker (W) 256 carcinosarcoma cells. To provide a more general demonstration of this phenomenon, we fluorometrically assayed brain indoles in 8 adult male rats injected (sc.) with 2×10^6 methycholanthrene (MCA)-induced sarcoma cells. Saline-injected control rats were divided into freely-feeding (FF, n=8) and pair-fed (PF, n=8) groups. Food intake was significantly decreased in tumor-bearing (TB) rats by day 23 post injection, with all rats being sacrificed on day 33. As in the W 256 model, plasma total Trp and albumin were reduced, while plasma free (unbound) Trp was elevated in TB rats. Brain Trp, 5-HT and 5-HIAA were also significantly increased in TB rats. To determine which brain areas exhibit the greatest changes in indole activity, we next assayed levels of Trp, 5-HT and 5-HIAA within both W 256 (n=8) and MCA (n=8) sarcoma lines as well as in FF (n=16) and PF (n=16) control rats in the following regions: hypothalamus, cortex, corpus striatum, hippocampus, mesencephalon, pons-medulla, cerebellum and remaining diencephalon-telencephalon. Tumors were induced as in previous experiments, with W 256 rats being sacrificed 1 day prior to their normal spontaneous death on day 10 and MCA rats killed after a TB rat exhibited 2 consecutive days of ad lib. food intake less than 2 g. In the W 256 model brain Trp was significantly increased in diencephalon-telencephalon, mesencephalon, cerebellum, cortex, hippocampus, hypothalamus and corpus striatum of TB rats. 5-HT was elevated in TB rats in the diencephalon-telencephalon and cerebellum, while increases in 5-HIAA were observed in the cortex, hippocampus, diencephalon-telencephalon, pons-medulla and cerebellum. In the MCA rats, Trp was elevated only in the diencephalon-telencephalon and corpus striatum of TB rats. Significantly increased 5-HT was observed in all areas except the hypothalamus and mesencephalon, while 5-HIAA was elevated in all areas except the hypothalamus. Thus, these data suggest that increased brain 5-HT activity in cancer anorexia is a general phenomenon. The absence of 5-HT changes in PF rats indicates that the biochemical alterations are not resultant from decreased food intake. Finally, the greater CNS regional changes in 5-HT with MCA tumors may reflect the more prolonged anorexia and greater cachexia suffered by these rats. Supported by USPHS grant CA 25786.

12.3 LESIONS OF THE DORSAL BRAIN STEM DISRUPTS FOOD INTAKE AND BODY WEIGHT IN RATS: PARALLELS TO THE LATERAL HYPOTHALAMIC SYNDROME.
Robert J. Contreras, Ellen E. Fox* and Margaret L. Drugovich*. Dept. of Psychology, Yale University, Box 11A Yale Station, New Haven, Ct 06520.

Research on the mechanisms of hunger has focused mostly on the lateral hypothalamus (LH) principally because bilateral lesions of the LH result in aphagia, anorexia and body weight loss (Anand & Brobeck, 1951). This is followed by the recovery of ingestive behaviors (Teitlebaum & Epstein, 1962), although LH lesioned rats maintain their body weights at subnormal levels. Powley and Keesey (1970) demonstrated that food depriving rats to 80% of their normal body weights prior to surgery shortened the period of aphagia and anorexia, although they still maintained a lowered body weight maintenance level similar to that of nondeprived lesioned rats. Since lesions to the dorsal brain stem also lead to chronic reductions in body weights (Contreras & Stetson, 1981), we examined the effects of preoperative food deprivation on food intake and body weight levels after brain stem lesions.

Of the 18 rats that were to receive lesions, 9 were reduced to 80% of their initial body weights by food deprivation, and the other 9 were fed ad libitum. Of the 12 rats that were to receive sham lesions, half were similarly food deprived and the other half fed ad libitum. Lesions were effected by a 28 gauge aspiration tube. After the operations body weight and food and water intakes were monitored for one month.

Lesions of the dorsal brain stem resulted in dramatic reductions in body weight that were never recovered. The nondeprived lesioned rats were anorexic for 10±2 days postoperatively during which time they lost an average of 80 g. The food deprived rats did not display postlesion anorexia and they gained an average of 20 g in the 10 days after surgery. The average body weights of these 2 lesion groups converged 5 days after surgery and were maintained at a constant percentage (76%) of the body weight levels of nondeprived sham rats for the last 20 days of the observation period. Furthermore, 6 days after surgery the average body weights of the two sham groups were not significantly different from each other.

These findings suggest that rats with lesions to the dorsal brain stem, which includes the area postrema and medial parts of the nucleus of the solitary tract, adjust their food intakes to maintain their body weights at a lower level, findings like those obtained following LH lesions. Our results do not challenge necessarily the preeminence of the LH in feeding behavior, but suggest that there may be redundancy in controlling mechanisms reminiscent of Jackson's principle of hierarchial organization.

12.4 REVERSAL OF HYPOTHALAMIC HYPERPHAGIA AND OBESITY FOLLOWING LESIONS OF THE AP-cmNTS.
Thomas Hyde*, Ricardo Eng, and Richard R. Miselis. (Spon.: R.O. Davies), Inst. Neur. Sci., Anim. Bio. Sch. Vet. Med., Univ. Penn., Philadelphia, PA, 19104.

The area postrema (AP) lies at the caudal end of the fourth ventricle on the dorsal medulla. The caudal medial zone of the nucleus of the solitary tract (cmNTS) lies ventral and lateral to the AP. Recent anatomical studies (Coil and Norgren, 1978) have shown that the AP and the cmNTS receive an intense afferent input from the subdiaphragmatic vagus. We have previously reported (Hyde and Miselis, 1980) that AP-cmNTS lesions cause a transient hypophagia and permanently reduced body weight in adult male albino rats. Furthermore, the lesions cause a polydipsia and enhanced salt appetite secondary to polyuria and urinary sodium loss. The disruption in food and water intake and body weight loss support the hypothesis that the sensory input to this region is vital for normal fluid and energy balance. Discrete lesions of the AP-cmNTS provide a "central vagotomy" preparation in which the role of visceral sensory input in ingestive behaviors can be assessed without the confounding motor deficits inherent in the subdiaphragmatic vagotomy preparation. We tested this hypothesis using the hypothalamic knife-cut induced hyperphagia and obesity model (Gold et al., 1977). Hypothalamic hyperphagia and obesity is reversed by subdiaphragmatic vagotomy (Powley and Opsahl, 1974; Sawchenko and Gold, 1981). Adult male Sprague-Dawley rats with parasaggital hypothalamic knife cuts became hyperphagic and obese. The knife-cut rats increased their weights by 44.5% over an 8 week period while the shams only increased their weights by 31.0%. AP-cmNTS lesions reversed the hyperphagia and obesity caused by the knife cuts, with body weights falling 32% over 5 weeks, back to the pre-knife cut level. Conversely, rats given AP-cmNTS lesions first never became hyperphagic or obese after knife cuts. These findings are similar to the subdiaphragmatic vagotomy effects on knife-cut obesity and VMH obesity. This supports the hypothesis that sensory input into the AP-cmNTS is vital for the expression and maintenance of hypothalamic hyperphagia and obesity. Alternatively, this lesion could be interrupting GI motor reflex arcs passing through the AP-cmNTS and out through the subdiaphragmatic vagus. Such loops could be vital to normal GI motor function. However, AP-cmNTS rats respond to food deprivation with a transient hyperphagia and gain weight at a heightened rate on a high fat diet. Studies using a "supermarket diet" to induce obesity, as well as an assessment of GI function in rats with an AP-cmNTS lesion are in progress to evaluate these possibilities. Thus, the AP-cmNTS lesion preparation may allow the study of visceral sensory function in ingestion without motor deficits.

12.5 TASTE REACTIVITY OF LATERAL HYPOTHALAMIC LESIONED RATS: EFFECTS OF DEPRIVATION AND TUBE FEEDING. Steven J. Fluharty* and Harvey J. Grill (SPON: C.R. Gallistel). Dept. of Psych. and Inst. of Neurol. Sci., Univ. of Penn., Phila., PA 19104.

Large bilateral lesions of the lateral hypothalamus (LHX) result in total cessation of ingestive behavior (Stage I). The specific nature of the ingestive deficits has not been systematically analyzed because existing tests require spontaneous ingestion. By utilizing a methodology that directly presents stimuli to the oral cavity we have examined the consumatory behavior of Stage I LHX-rats. We report that the taste reactivity (TR) and ingestion of orally infused substances appears normal in LHX-rats after food and water deprivation. Conversely, while tube feeding has no effect on these measures in intact rats, it results in a dramatic disruption of ingestion in LHX-rats.

Eighteen male rats received bilateral LH lesions. Pellets, a moist cereal, and H_2O were available ad lib and intakes were monitored daily. LHX-rats also received an average of 1 daily 12ml intragastric meal (sweetened condensed milk + water). Assessment of TR and intake of orally infused H_2O or sucrose (1.0M) began on the second post-surgical day. Slow motion analysis of videotapes was used to categorize the orofacial components elicited by intraoral injections of sucrose, NaCl, quinine, and water. Consumption of H_2O and 1.0M sucrose (1.0ml orally infused over 1 min) was also determined.

The average duration of adipsia and aphagia following lesions was 18.7±4.6 and 7.8±0.9 days, respectively. During this time and under conditions of 24hr food and water deprivation, LHX-rats exhibited normal TR and ingested 0.73±0.10 ml of H_2O and 0.98±0.01 ml of 1.0M sucrose. Conversely, when tested 90 mins after a tube fed meal, all LHX-rats passively or actively rejected H_2O and 13 of 18 animals demonstrated components of rejection sequences to all tastes examined. Further, ingestion of water was eliminated (0.05±.02ml) and 1.0M sucrose substantially reduced (0.36±0.08ml). This tube feeding effect does not appear to result from 1) the tubing procedure, or 2) GI distension because "dry-tubed" LHX-rats and those tubed 0.2M mannitol exhibit normal TR and ingestion. Collectively, these results suggest that the rejection of orally infused H_2O and taste stimuli that results from intragastric feeding in Stage I LHX-rats may result from exaggerated sensitivity to some post-absorptive consequence(s) of the meal. As such, these data further suggest that aphagic and adipsic LHX-rats may possess greater regulatory capacity than originally assumed.

12.6 HYPERPHAGIA AND OBESITY PRODUCED BY UNILATERAL HYPOTHALAMIC KNIFE CUTS IN THE RAT. Anthony Sclafani and Paul F. Aravich*. Dept. of Psychology, Brooklyn College, Brooklyn, N.Y. 11210.

Unilateral parasagittal knife cuts between the medial and lateral hypothalamus did not significantly alter food intake or body weight in chow-fed female rats, whereas bilateral knife cuts induced a robust hyperphagia and obesity. When switched to a high fat chow, however, the unilateral cut rats (n=10) overate and outgained control subjects (n=8), although their food intake and weight gain was still considerably less than that of the bilateral cut rats (n=8). The unilateral cut rats further increased their food intake and weight gain when given a mixed palatable diet (MPD: chocolate-chip cookies, sweetened milk, high fat chow), and they eventually reached a level of obesity (728 g) only slightly less than that of the bilateral cut rats (761 g), and significanly higher than that of the controls (572 g). Although initially their caloric intake on the MPD was similar (198 vs 206 kcal/day), the unilateral and bilateral cut rats differed in their selection of foods. Compared to controls, the unilateral cut rats overate the MPD, but the food selections of the two groups were similar. When switched from the MPD back to the high fat chow, the unilateral cut and control groups lost weight (69 vs 44 g/30 days, n.s.), whereas the bilateral cut group gained weight (62 g/30 days). Therefore, although the unilateral cut rats became as obese as did the bilateral cut rats on the MPD, the two groups differed in several respects. As previously observed, control rats gained excessive weight on the high fat chow and especially on the MPD, and the effect of the unilateral knife cuts was to potentiate this diet-induced obesity.

12.7 HYPERDIPSIA AND ENHANCED SODIUM APPETITE AFTER AV3V LESIONS IN RATS. Edward M. Stricker and Thomas W. Gardiner*. Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA, 15260.

Large ablations of the anteroventral third ventricle (AV3V) region of the forebrain result in a transient adipsia and permanent loss of the drinking response of rats to a salt load (Buggy and Johnson, AJP 233:R44, 1977). With more discrete lesions centered near the ventral portion of nucleus medianus, we find that some animals become adipsic and later exhibit drinking deficits, while other rats with similar lesions become markedly hyperdipsic and usually do not show drinking deficits. Of 53 lesioned rats examined thus far, 18 exhibited hyperdipsia, 7 after a period of adipsia. Their mean daily water intakes ranged from 90 to 148 ml, 2-3 times those of control animals, throughout the 90 day period of observation. Almost all of this excess consumption occurred at night. Preliminary experiments suggest that the hyperdipsic rats do not have diabetes insipidus because urine volumes during overnight fluid deprivation were comparable to control values. Furthermore, hyperdipsic rats given hypertonic NaCl solution by sc injection excreted a concentrated urine. They excreted this sodium load much more slowly than control animals, however, and the degree of sodium retention correlated highly with the magnitude of hyperdipsia. These findings suggest that the hyperdipsia may be provoked by a prolonged retention of the sodium ingested in chow. However, rats remained hyperdipsic whether deprived of food overnight or maintained on a sodium deficient diet.

Another phenomenon observed in several lesioned animals was an unusually large consumption of hypertonic (.5M) NaCl solution. Control rats usually ingest less than 5 ml of this unpalatable fluid daily, whereas 6 of 8 rats that were hyperdipsic when given water alone consumed between 10 and 35 ml of saline each day. Although these intakes are comparable to those of adrenalectomized rats, renal sodium losses during 24 -hr sodium deprivation were normal, and both renin and aldosterone values were not elevated. Also, preliminary measures of plasma sodium, plasma protein, and hematocrit yielded values comparable to those for controls. The basis for this excessive drinking of saline, as well as the hyperdipsia, remains to be investigated.

12.8 CONSUMMATORY BEHAVIORS AND WHEEL RUNNING ACTIVITY IN THE RAT FOLLOWING INTRAHYPOTHALAMIC INJECTIONS OF KAINIC ACID. M. Kalamatizadeh*, K. Sharifi Hossaini and M.S. Shahid Salles. Department of Physiology and Pharmacology, Shiraz University School of Medicine Shiraz, Iran.

Electrolytic lesions of the lateral hypothalamus (LH) produce aphagia, adipsia and akinesia. These have been interpreted as indicating the presence of eating, drinking centers and cells controlling locomotion within the lateral hypothalamus. We have previously shown that selective destruction of dopaminergic cells in or outside of the "mid lateral" hypothalamus reproduce the same syndrome, while a non-selective chemical lesion of monoaminergic cells did not reproduce the lateral hypothalamic syndrome. This finding supported the regulatory role of cells in the LH area in the control of ingestive behavior and locomotor activity. In order to further examine this hypothesis we have studied the behavior of rats following intrahypothalamic injections of kainic acid (KA). Kainic acid was dissolved in 0.9% NaCl (10 nM/1 µl) and administered over 240 sec in 25 rats. Rats given KA in the "mid lateral" hypothalamus showed lasting aphagia, adipsia and akinesia which invariably was lethal. Injections in the posterolateral hypothalamus encroaching on pars reticularis of substantia nigra produced permanent hyperdipsia without a significant change in locomotor activity or in food intake. Hyperdipsia disappeared during food deprivation and was absent when hypertonic saline was injected intraperitoneally. The fact that hyperdipsia was obtained in the absence of change in food intake and locomotion suggests that water intake is modulated by neurons in subthalamic region projecting to the LH area.

12.9 GLUCOPRIVIC FEEDING: PREVENTION BY PERIPHERAL BUT NOT BY CENTRAL SUGAR INFUSIONS. Robert C. Ritter. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University, Pullman, WA 99164 and WOI Regional Program in Veterinary Medicine, University of Idaho, Moscow, ID 83843.

Peripheral injections of antimetabolic glucose analogues, such as 2-deoxyglucose (2DG) or 5-thioglucose (5TG) cause increased feeding in a variety of mammals. The fact that intracerebroventricular (ICV) glucose analogue infusions also elicit feeding suggests that at least some of the glucoreceptors which mediate glucoprivic feeding are in the brain. Recent findings from my laboratory indicate that the receptors which mediate feeding in response to central glucoprivation are in the caudal brainstem (Slusser, Stone and Ritter, Neuroscience Abst 49.4, 1980). However, our findings do not rule out the participation of non-brain glucoreceptors in the control of glucoprivic feeding. Neither do our results prove that brain glucoreceptors are responsible for mediation of feeding in response to whole body glucoprivation.

In order to determine whether feeding in response to cerebral glucoprivation could be antagonized by elevation of plasma sugar concentrations, we examined the effects of intravenous infusions of 1.2 M glucose, 1.2 M fructose or 0.6 N NaCl upon feeding elicited by ICV 5TG. We found that feeding elicited by ICV 5TG is abolished by IV glucose but not by fructose or NaCl. The differential effects of glucose and fructose upon feeding elicited by central 5TG are similar to those reported by Rowland and Stricker for feeding elicited by peripheral 2DG. However, we also found that plasma catecholamine elevation elicited by ICV 5TG was not suppressed by intravenous glucose or fructose. This result may mean that glucose-induced prevention of feeding is affected at a site more accessible to blood born glucose (e.g. hepatic receptors) than that which contains the receptors mediating sympathoadrenal discharge. In fact we have found that ICV infusions of glucose (0.125 or 1.2 M) or fructose (0.25 M) fail to suppress feeding in response to peripherally administered 2DG. This result might support the existance of peripheral glucoreceptors for feeding. However, ICV sugar infusions also failed to prevent sympathoadrenal hyperglycemia. Therefore, it is also possible that ICV sugars do not reach the brain glucoreceptors in concentrations sufficient to antagonize the highly competitive glucose analogue. Experiments now in progress will differentiate between these alternative interpretations.

12.10 OROGASTRICALLY-MEDIATED INSULIN RELEASE MAY BE REQUIRED FOR TERMINATION OF DELAYED GLUCOPRIVIC FEEDING BY GLUCOSE. Sue Ritter and Nancy L. Pelzer*. Coll. Vet. Med., Wash. State Univ., Pullman, WA 99164.

Enhanced feeding in response to glucoprivation can still be observed from 6-8 hr after insulin or 2-deoxy-D-glucose (2DG), even though blood glucose has returned to normal levels. In fact, when food is withheld for 6 hr after injection of insulin or 2DG, rats consume as much in the 2 hr postglucoprivic feeding test as they do when food is continuously available during ongoing glucoprivation. This phenomenon is now referred to as delayed glucoprivic feeding (DGF). Recently, we reported that intravenous infusion of glucose from 1 1/2-2 hr after insulin fails to prevent DGF. Nevertheless, ingestion of an equivalent amount of glucose (7.9 Kcal) over the same time period abolishes DGF. DGF is also abolished when glucose infusion is accompanied by the ingestion of a saccharin solution, even though each substance by itself is without effect. Thus, it appears that glucorestoration must occur in combination with some orogastrically-mediated signal in order to terminate DGF. We have hypothesized that orogastrically-mediated insulin release may be the required signal, since other investigators have shown that postglucoprivic release of endogenous insulin is stimulated more effectively by ingested than by infused glucose. As a partial test of this hypothesis, we generated tolerance curves for ingested and infused glucose in normal rats and in rats exposed to insulin-induced glucoprivation. Glucose was administered 3 1/2-4 hr after insulin injection when exogenous insulin had disappeared from blood, as determined by radioimmunoassay. We found that after prior glucoprivation, clearance of both ingested and infused glucose was significantly impaired. After glucose infusion, however, the impairment was more pronounced. Moreover, infusion of glucose in combination with epinephrine, which is known to be elevated by glucoprivation and to inhibit glucose-stimulated insulin release mimicked the effect of prior glucoprivation. The differential clearance of infused and ingested glucose from blood would be compatible with a greater stimulation of insulin release by ingested glucose. If this hypothesis is born out by additional experiments, we might speculate that insulin suppresses DGF by making glucose available to peripheral tissues. Data we have recently reported indeed suggests that DGF is abolished only by restoration of nutrients to both brain and peripheral tissues. The fact that DGF can be abolished by β-hydroxybutyrate infusion, while infused glucose is ineffective, is compatible with this view as well, since β-hydroxybutyrate can be utilized by brain tissue and, in addition, does not require insulin for its uptake by peripheral tissues.

12.11 FACTORS INVOLVED IN THE CONTROL OF DELAYED GLUCOPRIVIC FEEDING AND POSTGLUCOPRIVIC HYPOTHALAMIC NOREPINEPHRINE TURNOVER. Steven I. Bellin and Sue Ritter, College of Veterinary Medicine, Washington State Univ., Pullman, WA 99164.

In rats, delayed glucoprivic feeding (DGF) can be demonstrated from 6-8 hr after a large insulin dose (Ritter et al, Am. J. Physiol., 234:E617-E621, 1978) when other signs of glucoprivation are no longer in evidence. Elevated rates of hypothalamic norepinephrine (NE) turnover are also associated with glucoprivation and, like enhanced feeding behavior, persist into the postglucoprivic period. The ingestion of isocaloric (7.9 Kcal) pelleted rodent chow or D-glucose (10.5 ml, 18% w/v solution), as well as the intravenous infusion of caloricallly equivalent glucose (4.4 ml, 2.4M) or DL-β-hydroxybutyrate (BOH, 5.1 ml, 2.4M) solution, from 1 1/2-2 hr following 2.5 U/kg regular insulin (s.c.), normalize apparent rates of hypothalamic NE turnover. However, isocaloric fructose solutions, [ingested (10.5 ml, 18% w/v) or infused (4.4 ml, 2.4M)] or ingestion of fat (7.9 Kcal lard) or saccharin, do not. These data suggest that restoration of a fuel available to brain tissue is both necessary and sufficient to normalize NE turnover rates after insulin. Similarly, DGF is abolished by ingested chow, ingested glucose or infused BOH. However, glucose infusion has no effect on DGF. Moreover, ingestion or infusion of fructose or ingestion of lard (7.9-47 Kcal) significantly attenuates, but does not abolish, DGF. Thus, in contrast to postglucoprivic NE turnover, it would appear that the abolition of DGF requires cooperative action of signals arising from receptors on both sides of the blood-brain barrier. If so, the effectiveness of ingested pellets or glucose and of infused BOH in abolishing DGF would reflect their access to receptors on both sides of the blood-brain barrier. The failure of fructose and fat to totally abolish DGF may reflect the exclusion of these nutrients from brain. However, their partial effectiveness supports the hypothesis that a signal of peripheral origin contributes to the termination of DGF. The differential effects of ingested and infused glucose on DGF are puzzling and may indicate that preabsorptive signals are required for termination of DGF by glucose. We hypothesize that orogastrically-mediated insulin release is a likely candidate for such a signal. Finally, the dissociation of feeding and enhanced NE turnover in these experiments suggests that NE neurons may not play a causal role in the termination of DGF.

12.12 CHRONIC DECEREBRATE RATS DEMONSTRATE PREABSORPTIVE INSULIN SECRETION AND HYPERINSULINEMIA. Harvey J. Grill and Kent Berridge*, Dept. Psychol. and Inst. Neurol. Sci., U. Pennsylvania, Philadelphia, Pa. 19104.

The role of the forebrain in regulating tonic insulin secretion, and of the caudal brainstem in analyzing and relaying gustatory information to the pancreas was examined in 15 chronic decerebrate rats. Supracollicular decerebration resulted in a dramatic and persistent rise in plasma insulin levels, which lasted throughout the 2 week period examined after transection. Baseline levels rose from 1-2 ng/ml to 4-8 ng/ml. This hyperinsulinemia was accompanied by intermittent glycosuria and was abolished by a 22 hr fast. In contrast, hemidecerebration produced only an occasional and transient rise in insulin secretion, which disappeared within 2 weeks, and was not accompanied by glycosuria. In spite of the metabolic disturbance displayed, evidence was obtained that the 22 h fasted decerebrate retains the capacity to respond to an oral glucose infusion (2.76 M) by rapidly increasing its plasma insulin levels by 1-3 ng/ml, prior to glucose absorption. These data suggest that a mechanism for analyzing taste information and neurally activating insulin secretion is complete within the caudal brainstem. Procedure: 15 male rats were maintained on a sweetened condensed milk diet for 3 days before duplicate 200 ul tail-blood baseline samples were taken, and urine was collected. Rats were then hemidecerebrated at midbrain level by blunt spatula transection. Urine and blood samples were taken at days 2,7,and 14 after hemitransection. Decerebration was then completed and rats were subsequently maintained by intubation. Urine and blood samples were taken at days 2,7, and 14 after this second stage transection. After 2 weeks, surviving rats were implanted with oral and jugular cannulae, and given 2 days to recover before being run in our standard preabsorptive insulin response test (Berridge, Grill, & Norgren, 1981): a 200ul baseline blood sample was taken via jugular cannula, and 1 ml of a 2.76 M glucose solution was infused into the mouth over 1 min. Blood samples were taken each min for the first 5 min, and every other min for the next 4. A no-stimulus control test was run 2 days later. All blood samples were centrifuged, and the plasma radioimmunoassayed for insulin and assayed for glucose. Urine was tested for glucose using Multistix test strips.

13.1 VASOPRESSIN POTENTIATION IN THE PERFORMANCE OF A LEARNED APPETITIVE TASK. G.F. Koob, A. Ettenberg, M. Le Moal, and F.E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, San Diego, California 92138.

Recent research has provided evidence of a role for the neurohypophyseal hormone vasopressin (AVP) in memory consolidation. However, the putative involvement of AVP in memory is based almost entirely on data drawn from paradigms employing aversively motivated tasks (e.g. conditioned avoidance paradigms). If AVP has general memory-enhancing properties, this should be demonstrable using a positively motivated (appetitive) task.

Naive male albino rats were individually placed into a large rectangular open box for 5 min. each. Recessed into the middle of one of the long walls of the box was an alcove that contained a standard metal drinking tube filled with water. While the rats all found and inspected the tube, none consumed any measurable amount of water during the 5 min. exposure. Upon removal from the box, the rats were treated with one of the following four injection procedures: a saline injection followed, 2 min. later, by another injection of saline (SAL/SAL); saline followed by a 1.0 µg injection of AVP (SAL/AVP); a 5.0 µg dose of the AVP receptor antagonist [1-deaminopenicillamine, 2-(o-methyl) tyrosine] arginine vasopressin, followed by a 1.0 µg injection of AVP ($AAVP_5$/AVP) or a 25.0 µg dose of the antagonist followed by 1.0 µg of AVP ($AAVP_{25}$/AVP). Immediately after this injection regimen, animals in all four groups were water deprived for 48h. The rats were then returned to the test box where the latency to make initial contact with a dry drinking tube was recorded for each animal.

When tested in this "latent learning" paradigm, AVP during training produced reliable improvement (faster latencies) in finding the water tube during a memory test conducted two days later. This effect was blocked by 25.0 µg of the AVP receptor antagonist but not by 5.0 µg. These results are, therefore, consistent with the view of an AVP involvement in memory consolidation.

This research was supported by federal grants NIDA 01785 and NIAAA 03504.

13.2 BRATTLEBORO RATS, WHICH CONGENITALLY LACK VASOPRESSIN, ARE HYPERRESPONSIVE TO ELECTRICAL SHOCK AND ACOUSTICAL STIMULATION. D.M. Gash and P.H. Warren.* (Spon. by Dr. Wayne Hoss). Depts. of Anatomy, Center for Brain Research, and Psychology, University of Rochester, Rochester, NY 14642.

Studies over the past decade from several laboratories have demonstrated that the neuropeptide hormone vasopressin (VP) has significant behavioral effects and may be involved in memory and learning processes. Since these studies have largely relied upon shock motivated behavior, an important issue to be addressed is the role of VP in an animal's response to painful or stressful stimuli.

In the present study we employed a sensitive quantitative test, based upon the startle response, to assess responsiveness to an electric shock and an acoustic stimulus. We compared the responsiveness of animals lacking the ability to synthesize VP (homozygous Brattleboro rats) with animals that do synthesize VP (heterozygous Brattleboro rats). Thirty homozygous and 10 age-matched heterozygous males were used as subjects. The homozygous rats responded to shock at 800 and 1000 µA at a greater amplitude then the heterozygotes ($p \leq 0.005$). The homozygotes similarly had a higher startle response to acoustic stimulation (20 ma, 110 DBA, 10 KHz; $p \leq 0.001$).

These data indicate that homozygous Brattleboro rats should have a better retention of the punishment effect in an approach-avoidance test than heterozygotes. Indeed, in recent studies in our laboratory (Brito et al. Brain Res. Bull. 6: 71-75, 1981) we have observed this effect. The present study suggests that at least part of the influence VP exerts on behavior may be due to modification of an animal's responsiveness to pain and stress.

Supported by USPHS Grant NS 15901

13.3 ANTINOCICEPTIVE EFFECTS OF CENTRAL AND SYSTEMIC ADMINISTRATION OF LYSINE VASOPRESSIN AND STRUCTURAL ANALOGS. J. H. Kordower, V. Sikorszky,* J. Cort* and R. J. Bodnar. Dept. of Psychology, Queens College, CUNY, and Dept. of Physiology, Mount Sinai Medical School, New York, NY.

The magnocellular neurosecretory peptide vasopressin is also distributed in such extrahypothalamic regions as the periaqueductal gray and substantia gelatinosa, suggesting a role in pain perception.[1, 2] This notion is supported by the observation that Brattleboro rats, deficient in vasopressin, display hyperalgesia and selective analgesic deficits.[3] Moreover, Berntson and Berson[4] found that systemic and central injections of vasopressin at doses of 16-100 ug increased tail-flick latencies. The present study extended these findings to physiological doses and sought to establish structure-activity relationships of vasopressin's anti-nociceptive effects. Pain thresholds were determined over six 2-trial sessions spaced 5 min apart as measured by the tail-flick and flinch-jump tests. Following baseline, nanogram doses of lysine vasopressin (LVP) or its prolonged analog was administered either intracerebroventricularly (0, 150, 500 ng/5 ul) or subcutaneously (0, 150, 500, 1500 ng/5 ul) 5 min prior to the fourth session. Injection order was incompletely counterbalanced and administered on alternate days. Tail flick latencies of 8 rats were significantly increased by central LVP 10 and 15 min following the 150 ng dose, and at 5, 10 and 15 min following the 500 ng dose. Systemic LVP increased tail-flick latencies 15 min following the 1500 ng dose. The prolonged LVP analog increased tail-flick latencies of 8 other rats only after central administration. However, it was effective at both doses across all post-injection intervals. Vehicle injections failed to alter latencies. By contrast, neither systemic nor central injections of LVP or its prolonged analog changed flinch-jump thresholds of 10 rats at any dose or post-injection test time. These results indicate that the anti-nociceptive effects of LVP are modality-specific and selective for noxious thermal, as opposed to electrical, stimuli. Given the dose and time course of vasopressin's effects, it appears that the antinociception is mediated by central mechanisms. Ongoing research with LVP analogs that selectively inactivate the acetyl or carboxyl terminals of the peptide chain will further define vasopressin's antinociceptive effect. (Supported by NIH Grants NS 14449 and 5S05RR07064.)

13.4 VAGOTOMY ABOLISHES THE INHIBITORY ACTION OF CHOLECYSTOKININ ON EXPLORATORY BEHAVIOR IN RATS. J. N. Crawley, S. E. Hays*, S. M. Paul* and F. K. Goodwin. Clinical Psychobiology Branch, NIMH, Bethesda, MD 20205.

Cholecystokinin (CCK_8) inhibits feeding behavior in fasted animals (Antin et al., 1975). Controversy exists over possible aversive abdominal responses to systemic CCK_8 administration (Deutsch and Hardy, 1977). Lesioning of sensory pathways from the abdomen to the brain by bilateral vagotomy attenuates or abolishes CCK_8-induced satiety in rats (Simansky, Jerome and Smith, 1980).

We have shown that CCK_8 reduces exploratory investigation of a wide variety of environmental objects (Crawley et al., 1981). In mice and rats, intraperitoneal CCK_8 reduced parameters of exploratory behavior, including duration of pauses, number of movements, and time spent in the corners of an open field, as well as approaches to novel objects and encounters with a female. Intraperitoneal and intraventricular routes of CCK_8 administration produced identical profiles of inhibition of exploratory behaviors. The intraventricular dose required for this effect was similar to the intraperitoneal dose, suggesting a lack of central specificity.

Unsulfated CCK_8 did not significantly reduce exploratory behaviors. Since sulfated CCK_8 binds with much greater potency than unsulfated CCK_8 to the peripheral CCK_8 receptor (Sankaran et al., 1980) but these two analogs have relatively similar potencies at the central CCK_8 receptor (Saito et al., 1980), these results provide a second indication for a peripheral site of the CCK inhibition of exploration.

Bilateral abdominal vagotomy blocked the inhibitory effects of CCK_8 on exploratory behavior. Vagotomized rats treated with CCK_8 either intraperitoneally or intraventricularly showed normal exploratory behaviors as compared to saline-treated controls. Sham-operated rats treated with CCK_8 replicated the previously reported reduction in exploratory parameters.

These results provide several further lines of evidence implicating peripheral CCK receptors in a sensory feedback pathway from the digestive organs to central sites regulating attention to environmental stimuli.

13.5 CEREBRAL VENTRICULAR TRANSPORT AND UPTAKE: IMPORTANCE FOR THE CCK SATIETY EFFECT. CA Baile and MA Della-Fera, Sch Vet Med, U Pa, Kennett Square, PA 19348.

CCK-8 is a potent and specific suppressor of food intake when injected into the lateral cerebral ventricles(LV) of sheep. Studies showing that feeding is increased during injection of specific CCK antibody (CCK-AB) into LV provide strong support for a role for endogenous brain CCK-8 in satiety. It is unlikely that the large antibody molecules entered the brain from CSF, thus the increased feeding was due to sequestration of CSF CCK by CCK-AB. These results, therefore, also suggest that CCK-8 must first be secreted into CSF before it reaches site(s) of action for satiety. Support for this hypothesis was obtained from preliminary studies indicating a change with feeding and fasting in immunoactive CCK concentration (iCCK) in LV CSF of sheep. However, in a repeat study in which CSF was collected from the cisterna magna(CM), iCCK concentrations were too low to measure. Apparently, loss of CCK occurred as it traversed the ventricular system.

Because of the very low endogenous levels of CCK in CM CSF, two proposals were made: 1) Exposure of CCK-8 to ventricular sites more rostral than CM is necessary for its satiety effect; 2) CCK-8 is either enzymatically degraded in CSF as it traverses the ventricles or CCK-8 is taken up from CSF by specialized ependymal cells (as shown for other CSF substances). To test the first proposal, we compared the effects on food intake of 75 min continuous injections into LV or CM of synthetic CSF or .64 pmole/min CCK-8 in 2 hr fasted sheep (N=5). LV CCK-8 injections decreased food intake 40-50% ($p<.05$), but CM injection of CCK-8 had no effect. In another study 2.55 pm/min CCK-8 injected into CM also had no effect.

To test the second proposal, two experiments were carried out: 1) CCK-8 was added to CSF and incubated for up to 24 hr at 37°C. There was no diminution in iCCK concentration over time, thus, enzymatic degradation of CCK-8 in CSF is probably not responsible for the low CM CCK concentrations. 2) To determine whether disappearance of CCK-8 did indeed occur as it traveled thru the ventricular system, .64 pm/min CCK-8 was injected into LV of sheep (N=4) for 3 hr (.03 ml/min) and CM CSF was collected every 30 min for measurement of iCCK. Inulin (2.5 mg/ml) was added as a marker for measurement of bulk absorption of CSF. Only about 5% of the CCK-8 was recovered from CM, thus about 95% of the CCK-8 was removed from more rostral ventricular areas by means other than enzymatic degradation or bulk absorption. In a repeat study using LV injection of .16 pm/min CCK-8 , the same results were obtained.

We propose that during feeding, CCK-8 is secreted into CSF and travels via CSF to ventricular sites at which it is actively taken up and transported to receptors responsible for its satiety action. Supported in part by NIH Postdoctoral Fellowship NS06595.

13.6 ROLE OF PEPTIDES IN THE CONTROL OF FOOD INTAKE OF OBESE RODENTS. C. L. McLaughlin and C.A. Baile, Dept. Clin. Studies, School Vet Med., Univ. of Penn., Kennett Square, PA 19348

The increased meal size characteristic of adult Zucker obese rats was shown to be present in weanling rats as early as 4 wks of age (.97 vs .70 g, $p<.02$) by using an automated feeding behavior data collection system. Food intake 60 min after a 5.5-hr fast was 67% greater in 4-wk old obese rats than lean rats (2.5 vs 1.5 g, $p<.01$) and 100% greater in 5-6 wk old obese Bar Harbor mice than lean mice (.71 vs .36 g, $p<.001$). The responses of obese rats and mice were compared with those of lean rats and mice to several peptides thought to play a role in the control of food intake. Serum concentrations of 3 of the peptides increase during a meal - cholecystokinin (CCK) and bombesin (BBS), released primarily from the duodenum, and pancreatic polypeptide (PP), released primarily from the pancreas. Food intake has been shown to be decreased in rats by exogenous administration of these peptides and by naloxone, a specific antagonist of opiates, which can stimulate food intake. As much as 4.0 µg/kg CCK-8, which decreased 60 min food intake of 4-wk old lean rats by 70%, had no effect on food intake of obese rats ($p<.01$). In obese mice 5-6 wks old 2 µg/kg CCK-8 also had no effect on food intake while decreasing that of lean rats 22% (.28 vs .36 g, $p<.05$). Adult Zucker obese rats were less sensitive to satiety elicited by a dose-range of concentrations of CCK-8 (.06 to 1.0 µg/kg) injected before meals scheduled 2 hrs apart and adult obese mice were less sensitive than lean mice to 1.0 µg/kg CCK-8 after a 3.0 hr fast (100 vs 50% of control, $p<.03$). BBS affected food intake similarly in both 4-wk old and adult obese and lean rats. However, obese mice were less sensitive than lean mice when 5-6 wks old and fasted 5.5 hrs, but were equally sensitive when they were adults. In adult mice 8 µg/kg PP decreased food intake less in obese than lean mice (94 vs 62% of control, $p<.04$). In adult rats, however, up to 128 µg/kg PP did not affect food intake of Zucker obese rats more than lean rats when injected during the initiation of the dark cycle (47 vs 97% of control, $p<.003$), but not when injected during the light (95 vs 68% of control, $p<.08$). Thus, while only obese mice are less sensitive to BBS and PP, both obese mice and rats are less sensitive to satiety elicited by CCK. This decreased responsivity in obese animals could result in increased average meal size and daily food intake.

13.7 STIMULANT EFFECTS OF NEUROTENSIN MICORINJECTION INTO THE VENTRAL TEGMENTAL AREA. P.W. Kalivas*, S.K. Burgess, C.B. Nemeroff and A.J. Prange, Jr., Biological Sciences Research Center, Univ. of North Carolina, School of Medicine, Chapel Hill, NC 27514

Neurotensin (NT) is an endogenous tridecapeptide which has a heterogenous distribution in the central nervous system (CNS), including high concentration in the ventral tegmental area (VTA). The fact that dopaminergic (DA) perikarya are also found in the VTA, and that these perikarya have limbic terminal fields which have been implicated in modulating spontaneous motor activity, raises the possibility that NT release in the VTA may alter spontaneous motor activity. To test this postulate, NT was bilaterally microinjected into the VTA and motor behavior quantified.

Male S.D. rats were chronically implanted with bilateral guide cannulae 1 mm above the VTA. One week following surgery, animals received a microinjection of NT or saline vehicle (0.6 µl/side/0.6 min). All cannulae placements were verified via light microscopic examination of cresyl violet stained brain sections. Automated measurements of motor activity were obtained using a Stoelting electromagnetic apparatus. Animals were adapted to the apparatus for 120 min prior to microinjection and behavior quantified for at least 120 min post-injection.

Administration of 5 µg NT (total dose/brain) resulted in a significant increase in motor behavior vs. saline controls. Using a standard ethogram, an observer ignorant of the treatment found that NT induced significant increases in exploratory behaviors (sniffing, rearing, locomotion) at the expense of resting or sleeping. The chemical specificity of this NT-induced effect was shown by demonstrating that in doses equimolar to 5 µg NT, neither TRH, LHRH nor D-Pro^{10}-NT altered spontaneous motor activity. In contrast, D-Tyr^{11}-NT was at least as potent as NT. The involvement of mesolimbic DA was investigated by pretreating animals in the lateral ventricle with 10 µg haloperidol. While this treatment did not alter baseline motor activity, it significantly decreased NT-induced motor activity. Further, 60 min following intra-VTA administration of 5 µg NT, animals were sacrificed and DA and DOPAC content determined using HPLC. As compared to saline, NT treatment caused a significant increase in the DOPAC/DA ratio in the n. accumbens, but no change in the striatum. These findings demonstrate that intra-VTA administration of NT results in an increase in spontaneous motor activity, probably via activation of the mesolimbic DA system. The existence of immunoreactive NT in the VTA suggests that these findings may reflect a physiological function of NT in the CNS. 13.8 CYTOPROTECTION BY INTRACISTERNALLY ADMINISTERED NEUROTENSIN AGAINST COLD-RESTRAINT STRESS-INDUCED GASTRIC ULCERS: CORRELATION OF TIME COURSE WITH EFFECTS ON GASTRIC PH AND ANTERIOR PITUITARY HORMONE LEVELS Charles B. Nemeroff, Daniel E. Hernandez*, Roy C. Orlando*, George A. Mason* and Arthur J. Prange, Jr., Biol. Sci. Res. Ctr., Depts. Psychiatry and Medicine, Univ. North Carolina Sch. Med., Chapel Hill, NC 27514.

Since central nervous system (CNS) administration of neurotensin (NT), an endogenous peptide, was reported to inhibit gastric acid secretion, we previously compared the effect of intracisternally (IC) administered NT and systematically administered cimetidine on the development of cold-restraint stress (CRS)-induced gastric ulcers in rats. After three hr of CRS, IC NT, but not IP cimetidine (an inhibitor of acid secretion), was cytoprotective in this model. In this study the relationship between cytoprotection and acid secretion was further investigated by simultaneous monitoring of gastric mucosal pathology and gastric pH at 30 min intervals over the three hr stress period. Since the gastric mucosa may be altered by pituitary hormone secretion, serum levels of growth hormone (GH), thyrotropin (TSH) and prolactin (PRL) were assayed. Groups of adult male S-D rats (200-250 g) ($n \geq 5$/group) were food deprived (24 hr), treated with IC saline (controls), IC NT (30 µg) or IP cimetidine (100 mg/kg), then immediately restrained with wire mesh and placed supine in a cold room (4°C) for 30,60,90,120,150, or 180 min. After CRS, the rats were decapitated and blood collected for hormone assays. The pH of the gastric contents was measured and the gastric mucosa examined for lesions with dissecting microscope. The incidence of gastric lesions was scored without knowledge of the treatment regimen. After 30 and 60 min of CRS, no gastric lesions developed in any treatment group. However from 90-180 min, saline-treated controls showed a significantly increased incidence of gastric ulcers; an increase paralleled in the cimetidine-treated group for all time periods except 90 min. In contrast, for the entire 180 min period, NT-treated rats showed a marked reduction in ulcer incidence. Despite the failure of cimetidine to remain cytoprotective, for each time period the pH of the gastric contents was approximately 6, a value significantly higher than either NT-treated (pH=4) or saline-treated rats (pH=4). Cimetidine did not significantly alter GH, TSH, or PRL levels when compared to saline-treated rats; NT-treated rats exhibited a smaller TSH response at 30 min, followed by a rebound rise in TSH after 90 min of CRS. No change in PRL or GH was noted after IC NT. These data indicate that the anti-ulcerogenic effect of NT is neither mediated by inhibition of gastric acid secretion nor by altered secretion of GH or PRL. The relationship between changes in TSH and cytoprotection following NT remains obscure (Supported by NIMH MH-32316, MH-34121, MH-33127, MH-22536 and NICHHD HD-03110).

13.9 THE EFFECTS OF D-AMPHETAMINE, METHYLPHENIDATE AND APOMORPHINE ON NEUROTENSIN-INDUCED HYPOTHERMIA IN MICE. G. Bissette*, D. Luttinger, C.B. Nemeroff and A.J. Prange, Jr., Biol. Sci. Res. Ctr., Univ. North Carolina Sch. Med., Chapel Hill, NC 27514

Neurotensin (NT), an endogenous tridecapeptide, produces hypothermia, muscle relaxation and analgesia after intracisternal (IC) or direct central nervous system (CNS) injection in rodents (Proc. Natl. Acad. Sci. 76:5368, 1979). Our group has also demonstrated that destruction of brain dopamine (DA), but not norepinephrine, containing systems with 6-hydroxydopamine significantly potentiates NT-induced hypothermia, as does pretreatment with the DA receptor antagonist, haloperidol (Brain Res. 195:69, 1980). To further characterize the interaction between NT and brain DA systems, the effect of 3 stimulant drugs (d-amphetamine, methylphenidate and apomorphine) on NT-induced hypothermia was studied. These pharmacological agents are generally acknowledged to act primarily on CNS DA circuits. Adult, male Swiss-Webster mice were lightly anesthetized with ether and injected IC with either NT (0.1-30 µg) or vehicle (0.9% NaCl, 10 µl). The mice were then immediately treated with intraperitoneal (IP) injections of d-amphetamine (0.5-2.0 mg/kg), methylphenidate (10 mg/kg), apomorphine (2.5-5.0 mg/kg) or vehicle. Thus each experiment included 4 groups of mice (n=8/group): (1) Vehicle IC + vehicle IP; (2) NT IC + vehicle IP; (3) Vehicle IC + Stimulant IP; (4) NT IC + Stimulant IP. Rectal temperatures were assessed at 0,30,60,90 and 120 minutes post-IC injection with the use of a digital display thermocouple; all experiments except otherwise noted were conducted at ambient temperatures of 25°C. D-amphetamine (2 mg/kg) completely blocked the hypothermic effect of IC NT (10 and 30 µg) whereas a lower dose of this stimulant (1 mg/kg) partially but significantly antagonized the hypothermic effects of both 1 and 10 µg NT. Although d-amphetamine produces a significant hypothermic effect in cold-exposed rodents, mice treated with NT and d-amphetamine and placed at 8°C showed less hypothermia than mice treated with NT alone. Like d-amphetamine, methylphenidate (10 mg/kg) significantly blocked the hypothermia observed after IC NT (10 µg). As previously reported, apomorphine (2.5 or 5.0 mg/kg) produced a significant hypothermia; mice treated with both apomorphine and NT did not show a greater decline in body temperature than mice treated with either agent alone. These data, taken together with previous findings, support the hypothesis that NT and indirect DA agonists (e.g. d-amphetamine and methylphenidate) are antagonists in the CNS. (Supported by NIMH MH-32316, MH-34121, MH-33127, MH-22536 and NICHHD HD-03110).

13.10 SEASONAL VARIATION IN TRH CONTENT OF DIFFERENT BRAIN REGIONS IN THE HIBERNATOR, CITELLUS LATERALIS. T.L. Stanton, A. Winokur and A.L. Beckman. A.I. duPont Institute, Wilmington, DE, 19899 and Univ. of Pennsylvania, Sch. of Med., Phila., PA, 19104.

Studies in our laboratory have shown that central administration of thyrotropin releasing hormone (TRH) produces state-dependent changes in body temperature, metabolic rate, motor activity and general arousal level in the ground squirrel (Citellus lateralis). These observations suggest that TRH may modulate the level of activity within neuronal systems. In the present study, we have investigated the possibility that changes in TRH concentration in some brain areas might be associated with naturally-occurring changes in the physiology and behavior of this seasonal hibernator. The variation of endogenous TRH content in 10 regions of the brain was measured between seasons and across the euthermic (i.e., not hibernating) vs. hibernation state.

Ground squirrels were wild-trapped in late spring and housed individually under natural light conditions. Euthermic animals were sacrificed in the mid-portion of each season: early August (Summer), early November (Fall), early February (Winter), early May (Spring). Hibernating animals, housed at 5°C throughout the winter, were sacrificed in early February. Brains were dissected into: pineal, olfactory bulb, hypothalamus (HYP), septum, preoptic area (POA), forebrain, hippocampus, cerebellum, midbrain, and brainstem. Each region was weighed, homogenized, methanol extracted and assayed for TRH content by radioimmunoassay.

Statistically significant decreases in TRH content occurred during hibernation when compared to one or more euthermic groups in the HYP, septum, POA, midbrain, and olfactory bulb. Only in the HYP was TRH lower than in all of the euthermic groups. Significant fluctuation in TRH during hibernation also occurred in the pineal, but the level of TRH in this region depended upon elapsed time in the hibernation bout. TRH content was considerably greater in the last quarter of the bout than in the first quarter ($p < .001$). Seasonal variation within euthermic groups was also evident in the olf. bulb, POA, midbrain, and pineal, in which TRH levels fell significantly in the winter. The greatest variation was observed in the pineal; TRH content was lower in winter compared to fall ($p < .02$) and spring ($p < .001$) and increased in fall relative to summer ($p < .01$). These results suggest that TRH may be involved in the control processes attributed to these brain areas, and support a role for TRH in the neural control of hibernation. 13.11 THYROTROPIN RELEASING HORMONE (TRH) AND THE TRH ANALOG MK-771 REVERSE ENDOTOXIN SHOCK VIA AN ACTION AT CENTRAL EFFECTOR SITES. John W. Holaday and Alan I. Faden. Dept. Med. Neurosci., Walter Reed Army Institute of Research, Washington D.C. 20012.

In previous reports, we have demonstrated the therapeutic efficacy of naloxone in reversing shock due to endotoxemia, hemorrhage, or spinal transection. Our concern was that this opiate antagonist would intensify traumatic pain even as it improved shock pathophysiology and survival. Recently, we have shown that intravenous (iv) TRH reverses endotoxic and hemorrhagic shock in rats without affecting nociceptive latencies (Science, in press). The purpose of the present study was to determine if TRH or the TRH analog MK-771 (pyro-2-aminoadipyl-histidyl-thiazolidine-4-carboxamide) exerted therapeutic effects in endotoxic shock via an action at neuroeffector sites within the central nervous system. Male Sprague-Dawley rats (250-300 g) were affixed with a transcranial guide tube, an external jugular-vein cannula, and a tail-artery cannula. On the day following surgery, conscious rats in their home cages were connected to microtransducers; cardiovascular and respiratory variables were monitored. Endotoxic shock was induced by iv injection of E. coli lipopolysaccharide endotoxin (15 mg/kg, Difco). Within minutes, arterial pressure fell 25-30 mmHg. At that time, TRH (10.0 µg, n=7), MK-771 (1.0 µg, n=6), or saline (n=6) were injected through the guide tube into the right-lateral ventricle in a volume of 20 µl over 20 sec. Within seconds, TRH and MK-771 resulted in large increases in mean arterial pressure (MAP), pulse pressure (PP), heart rate (HR), and respiratory rate (RR). Peak effects were observed 15 min post injection. At that time, TRH and MK-771 produced significant elevations in cardiorespiratory variables; saline had little effect.

	MAP(mmHg)	PP(mmHg)	HR(beats/min)	RR(breaths/min)
saline	9.7±3.8	11.7±5.1	25.3±34.3	38.0± 8.6
TRH (10 µg)	36.0±7.6	33.6±7.3	53.9±17.6	126.1±35.2
MK-771 (1 µg)	35.4±2.6	18.3±1.0	137.0±15.7	143.3±39.2

Although MK-771 produced a similar increase in MAP as TRH, it resulted in lesser increases in PP and greater increases in HR. These effects of TRH were centrally mediated since this small dose was without effect following iv injection in endotoxic rats.

Thus, the therapeutic effects of TRH and MK-771 in endotoxic shock appear to be centrally mediated, possibly expressed through autonomic mechanisms which affect cardiorespiratory function. Since intracerebroventricular TRH is without effect on nociceptive latencies (Holaday et al, Life Sci. 22, 1537, 1978), these results further suggest that TRH may have therapeutic utility in treating shock or acute hypotension similar to naloxone but without the adverse effect of intensifying pain.

13.12 CORRELATED BEHAVIORAL EXCITATIONS FOLLOWING MICROINJECTIONS IN RAT PERIAQUEDUCTAL GRAY OF MORPHINE AND ACTH(1-24). Y. F. Jacquet, Center for Neurochemistry, Rockland Research Institute, Ward's Island, New York City, NY 10035.

Excitatory effects (fearful hyper-reactivity and explosive motor behavior) were significantly correlated (Chi-square = 9.69; $p<0.01$) following separate microinjections of morphine sulphate (52 nmol) and ACTH(1-24) (17-34 nmol) into the periaqueductal gray of rats, indicating that the ACTH-elicited, and morphine-elicited behavioral excitations are mediated by the same sites in the periaqueductal gray. Subsequent microscopic study of 100µ cressyl-violet stained brain sections obtained from all the subjects showed that the microinjections were more effective when the sites were located within rather than below the periaqueductal gray. Analgesia was observed following morphine but not ACTH microinjections. When rats were microinjected with ACTH (6.8 nmol) 10 min prior to a microinjection of B-endorphin (2.9 nmol) in the same periaqueductal gray site, no antagonism of the B-endorphin-induced analgesia was observed, indicating that different neural mechanisms mediate the effects of the two neuropeptides. These results confirm that many of morphine's behavioral effects are mediated by specific sites within the periaqueductal gray, and add further support for the proposal (Jacquet, Y.F. et al, Science, 198:842, 1977) that morphine's dual actions - excitatory and inhibitory - are mediated by two classes of receptors, one, a stereospecific, naloxone-sensitive receptor that mediates the inhibitory (e.g., analgesic) action (the endogenous ligand of which was proposed to be B-endorphin), the other, a nonstereospecific, naloxone-insensitive receptor that mediates the excitatory (e.g., fearful hyper-reactivity and explosive motor behavior) action (the endogenous ligand of which was proposed to be ACTH (Jacquet, Y.F., Science, 201:1032, 1978)). In addition, these results are consistent with our proposal (1977, 1978) that the opiate abstinence syndrome may be due in part to the unmasking of the excitatory action of morphine (at the "ACTH" receptor) following weakening of the inhibitory action of morphine (at the "endorphin" receptor) due to selective tolerance development or selective naloxone blockade.

13.13 CHOLECYSTOKININ OCTAPEPTIDE (CCK-8) INJECTED IN CEREBROSPINAL FLUID (CSF) DECREASES PLASMA INSULIN CONCENTRATION IN SHEEP.

MA Della-Fera and CA Baile, Sch Vet Med, U Pa, Kennett Sq, PA 19348

We have shown CCK-8 to be a potent and specific suppressor of feeding when administered as a continuous injection into the lateral cerebral ventricles(LV) of sheep. Strong support for a physiological role for endogenous brain CCK peptides and specific CCK receptors in satiety was obtained from studies showing that significant increases in food intake occurred with LV injections of either a specific CCK receptor blocker or CCK antibody. Because CCK-8 is present in several CNS sites, though, it is likely to be involved in a variety of physiological functions controlled by the brain.

The present studies were carried out to determine whether brain CCK-8 could influence secretion of 3 hormones important in control of peripheral metabolism: GH, Insulin(I) and glucagon. First, the effect of 60 min continuous injections of 0(sCSF), .04, .16 and .64 pmole/min CCK-8 on plasma I and glucose(G) concentrations was determined (N=6). LV CCK-8 at .64 pm/min caused significant decrease in plasma I at 30 and 60 min after starting injection: by 60 min plasma I had decreased by 1.95±.1 ng/ml from preinjection levels with .64 pm/min CCK-8 ($p<.01$); sCSF had no effect on I. Lower doses of CCK-8 caused slight, but nonsignificant decreases in plasma I. Plasma G was not affected by any treatment. In other experiments the effect of continuous LV injection of sCSF or .64 pm/min CCK-8 on plasma GH and glucagon concentrations was studied. CCK-8 had no effect on plasma levels of either hormone, thus the decrease in I is not due to generalized suppression of hormonal secretion (eg, as caused by somatostatin secretion).

Desulfated CCK-8 (desCCK-8) binds less strongly to CCK receptors and is much less potent in decreasing feeding during LV injections in sheep. To determine whether the effect on I was also a chemically specific effect, plasma I and G concentrations were measured during 60 min LV injections of sCSF, .64 pm/min desCCK-8 and .64 pm/min CCK-8 . Plasma I was decreased by LV CCK-8 at .64 pm/min ($p<.05$), but desCCK-8 had no effect (60 min I, ng/ml: sCSF 2.2±.3, desCCK-8, 2.5±.3, CCK-8 1.2±.1). No treatment affected plasma G concentrations.

Finally, to determine the importance of the more rostral brain areas, we compared the effects on plasma I and G of LV and cisterna magna(CM) injections of sCSF or .64 pm/min CCK-8. LV CCK-8 decreased plasma I ($p<.05$), but CM injections had no effect (60 min I, ng/ml: LV sCSF 2.6±.4, LV CCK-8 1.6±.1, CM sCSF 2.8±.3, CM CCK-8 2.3±.4); no treatment affected plasma G.

These results suggest that brain CCK-8 acts on CNS sites involved in the control of insulin secretion, possibly via vagal efferents to the pancreas. Supported in part by NIH Postdoctoral Fellowship NS06595.

14.1 TRIGEMINAL EVOKED POTENTIALS IN UNANESTHETIZED CATS. E. H. Chudler*, W. K. Dong (SPON: K. Y. Chan). Dept. of Anesthesiology, Univ. of Washington, Seattle, WA. 98195.

We found that tooth pulp evoked far-field and near-field potentials were differentially affected by barbiturate and inhalation anesthetics; the latter potentials were markedly attenuated. Comparison of near-field potentials among anesthetized cats was impossible due to variability in their waveform and latency. Thus, a behavioral method was developed to study near-field evoked potentials in unanesthetized cats.

Under anesthesia, two channels were drilled into the dentin of a mandibular canine tooth. Wire electrodes for stimulation were secured in these cavities with dental amalgam and composite resins. Interelectrode impedances varied from 7kΩ to 16kΩ. Evoked potentials were recorded from an array of wire electrodes implanted in the skull. EMG leads were implanted into deep neck muscles.

A behavioral paradigm was established to allow the animal to terminate the stimuli presentation. Cats were trained to remain still for a period of 10 to 15 sec. During this time, electrical stimuli were delivered to the tooth and evoked potentials were recorded and computer averaged. If the cats held still, a food reward was automatically delivered. However, if the cat moved and the EMG exceeded a preset voltage, the shock was terminated and no reward was given.

Acute animal studies have demonstrated that activation of large myelinated (Aß) fibers by tooth pulp stimulation was sufficient to evoke far-field potentials (designated I, IIa, IIb, IIIa, IIIb with peak latencies of 0.9, 1.6, 2.3, 3.5 and 4.1ms) and early near-field potentials (IV, P_1, N_1 with peak latencies of 5.2, 6.2 and 9.9ms; P_2, N_2, P_3, N_3 with latencies from 25 to 160ms). Delivery of stimulus intensities to chronic animals that were below levels for escape evoked the same far-field and early near-field potentials.

Evidence from acute lesion studies and from comparing latency and refractoriness of surface recorded potentials to those of in-depth recorded potentials indicates the following main sources: I-trigeminal nerve/ganglion; IIa,b-principal sensory nucleus of V; IIIa,b-thalamus (VPM); IV, P_1, N_1-primary sensorimotor cortex. Additional lesion and mapping studies are needed to identify the origins of the other near-field potentials. With the behavioral paradigm described, evoked potentials can be recorded without contamination from drugs. It may also be possible to record evoked potentials associated with escape behavior and activation of high threshold afferents in the alert unanesthetized, unrestrained animal.

(Supported by USPHS Grant DE 05130).

14.2 FREQUENCY DEPENDENCE OF LATENCIES IN THE VISUAL EVOKED RESPONSE. J. M. Flinn* (SPON: I. Weiss). Depts. of Physics and Psychology, George Mason University, Fairfax, Va. 22030.

Phase characteristics of transient evoked potentials have received little attention, although they can be used to obtain information about the group delay, i.e., latency, as a function of frequency via the relationship $\tau_g = (2\pi)^{-1}\, d\phi/df$, where τ_g is the group delay or latency, f is the frequency, and ϕ the phase of the Fourier coefficients of the signal. In this experiment, latencies were obtained from the visual evoked potentials (VEPs) of 64 twelve-year-old girls. The recording was made using bipolar electrodes 6 cm apart astride C_4. Responses to 100 light flashes of 4×10^5 lumens/steradian were recorded; two runs were recorded with the light flash (runs 1 and 2) together with a control run (run 3). The slope of the phase as a function of frequency varied with frequency for runs 1 and 2 but not for run 3. Analysis of variance showed that there was a significant variation of latency with frequency, calculated over 5 Hz bands, for runs 1 and 2, but not for run 3. For run 1: $F(7,406) = 5.7$, $p < .01$; for run 2: $F(7,406) = 4.7$, $p < .01$; for run 3: $F(7,406) = 1.4$. For runs 1 and 2, the latency had a maximum of 201 ± 12 msec; this occurred in the frequency range 5-10 Hz. The minimum was 104 ± 11 msec, in the range 20-35 Hz. These results are similar to those obtained from the phase analysis of steady-state VEPs (Spekreisje, H., Estevez, O., and Reits, D. In: J. Desmedt (Ed.), Visual Evoked Potentials in Man. Oxford, Clarendon Press, 1977). This shows that similar phase and latency information is obtained by analysis of either steady-state or transient VEPs. Previous experiments have shown that harmonics of the stimulating frequency are observed in the steady-state VEP; thus the system is nonlinear. However, the fact that the flash stimulus, which acts as an impulse, produces the same phase data as the steady-state VEP shows that this nonlinearity is weak. Thus it should be possible to obtain latency as a function of frequency by using a transient stimulus without the necessity of sweeping through a range of modulating frequencies. This would be particularly useful in the analysis of VEPs due to patterned stimuli, where the latency may depend on both spatial and temporal frequencies.

14.3 VISUAL EVOKED POTENTIALS EVOKED BY LIGHT-EMITTING DIODES MOUNTED IN GOGGLES, R. P. Lesser*, H. Lueders*, N. Donovan*, G. Klem*, (SPON: K. L. Barnes). Department of Neurology, Cleveland Clinic Foundation, 9500 Euclid Avenue, Cleveland, OH 44106.

Visual evoked potentials to pattern reversal stimulation are accepted to be of more stable morphology than those evoked by flash via a photic stimulator. These potentials require, however, that the patient fixate on the field of stimulation and in certain circumstances, including functional visual deficits, refractive disorders or surgical monitoring a patient may be unwilling or unable to attend carefully to the patterned field.

We have compared the potentials following pattern reversal stimulation to those evoked by light-emitting diodes (LED) separated by 5mm and mounted in 4x4 arrays inside of goggles worn by the patient. Pattern reversal was delivered by a television system in which each check subtended 2^o of visual arc within a total field subtending 8^o of visual arc. The patient sat 1 meter from the television screen. For both stimulus modalities filter settings at half-amplitude were 1 and 100 Hz; 256 trials were taken for each average with at least two averages for each modality to each eye. Stimulus rate was 2/second. The montage utilized was O1-Cz, O2-Cz, Oz-Cz, A1A2-Cz (international 10-20 system).

Following goggle stimulation a series of positive and negative deflections occurred. There was more inter-individual variability in these deflections, compared to thosed evoked by pattern reversal, but within individuals the potentials evoked by right and left eye stimulation were relatively similar. This suggests that potentials evoked by LED-goggle stimulation may be of value in certain clinical states to define the presence or absence of an evoked potential as well as to assess the symmetry of conduction from the two eyes.

14.4 COMPARISON OF PATTERN ELICITED MASS POTENTIALS FROM THE RETINA, LATERAL GENICULATE NUCLEUS (LGN), AND THE VISUAL CORTEX OF THE CAT I. Ohzawa* and R. D. Freeman (SPON: T. E. Cohn), School of Optometry, University of California, Berkeley, CA 94720

Pattern-elicited electroretinograms (ERG), LGN and cortical evoked potentials (EP) from cats were measured to compare mass response properties at different stages of the visual pathways. The stimuli were sine-wave gratings phase reversed in either of two temporal modes, square- or sine-wave. Patterns were presented in pseudo-random order, and responses were averaged and Fourier analyzed by a computer. ERGs were recorded via stainless steel wires in the vitreous and the orbit behind the globe. LGN and cortical EPs were recorded via bipolar and steel screw electrodes, respectively.

For square-wave temporal modulation, the ERG consisted mainly of a vitreous negative peak at 120-200 mS after reversal. The a- and b-waves seen in flash ERGs were missing in these pattern ERGs. To show that the absence of a- and b-waves was not due to retinal damage, mean luminance modulation was added to grating patterns. A progressive recovery of a- and b-waves was observed with increased luminance modulation. ERG spatial frequency response did not show any fall-off at low frequencies for square-wave temporal modulation, whereas LGN and cortical EPs clearly showed a band-pass characteristic for the same conditions. To determine whether low-frequency fall-off, which implies lateral inhibition, was obscured by temporal transients, sine-wave temporal modulation was used in some recordings. Under this condition, ERGs showed a clear fall-off at low frequencies. This suggests that the generating mechanism of the pattern ERG involves lateral inhibition.

The amplitudes of cortical EPs were approximately proportional to log contrast. We found this relationship also in the LGN, but not in the retina. ERGs showed high contrast thresholds, and often a low saturation contrast with a log-linear region in between. Contrast thresholds for ERGs were variable, ranging from 3% to 10%. LGN and cortical EPs simultaneously recorded in interleaved fashion with ERGs showed much lower thresholds than ERGs, and had a clear response at the thresholds of the corresponding ERGs.

These contrast results are somewhat paradoxical in the sense that central structures show clear responses when the retina shows no response, and that LGN and cortical EPs do not saturate far beyond the retinal saturation contrast. One hypothesis for the former finding is that the local ERG is cancelled out by summation across the retina at low contrasts, and only appears when a nonlinearity becomes manifest at higher contrast.

14.5 PATTERN AND FLASH EVOKED POTENTIALS IN THE HOODED RAT.
M. Onofrj* and I. Bodis-Wollner. Dept. Neurology, Mt. Sinai School of Medicine, New York, NY 10029.

Thirty-two male adult hooded rats had evoked potentials (EPs) recorded with chronically implanted electrodes placed over area 17, the postbregmatic region, the nasion and the earlobe. The transient flash EP of the rat has 4 consistent components: N_1 at 31 ± 4 msec, P_2 at 46 ± 3 msec, N_2 at 65 ± 3 msec, and P_3 at 114 ± 9 msec. Reducing the maximum luminance of the Grass flash stimulator by a factor of 16 delayed P_2 by 10 ± 3 (S.D.) msec. Using 8 and 10 flashes per second following luminance reduction the phase shift of the steady-state EP was 30^{o}.

Pattern EPs to counterphase modulation of .3 cpd checks and .1 cpd square wave gratings were obtained in 14 out of 20 rats. The typical triphasic EP waveform was most consistent over the hemisphere contralateral to the eye. The measured components were P at 85 ± 5 msec, and N at 113 ± 13 msec. To 5 Hz counterphase modulation a clear 2nd harmonic EP could be recorded in 6 out of 13 rats. In 4 tested rats a +2 diopter lens consistently doubled the P and N amplitude. A +4 diopter lens increased it by only 10%.

Thus both the pattern and flash EP of the hooded rat are comparable in latencies and waveforms to EPs of higher mammalians. There has been controversy surrounding the acuity of the rat based on electrophysiological (Shaw 1974,1975) and refractive studies (Massof 1972; Block 1969). Using EP methodology we find agreement with Meyer and concur with the visual acuity limits established with behavioral (Wiesenfeld 1976, Birch 1979), refractive (Hughes 1979), and single cell (Brown 1965; Montero 1973; Wiesenfeld 1975) data.

14.6 DOPAMINERGIC DEFICIENCY CAUSES VEP DELAYS IN THE MALE HOODED RAT.
I. Bodis-Wollner and M. Onofrj* (SPON: M. Yahr). Dept. Neurology, Mt. Sinai School of Medicine, New York, NY 10029.

The hooded rat has reliable visual evoked potentials (VEPs) to both flash and patterned stimuli (Onofrj and Bodis-Wollner 1981). Now we studied in 8 rats the effects of alphamethylparatyrosine (AMPT), a dopamine (DA) depletor, and haloperidol, a DA blocker, on flash and pattern EPs. The latency of the various components of the transient flash EP started to shift 90 min following i.p. administration of 250 mg/kg AMPT. The delay peaked in 220 min: 19 min for P_2 (normal 46 ± 3 msec), 23 msec for N_2 (65 ± 3 msec), and 23 msec for P_3 (114 ± 9 msec), while the steady-state EP shifted by 145^{o}. Recovery was complete in 24 hours. In 4 rats the pattern EP to .1 cpd gratings showed a delay in P of 24 ± 4 msec (normal 86 ± 5 msec). The maximum effect of i.p. haloperidol 3 mg/kg occurred in 35-60 min. On the average, P_2 was delayed by 15 msec, and N_2 by 18 msec. The mean delay was 21 msec for the P component of the pattern EP.

Our flash EP data agree with those obtained by Dyer using similar pharmacological agents. Comparing VEP effects due to pharmacological manipulations to those obtained by luminance reductions, it appears that miosis is unlikely to explain these delays. Our study using patterns suggests that dopaminergic deficiency has a significant, reversible effect on the VEP and therefore implies a role of this neurotransmitter in the visual pathway of the hooded rat. We conclude that besides the known mechanism of VEP delays, retinal synaptic malfunction must also be considered. The relationship between these data and VEP changes in humans suffering from Parkinson's disease and those treated with phenothiazines (Bodis-Wollner and Yahr 1978,1980) require further study.

14.7 CONTRAST AND COUNTERPHASE-FREQUENCY EFFECTS OF THE THREE PRIMARY COLORS ON HUMAN VISUAL EVOKED RESPONSE.
W. R. Klemm, R. A. Goodson* and R. G. Allen*. USAF School of Aerospace Medicine, Brooks AFB, TX 78235.

Using a counterphasing checkerboard stimulus, we evaluated the visual evoked potential (VEP) in 10 subjects for the response to different contrast levels. For each color the highest contrast setting was used to test the effects of varying the reversal rate of the stimulus.

Overall mean luminance of each color was photometrically equated and kept constant. The VEP was computer averaged for 90 consecutive 1-sec epochs and the power (PSD) determined at the appropriate stimulus frequencies (plus their first two harmonics).

For each color and each of the stimulus frequencies (6, 11, 16 Hz) the magnitude of the VEP did not seem to be influenced by the amount of simultaneously occurring alpha activity. The magnitude of response did not always correspond to a person's impressions of how well he was perceiving the stimulus.

For each color, the contrast-response curves revealed small PSDs at low contrast (0.1) and larger PSDs at the 3 high-contrast settings (0.3 - 0.5). Magnitude of PSD varied markedly by color and by subject. The shape of the curves, depending on color and subject, often indicated a nonlinear saturation of responses. A given subject commonly had a physiologically "preferred" color which produced larger responses.

Most subjects responded best at 6 Hz, poorest at 11 Hz, with intermediate responses at 16 Hz. As in the contrast-response tests, there were differential VEP responses at each color.

Similar contrast- and reversal-rate effects occurred at lateral electrode sites, but unusual lateralization effects occurred in some subjects.

We conclude that these VEPs seemed to be independent of alpha. Also there seems to be considerable variation among subjects in the response to color, contrast, and reversal rate. Finally, the results suggest that white-light VEP responses may not necessarily reflect the response characteristics at specific colors.

14.8 MAGNETIC AUDITORY EVOKED FIELDS:TONE AND CLICK DIFFERENCES
M. Reite, J.T. Zimmerman* and J.E. Zimmerman*. Univ. of Colo. School of Medicine, Denver, CO 80262 and Nat. Bureau of Standards Boulder, CO 80302.

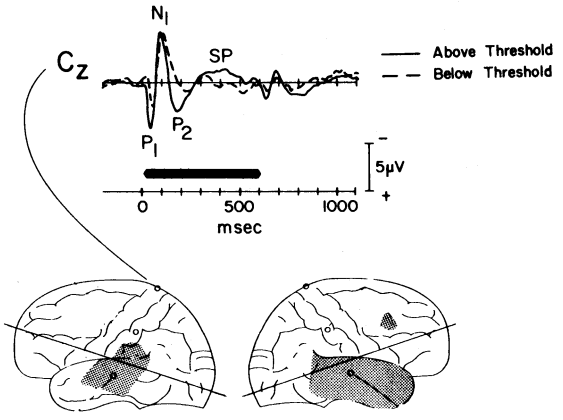
Previous studies in our laboratory have demonstrated that human magnetic auditory evoked fields (MAEFs) to click demonstrate interhemispheric asymmetry, being of greater amplitude contralateral to the stimulated ear, and that the current dipole responsible for click evoked fields is approximately perpendicular to the Sylvian fissure in the area of the primary auditory cortex. In this study we examined whether auditory fields evoked in response to tone stimuli could be differentiated from those evoked in response to click stimuli, and whether magnetic recordings could do this better than EEG recordings.

Ten normal adults served as subjects. Magnetoencephalographic (MEG) recordings were made using a figure-eight SQUID gradiometer in an aluminum shielded room. The sensor was placed 1/4 of the distance from T3 to C3 for left hemisphere recordings, and 1/4 of the distance from T4 to C4 for right hemisphere recordings. EEG recordings were obtained simultaneously from these positions in 7 subjects. MEG and EEG data, bandpassed between 1 and 40 Hz, was averaged for 500 msec after each of 128 aperiodic 92dB alternating clicks and 90msec long 2000 Hz tones. Recordings were made from both hemispheres in response to both ipsilateral and contralateral stimulation. MAEFs and AEPs were plotted and the maximum amplitude of each response occuring within 250 msec of stimulus onset was measured.

A repeated measures t test was performed for differences between tone and click stimulation for each hemisphere and for both contralateral and ipsilateral stimulation. Such comparisons were made for both MAEFs and AEPs. The results indicated MAEFs were of significantly higher amplitude for tones than for clicks for contralateral stimulation of the left hemisphere, and for both contralateral and ipsilateral stimulation of the right hemisphere. In general, EEG AEPs to tones were of lesser amplitude than for clicks; this effect was statistically significant for ipsilateral stimulation of the left hemisphere only. The larger MAEFs to tone may reflect a larger net current flow in auditory cortex as a result of the longer duration tone burst.(Supported by Office of Naval Research Contract No. N00014-79-C-0383).

14.9 *LONG-LATENCY AUDITORY EVOKED POTENTIALS IN CORTICAL DEAFNESS*
D. L. Woods, R. T. Knight *, and H. J. Neville Neuropsychology Laboratory, The Salk Institute, La Jolla, CA 92037

We recorded long-latency auditory evoked potentials (AEPs) to stimuli presented above and below perceptual threshold in a patient who became deaf as a result of the bilateral destruction of auditory cortex. The AEPs were similar in amplitude, latency, scalp distribution and refractory properties to those recorded in subjects with normal hearing. The differential effects of brain lesions on auditory-perceptual functioning and AEPs suggests that they are subserved by different neural systems.



14.10 *AUDITORY AND SOMESTHETIC 40HZ ERPS FROM THE HUMAN SCALP.*
R. Galambos. Speech, Hearing & Neurosensory Center, and Department of Neurosciences, Univ. of Calif., San Diego, La Jolla, CA 92093

Relatively little attention has been paid to human event related potentials (ERPs) initiated by stimuli repeated at high rates (beyond 20 per sec). However, as we have reported (Proc. Nat. Acad. Sci., Apr. 1981), clicks or tones generate large, stable nearly-sinusoidal waves when repeated at around 40 per sec; these auditory 40Hz ERPs evidently represents a consolidation, or superimposition of the 3 or 4 approximately sinusoidal waves called the middle (80-100 msec) latency auditory ERP components. We can now add that vibratory stimuli to finger or toe generate similar large stable ERPs when repeated at around 40Hz. The somesthetic response can be subdivided into two types: a large event localized to the scalp overlying the cortical projection of the limb stimulated, and a (usually) smaller one distributed widely over the scalp which more closely resembles the auditory ERP in amplitude. Dissimilarities do, however, exist in the optimal frequencies (tested: 20 to 60 Hz) and particular scalp sites where auditory and somesthetic 40Hz ERP response maxima occur.

When separate clicks are delivered to the ears the 40Hz ERPs they produce add approximately algebraically, i.e., the ERP wave response to the two clicks is larger when they are in phase and approaches zero when they are out of phase. A similar algebraic summation is seen when tactile and auditory stimuli are intermixed with appropriate control of the time interval separating them. These interactions within and across modalities may occur because extralemniscal generators with similar properties spread their effects widely and symmetrically through the cortex. This possibility, and others, will be discussed.

14.11 NEURAL RECOVERY FROM SEVERE HUMAN HEAD INJURY ASSESSED WITH MULTIMODALITY EVOKED POTENTIALS (MEPS): FUNCTIONAL CONSEQUENCES OF SECONDARY INSULT. P. G. Newlon*, R. P. Greenberg and D.P. Becker Div. of Neurosurgery, Med. Coll. of Va., Richmond, VA., 23298

Multimodality Evoked Potentials (MEPs; visual, auditory and somatosensory) recorded early after injury have been shown to aid assessment of brain dysfunction and outcome prediction in comatose head injury patients. Those who exhibit normal or mildly abnormal MEPs in the first 72 hrs. post-trauma generally reach a good/moderate outcome by 1 year, while a majority of patients with severely abnormal or absent MEPs have a poor outcome. Errors in outcome prediction made from early MEP tests may occur if patients suffer secondary insults later in their hospital course. We have examined changes in MEPs over time in these patients as they relate to occurrence of complication and resultant outcome, to determine whether serial MEP studies reflect the neurological effects of secondary insult. 109 patients who received multiple MEP studies up to one yr. post-trauma were studied and were assigned to the following groups, based on the most severe MEP abnormality exhibited in an early study ($\bar{X}$ Day 3): N=Normal, MA=Mildly abnormal, SA=Severely abnormal, A=Absent. These groups were subdivided into those with (C) and without (NC) complication. Insults included were pulmonary infection/edema, GI bleeding, ventriculitis, meningitis, inappropriate ADH levels, seizure, sepsis, gram(-) shock, respiratory/cardiac arrest and delayed hematoma. Outcome was defined as Good/Moderately disabled (G/M), Severely disabled/Vegetative (S/V) or Dead (D). Data analysis bore the following results: 1) Outcomes of patients in the N (n=22) and A (n=13) groups were not altered appreciably by complication. 2) When MEPs of patients in the MA(C) group (n=32) returned to normal (50% of cases) or remained MA (30% of cases), 90% of the patients made a G/M recovery despite complication. However, 6 MA(C) patients (20%) showed MEP deterioration over time and all had poor outcomes (2 S/V, 4D). 3) MEPs of the SA(C) group (n=16) improved in only 5 patients (31%). 2 patients made a G/M recovery, 2 were S/V and 1 D. MEPs of 4 patients (25%) remained SA and all did poorly (1 S/V, 3 D). 7 patients (44%) showed MEP deterioration with complication and had poor outcomes (2 S/V, 5 D). 4) Of the patients in the MA(NC) and SA(NC) groups 79% and 71% respectively showed MEP improvement and all had G/M outcomes. MEPs remained MA or SA in 4 patients who made good recoveries and 1 patient with SA(NC) which remained so, died. Although secondary insults may worsen outcome for patients who initially show MEP abnormalities, MEPs are sensitive to neurological change. Serial studies may help to determine which patients have suffered further brain compromise and which have not. Supported by NINCDS Grant 5-20627 and T.I. Award 5K07NS00346-03

14.12 EVOKED POTENTIAL ABNORMALITIES IN PATIENTS WITH INHERITED ATAXIAS. M. Nuwer, S. Perlman* and J. Packwood*. Dept. Neurology, Reed Neurological Research Center, U.C.L.A., Los Angeles, Calif. 90024.

Evoked potential tests have been shown to be sensitive tools for studying central nervous system abnormalities. We have investigated visual, brainstem auditory, and somatosensory evoked potentials in 20 patients with a variety of inherited ataxias. Such tests in these patients can help demonstrate subclinical neurological impairments and better define the physiological abnormalities underlying clinical symptoms and signs.

Visual evoked potential (VEP) tests were performed one eye at a time with checkerboard pattern-reversals, using 30' checks projected onto a square screen 13 degrees along each side, reversing 2/second, recording OZ-CZ. Brainstem auditory evoked potential (BAEP) tests were performed one ear at a time with 100 microsecond condensation clicks 65 dB above threshold, 10/second, recording from the ipsilateral mastoid to CZ. Somatosensory evoked potential (SEP) tests were performed with sufficient electrical stimulation of the median nerve to cause a 1 cm movement of the thumb, 2/second, recording from scalp over the contralateral hand region of somatosensory cortex to a posterior parietal reference, and often also recording both from the seventh cervical spine, and from Erb's point, to a mid-frontal reference.

VEPs were slow in most cases independent of the diagnosis. SEPs were slow in most patients with Friedreich's Ataxia, Combined Cerebral and Cerebellar Atrophy, and Ataxia Telangectasia. However, SEPs were normal in most patients with Olivopontocerebellar Atrophy (OPCA). BAEPs were present and normal in most conditions, including Friedreich's. However, BAEPs were abnormal in all of the OPCA patients. Left-right symmetry was preserved in SEP and VEP abnormalities, but BAEPs were often asymmetric when abnormal.

These findings agree with previous reports, extend the diseases and modalities tested, but disagree with a previous report of absent BAEPs in most Friedreich's patients.

15.1 SPROUTING OF DORSAL ROOT AXONS FOLLOWING NEURAL INJURY. Richard E. Coggeshall and Claire E. Hulsebosch, Depts. of Anatomy and of Physiology and Biophysics and the Marine Biomedical Institute, The University of Texas Medical Branch, Galveston TX 77550

Sprouting of dorsal root axons that follows partial denervation of the mammalian spinal cord has been indicated by several investigators using the silver staining method. However, this method is not adequate for quantifying the increase in axonal numbers which is called sprouting. Accordingly, the present ultastructural study was undertaken to quantify the numbers of myelinated (M) and unmyelinated (UN) axons in the dorsal roots on the operated (OP) and normal (N) side of the rat spinal cord after hemisection (HS) at birth or after cutting 3 consecutive dorsal roots above and below a spared root (SR) in rats one month old. Data from the pair of dorsal roots just cranial and caudal to the lesions as well as data from the spared roots are shown in the following table in which each number is a mean value from at least 4 rats allowed to survive 1 month or 3 months, as indicated, after surgery.

		HS 1 MONTH POST-OP		HS 3 MONTHS POST-OP		SR 1 MONTH POST-OP	
		OP	N	OP	N	OP	N
CRANIAL	MY	1340	1298	1353	1282	1398	1411
ROOTS	UN	3751	3183	4029	3371	4316	3541
SPARED		LESION		LESION	MY	1629	1641
ROOTS					UN	5226	4448
CAUDAL	MY	1346	1339	1473	1459	2191	2133
ROOTS	UN	4061	3237	5336	3975	5671	5610

The data indicate 1) there is no significant difference in the myelinated axon population in each pair, 2) there is a significant increase in the unmyelinated axon population of dorsal roots on the operated side except in the SR caudal roots, and 3) the increase in the unmyelinated population persists 3 months after hemisection. Therefore, the major conclusions are 1) that the unmyelinated axons are the sprouting population and 2) that survival time after the initial insult does not change the amount of sprouting. These data confirm that dorsal root axons sprout in response to spinal cord denervation and show that this sprouting can be quantified. Further work relating the amount of sprouting to age is underway. Supported by NIH grants NS 10161, NS 06246, NS 07377 and NS 11255.

15.2 SPROUTING AND SYNAPSE FORMATION BY AXONS WHILE SEPARATED FROM THEIR CELL BODIES. S. Rotshenker, Dept. of Anat. & Embryol. Hebrew Univ. Med. Sch., Jerusalem, Israel.

In previous studies (Rotshenker, J. Physiol. 292:535, 1979; Rotshenker and Reichert, J. Comp. Neurol. 193:413, 1980) we observed that axotomy of the nerve to one cutaneous-pectoris muscle of the frog induced sprouting and synapse formation in the intact contralateral muscle, thus producing a pattern of supernumerary innervation. In a recent study (Rotshenker, Neurosci. Abs. 10, 1980) I examined the ability of colchicine to imitate axotomy in producing contralateral sprouting and synapse formation after the drug was applied to nerves of left muscles and found that supernumerary innervation developed in both left and right muscles. The appearance of new synapses occured after about 2.5 weeks in right muscles but as early as 2 days in left muscles. The short latency response in left muscles raised the possibility that colchicine induced the sprouting of axons that were exposed to it directly independent of their cell bodies. To test this hypothesis I examined the ability of motor axons to sprout and form synapses while being separated from their cell bodies. Cutting the left 2nd spinal nerve that contains the axons innervating the muscle close to its exit from the spinal cord resulted in a failure to record end plate potentials (e.p.p.s) by the 4th day after the operation. E.p.p.s. were recorded throughout the first 3 days as faithfully as in intact muscle. The incidence of polyneuronal innervation detected electrophysiologically 2 and 3 days after the operation was 17.5±1.0%(SEM) in left muscles and 19.0±1.6%(SEM) in right muscles. In a second group of frogs the 2nd left spinal nerve was cut and 0.01-0.015 M of colchicine applied to the nerve to left muscles at axilla (about mid way between the spinal cord and muscle). The incidence of polyneuronal innervation detected electrophysiologically 2 and 3 days after the operation was 30.8±2.0%(SEM) in left muscles and 18.2±1.9%(SEM) in right muscles. This reflects a significant 1.7 fold increase over normal in the incidence of polyneuronal innervation in muscles whose axons were treated with colchicine while being separated from their cell body. In such muscles morphological studies produced anatomical evidence for sprouting and synapse formation. Our previous observations on the transneuronal induction of sprouting and synapse formation and the present finding that the same motor axons can respond in a similar way after being exposed to low doses of colchicine while being separated from their cell body further suggest that motor neurons may be induced to sprout in more than one way, whether by presenting appropriate stimuli to their soma and central processes or peripheral extensions.

15.3 DENDRITIC OUTGROWTH FROM AN ADULT INSECT MOTONEURONE AFTER NEURAL LESIONS. R.M. Pitman and K.A. Rand. Department of Physiology & Pharmacology, University of St Andrews, Fife, Scotland KY16 9TS.

Alterations in dendritic field following neural damage may reflect the ability of a neurone to undergo adaptive changes. However, the factors controlling dendritic modification are unclear. Deafferentation of interneurones in immature insects may be followed in different instances either by reduced growth or sprouting of specific dendrites (Murphey et al. J. comp. Neurol., 159: 407, 1975; Hoy et al. Soc. Neurosci. Abstr., 4:115, 1978), while similar lesions may produce no detectable change in dendritic field of adult insect interneurones (Tweedle et al. Brain Res., 60: 471, 1973). We report here experiments in which dendritic sprouting has been observed in an identified adult insect motoneurone following neural lesions.

We have studied the metathoracic 'fast' coxal depressor motoneurone of the cockroach, Periplaneta americana, by intracellular cobalt injection and silver intensification at various intervals after a number of nerve trunks to the metathoracic ganglion had been severed.

We have made the following observations: (1) Axotomy is not a potent stimulus for dendritic growth; although supernumerary processes may occasionally develop after severing the nerve trunk in which the axon of this neurone travels (nerve 5), the extent of this sprouting is limited. (2) Sprouting is usually more extensive if a number of nerve trunks are severed. (3) Extensive dendritic sprouting may follow lesions which damage neither the axon nor the dendrites of the neurone under study. (4) Processes may grow well beyond the normal dendritic field of the neurone. Dendrites of this motoneurone are normally restricted to the ganglionic neuropile ipsilateral to its cell body and axon. However, after nerve trunk lesions, processes may extend into anterior or posterior connectives, into the contralateral neuropile or into inappropriate segmental nerve trunks. (5) New processes frequently have varicosities both along their length and at their ends.

We conclude that dendrites of adult insect neurones may have a greater capability for outgrowth than has been previously thought; direct physical damage to neurone is not a pre-requisite for dendritic sprouting to occur.

15.4 EXPANSION OF THE RECEPTIVE FIELDS OF LEECH NOCICEPTIVE CELLS FOLLOWING DELETION OF SINGLE NEURONES. Susanna Blackshaw[1], John Nicholls[2] and Itzhak Parnas[3]. 1. Institute of Physiology, the University, Glasgow G12 8QQ, Scotland; 2. Neurobiology Department, Stanford University Medical School, Stanford CA 94305; 3. Neurobiology Department, Hebrew University, Jerusalem.

In the leech, the cell bodies of nociceptive neurones or "N" cells lie within the central nervous system. They are easily identified and much is known about their electrical properties, their arborization within the CNS, their synaptic connections with segmental motorneurones, and the way in which they sprout and regenerate these central connections after injury. In confirmation of earlier work, N cells do respond selectively to noxious mechanical stimulation of the skin, but not to touch, light pressure or stretch applied to the body wall (Nicholls, J.G. and Baylor, D.A., J. Neurophysiol. 31: 740-756, 1968). The skin fields of the 2 cells on one side of a ganglion overlap - each neurone innervates a well defined area extending from the ventral midline to the dorsal midline and covering the ipsilateral half of the body segment. In addition, and in keeping with its nociceptive role, one of the 2 cells is also driven by noxious stimulation of connective tissue lining internal viscera.

After 3 of the 4 N cells in a ganglion of a living animal have been killed by intracellular injection of Pronase, the receptive field of the remaining N cell spreads into the denervated area. Some enlargement of the skin field is apparent by 3 weeks. After 12 weeks the neurone has expanded its field to cover the entire area on the other side of the animal, a region it does not normally supply. The spread of N cell receptive fields is modality specific. When N cells have been killed, the fields of mechanosensory neurones responding to touch (T) or pressure (P) are unchanged.

15.5 TRANSPORT OF CYTOSKELETAL PROTEINS IN NEWLY-FORMED AXONS OF REGENERATING RAT SCIATIC NERVE MOTONEURONS. I. G. McQuarrie, M. King* and R. J. Lasek. Department of Anatomy, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

The polypeptide composition of the two slowest rate components of axonal transport has been determined for guinea pig retinal ganglion cells by using gel electrophoresis of optic nerve segments following intra-ocular injection of labeled amino acids (Black & Lasek, J. Cell Biol. 86:616-623, 1980). Each component has a unique composition; the faster component moves at 2-3 mm/d (SCb), and the slower at 0.25 mm/d (SCa). The microfilament network of the axon apparently advances with SCb, and the microtubule-neurofilament network with SCa. In rat retinal ganglion cells, SCb and SCa have the same rates and compositions (McQuarrie et al., Soc. Neurosci. Abstr. 6:501, 1980).

In similar studies on rat sciatic nerve motoneurons, SCb advanced at 3.4 $\pm$ 0.6 mm/d (clathrin peak) and SCa advanced at 1.2 $\pm$ 0.2 mm/d (neurofilament peak), when animals were 5-8 weeks old at the time of injection (400-750 uCi ^{35}S-methionine into the ventral horn at the T13-L1 interspace). When the L4 spinal nerve was crushed at one week after injection, the waves of labeled slow component proteins were trapped between the crush and the spinal cord. By 2 days later, when sprouting began, labeled SCb proteins had accumulated proximal to the crush. Subsequently, at axonal outgrowth times of 5-15 days, a peak of labeled SCb proteins advanced distal to the crush at a rate of 3.3 $\pm$ 0.2 mm/d. This rate was comparable to the axonal outgrowth rate of 3.6 $\pm$ 0.4 mm/d, arrived at by using two methods that yielded identical mean rates: the nerve pinch test, and the farthest advance of labeled neurofilament proteins. The SCb peak was enriched in actin, tubulin, and 32 kilodalton proteins; other SCb proteins, including clathrin and the 70 kilodalton group, did not have increased radioactivity levels at the site of the peak.

In summary, newly-formed axons of regenerating rat sciatic nerve motoneurons have an SCb rate that is unchanged from normal and is similar to the axonal outgrowth rate. Actin and tubulin appear to enter axonal sprouts preferentially. In these neurons, actin and tubulin are normally found in both SCb and SCa (McQuarrie et al., Soc. Neurosci. Abstr. 6:501, 1980). Since protein components of the two cytoskeletal networks are transported together and preferentially enter axonal sprouts in these vigorously regenerating neurons, we conclude that the presence of a dynamic association between the two networks may be a requirement for optimal axonal regeneration.

15.6 TRANSNEURONAL REGULATION OF SYMPATHOHIPPOCAMPAL SPROUTING. R. Madison* and J.N. Davis. (SPON: E. Olender). Depts. of Anatomy, Pharmacology and Neurology, Neurology Research Laboratory, Duke Univ. Med. Ctr. Durham, NC 27705.

Peripheral noradrenergic fibers from the superior cervical ganglion (SCG) appear in the rat hippocampal formation (HF) after damage to the fimbria or medial septum (MS). Unilateral section of the preganglionic trunk of the SCG (decentralization) prior to a MS lesion results in apparently less peripheral sprouting in the ipsilateral HF as judged by fluorescent microscopy. In order to extend and quantitate the effects of decentralization radiochemical measurements of norepinephrine (NE) were carried out bilaterally in the HF of adult male Sprague-Dawley rats after unilateral decentralization of the SCG and bilateral electrolytic MS lesions. Animals were sacrificed 4, 7, 9 or 12 weeks later and processed either for fluorescent microscopy or for radiochemical determinations of NE levels for the dentate and hippocampal gyri.

Normal (unoperated) animal dentate NE was 0.63 $\pm$ 0.10 µg/gm. Histochemical sprouting of peripheral sympathetics in the dentate on the side contralateral to SCG decentralization appeared vigorous and continued to increase over time. Dentate NE levels were 0.89 $\pm$ 0.17 at 9 weeks ($p < 0.05$ vs. normal dentate) and 1.39 $\pm$ 0.32 at 12 weeks ($p < 0.001$). By contrast fewer fibers were present in the dentate ipsilateral to the decentralization at 4 and 7 weeks. NE levels were 0.43 $\pm$ 0.06 ipsilateral and 0.82 $\pm$ 0.12 contralateral ($p < 0.05$) to the decentralization at 7 weeks after the lesion. Unexpectedly no difference in the density of peripheral fibers could be seen at 9 weeks or thereafter. NE levels also dramatically increased at 9 weeks ipsilateral to the decentralization (0.96 $\pm$ 0.06) and continued to increase at 12 weeks (1.22 $\pm$ 0.28). No differences in NE levels were noted in the hippocampal gyri at all times studied.

These data show 1) that peripheral noradrenergic sprouting continues to increase for up to 12 weeks after MS lesions and 2) that loss of afferent input reduces the extent of peripheral noradrenergic spouting. It seems likely that the increase in sprouting ipsilateral to the decentralization after 9 weeks represents reinnervation of the SCG by preganglionic fibers. These experiments demonstrate the regulation of a neuronal rearrangement by afferent input due either to nerve impulse flow or transneuronal transfer of a factor or factors. This unusual model of sprouting allows quantitation of regulatory mechanisms and should be useful in understanding some of the principles underlying neuronal rearrangements in the adult rat brain.

16.1 VESTIBULAR NERVE ACTIVITY INDUCED BY OFF VERTICAL AXIS ROTATION. Theodore Raphan, Walter Waespe*, Bernard Cohen, Dept. of Neurology, Mount Sinai School of Medicine, New York, N.Y. 10029.

Semicircular canal and otolith afferents were recorded in the vestibular nerve while monkeys were given steps of velocity about off vertical axes to determine the role of the peripheral labyrinth in generating the continuous nystagmus induced by this stimulus. Average frequency of firing was obtained by a computer program that counted the number of spikes within a 192 msec window and updated the count every 1.6 msec. The algorithm had a resolution of 5 Hz, a frequency response of a zero order hold system and a linear range up to 625 Hz. Neurons were tested using velocities from 3.5°-180°/sec and tilt angles of 30°, 60°, and 90°. For a step in velocity, semicircular canal units had an increase in frequency which decayed to a steady state with a time constant of 3-6 sec. These units did not show a direction specific steady state response to off vertical axis rotation (Goldberg & Fernandez, 1981). The average frequency of firing was either not affected or increased, and there was little or no modulation in relation to head position. Otolith units on the other hand modulated their activity in relation to head position. The firing rates of "regular" otolith neurons were approximately sinusoidal and the peak firing rates occurred at head positions that were approximately independent of the velocity of rotation, direction of rotation or angle of tilt. Phase differences between these modes of excitation were within 20° of each other. The depth of modulation was related to tilt angle and presumably was dependent on the neuron's polarization angle. Peak frequencies of irregular neurons, including those that had no steady state response to static head tilts, occurred at specific head positions while rotating. The phase of the peak frequency was not significantly altered with speed of rotation or phase of tilt. Differences in phase were within 20-30° for specific directions of rotation. However, there was a phase change in peak frequency for oppositely-directed rotation. It was close to 100° in some instances. The data indicate that the semicircular canals play a subordinate role in the generation of continuous nystagmus during off vertical axis rotation. The unchanging phase relation of peak frequency relative to given head positions for regular as well as irregular units during unidirectional rotation is consistent with the theory that sequential activation of otolith units induces traveling waves in the cellular structure of the maculae. The velocity of this wave is detected centrally and converted to a signal that activates the velocity storage integrator to generate the continuous nystagmus.

16.2 EFFECT OF STATIC HEAD POSITION ON THE DURATION OF VERTICAL OPTOKINETIC AFTER NYSTAGMUS (OKAN) IN MONKEYS. V. Matsuo*and B. Cohen. Depts. of Neurology and Opthalmology, Mt. Sinai School of Medicine, New York, N.Y. 10029., Spon.: H. Krieger, M.D.

Although horizontal OKAN is generally left-right symmetrical with regard to peak velocities and time constants, vertical OKAN is asymmetrical. When animals are tested on their sides, downward OKAN reaches higher velocities and is longer-lasting than upward OKAN. A testing apparatus recently became available that permitted us to induce OKN in various planes with respect to the animal and to the earth. An unexpected finding was that the time constant of vertical OKAN was modified by the attitude of the head.

Vertical OKAN was induced in 5 monkeys using full field stimulation. Eye movements were recorded using d.c. electro-oculography. Downward OKAN (re: the animals's longitudinal axis) was induced by rotating the optokinetic drum with the animals in various angles of tilt in the roll axis. One animal was also placed in the prone, supine and 25° pitch forward positions. Steady state slow phase velocities of OKN were similar regardless of head orientation, and peak velocities of OKAN were not markedly affected. However, time constants (TC's) of downward OKAN were much shorter when the animal was upright. Mean TC's were 14.7 sec, ± 6.9 when the animals were horizontal. In contrast, mean TC's were 1.9 sec, ± 1.1 when animals were upright. Downward OKAN TC's varied as a function of the angle of tilt, decreasing at a rate of approximately 10% of the maximum value every 10° of deviation from the lateral position. With the animal in the prone and 25° pitch forward positions, the time constants of downward OKAN were reduced to the range observed when animals were upright. When supine, time constant values were intermediate. Upward OKAN is weak or absent in normal animals (Matsuo et al., 1979). When present, upward OKAN also was most vigorous when the animal was in the lateral position and weakest when upright.

The results are consistent with psychophysical findings of Young et al. (1975) who reported that the sensations of pitching and linear vection during vertical OKN were strongest when subjects were in the lateral position and weakest when subjects were upright or 25° pitched forward. Activity responsible for the changes in time constant of downward OKAN presumably originates in the otolith organs since it was preserved in animals with their semicircular canals disabled.

16.3 DIFFERENTIAL PROJECTIONS OF REGULARLY AND IRREGULARLY DISCHARGING VESTIBULAR-NERVE AFFERENTS ONTO INDIVIDUAL SECONDARY NEURONS OF THE SUPERIOR VESTIBULAR NUCLEUS IN THE BARBITURATE-ANESTHETISED SQUIRREL MONKEY. J.M. Goldberg, C. Fernández* and S.M. Highstein. Depts. of Pharmacol. Physiol. Sci. and of Surgery (Otolaryngol.), University of Chicago, Chicago, IL 60637 and Dept. Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Vestibular-nerve fibers, in responding to brief electric shocks delivered via the perilymphatic space, show large variations in their firing thresholds; irregularly discharging (I) afferents have lower thresholds than do regularly discharging (R) afferents (Neurosci. Abstr., 6:224). The two afferent groups also differ in their conduction times (Brain Res., 122:545). These findings have been exploited to study the central projections of I and R afferents. Intracellular recordings were made from secondary neurons in the superior vestibular nucleus (SVN). Monosynaptic EPSPs were evoked by shocks delivered to the ipsilateral labyrinth. The difference in afferent thresholds depends on synchronizing the shock to the last occurrence of an action potential. For this reason, a two-shock paradigm was used. Shock strength is expressed in multiples of the extracellular field threshold (T) recorded in the SVN. The first shock was kept at a high intensity (16-32xT) so as to synchronize vestibular-nerve activity. The second shock was presented 4 msec later and was varied from 1xT to 16-32xT. Our vestibular-nerve data indicate that I afferents are recruited at 1-4xT, R afferents at 4-32xT. SVN neurons differ in the ways their EPSPs grow as the intensity of the second shock increases. Three broad and probably overlapping groups can be recognized. Some neurons have low EPSP thresholds (1-2xT) and show near-maximal EPSPs for shocks of 4xT or less. Other neurons have EPSP thresholds greater than 4xT and maximal EPSPs are evoked only at 16-32xT. Still other neurons have low EPSP thresholds (1-2xT) and their EPSPs continue to grow up to 16-32xT. The respective groups are likely to represent neurons receiving a predominantly I-fiber input, a predominantly R-fiber input, and a mixed (M) innervation of I and R inputs. The latent periods of EPSPs are consistent with this interpretation and the established differences in vestibular-nerve conduction times. I-input neurons have shorter latent periods than do R-input neurons. In M-input neurons, it is the later portions of the EPSPs which grow as shock intensity is raised and as the more slowly conducting R inputs are presumably recruited. Our results imply that the diversity of afferent information carried by I and R afferents is preserved at the level of the vestibular nuclei.

16.4 VERTICAL SEMICIRCULAR CANAL AND OTOLITH INTERACTIONS IN THE VESTIBULO-NECK REFLEXES OF THE ALERT CAT. John H. Anderson and C. Pappas*, Dept. Otolaryn. and Physiol., U. Minn., Mpls., MN. 55455

Because of the linkage of head with neck, disturbances of posture are greatest in the vertical planes and are likely to stimulate both the vertical semicircular canals and otolith organs. The aim of the present experiments was to determine the relative contributions to the neck muscle responses by the otolith and canal inputs and to provide evidence for participation by both the utricule and saccule. Alert, blindfolded cats were used. Each animal was restrained and subjected to sinusoidal roll rotations from 0.04 to 4.0 Hz with displacements of up to ±40 deg. The EMG response of the sternomastoid muscle, a rotator and ventral flexor of the head, was recorded.

When the animals were positioned in the normal, right side up position, the right and left muscles responded in a reciprocal manner and relative to contralateral angular acceleration, the EMG's showed phase lags of 130-150 deg at the low frequencies. Above 1.0 Hz the phase lag became significantly less, e.g., 80-110 deg at 3.0 Hz, and is presumably due to the canal inputs. At the lower frequencies the otolith inputs become relatively larger and would be expected to have a significant effect on the muscle activity. Some evidence for this was obtained by the vectorial addition of two independent sets of data. For this, one set of recordings was made while rotating the animal to either side after it had been placed upside down. This was done to selectively change the otolith input: It had the opposite sign compared to normal while the canal input remained exactly the same. The results showed a significant difference: The phase lag was much less at the lower frequencies (e.g., about 70-90 deg at 0.1 Hz) up to about 0.2 to 0.4 Hz, indicating that the otolith inputs (e.g., utricular) were, in fact, contributing to the EMG responses. A second set of recordings was made while rotating the animal after it had been turned 90 deg onto its side. In this situation the component of gravity along the animal's z-axis was modulated such that the otoliths (e.g., saccules) on the right and left were simultaneously stimulated instead of reciprocally so as for the normal, right side up position, although the canal input was exactly the same. The EMG of the muscle on the top side showed much less of a phase lag compared to normal, whereas the EMG of the muscle on the underside showed a phase similar to normal. Thus, the right and left EMG's were neither in phase nor 180 deg out of phase with each other. These results indicate that during vertical rotations, the canal inputs predominate at high frequencies whereas at lower frequencies the canal, utricular, and saccular inputs each make significant contributions.

16.5 MORPHOLOGY OF SECONDARY VESTIBULAR NEURONS LINKED TO THE POSTERIOR CANAL IN RABBIT AND CAT. W. Graf*, R. A. McCrea and R. Baker. Dept. of Physiol. and Biophys., New York Univ. Med. Ctr., 500 First Avenue, New York, N.Y. 10016.

The vertical vestibulo-ocular reflexes have been subject to behavioral and electrophysiological studies, yet less information has been contributed about the morphology of the neuronal network. The present study investigated the morphology of secondary vertical vestibular neurons by injecting HRP into cells connected to the posterior canal. Bipolar electrodes were implanted into the ampullae of the anterior and posterior (PC) semicircular canals of pigmented rabbits while vestibular neurons in cats were identified by natural and electrical stimulation. Axons monosynaptically activated by PC stimulation were injected in the contralateral rostral MLF (excitatory pathway) and later reconstructed after processing the brain with a DAB-$CoCl_2$ method. The cell bodies of these neurons were located in either the medial or ventro-lateral vestibular nuclei. In the rabbit, all of the axons bifurcated after crossing the midline, with one branch ascending and the other descending in the MLF. The ascending branches gave rise to collaterals which terminated in the trochlear and inferior rectus subdivision of the oculomotor nuclei. In addition a few of these axons also sent collaterals into the interstitial nucleus of Cajal, the paramedian pontine reticular formation and the periaqueductal grey. The descending branches were followed to the caudal part of the medulla in the MLF. These branches gave rise to collaterals which terminated in the vestibular nuclei, the reticular formation, the nucleus prepositus hypoglossi and the abducens nucleus. In the cat, we observed similar termination patterns with collaterals to both trochlear and oculomotor nuclei. However, axon collaterals of some neurons crossed the midline after terminating in the inferior rectus subdivision and reached a similar part of the contralateral oculomotor nucleus. Collaterals of these axons also terminated in the supraoculomotor region between trochlear and oculomotor nuclei, but no descending axonal branches to the spinal cord have yet been observed. Collaterals to the archicerebellum were not seen in either species. Our data indicate strong similarities in the morphology of PC linked secondary vestibular axons in the two species. Slight differences in termination pattern probably reflect the different kinematic properties of extraocular muscles required for compensatory eye movements in lateral- versus frontal-eyed animals. 16.6 GABAergic TERMINALS IN THE LATERAL VESTIBULAR NUCLEUS: AN IMMUNOCYTOCHEMICAL DEMONSTRATION OF THE CEREBELLAR CORTICOVESTIBULAR PATHWAY. C.R. Houser, J.E. Vaughn and R.P. Barber*. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

Physiological studies have demonstrated that Purkinje cells in the anterior lobe of the cerebellar cortex mediate a GABAergic inhibition of neurons in the dorsal part of the lateral vestibular nucleus (dLVN). Since the anatomical substrates of this pathway have not been completely elucidated, we have used an immunocytochemical method for the localization of the GABA synthesizing enzyme, glutamic acid decarboxylase (GAD), to describe the relative number, location and ultrastructural characteristics of GAD-positive (GAD+) axon terminals in the dLVN and to examine the effects of cerebellar cortex ablation on these terminals.

Specimens containing the dLVN were obtained from normal rats and from rats in which the vermis of the anterior cerebellar lobe was ablated 12 days prior to sacrifice. The tissue was processed for GAD immunocytochemistry and examined by both light and electron microscopy. In normal rats, GAD+ axon terminals were numerous in the dLVN, and were concentrated around the somata and proximal dendrites of large and medium sized neurons. A large number of GAD+ terminals also were present in neuropil regions, suggesting that GABAergic synapses may be located on dendrites of many sizes. Ultrastructural observations confirmed the presence of GAD+ synapses at these sites and showed that GABAergic terminals frequently were located adjacent to one another on neuronal somata and proximal dendrites, where they occasionally displayed an en passant pattern of synaptic contacts. Most GAD+ terminals formed symmetric or intermediate type synaptic junctions and contained moderate numbers of synaptic vesicles and mitochondria. Following ablation of the anterior vermis, the number of GAD+ terminals in the dLVN decreased by 73%, the loss being slightly greater around neuronal somata and proximal dendrites than within adjacent neuropil regions.

These results indicate that neurons of the dLVN are contacted by numerous GABAergic synaptic terminals, and that a large majority of these terminals originate from the cerebellar cortex of the anterior vermis. The large number of GABAergic terminals and their proximal location on many of the neurons suggest that the function of the dLVN in the control of posture and movement may depend to a large extent upon the modulation of GABAergic inhibition. Supported by USPHS Grant NS12116 from the National Institute of Neurological and Communicative Disorders and Stroke.

17.1 NEONATAL 6-HYDROXYDOPAMINE ADMINISTRATION ELIMINATES SPARING OF FUNCTION AFTER NEONATAL FRONTAL CORTEX DAMAGE. R. J. Sutherland, B. Kolb, J. B. Becker, and I. Q. Whishaw, Dept. of Psychology, The Univ. of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4.

Bilateral removal of the frontal cortex in adult rats causes a disruption of behaviour requiring accurate spatial orientation and chronically reduces the body weight set-point. Previous work has shown that if similar damage is produced in neonatal rats, then adult spatial orientation and body weight set-point appear to be normal. This sparing of function after neonatal damage depends upon the integrity of the remaining posterior neocortex (Kolb & Whishaw, J. Comp. Physiol. Psychol., 1981, in press). Several lines of evidence indicate that neocortical and hippocampal synaptic plasticity are modulated by the local availability of noradrenaline (NA) (Kasamatsu, et al., Science, 1976, 194, 206-209, J. Neurophysiol., 1981, 45, 254-266; Goddard, et al., Neurosci. Abstr., 1980, 10, 89). The present experiment examined the possibility that the behavioural sparing associated with early brain damage depends upon the availability of cortical NA.

Sixty Long-Evans X Wistar rats received neonatal or adult frontal cortex removal, neonatal 6-hydroxydopamine (6-OHDA)(3 X 100 mg/kg, ip) or saline injections, or both neonatal frontal removal and neonatal 6-OHDA. All rats were tested as adults in the Morris water maze, in running wheels, in a straight swimming alley, chronic body weight was recorded, and these measures were correlated with levels of cortical NA.

The most significant findings were that: 1) frontal cortex removal in adults produced a severe spatial deficit in the Morris water maze, 2) neonatal frontal cortex removal was associated with significant sparing in this task, 3) neonatal frontal cortex removal in rats depleted of cortical NA produced as severe a spatial deficit in the water maze as adult frontal removal, 4) neonatal 6-OHDA alone did not affect spatial behaviour, 5) chronic body weight set-point was normal in male rats with only neonatal frontal cortex removal or only neonatal 6-OHDA, but was reduced in rats with adult frontal cortex removal or neonatal frontal cortex removal following NA depletion, and 6) in females only the neonatal frontal cortex removal in rats depleted of cortical NA produced a chronically reduced body weight set-point.

These findings are consistent with an important role for NA systems in permitting the sparing of behavioural functions associated with early brain damage and extend to the neural systems involved in feeding and cognitive behaviours in the rat the notion that NA modulates neuronal plasticity.

17.2 EVIDENCE FOR RECOVERY OF FUNCTION FOLLOWING 6-HYDROXYDOPAMINE LESIONS OF THE DORSAL TEGMENTAL NORADRENERGIC BUNDLE. D.C.S. Roberts, D.S. Segal†, G.J. Vickers* and B.A. Pappas. Dept. of Psychology, Carleton Univ., Ottawa, Canada, K1S 5B6 and †Dept. of Psychiatry, U.C.S.D., La Jolla. CA. 92093.

6-Hydroxydopamine (6-OHDA) injections into the region of the dorsal tegmental bundle (DB) have been used by several laboratories to investigate the involvement of noradrenaline (NA) in a variety of behaviours. This treatment causes degeneration of the ascending projection from the locus coeruleus to the forebrain, and reduces NA levels in the hippocampus and cortex to approximately 5% of control levels. Because this depletion requires 2-3 weeks, most behavioural studies using the DB-6OHDA treatment have not been initiated until several weeks post-lesion. Despite the severe depletion of NA, in general, no consistant or major deficits have been attributed to this NA loss; although some subtle or unreliable effects have been noted. Because recovery of function occurs to some extent after most brain lesions, we tested the hypothesis that recovery occurs several weeks following the DB-6OHDA treatment, and that major deficits or alterations in behaviour may be apparent at time points closer to the lesion. We now report that behavioural effects are observed several days after the lesion which disappear or are attenuated by 3 weeks.

D-amphetamine (2.5 mg/kg) was found to produce significantly more intense stereotyped behaviours (particularly oral movements) in DB-6OHDA treated animals when compared to control animals, when tested 3 days post-lesion. This increase in stereotypy was also reflected by a significant decrease in locomotor activity during the peak stereotypy phase. In contrast, when tested 3 weeks post-lesion, the DB-6OHDA group showed less stereotypy, compared to controls. The augmented sterotypy could be reinstated, however, after drug challenge of repeated daily injections of amphetamine. The facilitation of oral stereotypy seen at post-lesion day 3 agrees with previous reports using NA synthesis inhibitors and blocking agents.

Similarly, the DB-6OHDA treatment was found to have time-dependant effects on acquisition of a two way shuttle box. When tested 3 days post-lesion, the DB-6OHDA group required significantly more trials to reach criterion (18 avoidances /20) during a one day training session (DB-6OHDA=68± 14 trials; control=35± 4). No differences were found between groups when testing was delayed 3 weeks. While the nature of the deficit (associative vs non-associative) observed several days after the DB-6OHDA treatment is not yet established, the results demonstrate that recovery may occur following the lesion, and suggest the "true effects" of the lesion may be manifest soon after the lesion. (Supported by the Medical Research Council).

17.3 EFFECT OF 5HTP ON H-REFLEX RECOVERY CURVES. J. Metz, H.H. Holcomb, and H.Y. Meltzer. University of Chicago, Department of Psychiatry, Chicago, Illinois 60637.

The recovery curve of the H-reflex is abnormally high in about 25% of psychiatric patients (Metz et al., Psychol. Med. 10, 541-548). We have conducted pharmacological studies to understand the neural transmitter mechanisms which may underlie this abnormality. In this study, we found that d,l 5-hydroxytryptophan (5HTP) decreases the H-reflex recovery curve less frequently in patients with primary affective disorders than in normal controls.

We administered 200 mg 5HTP orally to 10 normal subjects and 29 patients with affective disorders (RDC diagnoses: 11 depressed, 8 manic, 7 schizoaffective depressed, 3 sa manic). Subjects were tested twice on the recovery curve: a baseline test and a test 2 hours after 5HTP. Some patients were tested both with and without other treatment.

The normal group had lowered recovery after 5HTP relative to the baseline condition ($t = 3.06$, $p < .02$). Unmedicated patients, however, showed no significant effect of 5HTP. Eight of 10 normal subjects had lowered recovery following 5HTP, but only 11 of 27 unmedicated patients had decreased recovery (Fisher exact probability = .038). No significant differences were found among different classes of patients. Patients receiving antidepressants (5 of 7 decreased after 5HTP) or lithium carbonate (4 of 7 decreased) more closely resembled normals in their response to 5HTP.

The decrease in the recovery curve following 5HTP in normal subjects suggests that a serotonergic mechanism influences the excitability of the alpha-motoneuron. We have found a similar decrease in the recovery curve in normal subjects and in psychotic patients following acute or chronic treatment with chlorpromazine. The 5HTP effect, therefore, may be mediated by a decrease in post-synaptic dopaminergic activity. These results suggest a reduced sensitivity to serotonin or an abnormal interaction between serotonin and dopamine in some patients with affective disorders. Our results also indicate that a serotonin deficiency may underlie the abnormally high recovery curves found in psychotic patients.

17.4 6-HYDROXYDOPAMINE MODELS OF CHILDHOOD HYPERACTIVITY: EFFECTS OF AMPHETAMINE ON SWIMMING AND LOCOMOTOR ACTIVITY IN NEONATAL RATS. G. K. Hodge. Dept. of Psychology, University of New Mexico, Albuquerque, NM 87131.

Because stimulant medications are sometimes effective in attenuating the symptoms of childhood hyperactivity, and since drugs such as dextroamphetamine (DEX) are believed to act, in part, by facilitating dopamine (DA) function, it has been suggested that the symptoms of the disorder may be attributable to decreased DA activity. Support for this position stems from studies reporting that DEX attenuates hyperactivity of rat pups treated with 6-hydroxydopamine (6-OHDA).[1] At the opposite end of the developmental spectrum, DA agonists have been found to improve swimming behaviors in aged rats.[2] Normal swimming patterns in the rat emerge at about the same time in which 6-OHDA elicits hyperactivity. Since swimming requires complex coordination and integration of neural responses, this model of putative DA function may provide additional insight into the maturational dynamics of DA function and dysfunction in hyperactivity.

Following desipramine pretreatment, 5-day-old rats were injected intracisternally with either 100 µg/25 µl of 6-OHDA or 25 µl of the ascorbic acid/saline vehicle. Postoperatively, swimming was measured daily; open-field activity was measured on postpartum days 15, 19, and 22. Half of the animals in each group received exclusively either 1 mg/kg DEX or saline 30 min before behavioral observations (90 min for activity).

6-OHDA treatment retarded the normal course of development of swimming postures; swimming remained impaired until postpartum day 16. DEX impaired swimming in control animals through day 11; swimming tended to be facilitated thereafter until around the third week when there was no longer any difference compared to saline-injected controls. DEX reversed the swimming impairments of 6-OHDA-treated neonates; i.e., swimming developed normally. Although 6-OHDA induced hyperactivity at days 15, 19, and 22, DEX did *not* attenuate hyperactivity; in fact, it actually *increased* activity even more so on days 19 and 22 (results consistent with those of Pappas et al.[3]).

These data suggest the importance of DA systems in the acquisition and integration of certain motor behaviors. Whether the 6-OHDA preparation is a tenable model of childhood hyperactivity, however, remains more problematic.

17.5 AMPHETAMINE-ELICITED ROTATIONAL BEHAVIOR: SEX DIFFERENCES AND ESTROUS CYCLE VARIATIONS ARE NOT DUE TO DIFFERENCES IN BRAIN LEVELS OF AMPHETAMINE. Jill B. Becker, Kimberly A. Lorenz* and Terry E. Robinson. Neuroscience Laboratory and Department of Psychology, University of Michigan, Ann Arbor, MI 48109.

Sex differences have been reported in amphetamine (AMPH)-elicited behaviors. However, metabolic differences result in different brain levels of AMPH in male and female rats given the same systemic dose. In this study, whole brain levels of AMPH were determined following the i.p. injection of ^{3}H-d-amphetamine sulfate and subsequent separation of AMPH from its metabolites. When male and female Holtzman rats were injected with the same dose of AMPH, males had significantly lower brain levels of AMPH than females. From dose-response curves we estimated doses which would yield equal brain levels of AMPH in the two sexes, then confirmed the prediction. We could then study AMPH-elicited rotational behavior in male and female rats which had the same brain concentrations of AMPH at 5, 30 and 60 min post-injection.

Rotational behavior was studied in intact male and female rats employing automated rotometers. After 15 min of habituation, animals were injected with AMPH and rotational behavior was recorded for 1 hour. At 1.25 mg/kg AMPH there were no differences in brain levels of AMPH during the female estrous cycle. A dose of 1.56 produced brain levels of AMPH in males equivalent to the females at 1.25 mg/kg. Thirty min after injection, there were significant differences in the number of net rotations (# 360° turns in predominant direction minus those made in the other direction) made by the 5 groups. The number of net rotations made by male rats during the first 30 min was significantly less than the number made by female rats during estrus (E), diestrus 2 (D_2) or proestrus (P). Female rats during diestrus 1 (D_1) were not significantly different from males. There were also significant differences in the number of net rotations females made during different stages of the estrous cycle. Females in E made significantly more net rotations than D_1, D_2 or P females. Rats tested during the day of D_1 made significantly fewer net rotations than any of the other female groups. It is interesting that estrous females exhibited the greatest number of net rotations, yet 24 hours later on D_1 there was a dramatic decrease.

In conclusion, we find sex differences in AMPH-elicited rotational behavior in rats known to have equivalent brain concentrations of AMPH. We also find estrous cycle dependent variations in rotational behavior. This suggests that in female rats fluctuations of hormones within a physiological range can significantly alter the activity of brain dopamine systems.

(Supported by Grants No. NS16437 and HD05997).

17.6 SEX DIFFERENCES AND ESTROUS CYCLE VARIATION IN ROTATIONAL BEHAVIOR ELICITED BY ELECTRICAL STIMULATION OF THE NIGROSTRIATAL DOPAMINE SYSTEM. Terry E. Robinson, Dianne M. Camp* and Jill B. Becker. Psychology Department and Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

Electrical stimulation-induced rotational behavior is thought to provide a behavioral index of functional activity in the nigrostriatal dopamine (DA) system. We have used this behavioral model to investigate whether hormonal states influence the nigrostriatal DA system in male or female rats.

Sixty-five rats were implanted with bipolar stimulating electrodes aimed at the nigrostriatal DA bundle, as it courses through the lateral hypothalamus. Electrical stimulation of sites in or near these fibers produced vigorous contraversive rotational behavior. The most effective sites were located *within the DA fibers, while less effective sites were located* just dorsal to the bundle. These latter sites required higher current intensities to produce rotational behavior. The maximum current intensity used was 300μA (0.1 msec duration monophasic rectangular pulses). Ineffective sites were located either medial or ventral to the DA fibers.

Each animal was tested daily for rotational behavior for a 21 day baseline period, using the same current parameters each day. We found that the amount of rotational behavior observed in female rats varied across the estrous cycle. Vigorous rotational behavior on the day of estrus was followed by a significant drop on diestrus 1. The amount of rotational behavior then increased gradually, peaking on the next day of estrus. After 21 days of baseline testing half the females were ovariectomized (OVX) and half the males castrated (CAST). The remaining animals received a sham-operation. After one day of recovery, testing for rotational behavior continued for an additional 30 days. OVX of female rats resulted in a gradual and significant decline in electrical stimulation-induced rotational behavior relative to sham-operated females, males, or CAST males. These latter three groups did not show a decline in rotational behavior relative to baseline levels, and did not differ from each other. Thus, there are sex differences in the effects of gonadectomy on electrical stimulation-induced rotational behavior. OVX of female rats attenuates electrical stimulation-induced rotational behavior while CAST of male rats has no effect. The effect of OVX is not due to a generalized hypokinesia in OVX females since a time sample of spontaneous behavior failed to show group differences in the incidence of active behaviors (walking and rearing) or immobility in the test situation. We conclude that gonadal steroid hormones directly or indirectly modulate nigrostriatal DA activity in female, but not male, rats. *(Supported by Grant NS16437 to TER).*

17.7 NEUROBEHAVIORAL CONSEQUENCES OF MANGANESE CHLORIDE ADMINISTRATION IN RATS. Charles L. Kutscher* and Catherine M. Stoney* (SPON: J. A. Rosecrans). Psychology Research Lab., Syracuse University, 101 Stevens Place, Syracuse, NY 13210.

Manganese (Mn) toxicity in humans has been associated with a variety of extrapyramidal symptoms such as tremor, abnormal gait and loss of muscular control. Mn is ubiquitous in the environment because of its widespread use in manufacturing processes including gasoline distillation. Dietary administration of Mn produces changes in brain catecholamines (J. Neurochem. 36: 683, 1981) and serotonin levels (J.Tox. Environ. Health 4: 701, 1978), but no systematic studies of Mn intakes on behavior have been done. We studied various types of motor responses in male and female rats given 0, 0.5 or 1.0% $MnCl_2$ to drink from weaning (21 days) until day 180 of life. Mn produced no effects on latency of forepaw suspension (tested every 10 days from 40-90 days of age), wheel running, and rotorod performance (using two drum diameters and three speeds). No effect was detected in gait measured by walking animals up an inclined plane after inking the paws.

In males Mn produced a depression in body weight, but no weight changes were noted in females. Mn produced a dose-dependent reduction in both males and females in duration of cold water swimming (15±1°C). Effect of the amphetamine analogue phenylethylamine (PEA) on wheel turning was studied. In males the PEA-induced hyperactivity seen in the 0% Mn group was prevented by Mn administration in both the 0.5 and 1.0% groups. In females activity was not affected by either Mn or PEA. Brain levels of Mn, norepinephrine, dopamine and serotonin were noted and correlated with behavioral changes.

Mn dosages produced no overt clinical symptomatology other than weight deficit in males. The PEA challenge and swimming endurance tests were more sensitive than the conventional motor tasks used. Findings are consistent with the hypothesis that Mn administration alters motor function and provides the first comprehensive and systematic report of Mn-induced behavior changes in animals.

17.8 **DIFFERENTIAL BEHAVIORAL EFFECTS FOLLOWING REGIONAL DOPAMINE DEPLETION IN RAT NEOSTRIATUM.** **D.B. Neill*, M.R. Holdiness*, M.D. Rosen*, and J.B. Justice, Jr.* (SPON: H.D. Rees). Depts. of Psychology and Chemistry, Emory University, Atlanta, GA 30322.**

A number of studies have shown that near-total destruction of the dopaminergic innervation of the neostriatum in the rat produces a constellation of behavioral effects including hypokinesia, aphagia, and deficient sensorimotor function. It is difficult to account for all of these acute and chronic effects in terms of a single disrupted mechanism. In the present study, the hypothesis that spatially selective dopaminergic denervation of different neostriatal regions would produce distinct behavioral effects was tested. Adult male albino rats were bilaterally injected with 6-hydroxydopamine hydrobromide (4 ug as the salt in 2 ul of 0.5% ascorbic acid-isotonic saline vehicle) at one of three sites: just anterior to the globus pallidus (GP), in the body of GP, or in the tail of GP. Vehicle control groups were also prepared for each injection site. Upon completion of all behavioral testing, all rats were decapitated, their brains removed, blocked, and quickly frozen. Cylindrical punches (1.3 mm dia., 1 mm length) were taken through nuc. accumbens/olfactory tubercle and at 4 anterior-posterior levels of neostriatum. Dopamine concentration (ng DA/mg protein) was determined for each punch by a gas chromatographic/mass spectrometric assay.

The results showed that DA depletion in anterior neostriatum (in front of the ant. commissure) correlated with the post-operative reduction in spontaneous activity. Food intake in animals with anterior depletions appeared depressed because of a deficient ability to maintain any behavior, and recovered in parallel with activity. DA depletion in posterior neostriatum correlated with the reduction in food intake. Animals with posterior depletions often showed pronounced aphagia/hypophagia with little change in activity. The decreased food intake after posterior depletions seemed related to impaired sensorimotor coordination. DA levels were not significantly altered in nuc. accumbens/olf. tubercle by any injection.

Based on these and other findings, an hypothesis for the functional organization of the dopaminergic innervation of rat neostriatum will be proposed.

17.9 DOPAMINERGIC NATURE OF FEEDING INDUCED BEHAVIORAL STEREOTYPIES. Irving Goodman, James Zacny*, Augustine Osman*, Albert Azzaro & Carol Donovan*. Departments of Psychology & Neurology, West Virginia University, Morgantown, WV 26506.

Stereotyped behaviors, including pecking, locomotion, head shaking, mandibulating and swallowing can be induced by daily restricted feedings in weight-reduced, caged pigeons. These feeding-induced behavioral stereotypies (FIBS) occur with greatest frequency immediately following feeding and may last for hours thereafter. This study attempted to investigate the influence of dopamine agonists and antagonists on FIBS in the light of the established dopaminergic nature of another induced stereotyped behavior apomorphine pecking in avians.

Two groups of weight-reduced pigeons were fed their limited grain ration at the same time daily. Behavioral stereotypy was monitored on 3 hourly occasions preceding and following feeding. Individuals in one of the 2 groups received a single weekly injection of apomorphine (APO) (3 mg/kg, IP) over a 7 wk period. Statistical comparisons made overthis period between the 2 groups indicated a significantly greater number of animals engaging in FIBS and a greater number of FIBS in the APO group. Subsequently, the non-APO group received 7 weekly APO injections and exhibited a significant increase in FIBS, compared to its first 7 wk record. After several weeks, all animals were given the dopamine antagonist haloperidol (HAL)(1 mg/kg, IP). On the day of injection all FIBS ceased. A comparison of FIBS one day prior to HAL and on subsequent days revealed a significant reduction on days 1 and 2 following HAL, and a return to normal by day 5, the next tested day. Likewise, a lower dose of HAL (0.5 mg/kg) caused an absence FIBS on the injection day. A comparison with the pre-injection day FIBS showed a reduction on post-day 1 and a return to normal on post-day 2.

Three FIBS and 3 non-FIBS birds were sacrificed and levels of telencephalic catecholamines were fluorometrically determined. All 3 non-FIBS birds' brains contained normal levels of norepinephrine (NE) but low levels of dopamine (DA), whereas within the FIBS group 2 animals contained normal levels of NE and DA and a third animal contained a low amount of DA but also a low amount of NE.

These findings support the view that brain DA is significantly involved in the display and control of yet another type of stereotyped behavior, FIBS. This behavioral methodology appears to have some potential usefulness in assessing pharmacologically induced synaptic changes over time and their effect upon behavior.

17.10 QUIPAZINE-INDUCED BEHAVIORAL CHANGES IN SELECTED MEMBERS OF A PRIMATE SOCIAL COLONY. R.F. Schlemmer, Jr., and J.M. Davis. Illinois State Psychiatric Institute, Chicago, IL 60612

Quipazine (QUIP) is a potent centrally active serotonin (5-HT) agonist which has been used extensively to study 5-HT-mediated behavior in rodents. In this study, QUIP was administered to investigate the role of 5-HT systems in the mediation of social and solitary behavior in a primate species. In the 1st expt., 4 acute doses of QUIP (0.1-3.0(base)/kg) were administered to each member of a stable, adult Stumptail macaque social colony in a Latin-square design. Only 1 monkey received drug treatment per day & at least 2 wks. separated each QUIP treatment to the same monkey. In the 2nd expt., QUIP, 1.6 mg/kg was given once daily for 5 consecutive days to each member of the same colony in a crossover design. Only 2 monkeys received drug treatment at one time. Each experiment was preceded by a period of no less than 5 days where normal baseline behavior of the colony was observed. Saline was administered to all monkeys on baseline days & to those animals not receiving drug on treatment days. QUIP & saline were administered i.m. 15 minutes prior to behavioral observation. A daily 1 hr. behavioral observation was conducted by the same "blind" observer who quantified & recorded the bahavior of each monkey in the colony from a checklist of 48 social, solitary, & abnormal behaviors for this species. In general, QUIP reduced activity, induced several abnormal behaviors, & disrupted normal affiliative behavior. QUIP induced limb jerks (a myoclonic spasm of an extremity), body shakes & ptosis as abnormal behaviors. QUIP increased the distancing scores between the treated monkeys & other members of the colony & eliminated social grooming. QUIP also significantly reduced self grooming, food forage, & locomotion; but significantly increased checking (vigilance) & lying down. Emesis was also noted in some QUIP-treated monkeys. The threshold dose for most QUIP-induced behavioral changes was 0.3 mg/kg. Upon repeated administration, a rapid partial tolerance developed to many of the QUIP-induced behavioral changes including limb jerks, body shakes, ptosis, checking, & grooming; but tolerance did not develop to the reduction in general activity scores. Administration of the 5-HT antagonist cinanserin HCl, 5 mg/kg, 2½ hrs. prior to QUIP treatment antagonized all QUIP-induced abnormal behaviors, but failed to restore some affiliative behaviors to baseline levels. Although it has been suggested by some investigators that QUIP may affect dopamine as well as 5-HT systems, it appears from these results that the major behavioral changes induced in these monkeys by QUIP are mediated through 5-HT systems. Therefore, this study provides evidence for a role for 5-HT in the mediation of important affiliative, solitary & abnormal behaviors in primates. It is also interesting to note that several QUIP-induced behavioral changes resemble those induced in this species by hallucinogens such as LSD.

18.1 STRENGTH OF LOCOMOTOR RHYTHMICITY IN ONE- AND TWO-EYED APLYSIA. W. P. Jordan, M. E. Lickey, and S. O. Hiaasen*. Dept. Psychol., University of Oregon, Eugene, OR 97403.

Aplysia californica are diurnal with locomotor activity onsets near dawn in LD 12:12. In darkness the locomotor rhythm freeruns for several weeks. Each of the two eyes contains a circadian oscillator that freeruns in vitro, and these eye clocks are known to participate in the control of the circadian locomotor rhythm. The two eye clocks get out of phase (split) when Aplysia are left in darkness. Splitting does not occur immediately upon release into DD, but requires about 3 wk to develop (Hudson and Lickey, 1980). This suggests that the possession of two internal clocks may actually be a liability for long-term freerunning in DD, since split eyes may produce conflicting temporal signals. The experiments reported here test this prediction.

Forty-six Aplysia were entrained to LD 12:12 before release into DD. Prior to release, one eye was removed from 23 animals; the remaining 23 were two-eyed controls. Locomotor activity was recorded for at least 33 d in DD. At the end of locomotor recording the eyes from 15 Aplysia were removed and the phases of the eye rhythms were assessed in vitro.

Throughout DD the quality of the locomotor rhythm was better in one-eyed animals than in two-eyed ones. For days 4-13 in DD, 12 of the 23 two-eyed animals were arrhythmic by a standard adopted previously (Lickey and Wozniak, 1979), whereas, only 5 of 23 one-eyed Aplysia were arrhythmic ($p < .04$, Fisher exact test). These differential proportions of rhythmic versus arrhythmic animals were maintained throughout DD. Analysis of variance of the standardized peak standard deviations from periodogram analysis (Strumwasser, et al., 1967) found the one-eyed animals to be significantly better freerunners than were two-eyed Aplysia.

The phase of the eye rhythms from the 7 one-eyed animals tested were found to be aligned with the active portion of the locomotor rhythm recorded previously. The eyes from the 8 two-eyed animals tested had interocular phase differences of 6 hr or more. Thus, the relationship between eye phase and locomotion in these animals was ambiguous.

These results confirm the prediction that one-eyed Aplysia freerun more vigorously than do two-eyed animals. On the other hand, the results do not conform to the expectation that the superiority of the one-eyed animals should develop only after about 3 wk of DD when interocular splitting is known to develop. An explanation of this discrepancy will shed further light on the organization of the Aplysia circadian system. (Supported by PHS F32 NS06425 and NSF 77-28251)

18.2 CONTRIBUTION OF OPTIC NERVE TO PRC OF APLYSIA EYE CLOCK. R. G. Prichard and M. E. Lickey. Dept. of Psychology, University of Oregon, Eugene, OR 97403.

We have previously shown that the circadian oscillator in the Aplysia eye can be reset by LL/DD transitions in vitro. For eyes that are neurally attached to the brain only 12 h of LL are required as a precursor to resetting; for eyes that are detached from the brain at least 27 h of LL are required. This report concerns: (1) the response of the eye rhythm to DD/LL transitions, (2) for LL/DD, whether it is the duration of LL or the phase of LL/DD that is the cue for resetting, and (3) the PRC for attached and detached eyes for 6 hour light pulses.

In the first experiment, intact Aplysia were given DD/LL transitions after 18-72 h of preceding DD. The eyes and brain were then immediately removed for recording the eye rhythms. During recording in LL one eye was attached to the cerebral ganglion and the other was detached by cutting its optic nerve. The initial results indicate that the DD/LL does not cause appreciable phase shifts in either an attached or detached eye.

In the second experiment animals were switched from LD 12:12 to LL beginning at the time of dawn. LL/DD occurred 21 h later, 3 h before projected dawn. Just before LL/DD the eyes and brain were removed for recording, one eye attached and one detached. In various preparations various amounts of the initial portion of LL was replaced by darkness until a minimum duration of LL was found that would support resetting by LL/DD 3 h before projected dawn. As little as 6 h of light was a sufficient precursor for full resetting in attached eye; 3 h of light was insufficient. Full resetting did not occur in detached eyes even when the entire 21 h of LL was present. We conclude that it is the phase of LL/DD, not the duration of LL, that determines the magnitude of resetting by LL/DD.

In the third experiment animals were switched from LD 12:12 into DD beginning at the last dusk. In various preparations a 6 h light pulse was delivered beginning at each 3 hour interval of the first 2.5 days in DD. The eyes and brain were removed for recording just before the end of the light pulse. The PRC of detached eyes had small amplitude; maximum phase shifts of $\pm$ 2 to 3 h occurred in response to pulses during the projected night. Thus, six hour pulses gave a PRC with no higher amplitude than previously obtained by Jacklet (1974) with 1 h pulses. The PRC of attached eyes had a much higher amplitude; during the projected night 6 h pulses gave phase shifts of up to $\pm$ 12 hr. The difference in amplitude of the PRC's of attached and detached eyes is probably not due to a difference in photoreceptive ability, since both eyes received all but a few minutes of the light pulse while attached to the cerebral ganglion in vivo. NSF 28251 and PHS EY 05383.

18.3 OCULAR AND EXTRAOCULAR PHOTORECEPTORS GENERATE A RESPONSE IN THE APLYSIA CEREBRO-PEDAL CONNECTIVE. M. H. Roberts and G. D. Block. Dept. of Biology, University of Virginia, Charlottesville, VA. 22901.

Aplysia express a diurnal circadian rhythm in locomotor activity (Strumwasser 1967). Circadian pacemakers located within the retinae (Jacklet 1969) appear to play a role in timing the behavioral rhythm, although extraocular pacemakers and photoreceptors also participate (Strumwasser 1974, Lickey et al. 1977).

Previous work in our laboratory (Roberts and Block Neurosci. Abst., Vol. 6, 1980) has demonstrated that the cerebro-pedal connectives are critical pathways for the expression of the locomotor rhythm. Aplysia with these connectives severed continue to locomote, but the distribution of activity appears random even when the animals are exposed to light cycles.

The present study was undertaken with the aim of determining if light responsive units were present in the cerebro-pedal connectives. This would hopefully allow us to identify the extraocular photoreceptors controlling diurnal locomotor patterning. Our initial experiments employed an in vivo recording electrode (Block, Neurosci. Abst. Vol. 5. 1979) attached to the cerebro-pedal connective. Analysis of multiunit activity from this connective in unrestrained animals revealed the presence of a light evoked response which appeared as an increase in ongoing small unit activity and as a burst of large units. In an effort to determine the location of the receptors generating this response, a semi-intact preparation was employed. Electrical activity in the cerebro-pedal connective could be recorded while selectively illuminating parts of the body wall and central ganglia with a fiber optic probe. Results from these in vitro experiments revealed that illumination of the tentacles, rhinophores or eyes leads to a response in the cerebro-pedal connective. Furthermore, the response to illumination of any of the 3 structures appears identical, suggesting a common pathway. Experiments are currently underway to determine whether denervation of all 3 sensory structures blocks the diurnal locomotor rhythm. Supported by NS15264.

18.4 MECHANISM OF PHASE SHIFTING THE APLYSIA EYE BY SEROTONIN AND 8-BENZYLTHIO-cAMP: CHANGES IN K^+ CONDUCTANCE. A. Eskin, Dept. of Biology, Univ. of Houston, Houston, Texas 77004.

Serotonin (5-HT) treatments phase shift the circadian rhythm from the isolated eye of Aplysia. The characteristics of the phase shifts caused by 5-HT along with the transmitter-like properties of 5-HT indicate that 5-HT plays a role in the transmission of circadian information in the eye. The effect of 5-HT on the rhythm seems to be mediated by changes in cAMP since a variety of treatments which should elevate intracellular levels of cAMP precisely mimic the effects of 5-HT, phosphodiesterase inhibitors potentiate the effects of 5-HT, the effects of 5-HT and 8-benzylthio-cAMP are non-additive, and 5-HT causes large changes in cAMP in the eye. We have investigated the mechanisms whereby 5-HT and cAMP cause phase shifts and found that changes in K^+ conductance appear to be responsible for phase shifting by 5-HT and cAMP.

Previously, we found that membrane fluxes of Na^+, Cl^-, or Ca^{++} ions are not involved in the 5-HT effect. Since then we found that OK_o^+ treatment, which depolarizes membrane potentials of molluscan neurons by blocking Na-K pumps, phase shifts the rhythm. The phase response curve for this treatment is very similar to that of 5-HT instead of being like phase response curves of depolarizing treatments. This result led to the hypothesis that phase shifting by OK_o^+ was produced by release of 5-HT which in turn caused the phase shift. The fact that phase shifts produced by OK_o^+ and 5-HT are non-additive is consistent with this hypothesis. Another depolarizing treatment, hiK_o^+, did not produce phase shifts at the phase where OK_o^+ and 5-HT caused phase shifts, though this treatment should also have led to release of 5-HT. This result suggested that the phase shift of 5-HT resulted from a change in K^+ conductance since the effects of such a change in conductance would be reduced by the elevated K_o^+ of the hiK_o^+ solution (K_o^+=30mM). HiK_o^+ completely blocked the phase shift normally caused by 5-HT. The hiK_o^+ treatment by itself did not cause phase shifts. Since the 5-HT phase shift appears to be mediated by cAMP I investigated whether elevating K_o^+ would modify the effects of cAMP. The ability of 8-BT-cAMP to phase shift the rhythm was significantly reduced by an accompanying hiK_o^+ treatment. Thus both the effects of 5-HT and 8-BT-cAMP appear to involve changes in K^+ conductance. These agents are probably phase shifting by an increase in K^+ conductance and the resulting hyperpolarization of the membrane potential since depolarizing treatments cannot mimic the effects of either 5-HT or 8-BT-cAMP. These results provide additional evidence that cAMP mediates the effect of 5-HT since the effects of 5-HT and 8-BT-cAMP were both blocked by the same treatment.

18.5 ELECTROPHYSIOLOGY OF BULLA EYES: CIRCADIAN RHYTHM AND INTRACELLULAR RESPONSES TO ILLUMINATION. G.D. Block and W.O. Friesen. Department of Biology, University of Virginia, Charlottesville, Virginia 22901.

Circadian pacemakers have been identified in the eyes of several molluscan species including Aplysia (Jacklet, 1969), Navanax (Eskin & Harcombe, 1977) and Bursatella (Block and Roberts, 1981). We here report that the eyes of Bulla likewise express a circadian rhythm. In addition, the Bulla eye appears to be particularly favorable for neurophysiological studies by intracellular recording techniques.

Extracellular recording from the optic nerve of isolated eyes in continual darkness revealed a circadian rhythm in the frequency of spontaneously generated compound action potentials (CAPs). This frequency rhythm, whose maximum amplitude is 200 CAPs/hr, persisted for at least 3 cycles with a period ranging from 23-24 hr (Instant Ocean, HEPES 30 mM). Peak activity occurred within 1 hr of projected dawn.

Intracellular recording from the retina with the lens removed revealed several types of electrical activity in response to illumination. Photoreceptors, visible on the retinal surface, had a measured resting potential of -40 to -80 mV and responded to illumination with a transient depolarization of up to 110 mV. This depolarization resembles the response obtained from receptor cells (R-cells) in the Aplysia retina (Jacklet, 1969). Simultaneous recording from receptor pairs revealed electrical coupling between some, but not all receptors. Typically, coupled cells were adjacent, while no coupling was observed between distant cells.

Other retinal responses, observed during deeper penetrations, included: 1) a unit with small, spontaneously occurring spikes which hyperpolarized upon illumination, with a concomitant cessation of spiking activity; 2) a unit which depolarized upon illumination and simultaneously produced small spikes; and 3) a unit which depolarized upon illumination and produced large spikes. These were followed 1-1 by large unitary spikes in the optic nerve, independent of simultaneously occurring CAPs. Supported by NS15264.

18.6 SWITCH FROM NOCTURNAL TO DIURNAL LOCOMOTOR BEHAVIOR FOLLOWING EYE REMOVAL IN THE BUBBLE SNAIL, BULLA GOULDIANA. Philip A. Davenport* and Gene D. Block. (SPON: W. O. Friesen). Dept. of Biology, University of Virginia, Charlottesville, Virginia 22901.

We find that Bulla, like several other opisthobranchs, exhibit a circadian rhythm in locomotor activity. Bulla are nocturnal on light cycles (L:D,12:12) and when placed into darkness, most Bulla exhibit clear free-running locomotor rhythms (τ = 24-25 hr) for at least 1 month. Since the eye of Bulla expresses a circadian rhythm in the frequency of optic nerve impulses (Block & Friesen, this volume), we were interested in determining what role the eye plays in controlling locomotor behavior.

In order to assess ocular control of locomotor rhythmicity, the eyes of 12 Bulla were removed, either during locomotor free-runs in D:D or during entrainment to light cycles. Removal of the eyes during free-runs always resulted in major deterioration of the locomotor rhythm. Nevertheless, in most animals, rhythmicity persisted for several cycles following eye removal, suggesting the presence of an extraocular (highly damped ?) circadian pacemaker. If the eyes were removed while animals were exposed to light cycles, "entrainment" persisted but there was a 180° phase shift in locomotor activity so that eyeless Bulla became diurnal.

We are not yet certain whether diurnal locomotor behavior in eyeless Bulla remains under the control of an endogenous pacemaker or is reflexively driven by the light cycles. However, placing eyeless Bulla into darkness results in 1 - 3 cycles of continued "diurnal" behavior. Thus we cautiously suggest that the switch to diurnal behavior following eye removal involves a change in the entrained phase angle of an extraocular pacemaker. Supported by NS15264.

18.7 DEMONSTRATION AND MANIPULATION OF BILATERALLY DISTRIBUTED CIRCADIAN PACEMAKERS CONTROLLING VISUAL SENSITIVITY IN CRAYFISH. B. Barrera-Mera and Gene D. Block, Depto. de Neurociencias C.I.F.C. U.N.A.M. Mexico, 20 D.F. and Dept. of Biology, University of Virginia, Charlottesville, Virginia 22901.

The eye of crayfish exhibits a clear circadian rhythm of retinal sensitivity as measured by the amplitude of the electroretinogram (ERG)[1]. Furthermore, the ERG rhythms of both eyes remain in phase in constant darkness, suggesting that the two eyes are controlled by tightly coupled pacemakers or by a single circadian pacemaker[2,3]. In spite of the fact that split brain preparations continue to exhibit bilateral circadian rhythms[3], the unambiguous existence of two separate pacemakers has not been reported.

In the current series of experiments the trito and deutocerebrum of the crayfish (Procambarus clarkii) were removed and the protocerebrum bisected. This operation neurally disconnected the two optic lobes from one another. Following recovery from surgery, brief pulses of light (1-3 S, 0.2 Cd/m^2) were delivered to each eye of an otherwise dark-adapted crayfish. Analysis of resultant ERG records revealed a clear circadian rhythm in both eyes which persisted for more than 3 weeks without significant damping. The circadian rhythms in the two eyes were typically in phase with one another but could be desynchronized by: (1) changing the test stimuli frequency to one eye which resulted in a change in the circadian period of the same eye, or (2) providing a long duration (60 minute) light pulse unilaterally. The change in phase angles between the two ocular rhythms in these bisected preparations demonstrates the existence of bilaterally distributed circadian pacemakers which are coupled in the intact crayfish.

18.8 CIRCADIAN RHYTHM OF ERG B-WAVE IN FREE-MOVING ANOLIS. D. H. Fowlkes, C. J. Karwoski and L. M. Proenza. Vision Research Lab., Univ. of Ga., Athens, GA 30602.

The electroretinogram (ERG) was recorded from the free-moving lizard (Anolis Carolinensis). After a minimum of 3 wk entrainment to the solar light-dark cycle, silver wires (0.2 mm) were attached to the anesthetized (Alcaine) corneal surface of the immobilized lateral eye and under the scalp. Immediately following the implantation, usually performed at 1000 to 1100 h (E.S.T.), the animal was placed within a translucent hemisphere (18 cm dia.) situated on a horizontal white surface. The recording wires passed through a small hole in the top of the hemisphere allowing the animal free movement. The animal was then kept in constant darkness except that the hemisphere was illuminated once every 2 h with a 10 μsec flash (Grass Photostimulator PS2) which was about one log unit above threshold. ERG's were recorded through an AC preamplifier (Grass P15) with half amplitude filters set at 0.1 and 300 Hz.

During the first 24 h of recording (in constant darkness), b-wave amplitude during projected night was low (10-40 μV), began increasing shortly after projected sunrise, and was maximum (50-100 μV) 6-9 h after projected sunrise. Subsequent 24 h periods showed a similar pattern but with an increasing phase delay indicating a free-running rhythm with a period slightly longer than 24 h. The latency of the b-wave did not appear to vary with time of day. Since the latency and amplitude of the a-wave showed no circadian rhythm, the b-wave rhythm may originate from post-receptoral mechanisms.

18.9 ULTRADIAN RHYTHMS IN HAMSTER AND RAT EATING. L. P. Morin, Dept. of Psychology, Dartmouth College, Hanover, N.H. 03755.

Male hamsters and rats were housed under a variety of photoperiod conditions, with and without access to running wheels. An event recorder monitored the timing of eating from a modified tunnel feeder in which powder chow was continuously available. Power spectrum analysis of eating patterns indicates that timing of food intake is regulated, in large part, by endogenous ultradian rhythms in both species. Period length of these rhythms in hamsters varied from about 2.3 to 4.0 hr. In rats, the periods ranged from about 3.0 to 6.5 hr. In both species, two or more statistically significant ultradian rhythms were usually evident simultaneously. A circadian rhythm of eating was detectable in all rats, but only in some hamsters. Attempts to manipulate the periodicity of the hamster ultradian eating rhythms by phase shifting the light cycle, placing animals under a 2.5:2.5 hr light-dark cycle or by chronically exposing them to 24.6 or 23.3 hr days have been unsuccessful. The results raise questions pertinent to homeostasis and the regulation of food intake and to the generation of circadian rhythms.

18.10 DIURNAL RHYTHMS OF THE GUINEA PIG: RELATION OF EVOKED POTENTIALS AND BODY TEMPERATURE. Carl P. Browman, Anne H. Remmes* and Arthur D. Rosen. Departments of Psychiatry and Neurology, State University of New York at Stony Brook, Long Island 11794.

Time-of-day changes in visual evoked potential (VEP) waveform and body temperature were assessed in the guinea pig (Cavia porcellus). Six male animals age 99 days served as subjects. They were tested at 2-hr intervals from 8 am to 8 pm for two consecutive days, with additional single sessions at 8 am and 8 pm on separate days. The ECoG, recorded from the occipital cortex, was sampled at a 2 kHz rate for 250 msec. The first 10 responses within a session were excluded from data analysis. VEP waveforms were the average of 100 responses.

Five VEP components were reliably obtained: N15, P27, N51, P79, and N103. Latency variability across sessions for all subjects was rather constant and was similar to that across subjects. Variability generally increased from short-latency to long-latency components. Amplitude measures, in contrast, were highly subject specific. The degree of intersession amplitude variability was directly related to the particular animal. For the mean data, P27-N51 amplitude correlated with body temperature across time periods ($rho=.848$, $p < .05$). Correlation coefficients between body temperature and the other amplitude measures, as well as all latency measures, were nonsignificant.

A clear rhythm in body temperature is evident in our data. This is independent of most VEP waveform measures which generally did not show a systematic time-of-day change. Only P27-N51 amplitude correlates with body temperature. VEP latency variability is consistent across subjects and sessions, while there is considerable interindividual variability in amplitude measures. We concur with Kayser and Hildwein (1974) that diurnal rhythms of the guinea pig are for the most part difficult to demonstrate.

18.11 CENTRAL VISUAL PATHWAYS AND THE LIGHT-DARK DISTRIBUTION OF SLEEP IN 24-HR AND 1-HR LIGHT-DARK CYCLES. Cheryl L. Sisk and Friedrich K. Stephan. Dept. Psychology, Florida State Univ., Tallahassee, FL 32306.

In rats, about 30% of daily slow wave sleep (SWS) and rapid eye movement (REM) sleep occurs during dark hours in a 12 hr light-12 hr dark cycle (LD 12:12). The occurrence of REM sleep during darkness dramatically increases to 80-90% in rats under very short LD cycles, e.g., LD 0.5:0.5. The proportion of dark-occurring SWS is relatively unaffected by short LD cycles. This experiment investigated the roles of the primary, accessory, and hypothalamic retinal projections in the determination of this differential LD distribution of REM sleep within circadian- and ultradian-length LD cycles. Cortical EEG, neck EMG, and brain temperature were recorded in rats which received either 1) no lesion, 2) primary optic tract lesions anterior to lateral geniculate, 3) superior accessory optic terminal nuclei lesions, 4) inferior accessory optic terminal nucleus lesions, or 5) retino-hypothalamic tract/suprachiasmatic nucleus (RHT/SCN) lesions. For each rat, electrophysiological recordings were made in both a circadian (LD 12:12 or LD 10:14) and an ultradian (LD 0.5:0.5) LD cycle. Records were visually scored for the number of minutes spent in arousal, SWS, or REM sleep during light and dark for each recording day.

Primary and superior accessory optic tract lesions did not change the distribution of sleep and arousal on 24-hr LD cycles. Inferior accessory optic tract ablation increased the nocturnality of REM sleep but not SWS. RHT/SCN lesions abolished the circadian rhythm of sleep-wakefulness and its entrainment to the LD cycle. These results confirm and extend other studies which indicate that the RHT is responsible for the entrainment of circadian rhythms by light.

The dark-time enhancement of REM sleep observed in the intact rats on LD 0.5:0.5 was not abolished by any one of the four visual system lesions, although rats with primary optic tract lesions showed significantly more REM sleep in the light than other groups. Inferior accessory optic lesions accentuated the dark triggering of REM sleep so that virtually no REM sleep occurred during the short light periods. These results suggest that triggering of REM sleep by short dark periods is mediated by some hitherto undescribed retinal projection, or alternatively, can be mediated by several retinal projections.

The characteristic light-dark distributions of REM sleep in circadian and ultradian LD cycles may therefore be under different neural control by the central visual system.

18.12 SCN LESIONS ALTER THE FREE-RUNNING TEMPERATURE AND WAKE RHYTHMS OF RATS. C.I. Eastman, R. Mistlberger* and A. Rechtschaffen*. Univ. of Chicago Sleep Lab, Chicago, IL 60637

There are different multiple oscillator theories about the organization of mammalian circadian systems. In one (Pittendrigh and Daan, J. comp. Physiol. 106: 333-355, 1976), the circadian rhythm of activity is controlled by two oscillators which are normally coupled to sunrise and sunset respectively. In another theory (Aschoff and Wever, Fed. Proc. 35: 2326-2332, 1976), temperature is primarily controlled by one oscillator and activity by another. Moore-Ede et al. (Neurosci. Abstr. 6: 708, 1980) reported that in the squirrel monkey SCN lesions eliminated the rhythm of activity but not temperature; they suggested that the activity oscillator was in the SCN but that the temperature oscillator was elsewhere. The present experiments explored the role of the SCN in the generation of the circadian rhythms of temperature and wake in the rat.

Bilateral lesions of a variety of sizes were aimed at the SCN. Temperature was recorded from a thermistor on the brain surface. Wake and sleep were polygraphically scored by computer. All the data were stored in 30 sec epochs by a PDP-11 computer. So far, 10 SCN lesioned rats have been exposed to constant dim illumination (about 1.5 lux) and continuously recorded for up to four months. The circadian rhythms were assessed, in part, by computer produced "wheel-running style" graphs of both temperature and wake.

All SCN animals had abnormal rhythmic patterns compared to normal and sham lesioned controls. These abnormalities ranged from complete arrhythmicity in both temperature and wake to weak and labile free-running rhythms in both variables. In some cases, although the temperature rhythm was definitely abnormal, it seemed more regular and more robust than the wake rhythm. Some animals became more arrhythmic over months. One animal developed a bimodal pattern in both temperature and wake resembling "splitting", in which two components free-ran with the same frequency but about 180° apart. Histological analyses are in progress to evaluate the relationship between rhythm disruption and size and locus of lesion. The data will be discussed in terms of various multiple oscillator theories.

18.13 FUNCTIONAL SYMMETRY OF THE SUPRACHIASMATIC NUCLEI. F. C. Davis* and R. A. Gorski. (SPON: L. Mallach). Lab. of Neuroendocrinology of the Brain Research Institute and Department of Anatomy, UCLA School of Medicine, Los Angeles, CA 90024.

Evidence for the control of circadian locomotor activity/rest rhythmicity by two oscillators has been observed in mammals, birds, and reptiles. A pacemaker system of coupled but functionally distinct circadian oscillators has been proposed for rodent wheel-running activity rhythms (Pittendrigh and Daan, J. Comp. Physiol. 106: 333, 1976). We tested the possibility that the bilateral suprachiasmatic nuclei (SCN) are functionally distinct circadian oscillators by measuring circadian rhythm properties in hamsters with right- or left-side unilateral damage to this region known to be critical for normal circadian rhythmicity. Wheel-running activity was recorded from sham-lesioned and lesioned male Golden hamsters during entrainment to a light/dark cycle, during a phase advance of the light/dark cycle and during constant light (350 lux). Comparisons among sham-lesioned, left-side lesioned, and right-side lesioned animals were made for the following parameters: 1) time of activity onset relative to lights off during entrainment; 2) rate of phase-shift following advance of the light/dark cycle; and 3) circadian period during constant light. The occurrence of "splitting" (two activity components with different circadian periods) was also noted. Since it is difficult to lesion the SCN unilaterally, the volume of intact SCN tissue was measured for the right and left sides of each animal. A lesion was considered unilateral if the volume of the SCN on that side was less than 35% of that of sham-lesioned rats, while the volume of the SCN on the other side was 50-100% of that of the controls. Moreover, SCN volume on the lesioned side had to be 50% or less of that on the intact side. These animals were also required to show entrainment. Right-side (N=6) and left-side (N=6) lesioned animals were not significantly different in any of the circadian rhythm properties measured. Furthermore, the lesioned animals did not fall into two obviously functionally distinct groups which would suggest functional assymmetry independent of right- or left-sidedness. The separate circadian oscillators evident in splitting do not appear to represent the two halves of the SCN; three unilaterally lesioned animals showed splitting. The circadian period of lesioned animals was shorter than that of the 4 shams (23.99 vs. 24.49, $P < .01$). Incorporating the data from all animals of the study (N=28), we found a positive correlation between size of the SCN and circadian period ($R=.723$). It is concluded that the right and left sides of the SCN do not represent functionally distinct circadian oscillators. Supported by NRSA 1 F32 HD05916 to F.C.D. and NIH Grant HD-01182 to R.A.G.

18.14 CONTRAVARYING CIRCADIAN RHYTHMS OF EPSP AND POPULATION SPIKE IN HIPPOCAMPAL DENTATE GYRUS AND THEIR RELATION TO STATE. L.J. Cauller*, Z. Boulos and G.V. Goddard. Psychology Dept., Dalhousie Univ., Halifax, Nova Scotia, Canada B3H 4J1.

Field potentials evoked at 15 min intervals by single biphasic electrical pulses to the perforant path were recorded over several days from the hilus of the dentate gyrus in chronically implanted freely-moving rats. In agreement with Barnes et al. (Science, 197:91, 1977) the slope of the field EPSP was greatest during the dark phase of daily light-dark (LD 12:12 or 14:10). The height of the population spike contravaried with the EPSP rhythm such that a given EPSP value was associated with a larger spike during the light than during the dark. This agrees with the observation by West and Deadwyler (Neurosci., 5:1597, 1980) that the granule cells are more excitable during the light. The contravarying circadian rhythms followed phase shifts of the LD cycle and persisted under constant light (LL) with free-running periods greater than 24 h for up to 14 days.

We recorded on videotape the behavior of rats kept in LL and collected cortical and hippocampal EEGs to determine the state of the rats at the time of stimulation. The mean EPSP slope was greater during SA (still alert) than during SWS (slow wave sleep) but their was no difference in the size of the population spike between these states. Since the greater EPSP input produced an equivalent spike output, we agree with the conclusion by Winson and Abzug (J. Neurophysiol., 41:716, 1978) that the granule cells are less excitable during SA than during SWS.

The potentials evoked during either SWS or SA had smaller EPSPs and larger population spikes at the time of the light phase of the prior LD cycle than at the time of the dark. Thus the circadian rhythms remained evident when the data were separated by state. The AA (awake active) state occurred almost entirely at times when the light was normally off and was associated with with large EPSPs and small spikes, whereas REM (paradoxical sleep) occurred almost entirely at times when the light was normally on and was associated with small EPSPs and large spikes. Too few examples were observed at the opposite circadian phase to demonstrate L-D differences within either of these states.

When EPSPs were evoked by stimulus intensities below spike threshold following arousal to SA, they had greater peak amplitude, shorter peak latency, faster rise time and narrower width at half amplitude in the dark phase than in the light.

18.15 CIRCADIAN VARIATION IN RAT BRAIN REGIONAL NEUROCHEMISTRY. S.G. Speciale. Dept. of Psychiatry, Univ. of Texas Health Science Center, Dallas, Texas 75235.

Circadian or 24-hour rhythms have been demonstrated for a wide variety of physiological parameters, including body temperature, motor activity, hormone secretion and several CNS neurotransmitters, including indole- and catecholamines. It was of interest therefore to measure some additional transmitter markers in brain regions of rats synchronized to a lighting schedule.

Male Sprague-Dawley rats were adapted to an automatic illumination cycle (0600-1800 hours light; 1800-0600 hours dark) for three weeks prior to use. Rectal temperature measurements verified entrainment (maximal during dark, minimal during light phase). Animals (6-8 per time point) were sacrificed by decapitation at 0600, 1000, 1500, 2000 and 2400 hours, the brains removed rapidly and dissected into hypothalamus (hpth), caudate nucleus (cn), midbrain (mb), brain stem (bs) and hippocampus (hip), then frozen on dry ice. Trunk blood was also collected for plasma hormone assay.

For the initial phase of these studies the activity of glutamic acid decarboxylase (GAD) and choline acetyltransferase (ChAT), synthetic enzymes and neuronal markers for GABA and acetylcholine, respectively, were measured in these tissues using the radiometric assays of Fonnum et al. (Biochem. J. 115:465, 1969; Brain Res. 20:259, 1970). GAD activity was highest in the hpth, intermediate in hip and cn, while mb and bs were one-tenth the hpth activity. ChAT activity was highest in cn, intermediate in hip, hpth and bs, while minimal in mb.

Enzyme activities in a number of regions varied significantly with the time of day (the majority at $P < 0.005$ level or greater). GAD in hip was elevated 63% at its maximum (2000 hours) over the minimum at 0600 hours. mb GAD was relatively constant through the day, except for a large increase at 2400 hours. bs GAD was similar to mb but the elevation at 2400 hours was not as marked. cn and hpth GAD were bimodal; peaks occur at 1500 and 2400 hours in cn, while in hpth there are peaks at 1000 and 2400 hours.

mb and bs ChAT were relatively constant across the 24 hours except for significant increases at 2400 hours. cn ChAT was also constant except for a reduced activity at 0600 hours, differing significantly from values at 1500 and 2000 hours. hpth ChAT was bimodal, with maxima at 1500 and 2400 hours and minima at 0600 and 2000 hours. hip ChAT was without significant variation through the 24 hours.

These results will be correlated with those for other transmitter systems in these regions and circulating hormone levels.

18.16 DIURNAL AND PHOTOPERIOD-INDUCED VARIATION IN MUSCARINIC RECEPTOR CONCENTRATION IN SOME REGIONS OF THE RAT BRAIN. H.T. Tsui, S.H. Losee-Olson, F.W. Turek and W.L. Klein. Graduate Program in Neuroscience, Northwestern University, Evanston IL 60201

Cholinergic stimulation induces a 75 % loss of muscarinic receptors in cultured CNS cells(Siman,R.G. and Klein,W.L.,PNAS 76,4141-4145). Since Saito (Life Science 16,281-288) reported a circadian fluctuation of acetycholine levels in the telencephalon and pons plus medulla oblongata, but not in the mesencephalon plus diencephalon, we have tested for diurnal variation of muscarinic receptor concentrations in discrete regions of the rat brain. We also have tested the influence of photoperiod on hamster brain receptor levels and have investigated whether adding cholinomemetics to brain slices alters muscarinic receptor levels.

Rats maintained on LD 12:12 were killed at 4 hr intervals over a 24 hr period. The following areas were used: the suprachiasmatic nucleus, preoptic nucleus, the rest of the anterior hypothalamus, caudate putamen,amygdala, cortex and the brainstem. Of all areas examined,diurnal variations in receptor concentration were observed only in the caudate and the brainstem. The receptor level in caudate at midday was 33 % higher than the lowest of the other time points ($p<.01$,n =4). Receptor level in the brainstem peaked 2 h before lights on (32 % higher than the lowest, $p<.025$,n=4 to6) and stayed 23 % higher than the lowest concentration for the next 8 hrs. Receptor levels in various brain regions were also determined in hamsters maintained on LD 6:18 and 14:10 and killed at midpoint of the day. Hamsters kept on long days had significantly higher receptor levels in the cortex, and in the anterior and posterior hypothalamus than the short day hamsters (20-36 % difference, n=5, $p< 05$). No differences were seen in the caudate and the brainstem.

To determine if cholinergic activation of brain slices induces a loss of receptor, 300 um sections of brainstem were put on filter paper barely covered with oxygenated medium. The slices were incubated at 37°C in an oxygenated chamber within 15 min. of the animal's death. During a 6 hr incubation, with oxotremerine at 10^{-3} to 10^{-6}M, or without oxotremerine, receptor binding assays indicated no significant changes in receptor levels.

These results suggest that diurnal variation in muscarinic receptor concentration may exist in some regions of the brain where diurnal variation of acetycholine was previously observed and that muscarinic receptors in other regions may be affected by photoperiod. Presently we have no direct evidence that this variation results from changes in cholinergic stimulation. (supported by NIH grant NS-15299 to WLK and HD-12622 to FWT)

18.17 PRACTICE OF THE TRANSCENDENTAL MEDITATION (TM) AND TM-SIDHI PROGRAM MAY AFFECT THE CIRCADIAN RHYTHM OF URINARY 5-HYDROXYINDOLE EXCRETION. K.G. Walton, M. Lerom*, J. Salerno* and R.K. Wallace. Biochemistry Research Laboratory, Department of Biology, Maharishi International University, Fairfield, Iowa 52556.

A rise in the urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA), the main metabolite of serotonin, during or immediately after an afternoon practice session of the TM technique has been reported[1]. Similar results were obtained with total urinary 5-hydroxyindoles (5-HI) in subjects who practiced the more advanced TM and TM-Sidhi program[2]. However, in the latter experiments little or no rise of 5-HI excretion was associated with a morning (0800 to 0900) session in averaged data from 11 subjects. New data to be presented come from experiments in which the total urine was collected in 8 consecutive 3-hour periods per day for 3 days or longer. All subjects were practicing the TM and TM-Sidhi program regularly. The 5-HI excretion rate (calculated as mg/h for each 3 h period) from a subject who was studied for 14 consecutive days exhibited 27 maxima. Twenty-six of these peak periods either included (18 peaks) or came immediately after (8 peaks) practice sessions of the TM and TM-Sidhi program. The magnitudes of the two peaks present each day were consistently unequal. The afternoon maxima were 3 to 10 times larger in 11 of the 14 days, whereas the reverse was true of the other 3 days. Thus, at least in this subject, whose pattern was unusually regular, there was a clear rise of 5-HI excretion associated with the morning as well as the afternoon session.

The significance of a correlation between high 5-HI excretion and practice sessions of the TM and TM-Sidhi program is not known. However, there is the possibility that such a program might serve as a zeitgeber for CNS or peripheral rhythms in serotonergic activity. The amplitudes of circadian rhythms in brain levels of serotonin and 5-HIAA are quite large in rodents, but there is no data which would indicate whether these brain rhythms correlate with urinary excretion of 5-HI. Previous studies in man have suggested a circadian rhythm in 5-HIAA excretion, although detailed studies within subjects should give a clearer picture. A change in peripheral serotonergic activity might be involved in the redistribution of blood flow seen with the TM technique[3]. On the other hand, among the physiological effects reportedly due to practice of the TM and TM-Sidhi techniques, increased phase coherence of the EEG[4] and altered hypothalamic-pituitary-adrenal function[5] might both be due to altered CNS serotonergic activity.

18.18 TRANSCUTANEOUS NERVE STIMULATION (TNS) EVOKES FREQUENCY AND WAVEFORM DEPENDENT SUBJECTIVE SENSATIONS IN HUMANS. J.J. Katims* and L.K.Y. Ng. Division of Research, National Institute on Drug Abuse, Rockville, Maryland 20852

TNS treatment for relief of pain is now widely accepted in medical practice. Less well accepted are its applications transcranially for insomnia, anxiety, depression and drug withdrawal. As yet, little is known about its possible mechanisms of action.

Humoral changes associated with transcranial TNS in humans include alterations in catecholamines, thyroxine, endogenous opiate-like substances and gastric acid secretion. Recent evidence suggests that frequency of the electrical stimulus may be an important parameter in its therapeutic effect.

Twenty healthy volunteer subjects participated in a single blind investigation of the influence of various frequencies and waveforms of TNS on evoked subjective sensations. TNS was administered bilaterally anterior to the ear tragi at various frequencies (5-10,000 Hz) using either a sinusoid, biphasic square, or 0.2 msec biphasic rectangular pulse waveform. Current intensities were used which evoked a mild tingling sensation at the electrode sites approximately 0.25 mA peak to peak. With the sinusoid waveform stimulation the subjects reported 3 distinct frequency dependent sensations including: oscillations in visual field perception (without apparent movement of the retina, 5-19 Hz), a flickering illumination of the visual field (12-80 Hz), and a unique resonance sensation within the head (60-573 Hz). These same sensations also were reported with ipsilateral stimulation. Using a biphasic square waveform of stimulation the subjects reported all three sensations as occurring concomitantly (5-573 Hz) without resolution of frequency dependent channels. The 0.2 msec biphasic rectangular pulse waveform stimulation evoked no oscillatory, flickering or resonance sensations in 60% of subjects tested and the remainder reported only a slight cranial resonance sensation. The sensations described above do not resemble cochlear electrophonics or phosphene effects associated with TNS around the ears and eyes.

The findings from this study support the hypothesis that the neuronal systems which mediate subjective sensations possess frequency sensitive channels capable of waveform discrimination. This specificity may allow for the nonpharmacologic stimulation of discrete neuronal populations within the brain, a psychophysiological specificity which may have important diagnostic and therapeutic applications for the medical practitioner and neuroscientist.

19.1 ANALGESIC EFFECTS OF MORPHINE MICROINJECTIONS IN THE AMYGDALA OF THE RAT. C. G. Lineberry. Dept. Physiol., Sch. of Med. and Dent. Res. Center, Univ. N. Carolina, Chapel Hill, N.C. 27514.

Twenty-one rats were implanted for injection of drug solutions via 33 g cannulas placed in the amygdaloid nuclear complex. Analgesia was assessed by noting thresholds for reflex tail movement and vocalization elicited by electrical tail stimulation.

Ten rats were bilaterally injected with 0.5 µl solutions of saline, or 5, 10 or 20 µg morphine sulfate. Morphine produced dose-related increases in the vocalization threshold that averaged approximately 200% of control after 10 µg morphine.

Twenty sites in the amygdaloid nuclear complex were investigated in 11 additional rats using unilateral, 0.5 µl injections of 5 or 10 µg morphine, or saline. Ten of the twenty sites produced elevations in vocalization thresholds equal to or exceeding 150% of saline control values. Reflex tail movement thresholds were unaffected. The increase in mean vocalization threshold for active sites was 146±20% of saline control values after 5 µg, and 242±21% after 10 µg morphine. When 10 µg morphine was preceeded by s.c. naloxone (1 mg/kg), the mean vocalization threshold was 160±27% of saline control values (n = 9 sites). Viewed individually by morphine injection site, subcutaneous naloxone completely reversed the effects of morphine injections in 5 sites, partially reversed the effects in 3 sites, and was ineffective in one site. The effects of the 10 µg morphine microinjections were apparent within minutes after injection, reached peak values at 30 and 60 minutes, and declined by 50% by 180 minutes. These effects were comparable in magnitude and duration to those obtained with 4 to 8 mg/kg systemic morphine.

The results of these studies demonstrate dose-related, naloxone-reversible analgesic effects of unilateral or bilateral microinjections of morphine into the amygdaloid nuclear complex of the rat, in spite of numerous published reports that have failed to demonstrate such effects. In the only published report of analgesic effects produced by microinjection of morphine into the amygdala (Rogers, R.J., Pharmacol. Biochem. Behav., 6:385-390, 1977) only bilateral injections were effective in producing even a weak analgesic response as measured by the flinch-jump procedure. The analgesic effects of the morphine microinjections were confined to vocalization thresholds, indicating that the affective-emotional, rather than the sensory-reflexive dimension of pain is modulated by neural systems containing amygdaloid opiate receptors.

19.2 ENHANCEMENT OF MORPHINE ANALGESIA BY ENVIRONMENTAL CUES SIGNALLING PAIN. J. E. Sherman*, J. W. Lewis, R. E. DeWetter*, H. Strub* and J. C. Liebeskind (SPON: F. Krasne). Depts. of Psychology and Anesthesiology, UCLA, Los Angeles, CA 90024.

Central pain inhibitory mechanisms activated by direct electrical stimulation and by opiate drugs are now known to be activated also by noxious unconditioned (US) and conditioned (CS) stimuli. We have shown (Sherman et al., 1981) that opiate analgesia is enhanced after repeated noxious stimulation and suggested this to be partly attributable to conditioned fear. If so, this enhancement should only or best be seen in the same test environment (CS) in which noxious stimuli (US) were originally presented.

To test this hypothesis two groups of rats received 18 days of discrimination training in which one environment was paired with 45 sec of inescapable footshock (for shock sessions 1-7, .8 mA; sessions 8-9, 1.0mA) and the other was safe. For Group RM, shock was administered in a distinctive room, and handling without shock was conducted in the homecage environment. For Group HC, these environmental conditions were reversed. Exposure to the environments was alternated daily and was counterbalanced across groups. On the 19th day, all rats were transported to the distinctive room where they received morphine (5 mg/kg, s.c.). Pain sensitivity was assessed with the hot-plate test beginning 30 min after morphine.

RM rats displayed significantly greater morphine analgesia than HC rats ($p < .05$). Subsequent experiments revealed that this conditioning procedure itself caused significant analgesia that was unaffected by naltrexone (7 mg/kg, s.c.).

Thus the expectation of pain, i.e., conditioned fear, both diminishes responsiveness to painful stimulation and enhances opiate analgesia by activating nonopioid mechanisms of pain inhibition. (Supported by NIH grant #NS07628.)

19.3 CHANGES IN SENSITIVITY TO APOMORPHINE FOLLOWING REPEATED MORPHINE INJECTIONS ARE SPECIFICALLY RELATED TO THE PLACE WHERE MORPHINE IS EXPERIENCED. J. Stewart. Dept. of Psychology, Concordia University, Montreal, Canada, H3G 1M8.

An experiment was done to determine whether changes observed in the activity of the dopamine systems after repeated exposure to morphine are, at least in part, conditioned to environmental cues associated with morphine injections.

Activity was measured for 90 min immediately following a daily injection in two groups of rats, and sometime before a daily injection in two other groups of rats. In each condition, some animals received, intraperitoneally, 20 mg/kg morphine sulphate as the daily injection and others received saline. After at least two weeks of morphine administration, test days were run in which all animals were injected, intraperitoneally, with either saline or with 0.5 mg/kg apomorphine HCl. Following a morphine-free period of two to three weeks when all animals remained in their home cages, the same tests were repeated.

The results showed that animals that normally received morphine while in the activity boxes had significantly higher activity levels in response to apomorphine than did their saline control animals. Animals that received equivalent daily doses of morphine, but never associated with the activity boxes, responded to apomorphine as did their saline control animals. These effects were observed both during the period of daily morphine injections and following the morphine-free period. It appears that the changes that resulted in greater responsivitity to apomorphine were conditioned to, and thus were elicited by the environment that was associated with the morphine injections. The fact that these conditioned changes were elicitable several weeks after the last morphine injection are of considerable interest and parallel conditioned changes in body temperature previously reported by us (Eikelboom, R. & Stewart, J. Psychopharmacology, 61, 3, 1979, and 72, 147, 1981. (Supported by a grant from the Medical Research Council of Canada, MA 6678).

19.4 PINCH INDUCED CATALEPSY: A NATURAL DEFENSIVE RESPONSE INVOLVING BLOCKADE OF CENTRAL DOPAMINE SYSTEMS BY ENDOGENOUSLY RELEASED OPIOIDS. S. Amir and K. Ornstein*. Department of Isotope Research, The Weizmann Institute of Science, Rehovot, Israel.

Repeated pinching to the scruff of the neck in mice evokes a potent catalepsy, i.e. imposed postures, except inversion in a supine position, are retained for an exceedingly long time (Bouts of catalepsy lasting up to 20 min were observed). Moreover, concomitantly to this pinch-induced catalepsy (PIC) there is a profound analgesia (S. Amir et al., Life Sci. 28: 1189-1194, 1981); not only that the response latencies on a hot plate (53°C) and in tail-flick testing are delayed, but painful leg and tail-pinches potentiate catalepsy rather than inducing the normal pain responses. The coincidence of catalepsy and analgesia suggests that PIC is mediated by opioid-dopamine interactions.

Pretreatment with low doses of morphine (0.1-10.0 mg/kg) or with the dopamine antagonist haloperidol (0.1-1.0 mg/kg) markedly enhances PIC without inducing catalepsy in unpinched controls. In contrast, both the narcotic antagonist naloxone (0.1-1.0 mg/kg) and the dopamine agonist apomorphine (1.0-10 mg/kg) blocked the development of PIC. Naloxone did not reverse ongoing PIC (after the response had been established to a duration of >90 sec) but it readily abolished the analgesia. Apomorphine reversed PIC in all doses tested without affecting analgesia. These findings indicate that the development of PIC is mediated by endogenous opioids. Additionally, there is indication that the maintenance of PIC is mediated by blockade of dopaminergic transmission, which is independent of opioid activity subserving analgesia.

Recently, we reported that a catalepsy resembling PIC is elicited in mice attacked by a cat (K. Ornstein and S. Amir, JCPP, in press). This suggests that PIC may be a biologically meaningful defensive behavior, which is instrumental in reducing the frequency of attacks in predator/prey confrontations.

Only the concomitant occurrence of catalespy and analgesia enables an attacked mouse to withhold pain-induced struggling and escape attempts, which would reverse the advantages of catalepsy. This conicidence of analgesia and catalepsy is warranted by the above described opioid-dopamine interaction and can be split in its components by naloxone or apomorphine.

19.5 DOPAMINERGIC MEDIATION OF OPIATE REWARD. M.A. Bozarth and R.A. Wise. Center for Research on Drug Dependence, Department of Psychology, Concordia University, Montreal, P.Q. H3G 1M8 CANADA.

The rewarding properties of opiates appear to be mediated by a drug action in the ventral tegmental area (VTA). This notion has been suggested by studies showing that rats will self-administer morphine directly into this brain area, but not into other brain regions containing opiate receptors (Bozarth & Wise, Soc. Neurosci. Abst. 6:309, 1980). Since dopaminergic (DA) cells in the VTA have been implicated in reward from a variety of sources, it is of special interest to examine the involvement of DA in opiate reward.

The conditioned place preference (CPP) paradigm offers a useful method of assessing the affective properties of a drug. Rats that have experienced the rewarding effects of a drug associated with a specific environment will, when given the opportunity, return to the place where they experienced these effects (Rossi & Reid, Physiol. Psych. 4:269, 1976). In the present studies, CPP was measured using a shuttle box with a plywood floor on one side and a plywood floor covered with wire mesh on the other. The amount of time spent on each side of the box was automatically recorded. Rats were allowed access to the entire shuttle box for 15 min on 5 consecutive days. Next, they received 4 daily injections while being forced to remain on the non-preferred side for 30 min. Following the 4 days of conditioning, the rats were injected with vehicle and tested again for their place preference. Increases in the amount of time spent on the side of putative conditioning were interpreted as an indication of drug-induced reward. Rats subcutaneously injected with heroin (0.5 mg/kg) during the conditioning trials showed a preference for the side of the box where they experienced the drug effect. This CPP was blocked by pretreatment with either naloxone (3.0 mg/kg) or pimozide (0.5 mg/kg) suggesting that this is an opiate receptor mediated effect, and that it is dependent on a DA mechanism.

In another experiment, rats were unilaterally injected with morphine through chronically indwelling 22 gauge guide cannulae implanted in the VTA. A 2.5 µg dose of morphine sulfate was infused over 28 sec in 0.5 µl of Ringer's solution during the conditioning trials. Rats with cannula placements proximal to the DA cell bodies of the VTA showed a strong CPP while rats injected with morphine at sites caudal to this area did not. These results, combined with an earlier report showing CPP with VTA injections, but not with placements more dorsal (Phillips & LePiane, Pharmac. Biochem. Behav. 12:965, 1980), suggest that DA cells in the VTA are important in mediating the rewarding properties of opiates.

19.6 A COMPARISON OF THE STIMULUS-EFFECT CURVES OF MORPHINE FOR ANALGESIA AND INHIBITION OF GASTROINTESTINAL TRANSIT IN RATS. R. B. Raffa*, F. Porreca*, R. B. Murray, A. Cowan and R. J. Tallarida*. Department of Pharmacology, Temple University School of Medicine, Philadelphia, PA 19140.

According to Stephenson's modification of classical drug-receptor theory (Br. J. Pharmacol. 11:379, 1956), the sequence of events following the administration of an active drug (leading to an effect) can be divided into separate drug-dependent and drug-independent portions. The drug-dependent portion is the reaction between drug and receptor leading to a drug-receptor complex and is characterized by an apparent dissociation constant (K_A). The complex provides a stimulus (S) which, in turn, induces the effect (E). The relation between the stimulus and fractional receptor occupancy is assumed to be linear, whereas the relation between the magnitude of the stimulus and the magnitude of the effect is an unknown function, presumed to be independent of the drug. In this study, we examined two effects of morphine, one mediated centrally (analgesia) and one with both central and peripheral components (inhibition of gastrointestinal transit). Male Sprague-Dawley rats (180-220 g) were given s.c saline or morphine sulfate (0.3 to 30 mg/kg) 30 min prior to testing in 57°C hot-water tail flick and the charcoal meal tests (Green, Br. J. Pharmacol. 14:26,1959). Other rats were predosed with s.c. buprenorphine hydrochloride (0.3 mg/kg) or vehicle 30 min prior to morphine (3 to 80 mg/kg). The latter rats were tested 60 min after buprenorphine, a time at which buprenorphine's own agonist actions are minimal and partial irreversible blockade of morphine is produced (Tallarida and Cowan, Fed. Proc. 39:759, 1980). Both of these conditions are required in the calculation of K_A for agonists using the procedure of Furchgott and Bursztyn (Ann. N.Y. Acad. Sci. 144:882, 1967). The K_A for morphine was 2.9×10^{-5} M for analgesia and 1.1×10^{-5} M for inhibition of gastrointestinal transit. The stimulus-effect curves were found to have different shapes. In a plot of per cent maximum effect against stimulus, the curve corresponding to inhibition of gastrointestinal transit is roughly hyperbolic and passes through the constrained point S=1 at 50% effect. This same shape was previously observed in another smooth muscle preparation, namely, rabbit aorta (Raffa et al., Arch. int. Pharmacodyn. 241:197, 1979). On the other hand, the curve corresponding to analgesia is steeper, intersecting the first curve at S=1. These differences in shape support the applicability of Stephenson's theory to in vivo opiate action by reflecting the general differences in the effector mechanisms underlying endpoints mediated through the CNS and smooth muscle.

19.7 PHARMACOLOGIC CHARACTERISTICS OF MORPHINE (M) AND ETHYLKETOCYCLAZOCINE (EK) FOR ANALGESIA AND INHIBITION OF GASTROINTESTINAL TRANSIT (IGIT) IN RATS. F. Porreca*, R.B. Raffa*, R.J. Sheldon*, A. Cowan and R.J. Tallarida*. Dept. Pharmacol., Temple University School of Medicine, Philadelphia, PA 19140.

The interaction of an agonist with its pharmacologic receptor is characterized by a dissociation constant, K_A (1/affinity), and an A_{50}. The determination of K_A requires the use of an irreversible antagonist, a compound generally unavailable for opiates. Recently, Tallarida and Cowan have reported that under certain conditions, buprenorphine (B) seems to act as an irreversible antagonist of M for analgesia (Fed. Proc. 39:759, 1980). These observations have been extended to a second effect of M (IGIT) and a second compound (EK) for analgesia and IGIT.

Analgesia was measured 30 min after s.c. injection of M sulfate or EK methanesulfonate to groups of 8-12 male, S.D. rats (180-220 g) using tail compression and hot water (57° C) tail flick tests; IGIT was determined 20 min after a forced charcoal meal and 30 min following M or EK. When B was used as an antagonist, rats received B hydrochloride (0.3 mg/kg, s.c.) or vehicle 30 min prior to graded doses of s.c. M or EK. Testing for analgesia (tail flick) and IGIT took place 60 min after B, a time when B's agonist action is minimal in both endpoints. The dose-response curves of M and EK were shifted to the right with a decreased maximum after B allowing calculation of K_A's (method of Furchgott and Bursztyn, Ann. N.Y. Acad. Sci. 144:882, 1967). A_{50}'s (mg/kg) of M and EK were:

Compound	IGIT	Thermal	Pressure	Thermal/Pressure ratio
M	1.4	3.7	6.2	0.60
EK	2.7	0.4	0.6	0.67

Compound	IGIT(K_A)	Tail flick(K_A)
M	1.1×10^{-5} M	2.9×10^{-5} M
EK	7.5×10^{-5} M	0.28×10^{-5} M

K_A for EK (not previously reported) has been determined using two endpoints. It should be noted that the A_{50} does not equal K_A. The ratio of A_{50}'s of M and EK is approximately equal to 10 for both thermal and pressure tests as is the ratio of K_A's of M and EK for analgesia. The A_{50}'s do not support the contention that mu and kappa agonists may be differentiated on the sole basis of thermal/pressure ratios. Finally, since B is thought to act on the mu receptor, its ability to antagonize EK at this dose along with our previously reported identical naloxone pA_2 values against M and EK (8.1) indicate that M and EK may act at the same receptor to produce analgesia. (DA 02322 from NIDA)

19.8 THE EFFECTS OF INTRAVENOUS MORPHINE SELF-ADMINISTRATION UPON CONCURRENT FOOD AND WATER REINFORCED RESPONDING. N.E. Goeders, M.P. Sands,* D.R. Cherek, J.D. Lane, and J.E. Smith. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

This study was initiated to evaluate the effects of morphine self-administration on concurrent responding for food and water reinforcement. Male Fisher F-344 rats were trained to lever press for food and water presentation on concurrent FR10 schedules available on non-reversible option. Presentation of each reinforcer was contingent upon responding on the appropriate retractable lever. The first response on a lever resulted in the other levers being withdrawn, their stimulus lights extinguished, and a 120 sec limited hold initiated. After the completion of a fixed-ratio and presentation of a reinforcement or the limited hold elapsed, the lever was retracted and its stimulus light extinguished for a 30 sec time out. The levers were once again extended and the stimulus lights illuminated following the 30 sec time out. Once stable baselines of food and water responding were obtained, the rats were implanted with chronic jugular catheters and made physically dependent on morphine with hourly automatic infusions. All three levers were then re-extended, and the animals allowed to respond for either food, water or morphine reinforcement with 24 hr access. Morphine self-administration was maintained throughout both of the reversed 12 hr light, 12 hr dark daily cycles, and this in turn disrupted the animals' normal patterns of responding for food. Prior to morphine self-administration, patterns of responding for food and water tended to accompany the daily light and dark cycles, with over 75% of the food and water presentations occurring during the dark cycle. After morphine self-administration was initiated, periods of responding for greater than 20 food pellet presentations in rapid succession tended to decrease, while episodes of lever pressing for no more than 5 food pellets with less than a 5 min pause between presentations increased. Responding for food reinforcement became interspersed throughout each daily 24 hr period, with at least 40% of the food presentations occurring during the light (inactive) cycle. There was no significant difference from baseline values in the patterns of responding for water. Lesions produced by 6-hydroxydopamine and kainic acid in the nucleus accumbens are presently being studied to determine if food, water and morphine reinforcement processes are mediated through a common neuronal pathway. (Supported in part by USPHS Grants DA-01999 and MH-31835)

19.9 MORPHINE-INDUCED WATER CONSUMPTION. J. M. Stapleton, A. J. Castiglioni, F. Bermudez-Rattoni* and J. C. Liebeskind. Dept. Psychol., UCLA, Los Angeles, CA 90024.

Although opiates are thought to have primarily depressant effects, there is evidence that for certain measures, (locomotion, body temperature, and self-stimulation), their effects are biphasic in both dose and time. Soon after a moderately large dose of morphine, for example, depressant effects are seen, followed by delayed facilitation. Small, even subanalgesic doses can produce facilitation without prior depression. The opiate antagonist, naloxone, given alone, produces decreases in these measures. It is well established that naloxone also reduces feeding and drinking in rats, but there have been few reports of morphine-induced increases in appetitive behaviors. We have confirmed and extended Maickel et al.'s (Neuropharm., 1977) report of dose-dependent increases in fluid consumption induced by morphine (Stapleton, Castiglioni & Liebeskind, Proc. West. Pharm. Soc., in press). This presentation will summarize a series of experiments studying morphine-induced water consumption.

Morphine-induced water consumption does not show tolerance with repeated injections and can be reversed by naloxone. The time course of the effect is more similar to the time course for morphine-induced hypermotility than to the time course for analgesia or hyperthermia. Preliminary data suggest that the effect may be observed following microinjection into the lateral ventricle or lateral hypothalamus but not into frontal cortex.

It has been suggested that excitatory effects of morphine may be due to acute withdrawal effects, a rebound from the decreases seen soon after the injection. To test this hypothesis, rats were given morphine (10 mg/kg) or saline immediately before a 6 h test and later given naloxone (1 mg/kg) or saline 4 h after morphine. We reasoned that, if the morphine-induced increases in water consumption were due to withdrawal effects, they should not be blocked by naloxone given at this time, and might even be exacerbated. The results indicated that even given 4 h after morphine, naloxone blocked the facilitation of water consumption.

Current studies are seeking to uncover the mechanism involved in morphine-induced water consumption, including possible hormonal involvement. Morphine facilitation of water consumption and other excitatory effects of morphine, such as hyperthermia and hypermotility, may represent different behavioral manifestations of a common underlying neural process. These excitatory effects may be as important as the better known depressant effects in understanding the role of endogenous opioid systems in behavior. (Supported by NIH grant #NS07628.)

19.10 THE EFFECTS OF KAINIC ACID LESIONS OF THE NUCLEUS ACCUMBENS ON INTRAVENOUS MORPHINE SELF-ADMINISTRATION. J.E. Smith, C. Co*, C.M. Crenshaw*, T.S. Barr* and J.D. Lane. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

The mesolimbic dopaminergic system has been implicated in stimulant and opiate reinforcement processes. 6-hydroxydopamine lesions of the nucleus accumbens attentuate amphetamine (Lyness, et al, Pharmac. Biochem. Behav. 11:553, 1979) and cocaine (Roberts, et al, Pharmac. Biochem. Behav. 12:781, 1980) self-administration. Rats intracranially self-administer morphine into the nucleus accumbens (Olds, Neurosci. Abst. 5:535, 1979) and ventral tegmental area (Bozarth and Wise, Life Sci. 28:551, 1981). This experiment was initiated to determine the role of the nucleus accumben's neurons and brain stem feedback pathways in opiate reinforcement processes. Four pairs of adult male F-344 littermates were implanted with bilateral 23-gauge guide cannulae into the nucleus accumbens (A9.5,V-5.5,L ±1.2 - König and Klippel) and with chronic jugular catheters. Each pair of littermates was made physically dependent on morphine and then allowed to intravenously self-administer the drug (10 mg/kg, delivered over 5 sec with 24-hr access) on an FR10 schedule. After stable baselines of self-administration were obtained, each pair was lightly anesthetized with intravenous thiopental and one littermate bilaterally injected with 2 µg kainic acid in 1 µl into each nucleus accumbens while the other littermate received equivalent bilateral injections of the vehicle (saline). The animals were given two days to recover from the treatments, receiving automatic injections of morphine equivalent to their pre-lesion baseline intake and then again allowed to self-administer morphine. On the 14th day post-lesion, the rats were sacrificed by decapitation and the nucleus accumbens rapidly removed and homogenized. The content of dopamine (DA), norepinephrine (NE), serotonin (5-HT), aspartate (Asp), glutamate and gamma-aminobutyric acid (GABA) were concurrently measured and the high affinity uptake of choline (Ch), GABA, DA, and 5-HT determined. Kainic acid lesions resulted in significant increases in morphine intake [9.5 ± 3.0 to 21.8 ± 4.2 injections per 24 hours (values are mean ± S.D.)] while injections of vehicle had no effect (8.2 ± 2.1 to 11.6 ± 0.6). GABA and Glu content was decreased while DA increased. High affinity uptake of Ch was also decreased. The significant increase in morphine intake as a result of the lesion indicate that neurons involved in opiate reinforcement processes have been adversely affected, resulting in a compensatory increased intake to overcome this deficit. (Supported in part by USPHS Grant DA-01999-04).

19.11 ANALGESIA PRODUCED BY KINDLED SEIZURES IN RATS. D. W. Berman*, S. Caldecott-Hazard, Y. Shavit and J. C. Liebeskind (SPON: M. Demetrescu). Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The release of opioids by fully kindled seizures has been suggested by naloxone's reversal and morphine's prolongation of post-ictal depression (Frenk et al., 1979). Additional evidence for opioid release comes from the additive effect of morphine or an enkephalin analogue on the inhibition produced by a kindled seizure on subsequent seizures (Caldecott-Hazard et al., 1980). A more traditional index of opioid release, post-ictal analgesia, has been studied during the development of kindled seizures (Frenk and Yitzhaky, 1981). However, fully generalized seizures were not tested for post-ictal analgesia. The present investigation studied post-ictal analgesia after fully generalized seizures and during the kindling process, using both tail-flick and hot-plate tests. The hot-plate test is thought to assess higher levels of pain integration than the tail-flick test.

Chronic bipolar stimulation and recording electrodes were implanted in the amygdala and rats were stimulated daily to kindle seizures. After each daily stimulus, either tail-flick (5 trials at 1 min intervals immediately following the seizure) or hind-paw lick latencies on the hot plate (1 trial, either immediately, at 2 min, 30 min, or 24 hr after the seizure) were measured. Stimulation and analgesia testing continued until all rats showed 3 fully generalized (stage 5) seizures. One week later, the rats were injected with naloxone (2 injections of 10 mg/kg at 15 min intervals), given a seizure, and immediately tested on the hot plate. Another group of kindled rats was made tolerant to morphine, then also given seizures and tested on the hot plate.

Tail-flick analgesia was not seen during the kindling process or following fully generalized seizures. Analgesia on the hot plate was found following fully generalized (stage 5) seizures but not during earlier stages of kindling. The analgesia was complete immediately after the seizures and partially present at 2 min post-ictally. Paw-lick latencies at 30 min and 24 hrs were not different from those of non-stimulated rats. Neither naloxone nor morphine tolerance affected this post-ictal hot-plate analgesia. Thus, these findings suggest that non-opioid mechanisms are involved in kindled post-ictal analgesia. The presence of analgesia in the hot-plate but not the tail-flick test suggests an important role for supraspinal structures in this effect. (Supported by NIH Grants #NS07628 and #NS06289.)

19.12 OPIATE MODIFICATION OF INTERMEDIATES STAGES OF AMYGDALOID-KINDLING. William S. Stone* and Robert F. Berman. Department of Psychology, Wayne State University, Detroit, Michigan 48202.

Recent data from our laboratory indicate that naloxone and naltrexone may be effective in reducing the severity of Stage 5 amygdaloid-kindled seizures (Stone, Eggleton & Berman, 1980). Although several lines of evidence suggest an opiate influence on amygdaloid-kindling, most earlier attempts to demonstrate effects have been marginal or unsuccessful. This is somewhat unexpected in view of the epileptogenic properties of morphine and the enkephalins, and the high concentration of opiate receptors, terminals and enkephalins in the amygdaloid region. The present experiment was an attempt to further examine conditions under which opiates might affect kindling by examining earlier stages of the kindling process.

Thirty-eight adult, male, Long-Evans rats were stereotaxically implanted, bilaterally, with bipolar electrodes into the medial amygdala. After recovery from surgery, each animal was electrically stimulated (100 Hz, 0.1 msec pulse, biphasic, symmetrical, rectangular pulses) through one of the implanted electrodes beginning at 10 microampres to determine the afterdischarge (AD) threshold. Animals were then assigned to one of 5 groups and kindled with 1 sec of stimulation daily at the AD threshold. Two groups of rats were injected daily with 10 mg/kg morphine sulfate from the start of kindling up to Stage 3 (MS, n=9), or from Stage 3 to Stage 5 (MS-3, n=9). Additional groups were injected daily with 10 mg/kg naloxone HCl from initiation of kindling up to Stage 3 (NAL, n=5), or daily from Stage 3 to Stage 5 (NAL-3, n=6). A control group received daily saline injections throughout kindling up to Stage 5 seizures (SAL, n=9). Morphine and naloxone injections were made 15 or 20 min prior to kindling, respectively, and all injections were made intraperitoneally.

Naloxone injected rats (NAL) required an average of 21.8 ± 7.6 days to reach Stage 3 seizures. This was significantly longer than that required by saline (SAL, 9.4± 2.5 days) or morphine (MS, 14.0 ± 5.6 days) injected rats. In contrast, morphine reduced the number of days required to kindle from Stage 3 to 5 (MS-3, 1.7 ± 0.8 days) compared to saline (SAL, 4.2 ± 3.4 days) or naloxone (NAL-3, 5.7 ± 2.7 days) injected rats.

These results indicate that opiates are more effective in modifying earlier stages of amygdaloid kindling than Stage 5. Compared to the results of Stone, et al (1980), morphine at Stage 3 is more potent than at Stage 5. Naloxone from day 1 similarly had a greater effect. The findings presented here may be indicative of different mechanisms involved in the acquisition versus the maintenance of kindled seizures.

19.13 BRAIN STEM SITE OF ACTION FOR REM-SLEEP SUPPRESSING EFFECTS OF MORPHINE. I. de Andrés*, J.R. Villablanca and Ch. E. Olmstead (SPON: W. Wyrwicka). Ment. Ret. Res. Ctr. Depts. Anat. & Psychiat. UCLA, Los Angeles, CA. 90024

In all species, including man, morphine produces a marked reduction of rapid eye movement sleep (REMs). We reported that in cats with bilateral removal of the cerebral hemispheres (diencephalic) REMs is partially suppressed and barbiturates produce a dramatic REMs rebound (Arch.Ital.Biol.110:383;1972). We thought, therefore, that this preparation would be a good model for assessing telencephalic versus brain stem loci for the effects of morphine on sleep. Following a two-stage removal of the hemispheres, 4 cats were implanted with electrodes in the pontine reticular formation, nuchal muscles and the orbits and permitted to recover for at least 15 days. On day 1, a 4 hr. baseline recording preceded morphine SO_4 (1.5 - 2.0 mg/kp, i.p.) and the animals were followed for 4 to 24 hr post-injection. In 2 cases 8 to 12 hr recordings were repeated on days 2,3 and 4. Wakefulness (W), NREMs and REMs were defined on the basis of polygraphic and behavioral criteria. The hourly percentage of W, REMs and NREMs were calculated and the values are given in median and ranges. For the predrug period the values were: W, 55% (32.5 - 68%); REMs, 5.3% (1.3 - 8%); NREMs, 40.1% (30-65.5%);N:8. Morphine totally suppressed REMs for at least 4 hr (range 4 to 8). REMs showed a slow recovery to pre-morphine levels over the 4 to 12 hr post-injection. On days 2 and 3 there was a marked REMs rebound to 24.4% (20.7 - 25.6%) which tended to decline to pre-morphine levels by day 4. For NREMs there was a large increase during the 1st (81.7%; 59-97%) and 2nd (54.2%; 0-100%) post-morphine hours which decreased into a dominant W during the 3rd (100% 11.5 - 100%), 4th (100%; 15.8 - 100%) and 5th (63.8%; 3.0 - 100%) hours. Thereafter both W and NREMs tended to pre-morphine levels with some depression of W paralelling the REMs rebound of the last 3 days. In conclusion, the morphine induced REMs suppression appears to be due to a direct action upon REMs mechanisms in the brain stem. These morphine effects upon sleep-waking follow a protracted time course which suggests that the 3 stage behavioral effect of morphine described for intact and a-caudate cats (Soc.Neurosci.Abstr.4:489;1978) is partially organized at brain stem level. Supported by USPHS Grants HD-05958 and HD-04612.

19.14 STEREOSPECIFIC EFFECTS OF NALOXONE ON RAT HYPOTHALAMIC AND SEPTAL NEURONS. F. Baldino, Jr. and A.L. Beckman. Dept. of Pharmacol., CMDNJ Rutgers Med. Sch., Piscataway, NJ 08854 and Alfred I. duPont Institute, Wilmington, DE 19899.

The purpose of this study was to investigate the possible direct actions of both (+)- and (-)-naloxone on individual neurons in the preoptic/anterior hypothalamus (POAH) and septal area (SA) of the rat brain.

Male Sprague-Dawley rats (250-300g) were anesthetized with urethane (1 g/kg i.p.) and placed in a stereotaxic instrument. Recording of single unit discharges was accomplished through one barrel (NaCl, 4 M) of a five-barrel glass micropipette. A second barrel, filled with 0.5 M NaCl, was used for automatic current balancing and tests for spike discharge current sensitivity. Test compounds were administered iontophoretically through the remaining barrels which alternately contained aqueous solutions of morphine sulfate (0.02 M, pH=4), (-)-naloxone HCl (0.1 M, pH=4), and (+)-naloxone HCl (0.1 M, pH=4).

Morphine and (-)-naloxone, the active isomer of naloxone, were applied to 31 neurons, eleven in the SA and twenty in the POAH. Similar results were observed in both regions. Morphine depressed the spontaneous activity in 19 of 31 neurons. (-)-naloxone at currents less than 10 nA did not influence the firing rate of these neurons. However, (-)-naloxone applied in excess of 10 nA reduced spontaneous activity in 28 of 29 neurons. This effect of (-)-naloxone was stereospecific; (+)-naloxone, the inactive isomer, did not alter the spontaneous rate in 12 of 14 cells when alternately applied with (-)-naloxone at the same current intensity. Application of (+)- and (-)-naloxone with currents above those necessary to elicit the direct inhibitory action produced a diminution of spike amplitude and an increase in the duration of the action potential.

The results of this study indicate that naloxone reduces spontaneous activity via two mechanisms. One involves a direct stereospecific action and a second produces a non-specific reduction in spike amplitide and a prolongation of spike duration which is reminiscent of that produced by local anesthetics. (Supported by NIDA Grant DA 02254 and the A.I. duPont Institute).

19.15 EFFECTS OF OPIATES ON SENSORY EVOKED POTENTIALS IN THE DENTATE GYRUS OF THE CHRONIC RAT DURING CONDITIONING. E.P. Christian*, M.O. West, J.H. Robinson* and S.A. Deadwyler* (SPON: T.J. Miller) Dept. of Physiol. & Pharmacol., Bowman Gray School of Medicine, Winston-Salem, NC 27103.

A recent report demonstrated the existence in the rat of a dual component averaged evoked potential (AEP) to auditory (tone) stimuli which was confined to the outer molecular (OM) layer of the dentate gyrus. The early, N1 component was mediated by the perforant path projection to the dentate gyrus from entorhinal cortex, while the later, N2 component was controlled by projections from medial septum (Deadwyler et al., Science 211:1181-1183, 1981). Rats (n=6) were prepared for chronic recording by implantation of a removable microelectrode drive positioned above the dorsal hippocampus and dentate gyrus, and an ipsilaterally placed entorhinal stimulating electrode. Two of the animals were additionally implanted with intracerebral ventricular (ICV) cannulae. Animals were trained to criterion in 1) a single tone discrimination task or 2) a differential discrimination task. After extensive training in the single tone paradigm, the N1 component of the OM AEP (50 trial average) was attenuated or absent, while N2 amplitude remained constant. Following injections of morphine sulfate (7-10 mg/kg, i.p.), or the synthetic opioid peptide FK-33824 (Sandoz) (3 mg/kg, i.p.), significant increases were observed in N1 amplitude. N2 was either unchanged or was decreased in some cases. Direct ICV injections of morphine (20 µg) or FK-33824 (36 ng) produced even more pronounced increases in N1 amplitude without affecting behavior. Input-output (IO) curves of the extracellular perforant path elicited synaptic potential also changed after opiate administration in that curves were shifted to the left and the maximal potential was increased. Duration of the effect paralleled the time course for changes seen in the OM AEP. Naloxone (2 mg/kg, i.p.) injections alone had little effect on the OM AEP, but created a significant shift to the right and a lower maximal potential in IO curves. Naloxone administration *15 min prior to morphine* in most cases reduced the morphine effect on OM AEPs and IO curves. These results provide evidence that opiate agonists are capable of producing increased sensory activation of perforant path synapses.

Supported by NSF Grant #BNS 78-09787 and NIDA Grant DA 02048.

19.16 REGIONAL BRAIN GLUCOSE UTILIZATION DURING NALOXONE-INDUCED MORPHINE WITHDRAWAL. P. DiStefano*, G.F. Wooten, R.C. Collins and E.M. Johnson* (SPON: S.G. Eliasson). Dept. Neurol. and Pharmacol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

We have studied regional cerebral glucose utilization (GU) in rats during acute morphine withdrawal by ^{14}C-2 deoxyglucose autoradiography. One pellet containing 75 mg of morphine base was implanted S.C. on day 1. On day 4 two pellets were implanted S.C. On day 7 the pellets were removed and morphine withdrawal was induced by injection of naloxone 0.5mg/kg S.C. Fifteen minutes after injection of naloxone, when rats had developed tachypnea, hyperactivity, wet dog shakes and diarrhea, ^{14}C-2 deoxyglucose was administered. Controls included naive rats, morphine pretreated rats that received no naloxone on day 7, and naive rats treated with naloxone 0.5mg/kg S.C.

During naloxone-induced morphine withdrawal the most prominent increases in GU (relative to morphine dependent controls) occurred in central nucleus of amygdala (51%), lateral mammillary nucleus (40%), lateral habenular nucleus (39%), medial mammillary nucleus (35%), and medial septal nucleus (35%) (all $P < 0.01$). Significant increases also occurred in bed nucleus of stria terminalis (23%), interpeduncular nucleus (28%), anterior medial thalamus (30%), anterior ventral thalamus (30%), parataenial nucleus (25%), and lateral septal nucleus (26%). A 35% reduction in GU occurred in entorhinal cortex ($P < 0.05$). No changes were found in any other neocortical areas, hippocampal formation, dentate gyrus, basal ganglia, or posterior and ventral thalamic groups. GU in morphine dependent rats was decreased in frontal cortex, striatum, anterior ventral thalamus, and medial habenular nucleus; while GU was uniformly increased (23-54%) in hippocampus, dentate gyrus and preoptic hypothalamic areas. Naloxone 0.5mg/kg S.C. administered to naive rats produced no changes in regional GU.

Morphine withdrawal is associated with a marked increase in GU in the central nucleus of the amygdala and in several other limbic structures that may be activated in series by amygdalofugal pathways: these structures include bed nucleus of stria terminalis, lateral habenular nucleus, interpeduncular nucleus, mammillary nuclei, and anterior thalamic groups. Several of these structures, particularly the central nucleus of the amygdala, contain large concentrations of endogenous opiates and opiate receptors.

19.17 MODIFICATION OF MORPHINE ACTION BY THE PITUITARY.
B.G. Kasson* and R. George* (SPON: S. Eiduson). Dept. of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024.

Although a vast literature exists on the pharmacologic effects of opiates, there are few data on the modulation of opiate action by pituitary hormones. An approach taken in the past to begin investigation of this problem has been the examination of the effects of hypophysectomy on antinociceptive responses to morphine or various forms of electroshock. The results from early studies were inconclusive and contradictory. In 1977, J.W. Holaday et al. (P.N.A.S. USA 74:4628-4632, 1977), described a sensitization to opiate effects by hypophysectomy which was reversible by ACTH administration. We have conducted a more thorough examination of the effects of hypophysectomy upon morphine responses and have found some interesting differences not previously reported.

Male Sprague Dawley rats (160-180 gr.) were hypophysectomized by the parapharyngeal technique and compared with normal intact males for antinociceptive and thermoregulatory responses. It was found that, for antinociceptive responses, the two groups did not differ with respect to ED_{50} values (2.6 mg/kg hypophysectomized, 2.1 mg/kg intact) but hypophysectomy (Hx) dramatically altered the slope of the dose response curve. Hx animals, as shown by Holaday, were considerably more sensitive to morphine than intact animals, but only at high doses (greater than the ED_{50}), whereas, unlike that reported previously, with low doses of morphine (less than the ED_{50}) Hx animals were considerably less sensitive. Treatment of Hx animals with ACTH, at a dose which restored normal adrenal weight, not only shifted the dose response curve back to the same slope as intact animals but also significantly increased the ED_{50} (4.0 mg/kg). Temperature response curves were also altered by hypophysectomy. Hx produced a more hyperthermic response at any given dose of morphine. ACTH administration decreased the hyperthermic response and also made these animals less sensitive to the hypothermic effects of morphine. Further experiments will determine which other pituitary hormones play a role in the modulation of morphine actions. (This work supported by USPHS DA-01006).

20.1 HORSERADISH PEROXIDASE IDENTIFICATION OF THE MOTONEURONS TO THE TENSOR TYMPANI MUSCLE IN RHESUS AND OWL MONKEYS. Norman L. Strominger, Steven M. Silver*, Timothy C. Truscott, and Jerome C. Goldstein*. Department of Anatomy and Division of Otolaryngology; Albany Medical College of Union University, Albany, New York 12208.

The tensor tympani muscle was exposed in a series of monkeys using a transmastoid approach to the middle ear. An operating microscope was used to enhance visualization. Horseradish peroxidase (20%-15%, Sigma Type VI) was injected into the tensor tympani through a micropipette under air pressure. Dried flakes of the enzyme also were tattooed into the muscle belly in some cases. Animals were perfused transcardially two to three days postoperatively with 0.9% saline followed by 8% gluteraldehyde. Blocks of brainstem including the pons and midbrain were cut at 50μ on a freezing microtome in the transverse or horizontal plane. Material was reacted with tetramethyl benzidine and stained with neutral red and/or thionin.

Three cases with unilateral injections demonstrated the completely ipsilateral location of the motoneuron pool. Four other monkeys were given bilateral injections. Labeled perikarya formed a compact cluster in the ventral or parvocellular division of the motor trigeminal nucleus. The labeled cells were much smaller than large unlabeled motoneurons of the more massive dorsal or magnocellular division. In a couple of instances, enzyme leaked onto the chorda tympani nerve and labeling occurred in the superior salivatory nucleus. Cells so labeled were spatially some distance from the motoneurons to the tensor tympani. Neurons in the mesencephalic trigeminal nucleus did not contain label.

20.2 TOPOGRAPHIC ORGANIZATION OF MOTOR NEURONS INNERVATING PINNA MUSCLES IN THE CAT. J.M. Zook, H.A. Patterson and J.C. Middlebrooks. Coleman Lab. and Depts. of Physiology and Anatomy, Univ. Calif. San Francisco, San Francisco, Calif.,94143.

Many mammals rely upon the directional sensitivity of mobile pinnae to aid in sound localization and discrimination. Although control of pinnae movement is intimately related to the auditory system, little is known of this specific sensory-motor interaction. In the cat movement of the pinnae is controlled by at least seventeen distinct muscles. Most pinna muscles are innervated by the auriculotemporal and posterior auricular branches of the seventh cranial nerve, the facial nerve. Previous studies have shown that these branches of the facial nerve originate from motor neurons of the dorsomedial division of the motor nucleus of the facial nerve. We have systematically examined the innervation of the individual muscles effecting pinna movement by the method of retrograde transport of horseradish peroxidase (HRP). The results indicate that there is a topographic organization within the dorsomedial division of the facial nerve nucleus of the motor neurons innervating individual pinna muscles.

For these experiments individual pinna muscles were exposed under general anesthetic. With careful blunt dissection a muscle group with intact sheath was partially isolated from surrounding tissue. A 30% solution of HRP in saline was injected into the muscle. In all cases clusters of HRP-labeled cells were found in the dorsomedial division of the facial nerve nucleus. These clusters of labeled cells formed columns, or sheets, running the entire rostral-caudal extent of the nucleus. When viewed in the transverse plane labeled cells in each case were located within a different sector of the dorsomedial division. Little overlap was found in the position of these cell columns from muscle to muscle. For example, considering the transverse plane, labeled neurons were consistently found only in the medial part of the dorsomedial division after injections in the levator auris longus, labeled neurons were found only in the ventral part after injections in the depressor conchae and labeled neurons were found only in the lateral part after injections in the adductor auris superior.

Further investigations have been directed towards establishing the degree of overlap in the innervation of pinna muscles by these motorneuron columns using double retrograde label techniques. In light of this columnar organization the main question is the relationship between these columns and the nuclei from which pinnae movements are controled. To address this question we are investigating the specific organization of descending projections to the facial nerve nucleus and the relationship between this organization and co-ordinated pinna movement evoked by microstimulation at the sources of projections to the dorsomedial division of the motor nucleus of the facial nerve.

20.3 QUANTITATIVE STUDY OF BRAINSTEM MOVEMENT AND METHODS WHICH MAY BE USED TO REDUCE IT: DEVELOPMENT OF A NON-PULSATILE CARDIOPULMONARY PERFUSION SYSTEM FOR THE CAT. R.H. Britt and G.T. Rossi. Div. Neurosurgery, R155, Stanford Sch. Med., Stanford, CA 94305 and Palo Alto Veterans Hospital, Palo Alto, CA 94304.

For investigators attempting intracellular recording in the brainstem auditory pathway, brain pulsations caused by the cyclical arterial and venous pressure fluctuations from cardiac and respiratory cycles make penetration and remaining within neurons of 30-50μ difficult. The authors have quantitatively measured brainstem pulsations; measured the effects of standard methods used to reduce pulsations (pneumothoraces, elevation of the head, cerebrospinal fluid (CSF) drainage, and reduction of mean arterial pressure (MAP)); and have developed a new non-pulsatile cardiopulmonary bypass system which eliminates movement of the brain.

In 10 pentobarbital anesthesized cats a wide decompressive posterior fossa craniotomy was performed and the cerebellum aspirated. A reflective foil target was placed on the floor of the fourth ventricle on which a fiber-optic displacement transducer was focused. This system measured the planar, one-dimensional motion normal to the cat's dorsal medulla. Two types of displacement were recorded: 1) relatively low amplitude (110-266μ) and short duration (330-400 msec) excursions corresponding to the pressure wave peak of each systole and 2) a slower (10-12/min), high amplitude, plateau-like displacement (300-950μ) lasting for a time (2.4-5.1 sec) corresponding to each inspiration. Bilateral pneumothoraces reduced movement by 50%. Elevation of the head further reduced movement to a mean 68% below the original excursions. Lowering MAP from 113 to 35 mmHg, reduced cardiac induced movement by 40%.

To eliminate brainstem movement completely, a non-pulsatile cardiopulmonary bypass system was developed utilizing a Bio-Medicus centrifugal flow pump and a SciMed membrane oxygenator resulting in steady-state blood flow (MAP 50-70 mmHg). Brainstem auditory evoked responses remained normal for periods of 2 to 8 hours on bypass. Of 15 cats placed on bypass, problems typically developed after 2-3 hours including: 1) a bleeding disorder (probably hyperfibrinolysis) and 2) metabolic acidosis (correctable by adding bicarbonate). Because of limited donor cat blood, the feasibility of using blood substitutes (20% Fluosol-DA, Alpha-Therapeutic Corp.) is being investigated. The ability of this system to eliminate all brain pulsations has potential application in all neurophysiological studies requiring intracellular recording techniques. This system will be evaluated in a series of intracellular recording studies in cat cochlear nucleus.

20.4 GIANT RING-SHAPED TERMINALS IN THE COCHLEAR NUCLEUS OF CAT. Doyle R. Jones* (SPON: D.K. Morest). Dept. Anatomy, Univ. Ct. Health Center, Farmington, CT 06032.

Axonal terminals with neurofibrillar rings have been described in many parts of the nervous system. Cold acclimation of poikilotherms increases the number of these rings, which in the "cochlear gray" of lizards (Boycott et al,Proc. Roy.Soc.,'61) are described as particularly large (up to 4 μm in diameter) and formed by thick bundles of neurofilaments. Cold-induced neurofibrillar rings may reflect a compensatory process which maintains "physiological properties, such as intracellular transport and synaptic efficacy" during periods of cold-induced stress (Potter,J. Neurocytol.,'73). The present study describes a specific population of exceptionally large neurofibrillary rings in the anteroventral cochlear nucleus(AVCN) of the cat.

The morphology and locations of the giant ring-shaped endings were studied in AVCN of 9 adult cats with the Protargol and rapid Golgi methods. The origin of these endings was established by labeling with HRP following cochlear injections and by examination of cochlear nuclei in labyrinthectomized cats. The giant ring-shaped endings reside in the dorsal half of the anterior division of AVCN and like the end-bulbs of Held are terminals of cochlear nerve fibers. They arise from the largest axons in AVCN, disappear following labyrinthectomy, are labeled with HRP after cochlear injections, and are specifically related to bushy cells. These endings range up to 20 μm in diameter and are formed by thick bundles of neurofilaments which emerge from the axon trunk. The ring-shaped end-bulbs range in complexity from those which are relatively smooth with few appendages to those with many appendages. Some rings form in an appendage of a large end-bulb and occasionally two rings form in an end-bulb.

The key to the functional significance of these specialized nerve terminals may lie in their spatial distribution within AVCN, which is predominantly confined to a region of bushy cells receiving middle to high frequency input. Bourk (Dissertation, MIT,'76)reported that some of the PPO and PP1 units (presumably corresponding to bushy cells) with high characteristic frequencies(CF) have higher thresholds than those with lower CF. It is possible that the high CF, high threshold units correspond to bushy cells receiving ring-shaped end-bulbs. Perhaps these neurofibrillar rings reflect a lower level of turnover of neurofilament proteins in these endings.

20.5 CYTOARCHITECTURAL ORGANIZATION OF THE DORSAL COCHLEAR NUCLEUS. J. K. Moore. Dept. of Anat. Sci., SUNY at Stony Brook, Stony Brook, NY 11794.

The cytoarchitecture of the DCN has been studied in the hedgehog, several species of rodent, cat, monkey, and man, using drawings and photographs of Nissl and Golgi material to define cell types and cell mapping of the entire DCN to determine the distribution and density of the various cell types in different species. Regarding cell types and distribution; (1) most large neurons in all species are fusiform cells, with elongate to triangular somas in the size range of 15μ X 35μ, though somewhat larger in the cat. These cells may be either oriented radial to the nuclear surface or oblique to longitudinal in the deeper region of the DCN. Somas of deep and radial cells do not differ in appearance in Nissl material, but their dendritic arborization varies in that radial cells develop an apical dendritic branching that is highly arborized and covered with dendritic spines. Basal dendrites of radial cells and all dendrites of deep cells are more coarsely branching and have sparse appendages. The presence of spines on apical dendrites is presumably related to formation of synapses with granule cell axon terminals as described by Mugnaini et al., 1980. In monkey and man, all fusiform cells have a pattern similar to deep fusiform cells of nonprimate species: (2) true giant cells with large nuclei and somas up to 50-80μ are rare in all species, though most common in the cat: (3) most smaller cells are round (12μX12μ) or oval (12μX20μ), with nuclei smaller than fusiform cells and sparse chromatin. Their appearance in Nissl material is so uniform as to allow them to be regarded as a single cell type, but differential dendritic patterns occur in cells located in the superficial layers or deep region of the nucleus. These patterns have been described as the stellate, elongate, and cartwheel types. In primates cells of this type have dendritic patterns equivalent to cells of the deeper region in nonprimate species: (4) two categories of very small cell, the small fusiform cell and cochlear granule cell, are common in the superficial layers of the nucleus in nonprimate species, but are seen as scattered cells in the central DCN in both nonprimates and primates, including man.

20.6 THE NEURONAL ORGANIZATION OF THE MOUSE DORSAL COCHLEAR NUCLEUS. F.H. Willard* and D.K. Ryugo. Dept. Anatomy and Neurobiology, Univ. Vermont Med. School, Burlington, VT 05401; Dept. Anatomy, Harvard Med. School, Boston, MA 02115 and Eaton-Peabody Laboratory, Mass. Eye & Ear Infirmary, Boston, MA 02114.

In the mouse dorsal cochlear nucleus(DCN), sheets of large cells (x-sectional area of cell body >250 μm^2) project in a topographic fashion to restricted laminae in the central nucleus of the inferior colliculus(Ryugo et.al., Brain Res.,210:342-349, 1981). Moreover, all members of this distinctive class of large cells project to the inferior colliculus and are positioned in layers II(75%), III(15%), and IV(10%). Although they are distributed in different layers, the cells nonetheless appear morphologically similar in Nissl and HRP preparations; consequently, we have undertaken a more detailed analysis of these cells using Golgi techniques.

Two separate categories of large cells may be recognized on the basis of differences in dendritic morphology. Principal cells (a.k.a. pyramidal cells, fusiform cells, bipolar cells) constitute approximately 85% of the large cell population and are only found in layers II and III. Each cell has 3-5 primary dendrites whose branches radiate along a plane oriented perpendicular to the interface between layer II and III, and form disc-shaped dendritic fields. The disc-shaped principal cells form a series of laminae whose orientation corresponds to the cochleotopic course of auditory nerve fibers. This fibro-dendritic arrangement, so characteristic of other auditory nuclei, presumably underlies tonotopy in DCN.

The other group of large cells are confined to layer IV and the deepest part of layer III. These neurons have very long and relatively unbranched dendrites which extend in all directions. Therefore, they lack a planar shape and potentially may be contacted by primary fibers originating from long segments of the cochlear partition. Such cells correspond to what have previously been called giant cells.

Both principal cells and giant cells comprise the thin neuron sheets which project topographically to the inferior colliculus; their cell bodies and collicular projections maintain a cochleotopic order. Yet differences in their dendritic morphology and relationship to primary afferents suggest that each must subserve different aspects of auditory function.

20.7 INTRACELLULAR RECORDING AND STAINING OF FUSIFORM CELLS IN CAT DORSAL COCHLEAR NUCLEUS. W.S. Rhode*, D. Oertel and P.H. Smith. Dept. of Neurophysiology, Univ. of Wisconsin Med. Sch., Madison, WI 53706.

Fusiform cells in the dorsal cochlear nucleus (DCN) have been studied electrophysiologically and identified anatomically by the intracellular injection of horseradish peroxidase (HRP). In sodium pentobarbital-anaesthetized cats extra- and intracellular recordings were made from 15 fusiform cells which were reconstructed in camera lucida drawings. Before impalement, extracellular responses of these cells to tone bursts at their characteristic frequency (CF) display the "pauser" or "buildup" poststimulus time histograms (PST) described by Pfeiffer (Exp. Brain Res. 1:220, 1966) and often a "chopper" pattern is superimposed on the PST. After impalement tone bursts at CF frequently elicited a "chopper" pattern from the same cell. "On-off" response patterns were sometimes recorded to tones at frequencies away from CF.

In the absence of sound stimuli the intracellular potentials of fusiform cells were noisy and the cells occasionally discharged. In response to tone stimuli at CF, fusiform cells were depolarized by large, noisy excitatory postsynaptic potentials (psps) and then hyperpolarized following the tone burst. During the hyperpolarization the noisiness of the membrane potential temporarily decreased before returning to its resting level. We have observed no inhibitory psps even when the cells were polarized with current.

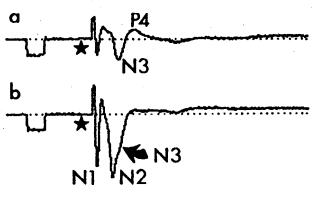
Fusiform cells are characterized by two tufts of dendrites, apical dendrites which extend dorsally to the surface of the nucleus and basal dendrites which extend vertically (Kane, J. Comp. Neurol. 155:301, 1974). Reconstruction of injected cells has demonstrated that typically 4 to 7 apical dendrites branch and may end in as many as 50 terminal processes. Apical dendrites are densely covered by spines. Basal dendrites, in contrast, lack spines. They branch less and are longer, reaching the deep DCN. Occasionally a basal dendrite has an apical branch which is covered with spines. Axons usually arise from a basal dendrite, but can arise from the cell body and run into the dorsal acoustic stria. Axon collaterals sometimes terminate in the region of the cell soma and dorsomedial to the soma in the higher frequency region of the DCN.

20.8 TEMPORAL PROPERTIES OF SYNAPTIC ACTIVITY IN THE DORSAL COCHLEAR NUCLEUS. Paul B. Manis* and William E. Brownell, Depts. of Neuroscience and Surgery (ENT), University of Florida College of Medicine, Gainesville, FL 32610.

Potentials evoked by repetitive electrical stimulation of the eighth nerve were examined in the dorsal cochlear nucleus (DCN) of decerebrate unanesthetized and barbituate anesthetized cats. Shock of the eighth nerve elicits a complex response, which for convenience may be divided into four successive components: N1 N2, N3, and P4. The illustration presents potentials recorded at two depths. Trace "a" was recorded from layer 2, while trace "b" was recorded 300 μm deeper. The calibration pulse is -1 mV by 1 msec, and the time of stimulus delivery is indicated by the star. The stimulus artifact has been suppressed.

The ability of these potentials to follow high rates of eighth nerve stimulation was examined by averaging the response of the last 5 of 30 stimuli at a given frequency. The N1 followed stimulus frequencies up to 350 Hz with little decrement, but was reduced at 500 Hz. The N2 component of the field potential followed stimuli up to 250 Hz quite well, exhibiting in some cases an increased magnitude between 100 and 250 Hz. The N2 decreased in magnitude more rapidly than the N1 at higher frequencies, being severely depressed at 500 Hz. In general, N3 behaved the same as N2. The P4 component was abolished for stimulus frequencies above 75 Hz. Similar results were obtained in a paired-shock paradigm. The N2 and N3 showed a slight facilitation for intervals between 7 and 30 msec. The P4 component was depressed by more than half over the same intervals and recovered to baseline for intervals longer than 50 msec.

The response components can be differentiated on the basis of their ability to follow high-frequency afferent volleys. The latency and current source-sink distribution of the N2 suggests that it is a monosynaptic response, although this needs to be verified by independent means. If the N2 is synaptically mediated, then this synapse is unusual compared to other central nervous system synapses, which usually show response decrement for frequencies above about 100 Hz. Rapid neurotransmitter release and degradation would be consistent with the high afferent discharge rates seen in the auditory nerve.



Supported by USPHS grants MH10320, MH07855 and NS12209.

20.9 SOME RECURRENT PROJECTIONS OF THE SUPERIOR OLIVE TO ANTEROVENTRAL AND DORSAL COCHLEAR NUCLEI IN CAT. Glenn R. Farley and W. Bruce Warr, Human Communication Laboratories, The Boys Town Institute, Omaha, Nebraska 68131.

The purpose of this study was to examine the differences in the organization of recurrent projections to the anteroventral (AVCN) and dorsal cochlear nuclei (DCN) using retrograde and anterograde tract-tracing methods. Injections of 30-50 nl of 30% HRP were made into either the AVCN or DCN, and, following survival times of about 24 hours, labeled cells were found bilaterally throughout the longitudinal extents of the same general periolivary cell groups, regardless of injection location. In most cases, labeling was greater ipsilaterally. Labeling was most profuse in the complex of cells embracing the lateral superior olivary nucleus (LSO) and in the ventral nucleus of the trapezoid body (VNTB), including a superficial cell group lying directly ventral to the medial nucleus of the trapezoid body. Injections into AVCN resulted in a greater preponderance of labeling in rostrally located cells in the ipsilateral lateral periolivary regions than in those located caudally, whereas DCN injections produced a gradient of labeling in the opposite direction. In regard to the possible collateral projections of olivocochlear neurons, injections in AVCN labeled neurons bilaterally in the VNTB and in the dorsomedial periolivary nucleus which, when examined in material counterstained for AChE, were found to be intensely positive for this enzyme. In contrast, injections in the DCN failed to produce this pattern of labeling, although cells in these nuclei were clearly labeled with HRP. A similar examination of the small AChE-positive neurons surrounding LSO produced no evidence of combined markings with HRP and AChE in any of our experiments.

The particularly heavy projection from the lateral periolivary cell croup to AVCN and DCN was further examined by injecting tritiated Leucine into the lateral nucleus of the trapezoid body at the level of the S-shaped portion of the LSO. Autoradiographs demonstrated heavy projections ipsilaterally to (1) the polymorphic and fusiform layers of the DCN, (2) the spherical cell area, and (3) to a lesser extent, to other portions of cochlear nucleus, excluding the granule cell layer. Also of interest was an apparent projection to the lateral dendrites of the ipsilateral medial superior olivary nucleus.

Our findings suggest that the descending influences upon AVCN and DCN, while by no means identical, exhibit a surprising degree of commonality in terms of their nuclear origins.

Supported by NIH Fellowship 1 F32 NS06337-01, and by NIH Grant NS 14832.

20.10 QUANTITATIVE EVALUATION OF CENTRIFUGAL CHOLINERGIC PATHWAYS TO THE RAT COCHLEAR NUCLEUS. D.A. Godfrey[1], J.L. Park[1]*, J.R. Rabel[1]* J.D. Dunn[2], J.T. Smith[1]* and C.D. Ross[1], Depts. Physiol.[1] and Anat.[2], Oral Roberts Univ., Tulsa, OK. 74171.

The contribution of centrifugal pathways to cholinergic synapses in the rat cochlear nucleus was studied by an approach involving lesions and quantitative histochemical mapping procedures. Surgical lesions were aimed just medial to the right cochlear nucleus to cut virtually all its central connections, leaving the left nucleus as control, and animals were sacrificed one week later. Distributions of cholinergic neural elements were estimated by measurement of choline acetyltransferase (ChAT) activities for tissue samples microdissected from freeze-dried 20µm-thick sections. Acetylcholinesterase (AChE) activities were measured, as a secondary marker, for samples from other nearby sections. For four rats in which the lesion missed the region medial to the cochlear nucleus, regional ChAT and AChE activities averaged across the group were not significantly different between left and right cochlear nuclei. Data for ChAT activities, in µmoles/kg dry wt/min (38°C), for the three rats with the most accurately placed lesions, are summarized below. (Average regional data given as lesion side/control side (%); AVCN, DCN, PVCN: anteroventral, dorsal, posteroventral cochlear nucleus; differences significant: +at $p < .01$, *at $p < .001$)

Region	Rat A	Rat B	Rat C
DCN molecular layer	30/167(18%)*	8/282(3%)*	23/231(10%)*
DCN fusiform soma layer	80/351(23%)*	30/476(6%)*	71/576(12%)*
DCN deep layer	46/248(19%)*	17/276(6%)*	72/399(18%)*
PVCN	43/236(18%)*	13/286(5%)*	44/358(12%)*
AVCN rostral part	56/553(10%)*	20/431(5%)*	130/393(33%)*
AVCN granular regions	138/416(33%)*	64/244(26%)+	100/183(55%)+

The lesion in rat A encroached least onto the medial part of the DCN, while the lesion in rat B encroached most. The higher lesion/control % in the DCN and PVCN of rat A might relate to a sparing of the caudalmost part of the trapezoid body by the lesion in this rat, while the higher AVCN and granular region % in rat C may relate to a sparing of the rostralmost part of the trapezoid body in this rat. These data for ChAT are consistent with the possibility that almost all cholinergic elements in the bulk of the rat cochlear nucleus represent fibers and terminals of cholinergic centrifugal pathways, while as much as a third of the ChAT activity in the granular regions may relate to cholinergic interneurons. Lesion-side AChE activities were usually at least 50% of control-side activities for any given region, suggesting that much of this enzyme activity may be related to cholinoceptive structures in the rat cochlear nucleus.

20.11 EFFECTS OF MODERATELY-INTENSE, PURE-TONE STIMULI ON AUDITORY SENSITIVITY AND COCHLEAR NUCLEUS SINGLE UNITS IN THE RABBIT. G.K. Martin*, B.L. Lonsbury-Martin and M.F. Frampton*. Dept. Otolaryngol., Univ. Washington Sch. Med., Seattle, WA 98195.

Auditory thresholds to 14 discrete test frequencies representative of the major portion of the rabbit hearing range were obtained using a classically-conditioned nictitating membrane response (Martin et al., Hear. Res., 2:65-78, 1980). Following determination of monaural thresholds, the effects of moderately-intense, continuous stimuli on pure-tone detection capability were evaluated in terms of amount and duration of threshold shifts using a standard protocol. Rabbits were first assessed at the test frequency using an adaptive testing procedure to determine preexposure threshold. Next, a 90-dB tone systematically related to the frequency of test tone bursts was presented for 3 mins. Immediately upon its termination, test stimuli were reinstated to track the magnitude and duration of the temporary elevation in threshold. An inverted U-shaped function best described the amount of threshold shift with the maximum effect of 15-20 dB occurring for test stimuli ranging from 4-11.3 kHz, while considerably smaller elevations were observed for test frequencies on either side of the sensitive mid-frequency region. Recovery times were linear in log time and paralleled the amount of hearing loss with greater threshold shifts requiring longer recovery periods. However, when initial threshold shifts approached 20 dB, recovery times frequently exceeded the routine 30-min recovery interval. Both trained and untrained animals were prepared for acute recording from single cochlear nucleus neurons in order to relate neural threshold shifts and recovery times to those measured in the earlier behavioral experiments under identical sound-exposure conditions. Two classes of pathological single unit responses were identified. For the majority of neurons, a decrement in driven discharge rate was noted for all stimulus levels tested. In contrast, a number of units demonstrated decreased poststimulatory activity for only threshold-related test stimuli, while for higher level tone bursts, discharge rate increased above control values. Short-lasting alterations were also observed for spontaneous discharge rates which could be either facilitated or decreased. In similar behavioral and neural studies in nonhuman primates, initial neural threshold shifts and corresponding recovery time courses were much greater than those predicted by their behaviorally measured counterparts. In contrast, preliminary findings in our rabbit preparation suggest a much closer correspondence between neural and behavioral results. A comparison of results between rabbit and monkey models for sound exposure will be discussed.
(Supported by The Deafness Research Foundation.)

20.12 MECHANISMS OF AUDITORY INFORMATION PROCESSING FOR PITCH PERCEPTION. G.E. Loeb, M.W. White*, and M.M. Merzenich. Coleman Memorial Lab., UCSF, San Francisco, CA 94143, and Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Recent attempts to restore hearing in deaf patients by selective electrical stimulation of the auditory nerve have focused attention on the problem of how sound is normally processed. The percepts reported by such patients suggest that the nervous system uses the subtle timing information inherent in the phase-locking of afferent activity to sound frequencies in the band 500-5000 Hz. These are the frequencies for which electrical stimuli cause pitch and loudness sensations not relatable to the predictions of place or periodicity pitch detection mechanisms.

We have proposed a neural mechanism for the extraction of pitch by spatial cross-correlation of the traveling wave on the basilar membrane. In our model, phase-locked neural signals from pairs of loci in each cochlea are non-linearly combined at the level of the medial superior olive (MSO). This converts the task of frequency detection from analysis of temporal-spatial cochlear patterns to spatial pattern recognition of the MSO neural ensemble. We here examine several properties which arise from computer simulations of this process and compare them with electrophysiological data which we and others have obtained in the cat anteroventral cochlear nucleus (AVCN) and MSO.

In particular, the model suggests that the loci whose signals are combined should be separated by about 0.4 wavelengths of the frequency to be detected. The output of the MSO, where the signals converge, should be highly sensitive to changes in the arrival time of these action potentials. A four-way excitatory/excitatory convergence is proposed (two loci from corresponding locations in each cochlea) which would account for certain complex psychophysical phenomena such as the pitch of dichotic band-delayed white noise and the pitch of the dichotic missing fundamental. Both are examples of phenomena consistent with a central representation of sound spectra which is binaural yet early enough in the synaptic chain for phase-locking to be preserved.

This model would account for the psychophysical reports of auditory prosthesis patients if their electrical stimulation resulted in neural activity with spatial localization and phase-locking similar to that produced by acoustic stimuli. We have demonstrated such activity in AVCN cells in cats during similar electrical stimulation.

Supported by NIH Contract # NS-0-2337 and Grant # NS-1-1804

20.13 AUDITORY INPUT TO CELLS IN THE DEEP LAYERS OF THE CAT SUPERIOR COLLICULUS. P.B. Schechter, Judith A. Hirsch* and Tom C.T. Yin. Dept. of Neurophysiology, Univ. of Wisconsin Medical School, Madison, Wis. 53706.

Previous studies of the superior colliculus (SC) of mammals have shown that some cells in the deep layers are polymodal, receiving visual, somatic and/or auditory inputs. Although the receptive field properties of the visual and somatic inputs have been mapped thoroughly, little is known about the auditory inputs to SC. We have studied the acoustic properties of these cells, with special emphasis on their binaural characteristics.

We have used two different preparations: barbiturate anesthetized cats stimulated with pure tone stimuli delivered dichotically and paralyzed, nitrous-oxide anesthetized cats with click and tonal stimuli delivered in a free sound field. In the paralyzed animals, the visual receptive field properties of the cells in the superficial and deep layers were also studied.

Cells which responded to the acoustic stimuli were not found in many of the penetrations that were made into the deep layers of the SC. In some cases such neurons were located in narrow laminae several hundred micra thick. Most cells were excited by input from the contralateral ear and inhibited by input from the ipsilateral ear. Thus, most cells were binaural and could be driven by pure tone stimuli. We also studied response areas, tuning curves, and interaural intensity and time difference functions. By using high frequency sinusoidal tones that were gated rapidly with a trapezoidal envelope, we found that even cells with high characteristic frequencies were sensitive to interaural time differences. This was consistent with results obtained from the free field preparation: some of the cells had spatially restricted auditory fields along the azimuth. One surprising finding was that many of the cells had response latencies of 6.5 to 10 msec. This is much shorter than measurements made in the inferior colliculus (IC) under identical conditions. This auditory input must be mediated via fast conducting pathways that do not traverse the IC and may be responsible for the component of the early brain stem evoked response that has been thought to originate from the IC.

20.14 A FLUORESCENT DOUBLE-LABELING STUDY OF ASCENDING AUDITORY PROJECTIONS TO INFERIOR COLLICULUS OF CAT. K. K. Glendenning, M. S. Bull*, and R. B. Masterton. Dept. of Psychology, Florida State University, Tallahassee, FL 32306

Retrograde labeling and degeneration studies have demonstrated that several auditory brainstem nuclei project to both the ipsilateral and contralateral inferior colliculi (IC). These studies have not shown whether the origin of these projections is in two separate subpopulations each projecting either ipsilaterally or contralaterally, or in a single population of neurons each sending axon collaterals to both colliculi. Retrograde double-labeling experiments with fluorescent compounds suggest that all three types of projection exist.

Cats were subjected to large bilateral injections (>1.0 ul) of 2.5% Fast Blue in one IC and 1.0% Nuclear Yellow in the other IC. A systematic variation of the survival times showed the optimal survival time for Fast Blue and Nuclear Yellow in this system to be about 72 and 10 hours, respectively.

Some labeled neurons were found in each of the divisions of the cochlear nuclei. The majority of these neurons were labeled only by the contralateral marker. A few neurons were labeled with the ipsilateral marker and only very few were labeled with both markers. In the superior olivary complex, the medial superior olive was fully labeled and the medial nucleus of the trapezoid body was sparsely labeled, each almost exclusively by the ipsilateral marker. In the lateral superior olive, however, at least three populations of neurons were intermixed. The largest population was labeled only by the contralateral marker, a somewhat smaller population was labeled only by the ipsilateral marker, and a small population was labeled by both markers.

These results indicate that collateral projections to both inferior colliculi arise from the cochlear nucleus and the superior olivary complex but this type of projection is not prevalent.

Supported by NIH Grant NS 00726-14.

20.15 EFFECTS OF NEONATAL UNILATERAL COCHLEAR ABLATIONS: AN ANATOMICAL INVESTIGATION OF ASCENDING PROJECTIONS TO THE INFERIOR COLLICULUS. K.S. Wrege* and L.M. Kitzes* (SPON: T. O'Connor). Depts. Psychobiol. and Anat., Univ. of Calif., Irvine, CA 92717.

Unilateral ablations of the left cochlea were made in 2 day old gerbils. At 4-6 months of age, the central nucleus of the inferior colliculus (ICCN) was examined physiologically in both neonatally lesioned and normal animals. In lesioned animals there was no evidence of auditory input from the ablated cochlea. Sigma IV HRP (30%, .15 µl) was then pressure injected into either the left or right ICCN. The animals were transcardially perfused 48 hrs later. The tissue was then processed according to the technique of Mesulam (J. Hist. Cyt., 1976) and counter-stained with neutral red. Data were collected from only those subjects in which 1) the reaction product was apparent throughout the injected IC, 2) there was no evidence of HRP diffusion beyond the limits of the IC, and 3) the medial superior olive contralateral to the injection was devoid of labelled cells. Labelled cells were counted in the fusiform layer of dorsal cochlear nucleus (DCN), and in postero-ventral (PVCN) and antero-ventral (AVCN) cochlear nucleus.

It is apparent in Nissl stained material that neonatal cochlear ablations result in severe transneuronal degeneration of both PVCN and AVCN on the lesioned side. In contrast, degeneration within the fusiform layer of DCN is minimal.

As demonstrated by the number of HRP labelled cells, normal animals exhibit ipsilateral projections to the IC from all 3 divisions of the cochlear nuclear complex. The ratio of ipsilateral to contralateral projections is 22% for DCN, 5% for PVCN and 1% for AVCN. In neonatally lesioned animals, the ipsilateral projections from PVCN and AVCN on the normal side are significantly greater than in normal animals ($p < .01$). In contrast, the ipsilateral projection from DCN does not differ significantly from normals. A differential effect was also apparent in the contralateral projections from the lesioned side. PVCN and AVCN exhibit greater reductions in their contralateral projections (90%) than does DCN (50% reduction). The ipsilateral projection from all 3 divisions on the lesioned side are significantly reduced (90%) compared to normal animals. The contralateral projections from the normal side are also significantly reduced, though to a lesser extent (40%).

These data show that neonatal unilateral cochlear ablations affect the morphology and connectivity of both ventral and dorsal cochlear nucleus. However, DCN appears less affected than either PVCN or AVCN, suggesting an important influence of descending input to DCN.

Supported by NIH grant NS-14479 and NIH training grant 24180.

20.16 PATTERNS OF LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE INFERIOR COLLICULUS OF THE RAT. C. Huang, Dept. of Physiology, Univ. of So. Ala., Mobile, AL 36688, J. W. Dickson, J. Fex Laboratory of Neuro-otolaryngology, NINCDS and L. Sokoloff Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20205.

The uptake of [^{14}C] 2-Deoxy-glucose (2DG) in the brain has been used extensively in the study of cerebral metabolic and functional activation. Although it is a potential tool for exploring the functional organization in the auditory system, a detailed and quantitative report has not appeared. This report deals with the effects of auditory stimulation in the inferior colliculus (IC) of the awake rat.

The general experimental protocol, including preliminary surgery and animal restraining, plasma sampling and analysis of glucose and 2DG, tissue processing and autoradiography, film reading and computation of local cerebral glucose utilization (LCGU) have been described (Sokoloff et al., 1977). Nineteen albino rats were divided into three groups. The first group of animals received binaural pure-tone stimulation at 2,4,8, and 16 kHz in a sound-proof room. Animals in the second group had one cochlea removed 24 hours before stimulation. The third group received no tonal stimulation and was placed in the sound-proof room or a laboratory with ambient noise.

In the stimulated animals, at least one of the IC showed one or two characteristic bands indicative of elevated metabolic activity. Densitometric readings for some of the bands showed a half-width of 100µm, approaching the practical limit of the resolution of the [^{14}C]2DG method. Frequently, a second band, approximately 500 µm in width also appeared. Values of LCGU for IC regions within the band often reached twice that of regions outside the band, which was 108 ± 25µ mole/100gm/min.

No such band was observed in animals that received no stimulation. However, LCGU for the IC from rats placed in the sound-proof room (135±7µ mole/100gm/min) did not differ significantly from that of rats receiving ambient noise (134±25µ mole/100gm/min). In the IC contralateral to the absent cochlea, LCGU was much lower, 55 ± 6 mole/100gm/min.

The results were consistent with previous evidence that the IC in the rat is primarily innervated through the contralateral cochlea, that the metabolic activation during sound stimulation within the IC can reach extremely high values and is not homogenous, suggesting a functional subparcelling. The three-dimensional representation of metabolic activation under pure-tone stimulation, noise stimulation, and no stimulation will be presented.

20.17 EFFECTS OF NEONATAL UNILATERAL COCHLEAR ABLATIONS: A PHYSIOLOGICAL STUDY OF THE INFERIOR COLLICULUS. L.M. Kitzes* and K.S. Wrege* (SPON: J. Sassin) Depts. Anat. and Psychobiol., Univ. of Calif., Irvine, CA 92717.

Unilateral cochlear ablations were made in 2 day old gerbils. When the animals were 4-8 months old, multiple and single unit responses were studied in the inferior colliculus (IC) ipsilateral to the normal ear. These ipsilateral responses were compared to data obtained in normal animals. Pt-Ir electrodes were advanced through the IC in 100 μm steps and the response threshold for ipsilateral stimulation was determined. In order to assess the quality of the normal ear in the experimental animals and to compare ipsilateral and contralateral thresholds, at least one penetration was made into the IC contralateral to the normal ear. In each animal, the neonatal cochlear ablations were confirmed by the absence of activity evoked by stimulation of the ablated ear. Electrode tracks were reconstructed in all animals. In a series of experimental animals used for anatomical anlysis, the IC was explored with glass micropipette electrodes advanced in 250 μm steps.

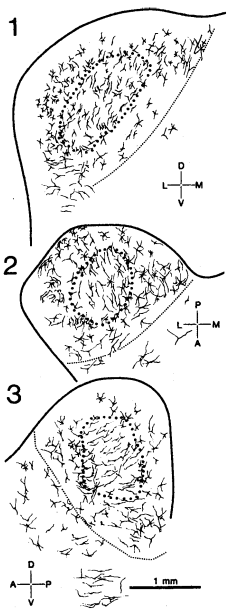
In normal animals ipsilateral stimulation evoked excitatory responses in only 30% of the examined loci. In the remaining 70% ipsilateral stimulation evoked either inhibitory responses, or no response. A designation of no response was made if stimulation evoked no response at a stimulus level more than 40 dB above the contralateral threshold. The 40 dB cut off value was required because of possible contamination of threshold determinations by acoustic cross over. In many instances where ipsilateral stimulation evoked no excitatory activity, inhibitory interactions were apparent at stimulus levels within 10 to 15 dB of the contralateral theshold. In 42% of the loci in which both ears were effective, ipsilateral excitatory thresholds were between 15 and 40 dB greater than contralateral thresholds.

The proportion of ipsilateral excitatory responses in the IC greatly increased in animals subjected to neonatal cochlear ablation. In contrast to normals, ipsilateral stimulation evoked excitatory activity in 80% of the examined loci. The thresholds of ipsilateral stimulation were well within the range of contralateral thresholds. At suprathreshold stimulus levels the multiple unit responses were reliable and robust.

Our anatomical data indicate that neonatal cochlear ablations result in altered afferent projections to the IC. These physiological data suggest that the amount of ipsilateral excitation is dependent upon the integrity of the contralateral pathways.

Supported by NIH grant NS-14479 and NIH training grant 24180.

20.18 STRUCTURE OF LAMINAE IN THE CENTRAL NUCLEUS OF THE INFERIOR COLLICULUS OF THE BAT (ANTROZOUS PALLIDUS). Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.



Studies of the architecture of the central nucleus of the mammalian inferior colliculus have demonstrated the orientation of some principal cell dendrites and the afferent axonal plexus into parallel, sheet-like aggregates termed laminae. These laminae could subserve physiological isofrequency contours imposed by cochlear nucleus axons on the central nucleus. To define the size and shape of individual laminae, serial maps of Golgi-Cox stained neurons have been reconstructed in the transverse, horizontal and parasagittal planes. These maps reveal that bat central nucleus laminae form gently curved and overlapping sheets stacked upon one another. The laminae are oriented as follows: in the transverse plane, from dorsomedial to ventrolateral at about a 75° angle (Fig. 1); in the horizontal plane, from anteromedial to posterolateral (Fig. 2); and, in the parasagittal plane, from anterodorsal to posteroventral, as inverted parabolae (Fig. 3). The laminae are most conspicuous in Golgi impregnations in the horizontal plane, and least apparent in Nissl-stained material. The pattern of nuclear organization recapitulates, with some important exceptions, the structure of individual nerve cells, and is present, with some variation, throughout the central nucleus. Four varieties of neurons are common to the central nucleus. The most common, (1) the disc-shaped cells, have a polarized soma from which dendrites emerge to form the long, flattened axis of the lamina. On the basis of the size of their perikaryon and dendritic field, both large and small disc-shaped cells occur. (2) Neurons with radiate, spherical dendritic arbors are also present. (3) Translaminar neurons have large dendritic fields orthogonal to the main axis of the laminae. (4) Both spiny and sparsely spined stellate cells occur. The dendrites of these classes of cells impose a distinctive pattern on the intrinsic and translaminar circuitry of the central nucleus.

21.1 BIOCHEMICAL AND HISTOCHEMICAL OBSERVATIONS ON THE FIFTH CRANIAL NERVE AND ITS RELATION TO MENINGES AND ITS BLOOD VESSELS. L. Liu-Chen, M. Mayberg*,M.A. Moskowitz. Dept. of Neurosurgery, Dept. of Neurology, Mass. General Hospital, Boston;Dept of Nutrition and Food Science, M.I.T., Cambridge, Ma 02139.

Histochemical and biochemical experiments using horseradish peroxidase (HRP) and radioimmunoassay were used to identify the existence of a neuronal pathway arising in the Vth cranial nerve and terminating in the meninges around the middle cerebral artery(MCA). In all 7 cats, cell bodies containing HRP were identified in the Vth ganglia after the enzyme was placed on the MCA. Neurons were found strictly ipsilaterally and were located among the cell bodies which project to the forehead. In other experiments the chemistry of the Vth nerve was examined in cat and rat. Measurable levels of substance P (SP) were detected in these species and ranged from 173.6 to 223.0 fmole/mg protein. In addition, levels of SP were easily measured in meningeal tissues (37.8-48.2 fmole/mg protein).

To determine the extent to which meningeal fibers containing SP arise from the Vth ganglia, the following experiment was performed. Male Sprague - Dawley rats (250-300 gms) were subjected to electrolytic lesioning of the right trigeminal ganglia using stereotaxic apparatus. The extent of the lesion was determined by the sensory deficits in response to pin prick over each division of the Vth nerve and the histological sections of this ganglia. Rats were sacrificed between 10 and 14 days after the lesion. SP content in the meninges was measured by radioimmunoassay. SP levels in meninges was significantly decreased on the lesioned side compared with control hemisphere. Animals subjected to electrolytic lesion but without evidence of sensory deficit failed to show a consistent reduction in SP content. Similar results were obtained in several preliminary experiments in cats following unilateral trigeminal ganglionectomy. These results suggest that trigeminal neurons which are SP-containing project to the meninges. The existence of such a pathway may be important in the transmission of pain or other sensory stimuli from meninges and its associated blood vessels.

21.2 ULTRASTRUCTURAL LOCALIZATION OF NEUROTENSIN-LIKE IMMUNOREACTIVITY IN THE DORSAL HORN OF THE RAT SPINAL CORD. V. Seybold and B. Maley. Dept. of Anatomy, Univ. of Minnesota Medical School, Minneapolis, MN 55455

The neurotensin-like immunoreactivity (NLI) observed within substantia gelatinosa at the light microscopic level is interpreted to be contained in axons and terminals of intrinsic neurotensin-containing neurons. After colchicine treatment, it has been possible to identify such cells in laminae II and III of the lumbosacral spinal cord of the rat (Soc. Neurosci. Abs. 6:428,1980). To confirm the localization of NLI in terminals and vari-cosities and to begin to appreciate the synaptology of neurotensin-containing neurons in the spinal cord, NLI profiles were studied at the ultrastructural level.

Normal and colchicine-treated (30 µg colchicine, intrathecally at the lumbosacral enlargement) rats were perfused intravascularly with phosphate buffered 4% paraformaldehyde and 0.1% glutaraldehyde. The lumbosacral spinal cords were excised, and 100 µm transverse sections were cut with a vibratome and immediately processed for immunohistochemistry using the PAP procedure of Sternberger. The rabbit anti-neurotensin serum was used at a dilution of 1/1000, and all antisera used in the procedure were diluted in 0.3% Triton X-100 and 1% normal sheep serum in phosphate buffered saline. Absorption controls revealed that the primary antiserum was specific for neurotensin.

The distribution of NLI processess and cell bodies observed at the ultrastructural level parallels the distribution observed in earlier studies. In normal animals, NLI was localized in varicosities and terminals within substantia gelatinosa. The terminals ranged in size from 0.5-2 µm and contained small, round, clear vesicles (40 nm) and several large granular vesicles (LGV, 100 nm). The DAB reaction product was generally observed to be adjacent to the cytoplasmic side of membrane-bound structures and over the LGV. Labeled terminals formed asymmetrical synapses onto unlabeled dendrites and spines. Axons containing NLI were unmyelinated and about 0.2 µm in diameter. NLI labeled cells, which were observed only in colchicine-treated rats, were contacted by unlabeled boutons (0.5-1 µm) containing round or pleomorphic vesicles.

These ultrastructural studies lend further evidence for a local modulatory role for neurotensin-containing cells in the dorsal horn.

Supported by grants from the Pharmaceutical Manufacturers Association Foundation and the Minnesota Medical Foundation.

21.3 THE LOCALIZATION OF BRAIN STEM ENKEPHALINERGIC AND SUBSTANCE-P NEURONS WHICH PROJECT TO THE RODENT NUCLEUS RAPHE MAGNUS. S.M. Prichard and A.J. Beitz. Dept. Anat., School of Med., Univ. of S. Carolina, Columbia, SC 29208.

The raphe magnus is considered an important component of the descending pain control system. The present investigation was undertaken to study the sites of origin of enkephalin (ENK) and substance-P (SP) projections to the nucleus raphe magnus (RM) in an attempt to elucidate some of the peptidergic systems which influence this region. Ten adult Sprague-Dawley rats were stereotaxically injected with HRP into the RM and 1-3 days later received an intraventricular injection of colchicine. The colchicine treated rats were sacrificed by intracardiac perfusion with 3.8% paraformaldehyde followed by PBS containing 25% sucrose. Brain sections were reacted with $CoCl_2$ and DAB to yield a black HRP reaction product in neurons projecting to the RM. Following HRP histochemistry alternate sections were incubated in antisera against ENK or SP and processed for PAP immunohistochemistry which yields a brown immunoreactive product in cells containing ENK or SP. Double-labeled neurons which contain either ENK or SP and project to the RM thus displayed both brown and black reaction product. Immunohistochemical controls were carried out by pretreating the antisera with homologous and heterologous antigens. The greatest number of both double-labeled ENK neurons and double-labeled SP neurons occurred in the nucleus (n) reticularis paragigantocellularis, the n. solitarius, and the n. cuneiformis. Double-labeled ENK cells were also observed in the inferior vestibular nucleus, the n. reticularis ventralis, the n. gigantocellularis, the n. pontis oralis and the superior colliculus. Additional substance-P immunoreactive neurons which project to the RM were found in the inferior vestibular nucleus and in an area located between the lateral reticular nucleus and the trigeminal nucleus caudalis. These results indicate that the majority of SP and ENK projections to the RM arise from the same brain stem nuclear groups. The functional significance of these dual inputs requires further investigation. (Supported by NSF BNS 7906486. We thank Dr. Robert Elde for the anti-ENK and anti-SP serum).

21.4 IS GABA THE NEUROTRANSMITTER OF BARNACLE PHOTORECEPTORS? L. C. Timpe*, K. King*and A. E. Stuart. Dept. of Physiol., U.N.C. Chapel Hill, C. H. North Carolina; Dept. of Neurobiology, Harvard Med. School, Boston, Mass.

We have examined the proposal that photoreceptors of the barnacle use gamma-aminobutyric acid (GABA) as their neurotransmitter (Millecchia and Gwilliam, Science 177:438-441,1972; Koike and Tsuda, J. Physiol. 305:125-138, 1980).

Recording intracellularly from the cell directly postsynaptic to the photoreceptors, the inverting or I-cell, we have studied the effects of bath-applied GABA and picrotoxin. The synapse between photoreceptor and I-cell inverts the response to light from a depolarization in the photoreceptor to a hyperpolarization in the I-cell, so we expect the natural transmitter to hyper polarize the I-cell. At concentrations less than 10^{-5}M GABA has no effect on the I-cell. At 10^{-5}M GABA slightly hyperpolarizes the I-cell; the response to a light in the presence of 10^{-5}M GABA is the same as in normal saline. Picrotoxin (10^{-4}M) affects neither the light response nor the resting membrane potential of the I-cell.

The proposal that GABA is the transmitter of photoreceptors is based partly on the observation that picrotoxin blocks the "off-response" of the visual system, a burst of impulses which can be recorded extracellularly from the circumesophageal nerve (Millecchia and Gwilliam, 1972). These spikes are generated in the A-cell, directly postsynaptic to the I-cell, when the I-cell depolarizes in response to the dimming of light. Recording intracellularly from A-cells we found that 10^{-4}M picrotoxin abolishes the large synaptic depolarization at the offset of light; this depolarization normally generates the spikes of the off-response. Our observation is consistent with the observation of Millecchia and Gwilliam. GABA is not the transmitter released from I-cells onto A-cells, however, because bath-applied GABA does not depolarize the A-cell.

The axonal GABA concentration of a known GABAergic cell, the inhibitory motoneuron of the lobster, is about 100mM (E. A. Kravitz and D. D. Potter, J. Neurochem. 12:323-328). Axons of non-GABAergic excitatory fibers from the same preparation contain 1mM GABA. Using high performance liquid chromatography we measured the GABA level of the barnacle's median ocellar nerve, which contains four large photoreceptor axons as well as many smaller fibers. If the total amount of GABA we measured were distributed uniformly in only the photoreceptor axons, its concentration would be less than 2mM.

Because GABA and picrotoxin have little effect on transmission from photoreceptor to I-cell, and because the photoreceptor contains only a small amount of GABA, we conclude that the barnacle photoreceptor is unlikely to use GABA as its neurotransmitter.

21.5 LIGHT STIMULATED RELEASE OF SUBSTANCE P FROM THE ISOLATED PERFUSED RABBIT RETINA. C. Schenker* and S.E. Leeman. Dept. of Physiology, Harvard Medical School, Boston, MA 02115 and Dept. of Physiology, U.Mass.MC, Worcester, MA 01605.

The vertebrate retina contains several subpopulations of peptidergic amacrine cells and immunohistochemical evidence suggests that each different peptidergic amacrine cell also corresponds to a different morphological subtype (for review see Stell etal, TINS, Dec 1980). It is therefore likely that each of these different cells subserves a different as yet unknown function and each may be activated by a different pattern of environmental light/dark input. Assuming that a neuron releases its transmitter upon activation one can use transmitter release to monitor the activity of chemically identified neurons. In this sense we have used the isolated perfused rabbit retina to monitor the activity of substance P containing amacrine cells under different conditions of stimulation. Perfusates were collected at 2min intervals and assayed for immunoreactive substance P (I-SP) by radioimmunoassay. In the dark a small and variable baseline efflux can be detected. Upon stimulation with flashing light (50msec pulses, 3Hz) the I-SP levels rise significantly above baseline during the period of stimulation. The rate of I-SP release varied with light intensity. At the highest intensity of light used (500$\mu W/cm^2$) the mean increment over baseline ranged from 10-20 fmol/2min. With light stimuli of lower intensity smaller increments in the release of I-SP over baseline were obtained. The release of I-SP (increment over baseline) also varied in duration with the duration of the stimulating period. This interesting feature of the pattern of release of I-SP is particularly apparent at high photopic stimulation. Under these conditions and for periods of stimulation of 3-12 min the total response time is ca. 2.5x the period of stimulation.

At this point one can only speculate about the role played by the I-SP containing amacrine cells in the retina. The persistence of the release of I-SP after cessation of a high photopic stimulus could indicate that the I-SP containing amacrine cells participate in the formation of an after-image.

Supported in part by grant AM 16510 to SEL and NIH training grant T32 GM0725 (CS).

21.6 BEHAVIOR ELICITED IN RATS AFTER INTRATHECAL ADMINISTRATION OF PEPTIDES. G.L. Wilcox, J.L.K. Hylden and V.S. Seybold. Depts. of Pharmacology and Anatomy, Univ. of Minnesota Medical School, Minneapolis, MN 55455

Biochemical and immunohistochemical evidence indicates that substance P (SP) and somatostatin (SOM) are contained in small diameter primary afferent neurons. Excitatory or inhibitory effects observed in response to these substances in neurophysiological studies supports their role as neurotransmitters in primary afferent neurons. Given a putative role in somatosensation one would expect exogenous application of these substances to the spinal cord would elicit behavior consistent with perception of a somatosensory stimulus. This observation of behaviors in mice in response to intrathecal SP and SOM (Hylden and Wilcox, Brain Res. In Press) led us to study the effects of these peptides in rats.

Rats (300 g, male, Holtzman) were implanted with indwelling 8.5 cm PE-10 intrathecal catheters a minimum of 7 days prior to the study. Animals exhibiting impaired motor function were excluded from the study. Rats were conditioned for 30 min a day for 3 days to sound insulated operant chambers equipped with interior lights and a one-way mirror. Peptides (in a vehicle of 0.01M acetic acid in saline), vehicle or saline (5-10 µl, 10 µl/min) were infused with an infusion pump connected with the catheter via PE-10 tubing. The rats were observed blind in the closed chamber for 3 min before and 5-15 min after infusion. Each bite to the abdomen or hind quarter and each episode of hind limb scratching was counted as 1 behavioral event.

Intrathecal SP (20 ng-10 µg) elicited dose related biting and scratching, with a maximum of 29 ± 5 responses/5 min occurring at the highest dose. The duration of the response was 5 min, and the peak effect occurred at 2 min after the start of the infusion. Intrathecal SOM (1-20 µg) caused dose related hind limb scratch-ing only, with a maximum of 40 ± 8 responses/10 min. The duration of the response was at least 10 min, and the peak effect occurred 5-6 min after the start of the infusion. Infusion of vasoactive intestinal polypeptide (VIP, 10 µg) or neurotensin (10 µg) was without effect.

These results are the first demonstration of behavioral effects of SP and SOM at the spinal level in rats. The different composition of behaviors elicited by each of the peptides suggests that each mediates different aspects of somatosensation. The differences in their time courses are consistent with the ob-served differences in their distribution within the laminae of the dorsal horn. Supported by USPHS grants DA01933, T32GM07397, and RR05385 and by the PMAF.

22.1 NEURAL DISCHARGE PATTERNS AND MECHANORECEPTOR TRANSDUCTION. D. J. Barker, Dept. of Physiology, Texas College of Osteopathic Medicine/North Texas State Univ., Fort Worth, TX 76107.

The work reported here stems from an attempt to infer transfer functions of mechanoreceptors in raccoon glabrous skin from quantitative studies of stimulus-response relationships utilizing a variety of mechanical stimuli. A mechanical model of the skin and underlying receptors was derived from a subset of the data. The model consisted of a skin simulation and a simulated neuron, and was constructed under the assumption that the temporal pattern of firing of first-order neurons reflected the shape of the generator potential which in turn was related to the force actually applied to the receptor core. For any given stimulus input, the model would output the neural response pattern. The nature of the transduction process could be inferred from the model and predicted outcomes tested experimentally. The data presented here concern an experimental test of the model. The data from which the model was constructed was collected in 9 acute recording experiments under pentobarbital anesthesia. Responses of single neurons innervating the glabrous skin of the nose were recorded from the trigeminal ganglion. Stimuli were delivered with a feedback controlled axial displacement generator. Single unit data was digitized and analyzed by computer. Responses of 23 neurons to constant velocity trapezoidal stimuli were used to construct the simulated mechanoreceptors on an analog computer. Based on the temporal pattern of firing, two distinct mechanoreceptor response types were discernable: the first type (N=13), called IR, included both slowly and rapidly adapting units and showed an increasing rate of discharge to a constant velocity ramp. The second type (N=10), called DR, showed the opposite firing pattern, a decreasing rate of discharge, to the same stimulus. The model suggested that the effective stimulus for the IR neurons was a filtered first derivative of the applied stimulus, or velocity, while the effective stimulus for the DR neurons was a filtered second derivative, or acceleration. The IR and DR neurons also responded differently to sinusoidal stimulation with respect to the point in the sine wave cycle where the second spike appeared. This difference was predicted by the model. The model was then used to predict the response of DR neurons to a constant acceleration (parabolic waveform). The model suggested that DR neurons would respond with an IR pattern in response to constant acceleration. This finding was confirmed in two subsequent experiments. The results suggest that the model may be useful in describing the transduction process of glabrous skin mechanoreceptors in raccoon rhinarium. Further experiments in other species will be needed to determine the generality and utility of this mechanoreceptor model. Supported by USPHS Grants 5326 and 06225.

22.2 EFFERENT INPUT MODULATES THE PHYSIOLOGY OF THE LIMULUS LATERAL EYE. R. Batra*, L. Kass*, and R. B. Barlow, Jr. Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

Circadian efferent activity increases the sensitivity of the Limulus lateral eye at night. At least two receptor mechanisms mediate the increased sensitivity: structural changes that enhance quantum catch (absorbed photons/flash) and physiological changes that increase gain (optic nerve impulses/absorbed photon). We report here several quantitative studies of the circadian changes in the physiological properties of single ommatidia in the dark adapted Limulus eye. In each study light stimuli were delivered to single ommatidia via a 70-μm light pipe that optically isolated the receptor and thus minimized the effects of lateral inhibition. The nighttime state of the retina was simulated by shocking the optic nerve.

Frequency transfer characteristics (FTCs) of optic nerve responses were measured for various response rates. The FTCs at high impulse rates exhibit a circadian rhythm. Those at night for high rates resemble those during the day for low rates.

Temporal distribution of optic nerve impulses also exhibits a circadian rhythm. For a dark adapted eye during the day the optic nerve discharge is irregular at low response rates and becomes progressively more regular at high rates. At night an irregular distribution of nerve impulses also characterizes high discharge rates. Interval histograms of the impulse discharge in the absence of illumination and at low light intensities reveal a peak at short intervals (less than 100 ms) which is pronounced at night, but reduced or absent during the day. This peak may reflect a period of elevated excitation in the neighborhood of a nerve impulse.

Coding of light intensity depends both on level of illumination and time of day. Single photon absorptions may be more likely to generate multiple impulses at night than during the day--a possible mechanism for increasing photoreceptor gain.

22.3 SYSTEM IDENTIFICATION APPLIED TO THE VENTRAL PHOTORECEPTOR OF *LIMULUS*. N. A. Farahbakhsh* and E. R. Lewis. Electronics Research Laboratory, University of California, Berkeley, CA 94720.

An irreversible thermodynamic network approach proved to be particularly convenient and enlightening in the characterization of linear responses and steady-state light adaptation in photoreceptors, and led directly to hypotheses regarding the mechanisms underlying those phenomena (Fuortes, M.G.F and Hodgkin, A. L., J. Physiol., 172:239, 1964; Baylor, D.A., Hodgkin, A.L. and Lamb, T.D., J. Physiol., 242:759, 1974). The network approach capitalized on the fact that when linear small-signal behavior and nonlinear large-signal behavior (such as light adaptation) are combined in a single device, the linear behavior can be characterized in terms of the pole-zero distribution of the small-signal impulse response and the nonlinear behavior can be characterized in terms of the shifting of that distribution in response to large signals. Recently-developed, digital-computer algorithms make possible the identification of pole-zero distributions implied by small-signal impulse response data in a manner much more precise and refined than that available for the earlier photoreceptor studies. We are applying one such algorithm (Provencher, S.W., Biophys. J., 16:27, 1976) to the small-signal impulse response of the ventral photoreceptor of *Limulus polyphemus*, looking not only at the steady-state pole-zero distributions corresponding to various degrees of adaptation, but also at the dynamics of the distribution shifts. Since small-signal impulse-response pole-zero distributions generally are directly interpretable in terms of networks of irreversible thermodynamic processes, the shifting of those distributions should lead directly to insights regarding the mechanisms underlying phototransduction and light adaptation.

22.4 DROSOPHILA MUTATIONS DISPLAYING SEMIDOMINANT EFFECTS ON RHODOPSIN CONCENTRATIONS. N.J. Scavarda*, J.E. O'Tousa* and W.L. Pak. Dept. of Biol. Sci., Purdue Univ., W. Lafayette, In. 47906.

A series of EMS induced single-gene mutations that reduce the rhodopsin concentration in the compound eye of Drosophila have been isolated.These fall into five complementation groups (nina A, B, ..E). The prolonged depolarizing afterpotential (PDA), present in photoreceptors of wild type when a substantial amount of rhodopsin is photoconverted to metarhodopsin, is either absent or reduced in size in these mutants. The third chromosome mutation, ninaE, is of special interest because (1) its effect is specific to one particular class of photoreceptors and (2) at least one allele, ninaE^{P332} exhibits semidominant effects with respect to both the ERG phenotype and rhodopsin concentration. Heterozygous ninaE^{P332} flies less than 2 days old display an ERG phenotype indistinguishable from homozygous mutant flies. As the heterozygotes age from 3 to 14 days, their ERG phenotype becomes progressively more wild type. In vivo microspectrophotometric measurements of homozygous ninaE^{P332} individuals indicate rhodopsin levels of 0-1% of wild type levels. Heterozygous individuals up to 2 days of age contain approximately 20% of wild type levels, while 3-14 day old heterozygotes have approximately 55% of wild type levels. Optical studies indicate that ninaE^{P332} has normal rhabdomeres in all classes of photoreceptors. Complementation analysis and preliminary mapping results suggest, however, that ninaE^{P332} may be allelic to the previously described ora^{JK84} (outer rhabdomeres absent: Koenig and Merriam, 1975; Harris et al., 1976), which lacks the rhabdomeres in R1-6 photoreceptors. O'Farrell's two dimensional gel electrophoresis was used to examine eye protein patterns in ninaE mutant and wild type flies. Flies were exposed to various regimens of light and dark adaption prior to immersion in liquid nitrogen, acetone-dry ice dehydration and dissection of the ommatidial layer. Preliminary findings indicate that protein patterns from wild type, homozygous and heterozygous mutant flies are affected differently by different adaption regimens.

22.5 VISUAL INFORMATION GENERATES CONCURRENT DIFFERENT CODE TYPES. C. Torda.Res.Dpt.N.Y.C.PA.Training,N.Y.,N.Y.,10028(currently at Stanford University,P.O.Box 4866,Stanford,Calif.,94305).

Photic stimuli activate specific tunable photoreceptors in the retina.Intracellular recordings of bioelectric processes of the illuminated rods of Bufo marinus were performed during changing concentrations of Ca of the intermembrane space of the outer rod segment in presence of changing concentrations of cyclic GMP.The conclusion was reached that the illumination dependent membrane hyperpolarization is a Ca-dependent process. The illumination intensity dependent rapid changes of hyperpolarization is made possible by near-threshold maintenance of membrane potential by cGMP. Several mechanisms involved in regulation of the cyclic GMP concentration have been identified. The Ca-dependent hyperpolarization seems to be the first encoding of photic stimuli.Through automatically ongoing prevalently parallel processing at various loci between retina and CNS centers the photic energy is transformed to spatial frequency codes. The ascending retinal 2-D codes are transformed in the lateral genicular to 3-D interference patterns.- Part of the visual stimuli ascending through the superior colliculuc activate saccade programming neurons contained in the intermediate and deeper layers of SC.The saccade programming neurons transmit this code into the firing rate of phasic units located in the rostral zone of the paramedian pontine reticular formation. By integration of these phasic pulses the periabducens neurons generate the tonic components of the saccade. The rapid saccades contain and transmit a partial code of the visual stimulus that originated them. Since this code ascends in a 1 or 2-D form it is able to function as a fast allocator of visual memory traces deposited in the diffuse memory system. Interference with memory retrieval of severe modifications of rapid saccades have been studied through behavior and bioelectric potential measurements during the early phases of conditioning of the nictitating membrane reflex of the rabbit to an unusual visual stimulus.The results led to the above conclusions.--One of the pertinent steps of impulse processing by the CNS is the evaluation of their novelty value. This is accomplished by match-mismatch processing at various loci incl. the hippocampus. Bioelectric measurements of the activities of CA3,CA1 hippocampal pyramidal neurons and dentate fascia granule cells during various experimental conditions, incl. transsection of the perforate pathways and exposure to new and old stimuli suggest presence of significant differences in CA3 bioelectric potentials during new and old stimuli, and presence of two types of CA1 pyramidals. The CA1(1) type codes the impulses into a form destined for incorporation into higher memory systems.The CA1(2) type(stimulus modality specific cells) program a decision for selection of the executory mechanisms able to create a stimulus adequate response.Encoding from retina to CNS depends on Ca gating.

22.6 ADAPTATION IN HAIR CELLS: IN VITRO INTRACELLULAR RESPONSES AND IN VIVO MICROPHONIC POTENTIALS FROM A VESTIBULAR ORGAN. R. A. Eatock and A. J. Hudspeth. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Hair cells of the bullfrog sacculus adapt in vitro to prolonged stimuli, showing a progressive decline in the extracellularly recorded microphonic potential and in the intracellular receptor potential (Eatock, R. A., Corey, D. P., and Hudspeth, A. J., Soc. Neurosci. Abstr. 5: 19, 1979). The intracellular studies have been extended so that adaptation of the receptor potential and receptor current of single cells can be compared. We also report in vivo adaptation of the microphonic potential.

For intracellular recording the sacculus is dissected from the animal and placed in a saline-filled chamber. Single hair cells are stimulated by displacement of a probe inserted between the stereocilia and the kinocilium of the hair bundle; either the receptor potential or receptor current is then measured, the latter by a two-electrode voltage clamp. In response to a prolonged deflection of the hair bundle (step stimulus), the receptor current rises to a peak, then declines with a time course that is consistent with the rate of adaptation of the in vitro microphonic response. Adaptation occurs to stimulus steps toward or away from the kinocilium, of saturating amplitude or within the operating range of 2^{o} hair bundle bend. The decline in response results from a change in the cell's displacement-response curve, which relates displacement of the tip of the hair bundle to the membrane potential or current. During adaptation the curve shifts along the displacement axis without a significant loss in sensitivity. Although the form of the receptor potential during a step is complicated by voltage-sensitive conductances, the shift in the cell's displacement-response curve follows the same time course whether the response is measured as receptor potential or current. Adaptation has at least two phases with different rates, the early phase being considerably faster than the later. By 100 ms after the onset of a step, the response approaches a plateau level of 0-60% peak value.

The natural stimulus for the frog's sacculus is thought to be linear acceleration. For in vivo studies of adaptation, the animal is mounted on an electrodynamic shaker which delivers steps of constant acceleration. The microphonic potential recorded from the sacculus reveals adaptation to such stimuli at a rate similar to that of the in vitro preparation. Because the mechanical properties of the sacculus have not been described, the relative contributions of mechanical and receptor relaxations to the in vivo adaptation remain to be determined.

22.7 THE BASIS FOR RESPONSE COMPRESSION & SHIFT OF THE OPERATING CURVE DURING ROD LIGHT ADAPTATION. K. N. Leibovic, Biophysics, SUNY/B Buffalo, NY 14214

It is well known that rod photoreceptors, functioning over some six orders of magnitude of light intensity, operate only over some three orders of magnitude, at most; and during light adaptation the operating range shifts to higher light intensities, while at the same time the response amplitude is reduced.

The basis for these phenomena was studied with the aid of intracellular recording in rods of Bufo Marinus. The retina was isolated from dark adapted animals and the responses to 100 mS flashes were recorded in the presence of different light backgrounds and at different levels of bleaching.

We have confirmed that the response is reduced in amplitude and speeded up in time in the presence of a background. We have, furthermore, obtained evidence that the response amplitude is reduced, but that the response kinetics remain invariant after bleaching up to 90% or more of the pigment. Based on our model of the internal transmitter we have carefully analyzed the response waveform in the light of our results. On the assumption that the internal transmitter levels, controlled by the light flux, modulate the outer segment membrane conductance, we have shown that bleaching reduces the effect of light on the amount of transmitter either released or sequestered.

We conclude that bleaching

(1) reduces response amplitude

(2) raises the threshold and shifts the operating range through the mechanism which reduces the effect of light on active transmitter.

This work was done in Dr. Dowling's laboratory at Harvard during the author's leave from SUNY/B.

22.9 CHEMICAL SYNAPTIC TRANSMISSION BETWEEN TYPE I HAIR CELLS AND THE CALYX OF VESTIBULAR PRIMARY AFFERENTS.
D.A. Schessel* and S.M. Highstein. Dept. Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

The mode of synaptic transmission between the Type I hair cell and the caliform terminal of vestibular primary afferents was investigated in the lizard Calotes versicolar. Afferents at the base of the horizontal semicircular canal were impaled within 1-6 microns of the synapse with horseradish peroxidase (HRP) or KCl loaded glass microelectrodes. Resting potentials were typically-60mV and spontaneous action potentials (APs) occurred at either irregular or regular intervals (500-5ms). A calyx termination in the horizontal semicircular canal crista was demonstrated for single irregular afferents injected intracellularly with HRP. In irregular afferents a high activity level of sub-threshold synaptic events (0.5-5mV) typical of the chemical EPSPs seen in Type II hair cell-afferent synapses in other systems was demonstrated. APs in irregular afferents arose from these summated EPSPs. Local application of $CoCl_2$ (15-20uM) reversibly blocked these EPSPs. Application of tetrodotoxin (TTX) 1uM blocked APs leaving sub-threshold synaptic activity unchanged. In control or TTX experiments the frequency of EPSPs and resting potential were modulated by hot and cold caloric probes. Resting potential changed by $\pm$ 8mV. With cold stimulation the smallest EPSPs were in the range of 0.5mV. At "normal" or calorically increased release rates EPSP rising and falling phases were roughly symmetrical. At calorically reduced release rates EPSP decay times were prolonged. Further, bridge hyperpolarization augmented, and depolarization decreased EPSP amplitude. These findings are consistent with chemical transmission between Type I hair cells and the calyx of vestibular primary afferents. Release rate dependent EPSP decay times suggest that the calyx adapts its time constant to sample discrete (not summated) events at high levels of synaptic activity.

23.1 ULTRASTRUCTURE OF AGING AT NEUROMUSCULAR JUNCTIONS OF FAST AND SLOW MAMMALIAN MUSCLES. M. A. Fahim* and N. Robbins. Dept of Anatomy, Case Wes. Res. Univ., Sch. of Med., Cleveland, Ohio 44106.

An ultrastructural morphometric comparison was made between the motor endplates of aged (29 mo.) and young mature (7 mo.) male CBF-1 mice, in the extensor digitorium longus (EDL; fast twitch) and soleus (Sol; slow twitch) muscles. In old mice, nerve terminals of both EDL and Sol exhibited pronounced loss of synaptic vesicles and increases in numbers of microtubules, neurofilaments and smooth endoplasmic reticulum compared with young mice. These changes were particularly severe in the Sol where postsynaptic folds devoid of nerve terminals of Schwann cells were occasionally observed. Also, axoplasmic fragmentation with envelopment of axon terminals by Schwann cells was observed in several aged terminals, as was the extension of Schwann cells into synaptic clefts, resembling the early stages of denervation. Mitochondrial area (as a % of nerve terminal area) was lower in all aged nerve terminals than in young terminals. Abnormal mitochondria, when present in axon terminals, were associated with similar abnormalities in the more proximal axon. Synaptic clefts were widened in old animals and the junctional folds of aged terminals were more branched with frequent vacuole-like vesicles in the subsarcolemmal zone. Lipofuchsin deposition was prominent within the muscle fibers of aged Sol and EDL muscles but other muscle structures were not qualitatively different from young mice. Thus, the major ultrastructural changes associated with age in this study were presynaptic, although minor postsynaptic changes were also evident. These findings contrast with corresponding physiological data (Robbins & Kelly, abst. this vol.) indicating no deficit in short-term evoked transmitter release at mouse neuromuscular junctions. Therefore, profound morphologic changes observed with aging are either not rate-limiting or are compensated by other factors.
Supported by NIA grant AG-00795.

23.2 EVOKED TRANSMITTER RELEASE IN YOUNG AND OLD MOUSE NEUROMUSCULAR JUNCTIONS. N.Robbins and S.S. Kelly* (SPON:J.P. Conomy). Dept. Anat., Case Western Res. Schl. Med., Cleveland, OH 44106.

Profound ultrastructural changes occur at aging neuromuscular junctions (e.g. Gutmann et al,J. Physiol. 219:331,1971; Fujisawa, Exp. Gerontol. 11:43,,1976; Fahim and Robbins, this vol.). In order to determine whether such changes imply functional deficit, and whether muscles with different activity patterns show differential age changes in synaptic function, neuromuscular transmission was examined in 3 muscle groups of young (11-13 mo) and old (34-35 mo) CBF-1 male mice. The muscles were: extensor digitorum longus (EDL), a phasic muscle; soleus (SOL), a tonic muscle, and the diaphragm (DIAPH), a rhythmically active muscle.

Action potential voltage threshold and resting membrane potential were unchanged with age in all 3 muscle groups. Endplate potentials (EPPs) were measured in curarized (2.6 uM) preparations stimulated at 2 and 20 Hz. In old EDL and SOL, initial EPP amplitudes were increased 122% and 93%, respectively, even though miniature-EPP (MEPP) amplitudes in uncurarized preparations were unchanged. During trains of 50 EPPs, plateau EPP amplitude was also increased by about 100% (EDL) or 67% (SOL). The ratio, $(\text{mean EPP amplitude})^2/(\text{EPP variance})$, showed the same proportional age-related increase as EPP amplitudes. Thus, the relative safety factor of transmission was markedly increased, most probably through an increase in average quantal content.

By contrast, under the same conditions, the DIAPH showed no change in EPP amplitude or safety factor with age, even though MEPP amplitude was increased 54%. Thus, DIAPH ages differently from limb muscles, and the two limb muscles with different activity patterns, show similar age changes in evoked release. Further, none of the aging muscles examined showed deficits in synaptic output during short trains. In old EDL and SOL junctions, where number of synaptic vesicles is reduced (Fahim and Robbins, op. cit.), compensatory mechanisms such as increased rate of vesicle recycling may serve to maintain transmitter output.

23.3 RAPID REORGANIZATION OF SYNAPSES ON MATURE PURKINJE CELLS. S. Chen* and D.E. Hillman (SPON: John Pearson). Dept. Physiol. and Biophys., New York Univ. Med. Ctr., 550 First Avenue, New York, N.Y. 10016.

Purkinje cells in adult rats responded to partial deafferentation of parallel fibers by alteration in spine size and synaptic profile contact lengths (Hillman & Chen, Soc. Neurosci. Abst 6:822, 1980). Observation of lesioned parallel fiber beams for early changes revealed reinnervation of Purkinje cell spines before degenerating boutons were removed. In addition, new synapses developed and new spines formed. Since reactive synaptogenesis could not completely compensate for the massive loss of afferents, synaptic contact size increased inversely to the deficit in afferents.

Adult rats were anesthetized and the cranium opened over the cerebellar vermis. Parallel fiber beams were sectioned twice at a 1 mm interval by inserting a microknife through the dura and transverse penetration of the folial crest. Animals were allowed to survive for 2, 4, 6, 9, 14, 21, 24 and 48 hours and were then perfused with phosphate-buffer paraformaldehyde and glutaraldehyde. Sagittal slices of the folia were postfixed with a osmium-ferrocyanide mixture and block stained with 2% uranyl acetate.

Ultrastructural examination of thin sections revealed that degeneration of parallel fiber shafts and boutons began by 4 hours. At 6 hours the shafts were fragmented and phagocytized by glia; while at 9 hours, dense boutons showed stripping from the spines. Other spines remained shrouded by ghosts of parallel fiber plasmalemmae that were sandwiched between the glia and the spine. At this time, the frequency of dual parallel fiber synapses on spines increased significantly over control preparations indicating marked synaptogenesis on original spines. Within 10 hours one parallel fiber bouton was normal and the other showed degeneration. Each normal bouton formed a new synaptic site that was adjacent to the original contact. Later (24 hours) numerous spines contacted two normal boutons. New parallel fiber connections also formed with spiny dendritic shafts and new spines emerged. These primitive contacts developed on dendritic shafts not shrouded by glia. Numerous coated vesicles were observed in dendrites near the reactive zone. As the synaptic site differentiated, synaptic vesicles accumulated at the synaptic site. Other changes included complex spine formation and small side projections of parallel fibers. Supported by USPHS Grants HD10934 and NS13742.

23.4 BILATERAL CIRCUITRY REMODELING IN THE DENTATE GYRUS OF YOUNG ADULT VERSUS AGED RATS AFTER A UNILATERAL ENTORHINAL LESION, S.F. Hoff, S.W. Scheff, C.W. Cotman. Dept. Psychobiology, University of California at Irvine, Irvine, CA 92717.

Partial deafferentation of the hippocampal formation after a unilateral entorhinal lesion brings about the reinnervation of the denervated zones by the remaining afferent imputs. We have studied the reinnervation in denervated zones and also the concurrent response in zones not directed denervated by the lesion in aged vs young adult animals. Unilateral electrolytic lesions of the entorhinal cortex were placed in 90 day old and 2 year old male Sprague-Dawley rats. These animals were allowed to survive for 2,4,10,60,120 or 180+ days post-lesion and were then sacrificed and prepared for electron microscopy. Over the time course synaptic profiles were quantified on electron microscopic montages of the dentate molecular layer, which was divided into inner (innervated by the commissural/associational system), middle and outer (innervated by the entorhinal cortex) zones. In all, 71,700 normal and degenerating synaptic profiles were counted over 130,000 square microns of tissue.

Within the denervated outer two-thirds of the ipsilateral molecular layer, approximately 85-90% of all synapses are lost after an entorhinal lesion. Synaptic replacement begins very quickly in young adult rats, but has a slower onset in aged rats. Both age groups attain their pre-lesion synaptic density by the end of the time course. The delayed onset of reinnervation in the aged rats appears to correspond to the slower removal of degeneration by glial cells (astrocytes). This response may involve the elevated glucocorticoid levels observed in aged rats, which cause astrocytic hypertrophy and stabilize lysosomal membranes, thus impeding the clearance of degeneration debris. It is interesting to note that within the ipsilateral inner molecular layer (non-denervated) both age groups demonstrate a non-degenerative loss and reacquisition of 20% of their synapses. Within the contralateral molecular layer, however, the young adult rats demonstrate a 37% loss of synapses after an entorhinal lesion, with the majority replaced by the end of the time course; aged rats do not show a significant change in synaptic density over the same time course. Our data show that aged rats have a diminished capacity to respond to a lesion as demonstrated by a slower rate of reinnervation in denervated zones and a lack of response in the contralateral molecular layer, possibly resulting from an age-related stabilization of neuronal circuitry and subsequent decrease in sensitivity to impaired circuitry activity. Supported by NIA grant AG00538 and NIMH grant MH19691.

23.5 MODIFICATIONS OF GRANULE CELL DENDRITES DENERVATED BY ENTORHINAL LESION. A. Caceres* and O. Steward (SPON: E. Rubel). Dept. of Neurosurgery, Univ. of Virginia, Sch. of Med., Charlottesville VA 22908.

Following lesions of the entorhinal cortex (EC), spine density on granule cells of the dentate gyrus falls 30% below control levels, and then increases to normal values with the reinnervation of the dendrites (Parnavelas et al., Nature:248,71, 1974). Although this and other aspects of the response of the dentate granule cell to partial deafferentation have been extensively studied, there are still no data about the effect of EC lesions on the organization of dendritic fields. This study presents some qualitative observations about such effects.

Adult male rats were sacrificed at 2,4,8,10,14,30 and 60 days after unilateral lesions of the EC. Tissue including the mid-septotemporal portions of the hippocampus was immersed in fixative overnight, impregnated by the rapid Golgi method and embedded in celloidin. Sections were cut at 180 μm and camera lucida drawings were made of granule cells at a final magnification of 580x. A minimum of 15 granule cells was analyzed for each survival time; granule cells of the contralateral hippocampus and from non-lesioned animals served as controls.

Dendritic fields of normal granule cells are highly polarized, with a characteristic inverted cone appearance. To obtain this shape dendrites arch rapidly after leaving the granule cell layer and with successive branching extend laterally as they ascend through the molecular layer; the majority of them end in close proximity to the outer boundaries of the molecular layer. Following EC lesions, dendritic fields of granule cells are narrower and dendrites display an abnormal morphology. The dendrites appear normal in the inner molecular layer; however, when they reach the denervated zone they suddenly change direction and follow a course that tends to be parallel to the granule cell layer. Moreover, the dendrites only occasionally reach the more distal portions of the molecular layer. In addition, there is a progressive dendritic distortion more evident in the outer molecular layer; this includes an apparent loss in dendritic mass, varicosities, and sudden reductions in dendritic diameter. These abnormalities are most evident between 8 and 14 days postlesion. By 30 and 60 days postlesion distortions are no longer evident although some cells still display abnormal dendritic fields.

The early postoperative changes may be related to the physical disruption of synaptic contacts, and/or the elimination of the presynaptic input either in terms of bioelectrical and/or trophic activity. The normal appearance of dendrites at long postlesion intervals may reflect dendritic remodeling with reinnervation.

23.6 THE EFFECTS OF COMPLEX OR ISOLATED ENVIRONMENTS ON CORTICAL DENDRITES OF MIDDLE-AGED RATS. Edward J. Green*, Barbara E. Schlumpf*, and William T. Greenough. Dept. of Psychol. & Neur. & Behav. Biol. Program, Univ. IL, Urbana-Champaign 61820.

Previous reports have described alterations in dendritic branching subsequent to housing rats in complex or isolated environments at weaning or as young adults. Studies involving older organisms have demonstrated the continuing neural responsiveness of the brain to experience, as reflected in gross morphological and biochemical measures. Recent evidence suggests that some neurons retain the capacity to grow and form new connections well into adulthood, and possibly, senescence. In the present experiment, female hooded rats (retired breeders) were housed two per cage until 15 months of age. They were then placed in either a complex toy-filled group environment (EC) with other rats of similar age or housed singly in standard laboratory cages (IC). After 45 days of differential housing their brains were removed and stained with the Golgi-Cox method. Each brain was evaluated independently for completeness of stain. Coronal sections (150μm) through visual cortex were taken, and 15 Layer IV stellate and Layer III pyramidal neurons from each animal were traced at 500x using a semiautomatic computer-microscope system. All data collection was done on coded slides which did not reveal the treatment of individual animals. The number of intersections of dendrites with concentric spheres spaced at 20μm intervals were used to estimate dendritic density. Preliminary statistical analyses reveal that stellate and pyramidal neurons sampled from EC rats each exhibited more total dendritic material than neurons from IC rats ($p<.02$ for both populations; two tailed Mann Whitney U test). Complete sphere analyses, as well as the results of a dendritic branching analysis will be presented. These results are the first demonstration of alterations in dendritic structure induced by differential environments in middle-aged rats.

23.7 EFFECTS OF HANDEDNESS TRAINING ON DENDRITIC BRANCHING OF NEURONS IN FORELIMB AREA OF RAT MOTOR CORTEX. John R. Larson* and William T. Greenough. Depts. Psychol. & Anat. Sci. & Neur. & Behav. Biol. Program., Univ. IL, Urbana-Champaign 61820.

Prior work has shown altered dendritic patterns in adult rat occipital cortex following extensive maze training (Greenough et al., Behav. Neur. Biol., 26:287, 1979; Chang & Greenough, Soc. Neurosc. Abst., 1490, 1978). The handedness reversal paradigm allows investigation of neurons in a region known from lesion and electrophysiological studies to be involved in performance of reaching (Peterson & Devine, J. Comp. Physiol. Psychol., 56:752, 1963; Dolbakyan, et al., Neuroscience, 2:73, 1977). Unilateral handedness training also provides the advantage of a within subject control, since hemispheres opposite trained and non-trained paws can be compared.

Male rats (70-80 days of age) were tested for initial paw preference in reaching into a 1 cm dia. tube for food, then subjected to one of three training procedures: training on the initially non-preferred paw (reversal), training on the preferred paw (practice), or training both paws (alternation) in 33 sessions over 15 days. An additional group of control rats was tested for preference but not trained. Posttraining tests indicated reversal training effectively altered paw preference while other training strengthened original preference. Golgi-Cox stained Layer V pyramidal neurons (the major efferent cells) of the forelimb region of motor cortex (located by electrical stimulation) in each hemisphere were traced with a computer-based tracking system. Dendritic fields were quantified by counting intersections of dendrites with concentric spheres centered at the cell body.

In the Reversal group, distal (greater than 250μm) regions of apical dendrites of neurons in the hemisphere projecting to the trained paw had more extensive dendrites than those in the hemisphere projecting to the nontrained paw. In the Practice group similar but smaller effects were observed. Control and Alternation rats had no consistent interhemispheric differences relative to paw preference in apical dendritic branching, although there was a tendency for Alternation rats to have more extensive basal dendritic branching in neurons in the hemisphere projecting to the preferred paw. Tests of handedness on tasks other than reaching for food indicated that handedness in the rat is not a very general trait and that training effects on handedness were task-specific.

23.8 CORRELATIVE HISTOCHEMICAL AND QUANTITATIVE IMMUNOCHEMICAL STUDIES OF SUBSTANCE P RECOVERY AFTER DORSAL RHIZOTOMY. A. Tessler, B.T. Himes,* R. Artymyshyn,* M. Murray, M.E. Goldberger. Departments of Neurology and Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Using the unlabeled antibody (PAP) technique, we have previously shown that deafferentation of the cat spinal cord by complete unilateral lumbosacral dorsal rhizotomy produces a reduction in substance P (SP) immunoreactivity in the deafferented dorsal horn at 10 days, which is followed by a partial return of SP in the dorsal horn. In order to establish the amount of the return we have used RIA to determine the amount of SP in the spinal cord of cats 10 and 30 days after unilateral lumbosacral dorsal rhizotomy. At 10 days the amount of SP immunoreactivity in the deafferented dorsal horn is reduced to 78% SP/mg protein of that found in the intact dorsal horn (N=5); at 30 days the reduction is 59% (N=6). Thus the 30 day dorsal horn contains 19% more than 10 day dorsal horn ($p<0.05$). Ventral horn immunoreactivity is not reduced at either time as determined by histochemical or immunochemical methods. Thus the results obtained by the two methods are roughly parallel, and we have used the immunohistochemical method in an attempt to locate the source of recovery of SP after deafferentation. This return is unaffected by lesions which destroy: 1) contralateral dorsal root afferents; 2) ventral root afferents; 3) ascending or descending fibers; 4) commissural fibers. These observations suggest that the restoration of SP reaction product depends on SP-containing interneurons located within lumbar spinal cord. In order to test the hypothesis that interneurons are responsible for the return, we have injected kainic acid, a neurotoxic agent that preferentially destroys nerve cell bodies, into the intact and chronically deafferented sides of the spinal cord and examined the SP reaction product. On the chronically deafferented side, where all neurons appear to have been destroyed, SP reaction product is virtually abolished from the dorsal horn at 10d post-injection. When all neurons are absent on the afferented side, SP immunoreactivity is only slightly reduced. These findings are consistent with the view that SP-containing interneurons contribute a small amount of the total SP present in the dorsal horn normally and that this amount increases in the dorsal horn chronically deafferented by dorsal rhizotomy.

23.9 TRANSSYNAPTIC REGULATION OF TYROSINE HYDROXYLASE AND DOPAMINE SYNTHESIS IN THE OLFACTORY BULB. T. Kawano*, H. Baker, F. L. Margolis and T. H. Joh, Roche Inst. of Mol. Biol., Nutley, N. J. 07110 and Lab. Neurobiology, Cornell Univ. Med. Coll. New York, N. Y. 10021

Lesions of the olfactory epithelium produce profound decreases in the content of the afferent neuron components, olfactory marker protein and carnosine, as well as a decrease in the size of the olfactory bulb (OB). To investigate the transsynaptic consequences of disruption of OB afferent input we examined both dopamine (DA) and norepinephrine (NE) metabolism. OB NE is restricted to terminals of centrifugal origin while DA is found in intrinsic neurons and their processes. Following permanent destruction of the olfactory epithelium by intranasal irrigation with 0.17M $ZnSO_4$ in mouse or surgical lesion in rat, DA and DOPAC but not NE (expressed as pmoles/gm tissue (mean ± SEM) in table below) levels fall dramatically. Parallel decreases in DA content and immunocytochemically demonstrable TH staining occur. With Triton X-100 lesions of the mouse olfactory epithelium only a temporary OB deafferentation is produced since stem cell replacement of receptor cells can occur. As with $ZnSO_4$ lesions DA and DOPAC but not NE levels initially decrease reaching lowest levels at 2-3 weeks and returning to prelesion levels between 7 and 8 weeks. Staining for TH initially decreases and then returns suggesting that these intrinsic neurons did not degenerate.

Treatment	NE	DA	DOPAC	TH Staining
None	1755 ± 90	1141 ± 161	421 ± 37	3+
$ZnSO_4$ 21d	2388 ± 222	381 ± 85	96 ± 16	±
Triton 21d	1674 ± 171	485 ± 51	139 ± 16	1+
Triton 49d	1971 ± 239	1227 ± 248	515 ± 114	3+
None (Rat)	1976 ± 72	330 ± 5	218 ± 28	3+
Lesion (Rat 28d)	2558 ± 294	101 ± 33	55 ± 22	±

The decreases in DA but not NE levels as well as the loss of TH staining in the periglomerular neurons indicate that the majority of OB TH is contained within these intrinsic DA neurons and not in NE systems. Support for the continued presence of these neurons in deafferented animals was indicated by the demonstration of DA accumulation in OB following L-DOPA administration to reserpinized control and lesioned animals even though TH staining in these animals was minimal. These studies provide evidence for reversible transsynaptic regulation of dopamine metabolism possibly through regulation of the expression of the TH gene in periglomerular DA neurons. (Supported in part by grants - NIMH-MH33190 and NHLBI-HL18974).

23.10 COMPARISON OF THREE TIME COURSES OF DEGENERATION AND REINNERVATION AFTER VARYING DEGREES OF DEAFFERENTATION IN THE LATERAL SEPTAL NUCLEUS OF THE ADULT RAT. P.M. Field* and G. Raisman*. (SPON. F. Ebner). Laboratory of Neurobiology, National Institute for Medical Research, Mill Hill, London NW7 1AA, England.

The hippocampus projects through the fimbria to the septum of the same side and also to a lesser extent to a discrete dorsolateral quadrant of the septum of the opposite side. The numbers of degenerating and non-degenerating synapses were counted, using the electron microscope, in this dorso-lateral part of the septum after contralateral, ipsilateral and simultaneous bilateral lesions of the fimbria at various survival times from one day to over a year.

The numbers of degenerating terminals in the septum reached a maximum at 2 to 3 days after unilateral section of the fimbria and at this time the sum of the degeneration on the ipsilateral side plus the degeneration on the contralateral side was equal to that caused by a bilateral lesion. At longer survivals there was a marked difference in the rate at which synaptic changes occurred after the bilateral lesion as compared with the unilateral lesion. From 4-7 days after a bilateral lesion the number of degenerating synapses in the septum continued to increase whereas during this period after the unilateral lesion it began to fall. At its maximum value, the amount of degeneration caused by the bilateral lesion greatly exceeded the sum of the maximum amounts of degeneration after the two individual lesions.

We propose that among the population of terminals the degree of asynchrony between the rate of degeneration and its removal (by astroglial phagocytosis) is such that at no time after a single lesion can all the degenerating terminals be seen. A model is proposed which would estimate the total amounts of degeneration due to the unilateral lesions.

The removal of degeneration after the bilateral lesion is delayed by several weeks as compared with the unilateral lesion. This may be due to the time required to activate more astrocytes or to the fact that the origin of the reinnervating terminals after bilateral lesions is different from that after unilateral lesions.

23.11 A REEVALUATION OF INTRASPINAL SPROUTING OF PRIMARY AFFERENTS. B.E. Rodin*, S. Sampogna* and L. Kruger. Depts. of Anatomy and Anesthesiology and Ahmanson Lab. of BRI, UCLA, L.A., CA 90024.

Intact dorsal root fibers have been reported to form anomalous projections within the spinal cord after surrounding dorsal roots have been severed. These findings are difficult to interpret because of technical problems in previous studies with metallic impregnation of degenerating and normal fibers and cord distortion following rhizotomy. The present study constitutes an attempt to reexamine denervation-induced sprouting in spinal cord by labeling the normal axonal trajectory of sciatic afferents with horseradish peroxidase (HRP) at various intervals following partial denervation.

The central projection of the L4, L5 component of sciatic nerve was examined in rats that had been denervated five days (acute), two wks., one, two or three mos. previously. Unilateral dorsal root ganglionectomies were performed when animals were 60-70 days of age; the L4 or L5 ganglion was left intact, and 2-6 surrounding ganglia were excised. Five days before animals were sacrificed, the sciatic nerve on the denervated side was exposed, severed and desheathed at its proximal cut-end. HRP crystals were applied to the nerve and six days later, the spared ganglion and spinal cord processed for visualization of HRP.

The central projection of sciatic afferents was the same following acute and chronic denervation. There was no evidence that the rostro-caudal trajectory of sciatic afferents had expanded during the various post-denervation intervals, and the location and density of reaction product within the spinal segments that normally receive these afferents did not substantially differ in acute and chronic preparations. In a few animals that survived at least eight wks. following ganglionectomy, the lateral projection in laminae I, II of low lumbar segments was denser and more widespread (5-7u) than in acute preparations. This was not a consistent finding even among animals in the same experimental condition, and probably reflects lateral displacement of afferents in dorsal horn with the dorsal column shrinkage that accompanies long-term survival after ganglionectomy. This was evidenced by the fact that, in these exceptional cases, the medial projection in lamina II was sparser than usual.

These results with rats do not support previous findings with cats that the central projection of primary somatosensory afferents is altered considerably following chronic partial denervation. Although these conflicting results might be attributable to species differences in plasticity, it is possible that previous evidence for sprouting in spinal cord is an artifact of the methods used to demonstrate it.

23.12 Development of long-term potentiation in the in vitro goldfish optic tectum. D. Lewis, T. Teyler, and V. Shashoua. Neurobiology Program, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272, and Dept. of Biological Chemistry, Harvard Medical School, Belmont, MA 02178.

We have previously reported methods for maintaining in vitro explants of goldfish optic tecta in an incubation medium which approximates goldfish CSF and a 99/1% O_2/CO_2 atmosphere (Teyler, Lewis, Shashoua, and Brogna. Neuroscience Abstracts 6 (1980) 294). Stable responses can be maintained for up to 8h. Stimulation of the severed optic nerve stump gives rise to a short-latency population fiber volley and a longer latency negative, monosynaptic response centering in the stratum opticum. Stimulation with tetanic frequencies from 0.2 - 50 Hz with an equal number of stimuli gives an inverted U function of monosynaptic response amplitude vs. frequency. Tetanus frequencies of 1 Hz for 100 sec and 5 Hz for 20 sec resulted in a significant increase in the amplitude of the monosynaptic response above control values of 1/60 sec stimulation. An increased response of approximately 30% is seen at 30 min and 1h posttetanus. This potentiation lasts up to 3h. Tetanus frequencies below and above 1 and 5 Hz showed no significant potentiation. Higher frequencies of 33 and 50 Hz, frequently used to produce LTP in the mammalian hippocampus, produced response depression in the optic tectum. Hippocampal LTP is seen within 10 min while the potentiation of the goldfish tectum takes longer to develop, 30 min at the earliest. Since the goldfish is a poikilotherm its metabolism is slower than the homeothermic mammals; therefore, LTP may take longer to develop. These results demonstrate that the phenomenon of long-term potentiation may not be unique to the mammalian hippocampus.

23.13 CALCIUM INDUCED LONG-TERM POTENTIATION IN THE HIPPOCAMPUS. R.W. Turner*, K.G. Baimbridge* & J.J. Miller (SPON: J.A. Pearson). Department of Physiology, University of British Columbia, Vancouver, Canada V6T 1W5.

The effects of a transient increase in extracellular calcium concentration on the Schaeffer-commissural evoked excitatory post-synaptic potential (EPSP) and population spike responses of CA1 pyramidal neurones was investigated using the rat in vitro hippocampal slice preparation. Brief exposure of slices (5-10 min) to twice the normal concentration of calcium (2mM) induced a marked potentiation of both the EPSP and population spike that could persist for at least 3 hours. The total intracellular calcium content of individual slices, measured by atomic absorption spectrophotometry, was significantly increased for at least 1 hour following return to the control medium. No long-term changes were observed in either the presynaptic fiber volley or antidromically evoked CA1 population spike, indicating that this potentiation could not be attributed to an increase in the number of fibers activated or a generalized increase in cellular excitability. The response of CA1 pyramidal neurones to the iontophoretic application of L-glutamate in the apical dendritic zone was also unaffected after exposure to the high calcium perfusate, indicating a lack of alteration in excitability restricted to this region of the synaptic input.

These data indicate that brief exposure of in vitro hippocampal slices to a high extracellular calcium concentration results in a long-term increase in synaptic efficacy which is similar in many respects to long term potentiation induced by tetanic stimulation of hippocampal excitatory afferents. The results further suggest that the mechanisms underlying calcium induced long-term potentiation may reside in presynaptic terminals and involve an enhanced transmitter release.

23.14 RESIDUAL CEREBELLOTHALAMIC TERMINAL FIELDS FOLLOWING HEMISPHERECTOMY IN THE CAT. Ch. E. Olmstead, J.P. McAllister* II, J.R. Villablanca and F. Gomez* MRRC and Depts. of Psychiatry and Anatomy, UCLA School of Medicine, Los Angeles, CA 90024.

As part of a study of recovery of function in animals with uni- and bilateral removals of the cerebral hemispheres we are examining possible sites for interactive remodeling in subcortical areas where projections of the deep cerebellar nuclei overlap with both corticofugal and corticopetal neurons. The areas selected were the ventrolateral complex of the thalamus (VL), red nucleus, pontine nuclear groups, the cuneiform nucleus and inferior olivary complex. We report here preliminary results from injections of ^{3}H amino acids into the nucleus interpositus, both anterior (INA) and posterior (INP), and the subsequent mapping of projections to the VL. Intact (N=7) and hemispherectomized (HEMI:N=8) adult cats received unilateral injections of ^{3}H leucine-proline (0.2µl; specific activity of 42 and 10 Ci/mmole, respectively) into either the INA or INP on the right side. The HEMIs had undergone ablation of the left hemisphere at least 6 months earlier. This included all of the neocortex along with the hippocampus and striatum. Five days after the injections the animals were perfused intracardially. Serial frozen sections were cut at 50µ throughout the entire brain and processed for routine autoradiography. In intact cats amino acids injected into an area restricted to the antero-medial 1/3 of INP were transported to the rostral lateral portions of the contralateral VL. Five HEMIs receiving injections into that same portion of INP exhibited terminal fields in lateral portions of the contralateral VL. These terminals were patchy and appeared qualitatively identical to those seen in intact animals. Cytoarchitecturally, the regions containing these terminals were conspicuously gliotic and devoid of thalamocortical relay neurons. Parts of what appeared to be neuronal cytoplasm were occasionally observed, but neuronal nuclei were rarely seen. Two of these 5 animals showed additional terminal labeling in partially gliotic regions of the nucleus ventralis medialis and in 3 HEMIs sparse terminal fields were also observed in both normal and gliotic regions of the parafasicularis, central lateral, anterior pretectal and posterior nuclei. We are now trying to ascertain whether the projections from INP, but not INA, may extend their normal terminal fields in the magnocellular portion of the red nucleus to innervate more of its parvocellular division. These results indicate that the INP projections to the VL persist despite degeneration of the thalamocortical neurons, suggest that the site of the terminals is not directly upon such neurons, and might reflect attempts at reorganization in response to cortical ablation.

23.15 A MODEL OF ALCOHOL-INDUCED BRAIN ATROPHY IN THE RAT. R. L. Wierimaa*, F. A. Holloway, J. A. Devenport*, and L. D. Devenport (SPON: D. M. Toth). Dept. of Psychiatry and Behavioral Science, Univ. of Okla. Health Sciences Center, Oklahoma City, OK 73190.

Cerebral atrophy (ventricular expansion, sulcal widening, and decreased density) is frequently associated with chronic excessive ethanol ingestion (e.g., Golden et al., Science 211:508, 1981). To begin unraveling the events intervening between alcohol and brain, we have developed an animal model. In so doing we have tested the possibility that adrenal steroids mediate the atrophic effects of chronic alcohol exposure.

Basing our methods on previous research (Devenport, Behav. Neur. Biol. 27:218, 1979; Devenport et al., Neurosci. Abstr. 6:382, 1981), rats were either adrenalectomized or sham-operated at 44 days of age. Half were maintained in separate cages in an alcohol inhalation chamber (modeled after Rogers et al., Behav. Neur. Biol. 27:466, 1979) where the atmosphere was adjusted to achieve continuous blood alcohol concentrations (BACs) of .2 mg percent (w/v). The rest were housed similarly, but their atmosphere was without ethanol. These conditions were in force across ages 46-65 days, after which blood samples were taken and, following anesthetic overdose, brains were removed.

Sham-operated rats required a considerably greater atmospheric concentration of ethanol (23.2 - 24.9 mg/l) than did adrenalectomized animals (16 - 19.3 mg/l) to reach the same BAC. Alcohol exposure reduced brain weights and volumes relative to controls. Body weights were unchanged. In keeping with our previous findings, adrenalectomy increased brain size above that of sham-operates. Unexpectedly, however, alcohol exerted a stronger effect in adrenalectomized rats than in sham-operates, suggesting that adrenocorticoids may play a protective role against the action of ethanol on gross brain structure.

23.16 TIME AND EXPERIENCE ALTER BEHAVIOR AND HIPPOCAMPAL NEUROCHEMISTRY AFTER DAMAGE TO THE CA3 SUBFIELD. G.E. Handelmann,* D.S. Olton, T.L. O'Donohue,* C.J. Cummins, M.C. Beinfeld,* and D.M. Jacobowitz. Dept. of Psychol., The Johns Hopkins Univ., Balto., MD; Lab. of Clinical Science, NIMH, and Lab. Neurochemistry, NINCDS, Bethesda, MD 20205.

Bilateral microinjections of kainic acid into the hippocampal subfield in rats caused a destruction of the CA3 pyramidal cells and an impairment in the ability to perform a spatial maze task, with eventual recovery of behavioral function. Previous experiments suggested that the recovery of function may be mediated by alterations in the distribution or function of the various hippocampal pathways. In this experiment, alterations in hippocampal pathways were investigated by measuring neurotransmitters or their synthetic enzymes in the hippocampus and related structures at various times after loss of the CA3 pyramidal cells. In addition, the extent to which these changes in neurotransmitter levels were influenced by experience on the spatial maze task was investigated. Neurochemical assays for choline acetyltransferase (ChAT), glutamic acid decarboxylase (GAD), glutamate, norepinephrine (NE), and cholecystokinin (CCK) were performed on ten dissected regions of the hippocampal system.

The analysis indicated that a number of alterations in hippocampal neurotransmitter systems occurred either immediately after the surgery or at longer survival times, and that some of these changes were influenced by test experience. ChAT and GAD activities were unchanged immediately after surgery but declined in many regions over time in untested rats. Test experience prevented the decline. Glutamate levels decreased in the CA3 region and its projection areas, and remained low. NE levels were lowered in some regions immediately after surgery, but they increased with time to above control levels. Test experience increased the levels even more. CCK levels were lowered in some regions immediately after surgery. Test experience increased CCK in some regions, including the CA1 subfield and the entorhinal cortex.

These findings suggest that test experience prevents a decline in septohippocampal activity after loss of the CA3 cells, and influences a number of neurochemical systems which may modulate hippocampal activity. These mechanisms may be responsible for the behavioral recovery of function.

23.17 INDUCED COLLATERAL SPROUTING OF HIPPOCAMPAL 5-HT FIBERS;A QUANTITATIONAL HRP STUDY IN THE RAT. F.C.Zhou* and E.C.Azmitia ; Department of Anatomy, Mount Sinai,CUNY,New York,N.Y. 10029.(SPON/Shriver)

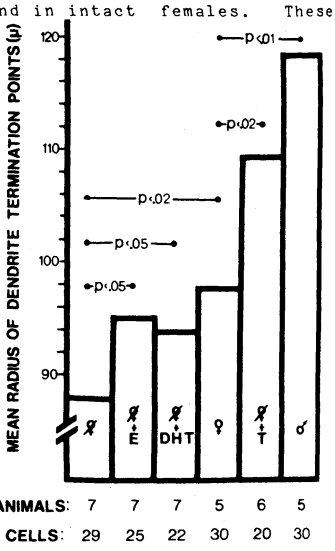
Serotonergic fibers from the median raphe nucleus (MR) use two pathways to innervate the hippocampus (HIPP)-a cingulum bundle(CB) and fornix-fimbria(FF) route (Azmitia and Segal,J.Comp.Neurol.179:641,1978). Removal of the CB 5-HT fibers results in structural and functional changes which recover after several weeks.This was attributed to FF 5-HT fibers undergoing collateral sprouting (Azmitia Nature 274;374, 1978). We here present evidence for reorganization of the raphe cells projecting to the hipp after 5,7-DHT destruction of CB-5HT fibers.

30 female rats were placed into four groups; uninjected control,sham injected,5,7-DHT (5 ugm in 400nl/min) microinjection into CB, and 5,7-DHT into CB followed by injection into FF (6.25ug in 500nl) 2 days before injection of HRP (Sigma VI,100nl of 10% solution) into dorsal hipp.These rats were perfused with 2.5% glutaraldehyde at various post-operated times (3,21,42 days).The HRP was visualized by TMB Method.

The organization of the raphe cells efferent to the dorsal hipp using the CB was different from those using the FF in that neurons located in the interfascicular part of the dorsal raphe nucleus (IF-DRN) used the CB route.The total number of neurons projecting to the dorsal hipp decreased by 58% and 95% 3 days following CB and CB-FF 5,7-DHT injections respectively.There was a significant increase in HRP labeled neurons in the MR 21 and 42 days compared to the 3 day group after CB injections (a 2% decrease and 38% increase compared to sham injected),but no change after CB-FF 5,7-DHT.The labeled cells were also seen to increase in size in the long survival CB group.No cells were localized in the IF-DRN in this CB group. These results indicate that CB-5HT fibers do not regenerate into the D-HIPP, but FF-5HT fibers increase their terminal territory by collateral sprouting in response to homotypic dennervation.Supported by NSF-grant BNS-79-06474.

23.18 GONADAL STEROID ADMINISTRATION CAUSES NEURONAL GROWTH IN A SONG CENTER OF ADULT FEMALE CANARIES. Timothy J. DeVoogd and Fernando Nottebohm. The Rockefeller University, New York, N.Y. 10021

Female canaries were ovariectomized at two weeks of age. At one year, they received Silastic implants containing estradiol (E), dihydrotestosterone (DHT), testosterone (T), or nothing (N). During the ensuing four weeks, the T-treated birds began to sing. After the four week period, all birds were sacrificed and their brains were stained by a rapid Golgi technique. The dendritic trees of cells in nucleus robustus archistriatalis, a telencephalic song control nucleus, were quantified using a computer-microscope system. The length, number of branches and dispersion of branches away from the cell body of dendrites from the brains of E- and DHT-treated birds were significantly increased over those of the N birds, yielding a pattern similar to that found in intact females. These dendritic parameters in the T-treated birds were significantly greater than in the E, DHT and intact female birds, approximating normal male dimensions. The figure to the right illustrates these changes for the mean distance from dendrite termination points to the cell soma.



Thus, gonadal steroids can cause neuronal growth in adult animals, and this growth is associated with acquisition of a species typical behavior.

Supported by PHS grants F32 NS05911 and 5R01 MH18343 and by Rockefeller Foundation grant RF 70095.

23.19 LESION-INDUCED CHANGES IN PDH ACTIVITY AND CALCIUM TRANSPORT IN HIPPOCAMPAL MITOCHONDRIA. Kessler, M.*, Baudry, M., Fuchs, J., Arst, D.*, and Lynch, G. Department of Psychobiology, University of California, Irvine, California 92717

Lesions of the perforant path have been widely used as a tool to study the phenomenon of sprouting and reactive synaptogenesis in the hippocampal formation. However little is known of the sequence of biochemical events which initiates and regulates sprouting. It has been shown that another form of hippocampal plasticity is accompanied by a transitory change in the phosphorylation of the α-subunit of pyruvate dehydrogenase (PDH). The demonstration of a link between this enzyme and the regulation of mitochondrial calcium transport has prompted the suggestion that hippocampal afferent fibers may exert a strong influence on calcium regulation in their targets. In light of this, we decided to investigate the effects of denervation on PDH activity and mitochondrial calcium transport in hippocampus before and during the period of sprouting.

Following unilateral entorhinal cortex lesions, the pyruvate-supported calcium transport is significantly decreased as soon as 1 day post-lesion whereas the succinate- and ATP-supported transport are not affected until about 3 days post-lesion. The pyruvate-supported calcium transport is maximally depressed at 5 days postlesion; it shows a 45% decrease as compared to the unoperated contralateral side, and remains significantly lower as long as 6 months post-lesion. There is also a progressive, although less marked, decrease in the succinate-supported calcium transport. The ATP-supported transport remains largely unchanged. The changes in pyruvate-supported calcium transport are highly correlated with the reductions in PDH activity.

These data support the idea that pre-synaptic elements influence PDH activity and calcium regulation in the hippocampus; the mechanisms by which this is accomplished are not known but it seems reasonable to assume that the phosphorylation and/or dephosphorylation of the alpha regulatory subunit of PDH is involved. The relationship of these denervation-induced disturbances to sprouting is unclear but a loss of calcium-buffering ability could serve to mobilize growth responses in both axons and dendrites. Finally, since both high frequency synaptic stimulation and deafferentation appear to affect PDH, it is possible that long-term potentiation and sprouting both employ, at some stage in their development, similar cellular processes.

Supported by Grant NSF-BNS76-17370-05.

23.20 GROWTH, DIFFERENTIATION, AND CONNECTIVITY OF EMBRYONIC NEURAL TISSUE TRANSPLANTED INTO THE CEREBELLUM OF THE RAT. B. H. HALLAS. New York College of Osteopathic Medicine, Old Westbury, NY 11568.

Mammalian embryonic neural tissue was transplanted into the cerebellum or forebrain of various age host rats to study the development, growth, differentiation and connectivity of the transplants. Neocortical tissue obtained from either 15-day or 18-day-old embryos was transplanted into the cerebellum or forebrain of 30-day-old host animals and the host animals were sacrificed in a developmental sequence, 1,2,3,4,5,8,15,30, and 90 days after transplantation. In this study, differential patterns of growth were compared between transplants placed in the cerebellum and those in the forebrain and between the two ages of neocortical tissue.

In the second phase of this study, embryonic neocortical tissue obtained from 15-day or 18-day-old embryos was transplanted into either the cerebellum or forebrain of 5-, 10-, 15-, 20-, 25-, 30-, 35-, or 180-day-old rats. All transplants were found to have survived and differentiated with the largest transplants observed in the 5-day-old hosts. In older host animals, the size of the 15-day transplants were found to be progressively smaller while all 18-day embryonic transplants grew to approximately the same size. In all age host animals, the transplants exhibited fully differentiated neurons identical to their in vivo counterparts and in no host animal was there evidence of a neuroglial scar separating transplant from the host brain.

In a third group of 15-day or adult hosts, 15-day or 18-day-old embryonic neocortical tissue was transplanted into the right cerebellar hemisphere. Ninety days after transplantation, either a 20% solution of Horseradish peroxidase was injected into the transplants or electrolytic lesions were made in the contralateral spinal cord, inferior olivary nuclei, or pontine nuclei and the resulting tissue processed for degenerating fibers by the Fink-Heimer stain. In additional animals, lesions were made in the transplants directly and the host brain processed for Fink-Heimer staining for the study of the efferents of the transplants. Through utilization of these two techniques, it was demonstrated that the neocortical transplants had established connections with the host brain, thus providing evidence that the embryonic neocortical transplants had become an integral part of the host's brain.

23.21 RECOVERY OF ALTERNATION BEHAVIOR AFTER ENTORHINAL CORTEX LESIONS. Thomas M. Reeves, Douglas C. Smith and Robert N. Holdefer. Dept. of Psychology, Southern Illinois Univ., Carbondale, IL 62901.

Previous investigators have found evidence that recovery of alternation performance in a T-maze, following unilateral entorhinal cortex (EC) lesions, is correlated with the time course of collateral sprouting of fibers from the intact entorhinal area (Loesche and Steward, 1977). A subsequent attempt to confirm the correlation of recovery of alternation behavior and sprouting did not find an impairment after unilateral EC lesions (Ramirez, 1979).

Since the report of Loesche and Steward (1977) is the only demonstration of a behavioral recovery that is correlated with collateral sprouting in the adult mammalian brain, the discrepancy between their data and those of Ramirez (1979) is a critical issue which we have attempted to resolve.

Fifty-six male Sprague-Dawley rats learned to alternate in a T-maze for food reward after being reduced to 80% ad lib weight. Eighteen rats with unilateral EC lesions were tested after a 3-day recovery period. Their performance on postoperative days 3-8 was significantly below their own preoperative levels (t-values ranged from 2.70,$p<.01$ to 6.20,$p<.0005$). By postoperative day 9, performance was at pre-lesion levels. Rats permitted a 10-day recovery period did not differ from their preoperative level by the second day of post-lesion testing. Thus, recovery was not facilitated by experience in the maze during the post-lesion interval, day 3-8. This was consistent with the data of Loesche and Steward (1977), as were the following findings: 1) animals with bilateral EC lesions showed permanent deficits (56-days) even with daily postoperative training, 2) secondary EC lesions, in rats which sustained a previous unilateral EC lesion, caused permanent deficits, and 3) transections of the commissure thought to carry the sprouting fibers (dorsal psalterium) resulted in permanent alternation deficits.

These behavioral data are consistent with a collateral sprouting interpretation. Preliminary data regarding the electrophysiological correlates of the time course of sprouting and return of alternation performance within individual unilateral EC-lesioned animals will be presented.

Supported by NSF grant BNS 8002251 to D.C.S.

23.22 TRANSIENT AND LONG-TERM POTENTIATION IN THE NEOCORTEX OF THE RAT. D.A. Wilson* and R.J. Racine. Dept. of Psychology, McMaster Univ., Hamilton, Ont., Canada L8S 4K1.

Post-tetanic potentiation (PTP) and long-term potentiation (LTP) were examined in the neocortex following high-frequency stimulation of the corpus callosum in both anesthetized and unanesthetized adult rats.

Biphasic stimulation (0.1 msec each pulse, 50-1000 uA intensity) of callosal fibers in one hemisphere produced biphasic (positive-negative) or monophasic (negative) post-synaptic responses recorded near the surface of the contralateral hemisphere. These waveforms reportedly reflect the bimodal nature of callosal terminations in the neocortex (Grafstein, B., J. Neurophysiol., 22;504,1959), with surface-positivity corresponding to activation of terminations in deeper layers, and surface-negativity corresponding to activation of terminations in superficial layers.

Test pulses producing sub-maximal responses (40-50% of maximum on I/O curve) were presented at 0.1 Hz, preceding and following high-frequency (400 Hz, 100 msec) trains applied to the callosum. The surface-negativity showed marked PTP and LTP following tetani. The positivity was generally unaffected. The short-term effects were similar to those reported by Clare, Landau, and Bishop (EEG and Clin. Neurophysiol.,13:21,1961) in the cat callosal-neocortical system. A more complete analysis of PTP revealed a decay process best described as an exponential function with time constants similar to those reported in the hippocampus (McNaughton, B., Brain Res.,199:1,1980) and frog n.m.j. (Magleby, K. & Zengel, J., J. Physiol.,257:449,1976).

High intensity tetani produced LTP, lasting longer than one hour at levels up to 100%. The phenomena of LTP threshold and saturation were found to be similar to those reported for the perforant path-granule cell synapse (McNaughton, B., Douglas, R., & Goddard, G., Brain Res.,157:2771978).

Further, preliminary investigation into the ontogeny of LTP in the callosal-neocortical system of the developing rat suggests that LTP cannot be consistently produced prior to the third post-natal week; a period of synapse proliferation and myelin formation.

These findings suggest that LTP of post-synaptic responses is not specific to the hippocampal formation, but rather may be a more generalized phenomenon of forebrain pathways.

23.23 FUNCTIONAL PLASTICITY IN OPTIC CENTERS OF ADULT RAT - A 2DG STUDY. A.W. Toga, D.A. Stein* and R.C. Collins Wash. Univ. Sch. Med., St. Louis, MO 63110

Unilateral enucleation during infancy results in changes in the number and pattern of ipsilateral retinofugal projections in several rodents. Recent evidence suggests that functional changes can also be induced in the visual system of the adult (Chalupa and Henderson, Brain Res., 192, 1980). We have examined this issue further by measuring the functional metabolic response of the visual system of adult pigmented rats at different times following monocular enucleation.

Glucose utilization was quantitatively measured using the ^{14}C-2 deoxyglucose autoradiographic method (2DG). All subjects were fasted for 24 hours prior to the experiment and prepared and tested in ambient laboratory illumination. Femoral arterial and venous catheters were inserted and one eye enucleated under halothane anesthesia. Animals in the immediate post enucleation group (N=5) were given 2DG 4 hours later when animals were alert and mobile. The second group (N=5) had their catheters inserted and were given 2DG 30 days following monocular enucleation.

For all subjects the metabolic rates of optic centers on the side contralateral to the intact eye were higher than on the side contralateral to the enucleated eye . Visual structures contralateral to the intact eye did not significantly increase their metabolic rates. Glucose utilization in all deafferented visual structures, however, was greater when measured 30 days following monocular enucleation compared to rates measured on the same day. The largest increases were observed in the superior colliculus, particularly the lateral aspects (.90 versus .60 µmoles/gm/min.) and the lateral geniculate nuclei (.94 versus .73 µmoles/gm/min.). Nucleus lateralis posterior and pretectum also had greater metabolic rates 30 days after enucleation compared to immediatley post enucleation. Metabolic increases were also observed in visual cortex, but these changes occurred on both sides of brain - 1.00 µmoles/gm/min. to 1.12 on the deafferented side and 1.08 to 1.22 µmoles/gm/min. on the stimulated side. Comparing the asymmetry (stimulated/enucleated) in metabolic rates of each structure shows that immediately following eye removal there are large differences between the right and left sides (up to 47% in caudal aspects of the S.C.). Whereas after 30 days these right left differences become attenuated (26% difference in caudal S.C.).

These metabolic data further indicate that functional anatomic changes ("plasticity") occur in the adult visual system following monocular enucleation.

23.24 SLOW WAVE FIELD POTENTIALS IN THE RAT BRAIN DURING THE ONSET OF PUBERTY. J.F. Masken and R.J. Morgan, Dept. of Physiology and Biophysics, Colo. State Univ., Ft. Collins, CO 80523.

Cross-correlation analysis was successfully applied in this study to evaluate changes in the relationships between the AMY, POA, and ARC with respect to slow wave field potentials (signals) recorded simultaneously from these regions of the brain. Recordings were made during the onset of puberty and in the course of the estrous cycle. The correlation of slow wave activity between the AMY and POA was, in general, higher than that between the AMY and ARC and POA and ARC. The correlation between slow wave field potentials between the AMY and ARC was the lowest. This was the case in both the prepubertal and post-pubertal state. The correlation for all three combinations, i.e. AMY-POA, AMY-ARC, and POA-ARC, was lower in the prepubertal state than in the post-pubertal state. The change in the level of correlation appeared gradually and before vaginal opening in the case of AMY-ARC, and POA-ARC, but the correlation for AMY-POA increased rather abruptly and right at the first estrous. Changes in delay times (the length of tme it takes a signal in one area to appear in another, e.g. from AMY to POA), direction of signal traffic (in which area did the signal originate), and total activity of the three areas were also apparent from the analysis. There were also changes, particularly in the direction of signal flow, that could be of significance with respect to daily fluctuation in Gn-RH and LH release.

24.1 SYNAPTIC EFFICACY AT SINGLY- AND DUALLY-INNERVATED NEUROMUSCULAR JUNCTIONS IN THE CUTANEOUS PECTORIS MUSCLE OF THE FROG. Y.-M. Yao* & J. N. Weakly. Dept. of Physiology, Univ. North Carolina School of Medicine, Chapel Hill, N. C. 27514.

A portion of the end-plates in some amphibian skeletal muscle fibers receives the terminations of two or more motor axons. Mallart & co-workers (1,2), using the pectoral muscle of Xenopus laevis, reported that in cases where two different axons form synaptic contacts at the same end-plate, the efficacy (e.p.p. amplitude) of each component synapse is less than that of singly-innervated junctions. The reduced synaptic efficacy was attributed to reduced transmitter release from the individual nerve terminals in dually-innervated junctions. Moreover, the mean amount of transmitter released by both axons together and, hence, the sum of e.p.p. amplitudes at compound junctions was significantly smaller than at singly-innervated end-plates. It was suggested that the reduction in individual and aggregate synaptic efficacy could be explained by postulating mutual inhibitory influences operating between closely spaced nerve endings.

To test the generality of this hypothesis, we examined the e.p.p. amplitudes of 452 singly- and 85 dually-innervated end-plates in 10 lightly-curarized cutaneous pectoris muscles of R. pipiens. Resting membrane potential and input resistance were not significantly different in singly- and dually-innervated fibers.

In agreement with the work in Xenopus, the e.p.p. produced by each nerve ending alone in the dually-innervated junctions was significantly smaller ($p < 0.05$ by two-tailed t-test, df=8) than the average e.p.p. at singly-innervated junctions. However, in the present experiments, the sum of the two e.p.p.s at dually-innervated sites was not significantly less ($p > 0.05$ by two-tailed t-test, df=8) than the average e.p.p. amplitude at singly-innervated junctions. The total e.p.p. amplitude at dual junctions was 0.89 ± 0.44 (mean ± S.D.) of the average single junction e.p.p. The finding that the sum of the e.p.p. amplitudes from dual end-plates is equal to the e.p.p. amplitude at singly-innervated synapses is consistent with the idea that two (or perhaps more) axons may compete without mutual inhibitory influences for a limited synaptic space on each cutaneous pectoris muscle fiber.

24.2 CORRELATED ANATOMY AND ELECTROPHYSIOLOGY DURING SYNAPSE ELIMINATION IN FROG MUSCLE. K. Morrison-Graham. UCLA School of Med., Dept. of Physiol., Ahmanson Lab. of Neurobiology, and Jerry Lewis Neuromuscular Research Center, Los Angeles, CA. 90024.

Transient multiple innervation has been well documented, both anatomically and electrophysiologically, in developing skeletal muscle. However, it is not certain if all the inputs to one synaptic site respond to nerve stimulation and if they remain functional until the time of their elimination. This question was addressed in the cutaneous pectoris muscle of recently post-metamorphic bullfrogs (R. catesbiana) by correlating the number of components in the endplate potential with the number of NBT-stained axonal processes entering the same synaptic site. During the first three post-metamorphic weeks, when most synapse elimination occurs (Letinsky & Morrison-Graham, J. Neurocytol. 9: 321, 1980), no evidence for morphologically intact but functionally silent processes was found. Rather, the percentage of the total terminal length occupied by different axons at one site corresponded to the percentage of neurotransmitter released as measured by endplate potential amplitude or quantal content.

The endplates were also classified morphologically by the appearance of their pre-terminal axons and terminal arborizations. In general, thin pre-terminal axons formed small synaptic contacts which either shared the same synaptic gutter with thicker axon terminals or formed independent varicose contacts, and contributed less than 20% to the total nerve-evoked release. Similarly, when pre-terminal axons were the same thickness and their terminal expanses looked similar, their amounts of evoked release were comparable. Endplates were also found which had morphological characteristics intermediate to these two categories; these latter endplates had inputs with intermediate percentages of evoked release.

Staining for ACh receptors (using Rhodamine-labeled α-BGT) and/or AChE activity was also done on identified endplates which had been characterized electrophysiologically and anatomically. These post-synaptic components were well localized under the regions of thickened NBT in all endplates examined. However, small patches of post-synaptic membrane with ACh receptors and AChE activity, devoid of overlying nerve processes, were also found near NBT-stained varicosities formed by thin pre-terminal axons during the period of synapse elimination (Morrison-Graham, Soc. for Neurosci. Abstr. 6: 567, 1980).

These results suggest that axonal processes undergoing elimination may decrease their terminal arborization gradually while continuing to release transmitter in proportion to the amount of pre-synaptic membrane they contribute to the synaptic site.

24.3 PERSISTENCE OF MULTIPLE INNERVATION IN MOUSE MUSCLES PARALYSED NEONATALLY WITH BOTULINUM TOXIN. W. G. Hopkins*, M. C. Brown* and R. J. Keynes* (SPON: A. D. Smith).
University Lab. of Physiology, Oxford OX1 3PT, U.K.

The effect of botulinum toxin-induced paralysis on the elimination of neonatal multiple innervation of muscle fibers has been investigated using silver-stained, whole mount preparations of mouse muscles, the gluteus maximus and tensor fasciae latae. Toxin was injected into the muscles of 6 day old mice, when 20-50% of fibers are multiply innervated. Contralateral control muscles were excised at this time, and paralysed muscles on succeeding days up to one week later. It was found that the percentage of fibers contacted focally by more than one axon in the control and blocked muscles did not differ significantly throughout the period of block. Therefore there was probably neither retraction nor regrowth of axons in the blocked muscles.

The long-term effect of paralysis was investigated following injection of toxin at age 0-4 days. Focal multiple innervation assayed electrophysiologically and histologically persisted for at least several months in tensor fasciae latae, and there was also a stable ectopic innervation of gluteus muscle fibers from sprouted spindle motor axons. It is possible that myelination stabilises and thereby prevents elimination of these excess focal and ectopic axons.

24.4 NEONATAL UNILATERAL ADRENALECTOMY AFFECTS THE NORMAL PATTERN AND DENSITY OF INNERVATION OF THE REMAINING ADRENAL MEDULLA. L. L. Ross, A. J. Smolen and J. Cherry*. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

During the first month of life there is a striking reorganization of the pattern of preganglionic innervation to the rat adrenal medulla. Up to 3 weeks of age, the adrenal medulla is innervated by neurons located both ipsilaterally and contralaterally in the zona intermedia of the spinal cord. It is not known if some of these neurons project bilaterally to both adrenals. By the fourth week, there is a marked reduction in the total number of neurons projecting to the ipsilateral adrenal and a near-total loss of the neurons projecting to the contralateral adrenal. In a previous study, we demonstrated the importance of supraspinal input to the regulation of the development of the normal pattern of innervation of the adrenal medulla. An additional regulatory role may be played by interadrenal interaction mediated by the bilaterally-projecting neurons which may exist in the neonatal rat spinal cord. The present study was designed to assess the extent of such interaction by examining the effect of neonatal unilateral adrenalectomy on the development of innervation to the intact adrenal medulla.

On postnatal day 3 the right adrenals of rat pups were removed. On days 15 and 25 counts were made of the numbers of cells and synapses in the left adrenal medullas of some animals while HRP was injected into the left adrenals of other animals. On day 15 in the adrenalectomized animals the numbers of HRP labeled neurons in the spinal cord were reduced when compared with normal 15 day animals. Neurons on both sides of the cord were affected, but the contralaterally projecting neurons were more severely affected. By day 25 both experimental and control animals were the same with respect to number and distribution of labeled neurons. The number of synapses in the medulla of the adrenalectomized rat was 50% less than that of the controls at 15 days and 40% less at 25 days.

Thus, unilateral adrenalectomy results in a premature reduction of the total number of labeled neurons which innervate the remaining adrenal. The loss is particularly severe amongst the contralaterally projecting neurons. This preganglionic neuron loss is accompanied by a marked loss of the numbers of synapses in the remaining adrenal medulla. These findings support the concept of bilaterally projecting preganglionic neurons in the neonatal animal.

24.5 AUTOMATED ANALYSIS OF SYNAPTIC SIZE AND NUMBER IN THE CEREBELLUM. D.E. Hillman, M. Chujo* and S. Chen*. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Recording of synaptic profiles from thin sections was accomplished by software for an interface between a scanning-transmission electron microscope and a computer (Hillman, et al SEM/I, pp. 125-139, 1980, Chicago, IL). Algorithms were implemented through software for analysis of shape, size and number of synapses. The method greatly improved the reliability and rate at which data could be collected. Software allowed arbitrary positioning of the scanning beam by feedback to the computer from the scanning detector. First, the beam was directed in a low resolution raster mode for locating dense objects as defined by a density threshold that was either manually or automatically set. Once located, the boundary of the objects were extracted as two-dimensional coordinates. The boundary data for each object was immediately processed for orientation, size and shape. Profiles of synaptic contacts on Purkinje cell spines were enhanced by staining and used for length determination. The computer defined the synaptic length along the contact curvature and accumulated the data for average profile length. Average contact area was estimated from profile length as diameter for a disc and then corrected by applying a factor from reconstruction of serial sections. The number of synapses was determined by stereological means utilizing a normalizing procedure to correct for varied shapes and distributions of profiles in thin sections. The sampling probe consisted of equally spaced parallel lines that were analyzed for the number of crosses made with the boundary of circles representing the area of each synaptic profile. Sampling bias due to patterns in the distribution of synapses was eliminated by random redistribution of these circles. Analysis of cerebellar tissue from controls, developmental conditions (such as malnutrition and genetic mutations) and deafferentation in the adult revealed marked increases in Purkinje cell spine contact size that was reciprocal to the deficit in the number of synapses on Purkinje cell spines.

24.6 PARTIAL DEAFFERENTATION, SPROUTING AND REINNERVATION IN THE CRAYFISH CNS. R.J. Strandburg. Dept. of Psychology, UCLA, Los Angeles, CA 90024.

It has been amply demonstrated that following partial deafferentation, intact neurons will sprout to fill denervated muscle and CNS target cells. Moreover, in muscle tissue, regenerating axons can reinnervate fibers with sprouted inputs either by functionally replacing the sprouted terminals or by coexisting with them. Reinnervation by previous inputs is, however, not necessarily complete. In this study, the sprouting of sensory inputs to an identified target cell in the crayfish CNS (sixth abdominal ganglion) following partial deafferentation was examined, and the ability of regenerating axons to reinnervate that cell, to "silence" sprouted inputs, and/or to be excluded by them was assessed.

Specifically, the response of interneuron A (A) to water current activation of its third root (R3) sensory inputs was examined under a variety of experimental conditions. At the outset of each condition, all other (non-R3) sensory inputs to A were removed. In the first group, the efficacy of R3 inputs was tested immediately after this partial deafferentation to establish a baseline response in A. In the second group, 12 weeks elapse before testing to permit sprouting of R3 afferents. In the third condition, several roots are directed to the ganglion 12 weeks after the initial deafferentation, and an additional 12 weeks elapse permitting these roots to regenerate into the ganglion either to (1) reinnervate A and possibly displace or repress sprouted inputs or (2) be excluded from A by the sprouted terminals. Finally, a fourth group was run in which the regenerating roots were directed to the ganglion at the time of the initial deafferentation thus placing the regenerating axons and the sprouting collaterals in more equal competition.

It was found that, by physiological criteria, both sprouting and reinnervation by regenerating roots took place. Sprouting was most successful when unchallenged by regeneration. Regeneration was most successful when (presumed) sprouting had not previously occurred. Once sprouting had occurred, it largely survived subsequent invasion by regenerating afferents, though it appeared to be somewhat reduced by their return.

24.7 METAMORPHOSIS AND DESCENDING INPUT TO LUMBAR SPINAL CORD: AN INVESTIGATION USING TWO RETROGRADE TRACERS IN RANA CATESBEIANA. Cynthia J. Forehand and Paul B. Farel. Neurobiol. Prog. and Dept. Physiol., Sch. Med., Univ. N. Carolina, Chapel Hill, N.C. 27514.

The metamorphosis of tadpole to frog is accompanied by a dramatic change in the environmental challenges the animal must face. For example, the transition from aquatic to terrestrial life entails behavioral and electrophysiological changes in the mode of locomotion (Stehouwer and Farel, Neurosci. Abstr., 7, 1981). Whether such changes in the way the animal responds to its environment result from growth of new neural pathways or from a remodeling of existing connections during metamorphosis is unknown. A previous investigation (Forehand and Farel, Neurosci. Abstr., 6: 847, 1980) used the retrograde transport of injected horseradish peroxidase (HRP) to show that the same supraspinal areas project to lumbar spinal cord in tadpoles and juvenile frogs. In the present study, two temporally spaced retrograde tracers, HRP and tritiated, enzymatically inactive HRP (^{3}H-APO-HRP, New England Nuclear), were used to demonstrate that at least some projections to lumbar spinal cord arise from the same cells before and after metamorphosis.

An initial study showed that retrogradely transported HRP remains demonstrable in the neurons of tadpoles or juveniles after 30-40 day survival periods, although the number of labeled cells decreases. In the present study, HRP was injected into the lumbar spinal cords of Stage XVII Rana catesbeiana tadpoles and, after metamorphosis, ^{3}H-APO-HRP was injected into the lumbar cords of the same animals. Four days later, the animals were sacrificed and 15-µm cryostat sections of the brainstems were processed for HRP histochemistry and ^{3}H autoradiography.

Neurons that contained both HRP and ^{3}H-APO-HRP were unambiguously identified in the cerebellar nucleus, vestibular nucleus, brainstem reticular formation and rostral spinal cord. In addition to these doubly labeled cells, many neurons contained only the ^{3}H-APO-HRP, but relatively few neurons contained HRP alone. This result is expected because the HRP label diminishes with long survival times. However, nearly all cells in which HRP could still be histochemically demonstrated also contained ^{3}H-APO-HRP, indicating that many of the neurons which project to lumbar spinal cord in tadpoles retain this projection through metamorphosis.

These findings are consistent with the idea that long descending tracts are conserved through metamorphosis. The possibility thus remains that remodeling of existing neuronal connections occurs to mediate behavioral adaptations to terrestrial life.

24.8 CHANGES IN STRUCTURE AND CABLE PROPERTIES OF DENDRITIC TREES FOLLOWING AXOTOMY OF LAMPREY SPINAL CORD NEURONS. B. N. Christensen and M. D. Christensen*. Dept. of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

It has been reported previously that following spinal cord transection, the dendritic trees of lamprey reticulospinal neurons are structurally altered (Cohen, M.J. In: Simpler Networks and Behavior, 1976, p. 45). Individual dendrites decrease in length and there is an absolute loss of finer branches. We have investigated the dendritic tree response following axotomy of giant interneurons in the lamprey spinal cord. Our emphasis has been on a quantitative investigation of changes in physical structure and electrotonic length of dendritic trees and the effect of these structural changes on monosynaptic transmission.

At different survival times following spinal cord hemi- or transection, voltage transients produced by a brief current pulse applied to the soma through an intracellular microelectrode were recorded from individual interneurons. These transients were analyzed to determine the cable properties of the dendrites using the Rall model. The cells were then injected with HRP for later structural analysis. Labeled cells were reconstructed photographically from 10 µm thick transverse sections, and dendritic lengths and and diameters measured from photographic enlargements using a digitizing tablet. We found a marked change in the structural organization of the dendritic trees within 1 week following axotomy. These changes include loss of fine dendritic branches and shortening of major dendrites. These findings were correlated with a decrease in the electrotonic length of individual dendrites.

25.1 DEVELOPMENTAL PROTEIN MALNUTRITION IN RATS: ADAPTIVE CHANGES IN BRAIN INDOLEAMINE METABOLISM IN SMALL-FOR-GESTATIONAL-AGE OFFSPRING. Maravene Miller, Rachelle Hasson* and Oscar Resnick*. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Small-for-gestational-age (SGA) pups (> 20% reductions in body weights) were born to dams fed a very low protein diet (6% casein) during a 5 week pregravid period, pregnancy and lactation. The severe in utero malnutrition caused the SGA pups to show marked elevations for brain serotonin (5-HT), 5-hydroxyindoleacetic acid (5-HIAA), and tryptophan (TRP) at birth (Table below) compared to pups from dams maintained on a normal diet (25% casein) during the same time interval. After birth, the severe postnatal nutritional lacks caused the SGA pups to show an almost total failure of growth (> 60% reductions in body weights) which is characteristic of the onset of infantile marasmus. These lactational deficits were also responsible for the 40-180% greater than normal increases in brain indoleamine metabolism of the SGA-marasmic pups for days 3-21. Interestingly, these increases in brain 5-HT, 5-HIAA and TRP levels for the SGA-marasmic pups at birth and older ages were markedly higher (47-236%) than those reported by our group (Exp. Neur., 57: 142, 1977) for a milder form of developmental malnutrition in rats (use of an 8% casein diet). These data indicate that the adaptive responses shown by the developing brain to pre- and postnatal malnutrition are highly dependent not only on the duration of the protein lacks in the dam but also on the severity of these protein inadequacies.

Day of Birth (Mean ± S.E.)

25.2 SENSORIMOTOR EFFECTS OF PERINATAL DIETARY HISTIDINE SUPPLEMENTATION IN RATS, J. M. Bell*, P. K. Lundberg*, S. Finger and S. Henkel*. Dept. of Psych., Washington Univ., St. Louis, MO. 63130.

Lundberg (Diss. Abstr., 1981) has found that offspring of rat dams exposed to a 1.3% l-histidine-supplemented diet performed differently from control animals on certain neonatal reflexive behaviors. Negative geotaxis performance was superior to controls while swimming development was delayed. Additionally, tail flick latency data suggested that weanlings fed the histidine-supplemented diet showed an augmented analgesic response after morphine administration. Natelson, Janocko, and Jacoby (1981) have reported that rats fed tryptophan-deficient diets developed more gastric erosions after immobilization. Since histamine is a potent stimulus for gastric acid secretion, dietary histidine enrichment may predispose the animals to a greater incidence of stress-induced gastric erosions. Thus the goal of the present study was to compare the effects of pre-weaning (PRE), post-weaning (POST) or pre- and post-weaning (PRE/POST) dietary histidine supplementation upon various reflexive behaviors, open field behavior, analgesic response to morphine administration and the incidence of gastric erosions following restraint in the cold. Dams were randomly assigned to a 1.3% l-histidine-enriched diet (Nutritional Biochemicals) or a control diet 2 weeks prior to mating. Litters were sexed, weighed, and culled to 10 pups on postnatal days 1 (PN1), PN7, 14 and 21. Behavioral testing included surface righting (PN3-7), negative geotaxis development (PN6-12), pivoting activity (PN7, 9, 11), swimming development (PN6-20), and a battery of tests to assess neurological dysfunction (PN30). Histidine-exposed offspring (PRE and PRE/POST) again exhibited negative geotaxis latencies faster than those of controls and POST groups. Swimming development was also delayed. The mean percentage analgesia achieved in the PRE/POST group (59%) was greater than that of the PRE (11.5%) or POST-weaning groups (20.5%). The assessment of the ulcerogenic potential of dietary histidine supplementation is presently under way as is the determination of serum corticosterone levels.

25.3 FETAL ALCOHOL EFFECTS IN THE RAT HIPPOCAMPUS: A TIMM'S AND ANTEROGRADE HRP STUDY. J.R. West and C.A. Hodges-Savola*. Dept. of Anatomy, College of Medicine, University of Iowa, Iowa City, IA 52242.

In an attempt to determine the effects of prenatal ethanol exposure on the developing central nervous system, pregnant Sprague-Dawley rats were maintained on a liquid diet (Bio-Serv, PR-11) containing 35% ethanol derived calories from days 1-21 of gestation. Their ethanol consumption was approximately 12g/kg/day. Controls were either pair-fed the liquid diet in which isocaloric maltose-dextrin replaced the ethanol, or given lab chow and water. At birth all litters were culled to eight pups and the ethanol and pair-fed litters were cross-fostered to normal mothers. All were allowed to reach an age of 60-90 days at which time they were used for either Timm's or anterograde horseradish peroxidase (HRP) experiments. The modified Timm's sulfide silver method revealed dramatic changes in mossy fiber topography at midtemporal hippocampal levels in 9 of 10 ethanol-exposed rats. The alteration was in the form of an aberrant distal infrapyramidal terminal band in hippocampal subfield CA3a. To further examine the aberrant mossy fibers, small iontophoretic injections of HRP (Sigma type VI, 20% w/v in 2% DMSO) were made in the dentate gyrus at septotemporal levels where the aberrant Timm's staining occurred. Appropriate survival times (15-22 hrs) revealed the morphology of the mossy fiber axons. HRP-labeled mossy fibers were observed leaving the suprapyramidal bundle at several locations to penetrate the pyramidal cell layer and occupy a position similar to that of the aberrant staining in the Timm's material. The distal infrapyramidal mossy fibers possessed periodic swellings characteristic of the suprapyramidal mossy fiber axons. Therefore, although the prenatal ethanol exposure produced mossy fibers that terminated in an inappropriate area, the morphology of the axons appeared normal. The presence of abnormal brain circuitry in the absence of obvious external malformations suggests that these changes might best be termed fetal alcohol effects rather than fetal alcohol syndrome. Supported by grant AA 03884 from NIAAA.

25.4 MORPHOLOGIC ALTERATION IN HIPPOCAMPAL CA1 PYRAMIDAL CELLS FOLLOWING PERINATAL ETHANOL ADMINISTRATION. D. L. Davies and D. E. Smith. Dept. of Anat., Louisiana State Univ. Med. Ctr., New Orleans, LA 70112.

Elaboration of the dendritic arbor is a key developmental event which results from the interplay of numerous genetic and microenvironmental factors. The extent, intricacy and geometric pattern of the resulting dendritic array significantly influences the cell's capacity to interact with neighboring neurons, glia and the extracellular milieu.

The effects of ethanol on the dendritic arbor have been examined in postnatal mice following a relatively mild alcoholic insult timed to coincide with the birth and subsequent maturation of neurons in hippocampal CA1 sector. These cells are born during the last half of gestation in the fetal mouse (Angevine, Exp. Neurol. Suppl. 2:1, 1965).

Pregnant C57BL/6J mice were assigned to one of 3 groups: controls given free access to chow and water, experimentals supplied with a liquid diet containing 25% of its caloric value as ethanol (5.4% v/v) and nutritional-controls pair-fed a liquid diet with sucrose isocalorically replacing ethanol. This diet regimen was initiated on gestational day 12 and maintained until postnatal day 7. At birth, litters were culled to 6 pups to enhance maternal nurture; however, body weights of ethanol exposed pups remained below control values indicating possible attendant nutritional or metabolic derangement. Golgi impregnated material from litters sacrificed at 7, 14 and 21 postnatal days was assessed for changes in hippocampal CA1 pyramidal cells.

Preliminary examination of dendritic length and soma volume at 7 days revealed that both the controls and experimentals were at equivalent developmental stages. By 14 days, basal dendrites of controls were substantially expanded in size and complexity; whereas the dendritic arbors of ethanol-exposed experimentals exhibited a developmental delay. Measurement of these stunted dendrites showed a 20% reduction in total dendritic length with a concurrent decrease in soma size. By 21 days, the reduced arbor remained detectable, but was less dramatic, suggesting the possibility of neuronal recovery.

This investigation was supported, in part, by a research grant from the Distilled Spirits Council of the United States, Inc.

25.5 FETAL ALCOHOL EFFECTS ON ACTIVE AND PASSIVE AVOIDANCE. J.A. Holloway, and. M. Church*. Dept. Psychiat. & Behav. Sci., Univ. Okla. Health Sci. Ctr., Oklahoma City, OK 73190.

Children with Fetal Alcohol Syndrome are reported to have learning and memory deficits. Therefore, we examined if animals exposed to ethanol prenatally would also demonstrate such deficits. Female rats were exposed to a liquid diet containing ethanol (35% or 40% calories ethanol derived) from the 4th day of gestation until partuition. Pups born to these mothers were tested for retention of a passive avoidance task and learning and retention of an active avoidance task. Pair-fed sucrose (nutritional control) females and ad lib lab chow females were bred and their offspring used as controls. At 28 days of age offspring were put into the lighted compartment of a passive avoidance apparatus and their latency to enter a dark compartment where they received mild foot shock was recorded. Their retention of this task was assessed both 1 hr. post-training and 72 hr. post-training. Both offspring of ethanol exposed mothers and pair-fed sucrose controls showed passive avoidance retention deficits at both times tested when compared to the ad lib lab chow control offspring, although the ethanol exposed animals showed greater deficits. Therefore, the malnutrition effect of the diet produced by insufficient dietary intake of both the ethanol exposed mothers and pair-fed mothers may have contributed to these retention deficits in offspring.

From 58-70 days of age offspring of the 3 groups were trained in a step-up one-way active avoidance task and tested for retention 24 hrs. later. Only the ethanol exposed offspring demonstrated deficits in learning and retention of the task.

Thus, animals prenatally exposed to ethanol show deficits in both active and passive avoidance performance. The pattern of results is not consistent with the hypothesis that prenatal exposure to ethanol produces only response inhibition deficits. In that case, one would expect passive but not active avoidance deficits. These data do point to long term learning and memory deficits in offspring as a result of the mothers' prenatal intake of ethanol.

WITHDRAWN

25.7 BEHAVIORAL EFFECTS OF CHRONIC LOW LEVEL PERINATAL EXPOSURE TO BENZENE AND TOLUENE. J. Kostas* (SPON: W. Shain). Toxicology Institute, Div. of Labs and Research, New York State Dept. of Health, Albany, NY 12201.

The behavioral toxicity of chronic low level exposure to benzene and toluene was examined. Nylar mice were exposed to either benzene or toluene from conception to adulthood. Experimental dams were given drinking solutions of either 400, 80, 16, or 0 ppm benzene or toluene by weight in distilled water. The offspring were maintained on the same levels of solutions. Solution consumption of experimental dams and the offspring was not significantly different from control consumption. The exposed offspring showed no differences from controls in mortality rate, weight gain, or in the development of eye and ear opening, startle reflex and surface righting response. However, toluene exposure resulted in reduced habituation of activity in an open field (at 400 ppm) and depressed rotorod performance (16, 80, and 400 ppm). Benzene exposure resulted in a dose-dependent reduction of habituation of activity (16, 80, and 400 ppm), reduced center field crosses (females only at 80 and 400 ppm) and depressed rotorod performance (80 and 400 ppm). Toluene-exposed males also exhibited altered aggressive and social behaviors. A nonsignificant decrease was seen in blood leucocyte counts of benzene-, but not toluene-, exposed animals.

Results reveal several behavioral measures sensitive to exposure levels as low as 16 ppm. Moreover, the subsequent behavioral testing proved to be more sensitive to exposure to these substances than did the overt toxicological measures. While alterations in performance on these tasks indicate functional deficits, specific mechanisms have not been identified. For example, a lack of habituation in the open field may indicate deficits in utilization of sensory cues, alterations in emotionality or inhibitory processes. Nevertheless, the test profile has characterized the behavioral toxicity of benzene and toluene with regard to 1) dependence of effects on the particular task 2) differences between benzene and toluene on the pattern of effects observed and 3) dependence of effects on the level of exposure and, in at least one case, the sex of the animal.

25.8 DISRUPTION OF NUCLEIC ACID AND PROTEIN SYNTHESIS BY CHRONIC PRENATAL CARBON MONOXIDE EXPOSURE. L.D. Fechter, Dept. of Environmental Health Sciences, The Johns Hopkins University, Baltimore, MD 21205.

The consequences of acute asphyxia on the developing central nervous system have received substantial attention and both histopathological and biochemical sequelae have been documented. Despite the high frequency of occurence, less experimental attention has been focused on chronic, but mild hypoxia in the fetus although it represents both a serious environmental problem and therefore another legitimate model of prenatal hypoxia. Moreover, the pattern of CNS disruption produced by mild chronic hypoxia may well differ from that seen after asphyxiation. We have previously reported a variety of behavioral alterations following chronic prenatal carbon monoxide exposure including delays in development of simple sensory-motor tasks and permanent disruption of learning and/or retention of a conditioned avoidance task. Such effects are observed following exposure to carbon monoxide at concentrations far lower than those which disrupt neurotransmitter synthesis. We have reported, however, a reduction in whole brain protein concentrations at birth following such exposure. We have completed additional neurochemical experiments which indicate that prenatal CO exposure does not alter levels of nucleic acids at birth, but does decrease both content and concentration of protein. We have now measured nucleic acid and protein levels in brain regions of subjects at 21 days of age. We have seen a significant reduction in cerebellar protein content and concentration and, also, a significant reduction in the protein to DNA ratio in the cerebellum. No change in DNA content or concentration was seen in experimental subjects. If DNA levels are taken as a measure of cell number, the data suggest that prenatal CO exposure reduces mean cell size, but not cell number in the cerebellum.

25.9 BRAIN GROWTH AND IRON CONTENT IN IRON-DEFICIENT ANEMIC RATS. Y. Ohira*, V.R. Edgerton, J. Hegenauer*, and P. Saltman*. (SPON: L. Goldberg). Department of Kinesiology, UCLA, Los Angeles, Calif. 90024, and Department of Biology, UCSD, La Jolla, Calif. 92093.

Severe iron deficiency was produced in female weanling Sprague-Dawley rats. Following five weeks on an iron-deficient diet.Mean body weight was 117 and 211 g ($p < 0.001$) in iron-deficient and normal control rats, respectively. Hemoglobin was 6.0 and 15.4 g/dl ($p < 0.001$), and plasma iron was 60 and 178 µg/dl ($p < 0.001$). Absolute brain weight was 1.67 and 1.89 g ($p < 0.001$) and relative weight to body weight was 1.52 and 0.92% ($p < 0.001$). Total iron content measured by an atomic absorption spectrophotometer was 14.5 and 20.2 µg/g ($p < 0.01$). After subtracting hemoglobin iron, however, no significant difference was observed between two groups (12.1 and 13.4 µg/g). Mitochondrial total iron was 20.9 and 25.0 µg/g protein ($p > 0.05$). Another set of rats was treated orally with tracer dose of ^{59}Fe and assimilation of ^{59}Fe was measured four days later. The ^{59}Fe found in each group was 6.2 and 3.8 ng/g ($p < 0.01$) for whole brain and 27.7 and 15.7 ng/g protein for mitochondria. Even though tissue iron was not depleted significantly, there was a greater iron uptake in the iron-deficient brain than found in the normal. These data also suggest that severe iron deficiency reduces the rate of general brain growth. This study was supported in part by a USPHS grant from National Institute of Arthritis, Metabolism, and Digestive Diseases, AM-12386.

25.10 **THE EFFICACY OF BRAIN STIMULATION REWARD IN PROTEIN MALNOURISHED RATS.** **Robert D. Hall. Worcester Foundation for Experimental Biology, Shrewsbury, Mass. 01545**

A persistent problem in animal studies of developmental malnutrition and its effects on learning has been the lack of an effective reward whose efficacy is clearly independent of dietary manipulations. One possibility that has not been examined is brain stimulation reward. At least two considerations, however, suggest that intracranial reinforcement might be more efficacious in malnourished animals than in well-nourished ones: (1) In several rat models of developmental malnutrition the levels of brain catecholamines and indoleamines are substantially higher than they are in well-nourished animals. To the extent that brain stimulation reward depends on the monoaminergic systems and the levels of their transmitters one might expect it to be more efficacious in malnourished rats than in well-nourished ones. (2) Animals reared and maintained on diets that restrict growth might exhibit an enhancement of intracranial self-stimulation rates like that resulting from acute food deprivation. This study was undertaken to evaluate these possibilities with a view towards using brain stimulation reward in studies of complex learning by developmentally malnourished rats.

Malnourished rats were born to dams maintained on an 8% casein diet from 5 weeks before mating until their pups were weaned at 21 days of age. The offspring were maintained on the same low protein diet throughout the experiment. Well-nourished rats were reared on an isocaloric 25% casein diet. The efficacy of medial forebrain bundle stimulation was assessed in an initial experiment by measuring self-stimulation rates on Fixed Ratio (FR) reinforcement schedules whose values were increased each day by 3 up to FR 12 at which value rats were run for 5-7 days. In the main experiment this paradigm was extended to FR30. Then in a single session FR values starting at 4 were increased every 5 reinforcements until an extinction criterion of more than 10 minutes between reinforcements was reached. Finally, abbreviated intensity functions with only 3 current values were determined.

There was no indication that the intracranial reinforcement was more efficacious for the malnourished rats than it was for the well-nourished ones. Measures of response rate under the various conditions and breakdown ratios on the increasing ratio test were comparable for the two groups of rats. This finding suggests that brain stimulation reward may indeed be a useful tool in the investigation of learning capacity in malnourished rats.

25.11 EFFECTS OF SHAKING STIMULATION ON PRENATAL CHICK BEHAVIOR. J. H. Gassler* and M. L. Kirby (SPON: R. Holt). Dept. of Anatomy, Med. Col. of Georgia, Augusta GA 30912.

In a previous report (Gassler et al., Neurosci Abstr. 6:641, 1980) we found that shaking stimulation accelerated hatch time significantly in chicks when applied intermittently during the second half of incubation. This report documents further behavioral studies on intermittently shaken chick embryos. We have examined Type III movements and pre-hatch positions in 16-19 and 16-21 day embryos respectively. We have added an acute group of shaken embryos (never shaken prior to the recording session) to our motility, Type III and pre-hatch position studies. In order to assess the effects of early versus late stimulation, two groups of eggs were incubated: one group received intermittent shaking stimulation from incubation days 10 through 16; the second group of experimental eggs received the same shaking stimulus from day 16 to pipping. This study showed that eggs shaken from day 16 to pipping had an accelerated hatch time of seven hours over controls. Eggs shaken on days 10-16 showed no acceleration in hatch time. Motility studies showed that, contrary to our previous report, chronically shaken embryos (shaken from day 10) increase their motility only on day 17 when the shaker was turned on. The motility dropped to resting values after two hours of shaking. Acutely shaken embryos (shaken once) showed no changes in motility on any day. Type III movements decreased after the shaker was turned on in acute and chronically shaken 16 day embryos. Type III movements increased on day 17 after two hours of shaking in the chronically shaken group only. Chronically shaken embryos on days 17, 20 and 21 showed significant differences from controls in pre-hatch positions, indicating accelerated development. Experimental 16, 18, and 19 day embryos showed no differences from controls. Because acutely shaken embryos show no changes in motility when subject to shaking, the motility changes in the 17 day chronically shaken embryos must be caused by exposure to more than one shaking cycle. It cannot be determined however, how much shaking must occur prior to day 17 in chronically shaken embryos to cause the above mentioned changes in overall motility and incidence of Type III movements. The hatching study mentioned above seems to indicate that shaking has no effect on behavior prior to day 16. We cannot rule out shaking effects prior to day 16 on motility or pre-hatching behavior until studies are carried out where shaking is begun on day 16 and motility, Type III movements and pre-hatching positions are examined on subsequent days.

26.1 ACTIVITY OF CEREBELLAR CORTICAL NEURONS DURING VOLUNTARY CO-CONTRACTION AND RECIPROCAL INHIBITION OF ANTAGONIST MUSCLES. Robert C. Frysinger*, Daniel Bourbonnais* and Allan M. Smith. Centre de recherche en sciences neurologiques. Université de Montréal, Québec, Canada.

This study was designed to examine the activity of single cerebellar neurons during the reciprocal inhibition as well as the co-contraction of antagonist muscles. To accomplish this, a Macaca fascicularis monkey was trained to perform two different motor tasks with the same hand. The first task consisted of maintaining an isometric precision grip of the thumb and forefinger on a hand-held strain gauge. This lateral pinch is achieved by a general co-activation of the antagonist muscles of the hand and forearm. In the second task the monkey was required to follow a visual cue in order to position the open hand within a 6° target zone by either flexing or extending the wrist. A torque motor added a 10 gram/centimeter force which the monkey was required to overcome in order to position and maintain the manipulandum within the target zone. Position correctly maintained for a one second period was rewarded with fruit juice. A study of the activity of the 6 muscles of the wrist during the flexion and extension movements indicated that antagonist muscles showed a pattern of reciprocal activity, as opposed to the pattern of co-contraction seen in the prehension task. During the performance of both motor tasks, recordings were made from single neurons located approximately in the culmen-simplex area of the ipsilateral cerebellar cortex. In accordance with previous studies, units were found which decreased firing frequency during prehension in spite of a general activation of all forearm muscles. Preliminary evidence from 15 units recorded during both prehension and wrist displacement suggests that neurons showing changes during grasping are activated in one movement direction in the wrist displacement task, and either show no change or a decrease in activity with movements in the opposite direction. In general, the results appear to support the suggestion that cerebellar cortical neurons play an important role in switching between reciprocal and co-active modes of muscle activation.

26.2 CHANGES IN PURKINJE CELL RESPONSIVENESS TO CF INPUT FOLLOWING PAIRING OF OLIVARY STIMULATION AND FOREPAW DEPLACEMENT. John F. Brons and Lee T. Robertson. Neurol. Sci. Inst., Portland, OR 97210.

It has been postulated that interactive effects of climbing fiber and parallel fiber systems on cerebellar Purkinje cells (P-cells) are important in motor learning. This study shows that a conditioning procedure can induce long-term changes in the pattern of spike responses associated with climbing fiber activation.

The activity of 26 P-cells was recorded extracellularly in the intermediate cortex of Lobule V. P-cells were identified by the occurrence of spontaneous complex spikes (CS) and simple spikes (SS). The interaction of climbing fiber activation and forepaw movement on P-cell activity was examined by a three step conditioning procedure: 1) stimulation of the contralateral inferior olive (IO), 2) pairing of IO stimulation with ipsilateral forepaw displacement produced by a computer controlled solenoid, and 3) stimulation of the contralateral IO. A minimum of 40 trials was used for each step.

The IO was electrically stimulated with single negative pulses (0.5 ms) at suprathreshold levels (100-400 uA) for eliciting a CS in each cell. The CSs were followed by pauses in SS activity, which ranged from 12 to 165 ms in duration (91 ± 36 ms, mean ± sd) During pairing, IO stimulation was followed by a 3 mm forepaw displacemennt with 100 or 150 ms interstimulus intervals.

In 14 cells, repeated stimulus pairing produced a greater uniformity in the duration of pauses of SS activity elicited by IO stimulation. Pauses of SS activity terminated 43 ± 27 ms (mean ± sd) prior to onset of paw movement. This uniformity resulted from longer pauses shortening in 7 cells and from shorter pauses lengthening in 7 cells. Resumption of SS activity after each pause appeared as a conditioned anticipatory response to the onset of paw movement. Similar results were seen with both 100 and 150 ms interstimulus intervals. The conditioned response persisted in half of the cells for at least 2 min during the final IO stimulation step.

These results suggest that stimulus pairing can alter the responsiveness of P-cells to climbing fiber input and that this is partially attributable to changes in the processses underlying the post-CS pause in SS activity.

26.3 EXCITABILITY CHANGES IN SIMPLE SPIKE PURKINJE CELL ACTIVITY FOLLOWING A CLIMBING FIBER INPUT. C. J. McDevitt*, T. J. Ebner, and J. R. Bloedel. (SPON: F. Torres). Depts. of Neurosurgery and Physiology, University of Minnesota, Minneapolis, 55455.

Many previous studies have suggested that a reduction of simple spike activity in a Purkinje cell follows the period of inactivation after a climbing fiber input to the same cell. However, the design of these studies did not enable an accurate assessment of the regularity with which this effect occurred following a spontaneous climbing fiber input in different Purkinje neurons. Therefore experiments were performed in decerebrate, unanesthetized cats to quantify the changes in the simple spike discharge of Purkinje cells following their spontaneously evoked response to a climbing fiber input. A total of 98 Purkinje cells identified by the presence of spontaneous complex spikes were recorded in the anterior lobe of the cerebellum with glass microelectrodes. Post stimulus time histograms (Σ =100) of the simple spike activity triggered on the occurrence of a complex spike were constructed and examined for changes in simple spike activity following the climbing fiber input. The average simple spike activity for 40 msec following the inactivation period was compared with the average background firing rate for each cell. In all cells an initial inactivation period (7-15 msec) was present. Following this inactivation, three different excitability profiles in the simple spike discharge were observed. For most cells (N=67) a brief increase in simple spike activity was observed, and for 14 Purkinje cells there was no change in simple spike activity when compared with the background. For the remaining cells (N=17), a decrease in simple spike firing rate was observed following the spontaneous climbing fiber input. These changes in simple spike activity following the spontaneous climbing fiber input could not be correlated with the average background firing rate of the cell. As has been shown previously, when many climbing fibers were synchronously activated by electrically stimulating the inferior olive, a reduction of the simple spike activity was evoked independent of the excitability change observed when the climbing fiber input occurred spontaneously. These results show that the most common change in impulse activity following the inactivation period evoked by a spontaneous climbing fiber input is an increase in the simple spike discharge rate. Although a decreased rate can occur, this effect can be most readily produced by electrical stimulation of the inferior olive. This work was supported by NIH Grant #2R01-NS 09447-10.

26.4 THE EFFECT OF DESCENDING PROJECTIONS ACTIVATED BY DENTATE EFFERENT PATHWAYS ON THE STRETCH REFLEX. J. L. Vitek*, T. J. Ebner, J. R. Bloedel. (SPON: C. Terzuolo). Departs. of Neurosurgery and Physiology, Univ. of Minnesota, Minneapolis, 55455.

Dentato-reticulospinal and dentato-rubrospinal projections have recently been demonstrated in the cat. These experiments were performed to examine the combined action of these systems on the stretch reflexes in decerebrate cats. The rectified, integrated EMG activity from the gastrocnemius-soleus (GS) and anterior tibialis (AT) muscles of the hindlimb were averaged during sinusoidal stretching (.1-5 mm, .25-15 Hz) of each muscle in a reciprocal fashion, i.e. GS was stretched as AT was shortened. Electrical stimulation of the dentate nucleus was applied with a stereotaxically placed monopolar stainless steel electrode (exposed tip of 25 u) or a small concentric bipolar stimulating electrode (interpose distance = 500 um). Capacitatively coupled current pulses (.2 msec in duration) at various combinations of current intensity (monopolar electrode 10-500 uA, bipolar electrode 400-1200 uA) and stimulus frequency (50-350 Hz) were used to stimulate the dentate. Electrode placement in the dentate was verified by histological sections and by monopolar recording of the field potential evoked at the fifth cervical segment. This field potential had been demonstrated previously to occur with a latency of 2-3 ms when the electrode is positioned within the dentate nucleus. Stretch reflexes in the decerebrate cat were characterized by extensor hyperreflexia and most commonly an attenuated or absent reflex in the flexor when it was stretched. However, co-activation of the flexor in phase with the stretch of the extensor was routinely present. Dentate stimulation produced changes in both the amplitude and the phase relationship of these proprioceptive reflexes. In almost all experiments, the GS stretch reflex as well as the co-activation response of the AT during stretch of the GS was reduced or even abolished. In contrast the flexor's response to stretch was increased, resulting in a reciprocal pattern of reflex activity in these muscles. In addition to demonstrating these specific effects, these experiments show that dentate efferent projections which do not include the thalamus or sensorimotor cortex can modify both the amplitude and organization of proprioceptive reflexes in the spinal cord. This work was supported by NIH Grant #2R-1-NS 09447-10 and NIH Contract #N01-NS-0-2338.

26.5 THE COMPARISON OF IPSILATERAL AND CONTRALATERAL EFFECTS OF DENTATE NUCLEUS INACTIVATION ON THE LATENCY, SPEED AND ACCURACY OF A GOAL-DIRECTED MOVEMENT IN MONKEYS. E. Trouche, D. Beaubaton and E. Legallet (SPON: C. Palmer). CNRS-INP, Marseille, France.

Experiments using exclusion or stimulation procedures demonstrate in monkey a predominant ipsilateral control of the dentate nucleus (DN). However, anatomical data give evidence of bilateral dentatofugal connections. The purpose of the present study was to compare the effects in both limbs of unilateral DN inactivation on spatio-temporal variables of a goal-directed movement in monkeys. The investigations were carried out on five baboons (Papio papio) performing in a cage designed to standardize the working posture. The animals were trained to press a lever situated on a vertical panel, to hold it until an illuminated target appeared, to release the lever and touch the target with one finger. The finger enterring into contact with the panel provided automatically the rectangular coordinated of the pointing response. Reaction time was defined as the time between illumination of the target and release of the lever, movement time as that between release of the lever and contact with the panel. Data analysis was carried out on the averages of reaction times, movement times and spatial errors. After the DN had been electrophysiologically located, unilateral lesions were made. In the arm ipsilateral to the lesion, DN exclusion brought about prolongation of reaction times, modification of movement times and the appearance of systematic errors. In the contralateral limb, only the movement times were impaired and a faster recovery was observed in this case. These results suggest that in monkey DN may exert a bilateral control of speed of movement. Conversely the control exerted by DN, on movement initiation and terminal accuracy is strictly ipsilateral.

26.6 LOCALIZATION OF IONIC CONDUCTANCES IN SOMA DENDRITIC REGIONS OF PURKINJE CELLS: AN IN VITRO STUDY IN GUINEA PIG CEREBELLAR SLICES. M. Sugimori* and R. Llinás (SPON: D. Chiarandini). Dept. Physiol. & Biophysics, New York Univ. Med. Ctr., New York 10016.

Electrical activity of guinea pig Purkinje cells has been demonstrated to consist of a Na^+-dependent action potential at the soma and Ca^{++}-dependent action potentials mainly, but probably not exclusively, in the dendrites (J. Physiol. 305, 197-213, 1980). A detailed study of the distribution of ionic conductances was recently obtained in the in vitro cerebellar slices by intrasomatic recording of Purkinje cells in the absence of extracellular Ca^{++} combined with an iontophoretic application of Ba^{++} at different levels along the vertical axis of the dendritic tree. This experimental paradigm demonstrated the electrical activity of Purkinje cell dendrites when Ba^{++} ions were released in the distal half of the molecular layer in the presence of TTX. Simultaneous recording with an extracellular electrode at dendritic level indicated a large extracellular negative field potential simultaneously with somatically recorded Ba^{++}-dependent action potentials. The action potentials quickly disappeared when the Ba^{++} electrode was removed from the vicinity of the dendritic tree. However, action potentials of smaller amplitude could be obtained when the Ba^{++} ejecting electrode was located at somatic level. At this level it was difficult to demonstrate whether the inward current was flowing at somatic level or at proximal dendritic level. This ambiguity was resolved when action potentials produced by Ba^{++} ejection at somatic level were seen to generate an extracellular positivity at that location, indicating that the soma served as a source of current and thus that Ba^{++} spikes were being generated mainly across the dendritic membrane. A similar set of results was then obtained for the normal Ca^{++} action potentials using a fire-polished extracellular current measuring microelectrode placed against the dendritic membrane. Here activation of the TTX-resistant action potentials recorded at somatic level produced all-or-none inward currents at dendritic level while at somatic level such action potentials were accompanied by outward current. The present results further indicate a spatial distribution for the Na^+ and Ca^{++} conductances in the Purkinje cell which confirm our proposal that Ca^{++} conductances are mainly dendritic while sodium conductances seem to be restricted to the somatic level. Supported by USPHS grant NS13742 from NINCDS.

26.7 EFFECTS OF EXTRACELLULAR POTASSIUM ON THE EXCITABILITY OF THE PARALLEL FIBERS. R. C. Malenka, J. D. Kocsis, and S. G. Waxman. Dept. of Neurology, Stanford Sch. of Med. and Veterans Administration Medical Center, Palo Alto, CA 94304.

Changes in extracellular potassium concentration ($[K^+]_o$), have been shown to effect several aspects of neuronal functioning. In this study, we examine the effects of $[K^+]_o$ on the excitability of the non-myelinated parallel fibers (Pfs) of the rat cerebellar cortex. Rat cerebella were continuously superfused with normal Ringer solution (NS) or with solutions containing varying concentraions of K^+ (5-30 mM). Local microstimulation of the Pfs was employed and the "on-beam" Pf field potential was recorded within 70µm of the cerebellar surface.

Double stimulation experiments have shown that the Pfs exhibit a pronounced supernormal period (SNP) following a single conditioning volley as evidenced by a decrease in the latency of the Pf volley. When the superfusate was changed from NS (3 mM K^+) to a 10 mM K^+ solution, the magnitude of the latency reduction during the SNP decreased as did the duration of the SNP. No SNP was exhibited in a 15 mM K^+ solution. Further analysis revealed that as the $[K^+]_o$ increased, the latency of the Pf volley continuously decreased while with further increases in $[K^+]_o$, the latency of the Pf volley increased beyond control values indicating a subexcitable state. With even greater increases in $[K^+]_o$ the Pf volley was obliterated indicating conduction block. During relatively high frequency stimulation (20-70 Hz) increases in $[K^+]_o$ are observed and consecutive Pf responses reveal a similar continuous change in excitability; an initial superexcitable state followed by a subexcitable one.

Increases in $[K^+]_o$ can also be recorded in areas lateral to the activated Pf beam. If the excitability of the Pfs is related to $[K^+]_o$ the excitability of adjacent nonactivated Pfs, where $[K^+]_o$ has increased, should change. Pairs of stimulating microelectrodes were placed on the cerebellar surface (100-500 µm apart) so that stimulation of the "off-beam" electrode elicited no Pf activity at the "on-beam" recording electrode. Following off-beam stimulation (50 Hz for 1.5 sec) the latency of the on-beam Pf volley decreased and its amplitude increased, indicating an increase in Pf excitability. The change in Pf excitability was only observed when the off-beam stimulating electrode elicited detectable $[K^+]_o$ changes at the on-beam recording site.

These results suggest that small increases in $[K^+]_o$ may contribute to an increase in Pf excitability while greater increases in $[K^+]_o$ lead to a decrease in Pf excitability. The extremely small diameter of these axons could make them particularly sensitive to changes in intra- or extracellular ionic concentrations.

26.8 DISTRIBUTIONS OF CHOLINE ACETYLTRANSFERASE AND ACETYLCHOLINESTERASE ACTIVITIES IN REGIONS AND LAYERS OF RAT CEREBELLUM. C.D. Ross, J.T. Smith* and D.A. Godfrey. Dept. of Physiology, Oral Roberts University, Tulsa, OK 74171

Two entire sagittal sections of cerebellar vermis from each of 5 rats were each microdissected into over 100 samples of molecular (ML), granular (GL) or white matter (WM) layers, the exact location of samples recorded onto a map of the section and assayed for choline acetyltransferase (ChAT) or acetylcholinesterase (AChE) activities. Highest activity of both enzymes was in the GL of the "vestibulocerebellum", the nodulus and ventral uvula (lobules X and IXc of Larsell). Differences of 14-(ChAT) and 7-(AChE) fold were found between lowest and highest average activities in samples of GL from lobules VIa (ventral) and X of the 5 rats. Data for samples from major folia were combined and averages determined (± S.E.M.) for 5 rats (ChAT: µmoles/kg dry wt/min @ 37°; AChE: mmoles/kg dry wt/min @ 37°).

26.9 **INCREASED NOREPINEPHRINE METABOLISM AND REDUCED β-RECEPTOR BINDING IN THE CEREBELLUM OF THE MUTANT MOUSE DYSTONIA MUSCULORUM.** **Donald Kay Riker, Ruben Zito*, Robert Roth, and Anne Messer. Depts. Pharmacology, Medicine, & Psychiatry, Yale Univ. Sch. Med. & West Haven VA Med. Ctr., New Haven, CT 06510 & NYS Dept. of Health, Albany, NY 12201**

The neurological mutant mouse dystonia musculorum (dt/dt) exhibits bizarre appendicular and truncal dystonia and clasping hyperflexion when suspended. No gross cerebellar histopathology has been reported, although red nucleus pathology and sensory polyneuropathy have been noted (Duchen & Strich, Brain 87:367, 1964; Messer & Strominger, Neurosci. 5:543, 1980). We evaluated striatal dopamine and cerebellar norepinephrine (NE) metabolism in this mutant and compared the results to those obtained from wild-type (+/+) control BALB/c or B6C3 backgrounds. Tyrosine hydroxylase (TH) activity and steady-state 3,4-dihydroxyphenyl-acetic acid and homovanillic acid levels were similar in the striata of mutants and controls. In the mutant TH activity and steady-state levels of the NE metabolite MHPG were elevated in the cerebellum 38% and 42-66% respectively. However, NE levels (~350ng/g) and a Purkinje cell (PC)-specific marker, cGMP-dependent protein kinase (cGMPK), were unchanged in the mutant cerebellum. Preliminary results suggest that ^{3}H-dihydroalprenolol β-receptor binding sites measured at saturation (18nM) are not significantly different in the neocortex or myocardium of mutants. On the contrary β-receptor binding appears reduced 65-70% in the cerebellum compared to controls.

We favor the hypothesis that there is a primary reduction in afferent information reaching the cerebellum during development. Secondarily, the locus coerulus, which supplies most of the cerebellar NE innervation, has responded to this decrease in impulse traffic by a compensatory increase in NE metabolism. This would seem to encourage afferent-evoked discharge of the PC (Woodward et al, Fed. Proc. 38:2109, 1979). A tertiary consequence might be "down-regulation" of cerebellar β-receptors. An alternative hypothesis, inherited loss of β-receptors, could be a primary event. However, their loss only in the cerebellum, the apparent normal density of PC's (ie-normal cytoarchitecture and cGMPK levels), and lack of evidence for reactive sprouting (ie-normal NE levels) suggest that cerebellar NE metabolism is activated in response to reduced impulse traffic, not target cell derangement. **(Supported by the Dystonia Medical Research Foundation, Beverly Hills, CA).**

26.10 THE DENSITY OF GRANULE CELLS AND MOLECULAR LAYER SYNAPSES IN THE RAT CEREBELLAR CORTEX. R. J. Harvey, R. M. A. Napper* and M. S. Phillips*. Dept. Anatomy, Univ. of Otago Med. Sch., Dunedin, New Zealand.

The cerebellar cortex is widely believed to be a flat uniform sheet which has been topologically deformed into the deeply folded form that it takes in an adult mammal. We have made some quantitative studies to determine the numbers of granule cells and the number of synapses which they make. We counted the granule cells in measured areas of granular layer from high-power optical micrographs of thin (1 or 1.5 μm) methacrylate sections of rat cerebellum, and used these values to obtain the volume density of granule cells (similar to the method used by Friedrich & Brand (Neurosci., 5:349-356, 1980) in the cat); the value obtained for fixed dehydrated material was $2.0 \times 10^6/mm^3$. The length of the "unfolded" cortical sheet measured along the Purkinje cell layer in parasagittal sections through the vermis is around 80 mm and the mean thicknesses of the granular layer and molecular layer are 180 and 270 μm respectively. From this, the number of granule cells underlying 1 mm^2 of cortex is 3.6×10^5. From transmission electron micrographs of the molecular layer cut in a plane perpendicular to the parallel fibres, preliminary results suggest that the mean density of parallel fibres is in the region of $4.2 \times 10^6/mm^2$. Thus the number of parallel fibres intersecting a section 1 mm long through the full depth of the molecular layer will be 1.1×10^6. These fibres are the axons of those granule cells lying beneath a strip of cortex 1 mm wide whose length is equal to the length of the parallel fibres. From this the mean length of the parallel fibres is 3.1 mm, a figure close to the middle of the range of lengths found by Schild (J.Physiol.(Lond.), 303:25P, 1980). Each parallel fibre makes about 600 contacts/mm length (Palay & Chan-Palay, The Cerebellar Cortex, Springer, 1974). This means that beneath 1 mm^2 of cortical surface, there are 6.6×10^8 parallel fibre synapses. The majority of these are believed to be with the long dendritic spines of Purkinje cells (Palay & Chan-Palay, op.cit.). There are around 1000-1200 Purkinje cells/mm^2 in the rat, so the above results imply that each must receive more than 3×10^5 parallel fibres. It is believed that a Purkinje cell spine rarely receives more than one contact from a parallel fibre, but the number of contacts suggested by our results is very much greater than the number of spines which has been estimated for rat Purkinje cells (1.8×10^4); this large discrepancy is under investigation.

26.11 DETAILS OF CEREBELLAR ORGANIZATION REVEALED BY DIGESTIVE PREPARATION FOR SCANNING ELECTRONMICROSCOPY. B. F. Reese* and D. M. D. Landis (SPON.: T. S. Reese). LNNS, NINCDS, NIH, Bethesda, MD 20205, and Dept. of Neurology, Harvard Medical School, Massachusetts General Hospital, Boston, MA 02114.

The scanning electronmicroscope (SEM) is a powerful technique for visualizing surfaces of cells and tissues at a level of resolution beyond the reach of the light microscope. However, its usefulness in examining the brain has been limited by the lack of a preparative method to expose regularly the true outer surfaces of neurons and glia. We present here an approach to preparation of the cerebellum for SEM which depends on acid digestion to weaken intercellular attachments. Adult rats were perfused with aldehydes and their cerebellum tissue-chopped at 600 μm. Slices were then digested in 4 percent osmium tetroxide (unbuffered) or in 4 N HCl at 40-60°C for 2-24 hrs (depending on temperature). These slices, which are quite fragile after critical point drying, were pulled apart to reveal neuronal and glial surfaces inside. The main advantage of these methods is that neurons and glia are not broken open, but instead separated along their natural surfaces to expose large three-dimensional fields of cerebellar processes which can easily be visualized in a SEM. Examples of cerebellar structures particularly well visualized are: 1. Complete granule dendrites including their interdigitations with adjacent granule dendrites. In contrast, the Golgi technique only shows one granule dendrite at a time while freeze-fracture shows only fragments of dendrites. 2. Glial sheaths and basket cell terminals remain intact over hemispheric areas which formerly abutted Purkinje cell bodies. The detailed views of these synaptic patterns, and their interrelationships with glia, may allow investigation of subtle changes during development or in different functional states. 3. Axon hillocks and ascending axons of granule cells. The organization of these axons into bundles is readily appreciated. 4. The mosaic pattern of glial processes abutting blood vessels on the surface of the brain. The pattern of glial processes at blood vessels differs from that on the cerebellar surface.

We began by applying this method to normal rat cerebellum because its structure was already well understood. So far, we have mainly confirmed earlier concepts of cerebellar structure. But a better and quicker method of seeing structures directly provides a means to look for subtle changes during development or after experimental manipulations, and to understand aspects of intercellular relationships in regions of the brain that are not so well understood.

26.12 VISUAL AND AUDITORY INPUT AND OUTPUT RELATIONS OF THE LATERAL CEREBELLUM: THE PARAFLOCCULUS. A. Azizi, R.A. Burne and D.J. Woodward. Dept. of Physiol., The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

Previous anatomical and electrophysiological evidence from this laboratory has demonstrated the existence of visual and auditory cortical inputs to the paraflocculus of the cerebellum. In this report we describe data indicating a convergence of natural visual and auditory stimulation onto parafloccular neurons, and in addition the existence of specific projections onto the deep cerebellar nuclear cells and output of these nuclei which influence the cerebral cortex. The techniques of 1) presentation of time locked tone and moving visual stimuli, 2) orthograde transport of labeled amino acids and 3) electrical stimulation of visual cortex were employed.

Single unit recordings of 32 units in the paraflocculus of unanesthetized immobilized rats showed evidence, through histogram analysis, for excitatory and/or inhibitory mossy fiber and climbing fiber inputs. Responses were elicited following presentation of pure tones (Sinusoidal waves 200 Hz to 20k Hz, 65-80 db. intensity) in auditory field and/or computer controlled visual stimuli (bars of light moving at specific orientations) in the visual field. Some units (11) showed evidence of facilitation when a combined auditory and moving visual stimuli were presented to the animal.

Hydraulic injections (.15-.3 μl) of ^{3}H-leucine (77 μCi/μl) into the paraflocculus resulted in afferent terminal labeling over specific regions of the ipsilateral lateral and interpositus nuclei of the cerebellum. Autoradiographic silver grains were primarily localized over the ventral caudal region of the large cell subdivision in the lateral nucleus and over the small and large cell subdivisions of the ventral caudal interpositus nucleus.

Single unit recordings were obtained from identified neurons in the lateral nucleus of halothane anesthetized rats. Histogram analysis showed evidence of excitatory and/or inhibitory inputs following electrical stimulation of the visual cortex (single pulse, .2 msec duration, -.07 to -.6 mA, 1-20 Hz) with latencies ranging from 3-10 msec. Electrical stimulation of lateral and interpositus nuclei evoked multiunit and single unit responses in the sensory and motor cerebral cortices.

The observations indicate a convergence of auditory and visual sensation in the paraflocculus. Further, specific projection areas in deep nuclear zones are identified which may have a role in relaying the output of visual-motor integration onto the brain stem and the cerebral cortical areas. Supported by grants NSF BNS77-01174, NIDA, DA02338-01 and the Biological Humanics Foundation.

26.13 PONTINE RELAY FROM VISUAL CORTEX TO UVULA AND PARAFLOCCULUS. F. Robinson*, J. L. Cohen*, J. May*, A. Sestokas*, M. Glickstein. Walter S. Hunter Laboratory of Psychology, Brown University, Providence, RI 02912.

Visual cells in the rostral pons of cat project to the uvula and paraflocculus of the cerebellum (Robinson et al., Abstract Soc. Neurosci. 6:510, 1980). The present study addresses two questions raised by these results. First, do pontine cells which project to uvula and paraflocculus relay information from cortical visual areas? Second, do uvula and paraflocculus receive their visual projections from anatomically separate populations of cells in the rostral pons? To answer these questions we compared the location of visual cortical terminals in the pons to the location of pontine cells that project to the uvula and paraflocculus.

Pontine terminals of visual cortical cells were labeled by injecting ^{3}H proline into the medial bank of the middle suprasylvian sulcus and into area 18. In the same animal, cells projecting to uvula or paraflocculus were labeled by making iontophoretic deposits of horseradish peroxidase (HRP) into one or the other cerebellar structure. Adjacent sections through the pons were alternately processed by autoradiography (ARG) and HRP. The locations of ARG labeled terminals or HRP labeled cells were marked on an outline of each section with an x-y plotter driven from the microscope stage. The overlap of labeled terminals and filled cells was studied by superimposing the outlines of adjacent sections.

We found that there was considerable overlap of ARG labeled terminals and HRP labeled cells in the rostral pons. The uvula and paraflocculus, therefore, both receive input from extrastriate visual areas via pontine relay cells. Further, the uvula receives its projections from cells clustered near (<400 µm) the pyramidal tract as it courses through the pons and from another group of pontine visual cells near the midline. The paraflocculus receives fibers from cells which are further away (>400 µm) from the pyramidal tract. Unlike uvula, the paraflocculus receives few fibers from the group of pontine visual cells near the midline. The uvula and paraflocculus thus appear to receive visual information from different sets of pontine relay cells.

26.14 FLUORESCENT DOUBLE-LABEL STUDIES OF THE PONTOCEREBELLAR SYSTEM. G.A. Mihailoff. Dept. Cell Biology, The Univ. Tx. Hlth. Sci. Ctr. Dallas, TX 75235.

In the course of deciphering the organizational features of the pontocerebellar system through HRP transport methods, one crucial question that has evolved concerns the degree to which individual pontocerebellar axons collateralize and distribute to multiple cerebellar cortical locations. This general issue of potential collateral branching can actually be divided into at least two components: 1) to what extent do pontocerebellar neurons distribute unilaterally to more than one cerebellar lobule; and 2) to what extent do they project bilaterally to corresponding lobules on both sides of the cerebellum. We have approached these two questions by employing double-label tracer studies involving the retrograde transport of two different fluorescent dyes injected in a restricted manner into individual lobules of the cerebellar hemispheres of pigmented (Long-Evans) rats. Two different dye combinations were nearly equivalent in their effectiveness. Nuclear Yellow and Propidium Iodide (Sigma); and Nuclear Yellow with Fast Blue (Illing). The latter combination was used more extensively because double-labeled neurons were more easily identified since both dyes fluoresce at the same excitation wavelength (360 nm). In order to determine the extent of unilateral pontocerebellar axonal branching, paired dye injections (.06-.08 µl) were made into individual hemispheral lobules using the following combinations: Crus I and Crus II; Crus I and Paramedian; and Crus II and Paramedian. Our findings, although only semi-quantitative, indicated that fewer (<10%) pontocerebellar neurons than expected (on the basis of previous HRP studies) were double-labeled and thus suggested that a relatively small number branched to adjacent hemispheral lobules. Often a restricted cluster of pontine neurons exhibited a mixture of singly labeled cells each projecting to separate lobules. This, however, was not the case for the adjacent nucleus reticularis tegmenti pontis (NRTP) where considerably more double-labeled neurons were noted. With regard to bilateral pontocerebellar axonal branching (paired bilateral dye injections in Crus I, Crus II, or Paramedian), the incidence of double-labeled cells was slightly greater (10-20% of labeled population) particularly in Crus I & Crus II cases. Similar to observations in paired unilateral injections, the number of double-labeled cells in NRTP after bilateral injections was slightly elevated over that of the pontine gray. Furthermore, our findings support previous HRP studies which demonstrated the existence of bilateral, mirror-image pontine cell groups projecting to a single cerebellar lobule. 26.15 AN ANATOMICAL STUDY OF THE DISTRIBUTION AND MORPHOLOGICAL CHARACTERISTICS OF PERIOLIVARY RETICULAR NEURONS, G.A. Bishop and J.S. King, Department of Anatomy, The Ohio State University, College of Medicine, Columbus, Ohio 43210.

Anatomical, physiological and pharmacological studies have suggested that neurons in the reticular formation immediately adjacent to the inferior olive (IO) are involved in olivary circuitry. However, to date, conclusive anatomical confirmation of such a projection is lacking. In this study we have addressed three questions: 1) Are there neurons in the periolivary reticular formation (PRF) which project to the IO?, 2) if present, what is their distribution? and 3) what are the morphological characteristics of these neurons? The first two questions were addressed using extracellular injections of horseradish peroxidase (HRP) into the IO. In these experiments a ventral approach to the brainstem was used. Slow pressure injections of 0.03-0.05 µl of 30% HRP were made unilaterally into the IO. Data was analyzed from only those experiments in which the enzyme was confined to the olivary complex. Results indicate that neurons located dorsal to the IO, on or immediately adjacent to the midline project to the IO. Although the major portion of this projection is ipsilateral, there is also a contralateral component. Another population of PRF neurons, located dorsal and lateral to the IO are also retrogradely labeled with HRP. The morphology of PRF neurons was determined by using intracellular injections of HRP into single nerve cells. Results from these experiments confirm and extend the findings of the extracellular studies. Axons from single PRF neurons, located near the midline, distribute bilaterally to the IO. In addition, there are some neurons located immediately dorsal to the IO with dendrites that penetrate into the olivary neuropil. To date electron microscopic analysis of these dendrites indicate that they are postsynaptic. Finally, another population of neurons, located between olivary nuclei or ventral to the medial accessory olive also extend their dendrites into the neuropil of the IO. Thus, the present results suggest a potential anatomical substrate for the inhibitory responses recorded within the IO (Llinas et al '74). In addition, the labeled PRF neurons could represent, in part, the source of serotoninergic afferents to the IO (Wiklund et al '80 and King et al '81). It has been postulated that this system of afferents plays an inhibitory role in olivary circuitry (Wiklund et al '80). (Supported by funds from the Bremer Foundation, a Biomedical Research Support Grant and USPHS NS-08798).

26.16 WIDESPREAD SOURCES OF INPUT CONVERGE UPON MIDBRAIN NUCLEI KNOWN TO PROJECT TO THE INFERIOR OLIVE IN THE CAT. J.A. Saint-Cyr, Playfair Neuroscience Unit and Dept. Anatomy, University of Toronto, Toronto, Ontario, Canada.

In 12 cats anesthetized with Ketaset, either electrophoretic deposits of HRP (8 cats) or pressure injections of WGA-HRP (.1-.025 ul) (4 cats) were made unilaterally in and around midbrain cell groups previously shown to project heavily to the inferior olive (IO). These areas include: caudal-medial subparafascicular-parafascicular (sPf-Pf) nuclei; ventrally adjacent fields of Forel (FF); rostral extremity of the interstitial nucleus of Cajal (INC_R); nucleus of Darkschewitz (ND); caudal INC (INC_C); parvocellular red nucleus (RNp). In the cases of WGA-HRP, excellent anterograde labelling of fibres and terminal areas confirmed the projections to the IO and other brain stem nuclei. Anterograde labelling of lesser intensity was also seen in some HRP cases. Apart from a few local projections and interconnections within the midbrain groups injected, four main populations of neurons were retrogradely labelled. Care was taken to exclude cell groups labelled due to spread of the injection to the oculomotor complex. 1) Cerebellar nuclei-all contralateral: dentate projects to RNp and ND; interpositus posterior to INC and sPf-Pf-FF; infracerebellar to INC_C. 2) Vestibular nuclei: superior nucleus bilaterally but stronger ipsilaterally to INC_R, sPf-Pf-FF and ND; medial and descending nuclei weakly with strongest contralaterally to INC and ND. 3) Reticular formation: rostral to the superior olive (SO), mainly ipsilaterally to INC-ND and laterally adjacent tegmentum; between rostral pole of IO and SO, bilaterally but slightly more contralaterally to same midbrain area; between cervical cord and IO, bilaterally to midbrain. 4) The motor cortex projection is ipsilateral to the entire cell group and arises principally from layer V cells in area 6, and the rostral portions of areas 4 and 3a. Autoradiographic studies using tritiated amino acids have confirmed many of these projections.

Three additional retrogradely labelled cell groups identified as projecting to the midbrain were: 1) ventral horn of the upper cervical cord, strongest ipsilaterally, principally from laminae 7 & 8, 2) ipsilateral nucleus tegmento-peribrachialis surrounding the brachium conjunctivum, 3) ipsilateral zona incerta and the adjacent caudal hypothalamus.

Thus, the meso-diencephalic cell group receives converging afferents from widespread sources and projects to a limited number of brain stem and spinal centres, the most notable being the inferior olive. (Supported by MRC Grant MA 7209)

26.17 CEREBELLAR RESPONSES TO ELECTRORECEPTOR INPUT IN CATFISH. Shang-Liang Tong* and Theodore H. Bullock. (SPON: K. S. Cole). Neurobiol. Unit, Scripps Instit. Oceanog. and Dept. Neurosci., U.C.S.D., La Jolla, CA 92093.

Unit spikes from large cells in the cerebellum of curarized catfish (Ictalurus nebulosus), prepared under MS 222 or ice water, were recorded, and histograms made by computer, during stimulation by weak electric fields in the bath. Either homogeneous fields - transverse or longitudinal - or small dipole fields were used. Receptive fields and best dipole orientation and direction were noted, as well as integrative properties.

Electrosensory units are found mainly in the lobus caudalis pars lateralis, i.e. the posterior lateral corner including <5% of the cerebellum, between 0.3 and 1.5 mm deep; a few are encountered in the corpus. With our criteria we can not tell the cell type, e.g. Purkinje vs basal cells. Background firing varies from 10-60 spikes/sec. down to one spike every few seconds; some units are relatively regular, some quite irregular. A few burst at the respiratory rhythm.

Responses to long (250 ms) pulses of current in the bath may be phasic, phasic-tonic or apparently tonic; pure tonic responses are rare. 90% of units increase discharge at ON of inward current (external anode; cathode in the stomach) and decrease at OFF; others behave in the opposite way. Minimum thresholds are <1 μv/cm. Electrosensitive units are generally unimodal, i.e. do not respond to mechanical, acoustic or photic stimuli. 68% of units respond best in the 90° between head positive and ipsilateral side positive.

Hand held bipolar stimulating electrodes 2 mm apart moved around the fish close to the skin defined receptive fields. At each locus that elicits a detectable change from background in a histogram of several stimulus pulses, there is a best orientation and direction ($\vec{E}$ vector). Units vary widely: receptive fields may be small or large, unilateral or bilateral, bilateral symmetrical or asymmetrical, with foci of inward or outward current or two foci widely separated. Units vary also in latency, intensity function and dynamics with stimulus repetition rate.

26.18 EFFECTS OF CEREBELLAR LESIONS ON SENSORY-MOTOR COORDINATION IN THE ELECTRIC FISH EIGENMANNIA SPEC. K. Behrend Inst. f. Zoologie Abt. Biophysik Univ. Mainz 6500 Mainz W-Germany

Electric fish evaluate their environment by measuring local disturbances of their own electric field caused by objects of different conductivity than the surrounding water.The role the cerebellum plays in a mottor act aimed to gain more precise information about these objects(Heiligenberg,W.,J.Comp.Phys.103, 247-272,1975)has been investigated by lesioning the electrosensory part in the lobus caudalis of the cerebellum(Bastian,J.,90,1-24,1974).The animals swam in their tankwhere metal rods of 4 mm diameter could be placed at various places,eliciting a "probing behavior" consisting of backwards swimming towards the object and bending the body around the object.The animals movements were recorded on video tape and analyzed frame by frame giving a time resolution of the movemnt of 20 msec.After the lesion besides other rather small disturbances the most striking difference was a "yaw" during the probing behavior and also during forward swimming giving the animal an eel like appearance.Since normally the head is kept very stable with respect to the object the yaw introduces a different field composition than normally which must impairthe object evaluation and,infact,lesioned animals are more apt to avoid the metal rod than to investigate it by the probing behavior.This suggests a role of the cerebellum in improving sensory evaluation of the environment by giving motor commands which in this case counteract the yawing of the head thus compensating effects on the electric field caused by the fish's own movements.

26.19 EFFECTS OF CEREBELLAR STIMULATION UPON MIDBRAIN SENSORY RESPONSES IN A TELEOST FISH. Luis Crispino*. (SPON: Theodore H. Bullock) Neurobiology Unit, Scripps Instit. of Oceanog. and Dept. Neurosci. U.C.S.D., La Jolla, CA 92093.

The effects of cerebellar stimulation upon midbrain evoked potentials and/or unit responses of different sensory modalities have been analyzed in curarized catfish (Ictalurus nebulosus).

Sensory stimulation consisted of flashes for the visual system and clicks, electric pulses and table tapping for the acousticolateralis system, all of arbitrary stimulus parameters. Flash evoked potentials were recorded from the optic tectum. Acoustic evoked potentials and acoustic, electrical, and mechanically sensitive units were recorded from torus semicircularis. Slow evoked wave averages and poststimulus histograms were obtained from the recorded data by means of a special purpose computer.

A train of square pulses (0.1 ms., 100/sec., for 150 ms., found by trial to be approximately optimal) was delivered to the cerebellum before the sensory stimulus, at various intervals. Stimulation was applied to the areas of the cerebellum receptive to each modality, according to S.L. Tong and L. Lee (pers. comm.), and to other areas.

The effects of such stimulation are an enhancement of the visual evoked potential and a decrease of the acoustic, electric and mechanical responses. The effect for all modalities is maximum at the interval of 15-20 ms. between the end of the cerebellar stimulation and the sensory stimulus and declines slowly to 100-120 ms.

Attributing the action to peripheral inhibition can be rejected for the electric response since efferents are said to be absent (T.H. Bullock, Ann. Rev. Neurosci., in press). The response obtained by stimulation of the proximal stump of the posterior lateral line nerve (excluding receptor organs) was also affected by the cerebellar stimulation. Second order neurons recorded from the medulla following electrosensory activation did not show any change when the cerebellum was stimulated.

These results provide evidence of a central modulating action on the afferent responses seen in the midbrain, carried out by the cerebellum.

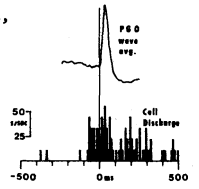
27.1 PONTINE RETICULAR NEURONS AND PGO WAVE INITIATION: INTRACELLULAR RECORDINGS DURING NATURAL REM SLEEP. R. W. McCarley and K. Ito. Harvard Medical School, Boston, MA 02115.

PGO waves are characteristic EEG spikes occurring in Pons, Lateral Geniculate nucleus (LGN), and Occipital cortex during and just before REM sleep. Previous work in this laboratory has pointed to midbrain PGO burst neurons as responsible for the final step in brainstem to LGN transmission of PGO waves. We now report intracellular recordings (potassium citrate electrodes; stable DC potentials more negative than 45 mV) of pontine reticular formation (PRF) neurons whose inputs and discharge characteristics make them prime candidates for the initiators of PGO wave generation. Intracellular recordings during naturally occurring sleep-wake cycles in cats revealed long lead high coherence (LLHC) neurons whose depolarizing PSPs/discharges began about 100 msec prior to the onset of ipsilateral LGN PGO waves, as analyzed both by film and by computer generated cross-correlogram data. The figure shows the cross-correlogram for one LLHC neuron and the average of 10 PGO wave forms (discharge onset-to-PGO wave time is 80 msec; range was 70-110 msec). On the average a 12-fold increase in discharge rate occurred prior to PGO waves, with a high and reliable degree of coupling. A discharge acceleration occurred, on the average, before 86% of all isolated PGO waves. We have thus far recorded 5 neurons of this type. While histology is pending, our stereotaxic coordinates indicate recording sites in the dorsal portion of the rostral PRF about 1-1.4 mm lateral to midline, an area known to contain neurons involved in eye movement generation. All LLHC neurons received monosynaptic excitatory input from microstimulation sites in contralateral PRF and most from bulbar and mesencephalic reticular formations also. One neuron was antidromically activated from contralateral pons and one from midbrain. Carbachol stimulation at the recording site by passive diffusion (8μG/μL concentration in a pipette with a 15μM tip) markedly enhanced PGO wave activity while controls of diffusion with saline at the same site or more distant sites with carbachol did not produce such an enhancement. To our knowledge, this is the first report, either in extracellular or intracellular recordings, of a group of PRF neurons with the characteristics of such a long lead and such regularity of coupling of discharge to PGO waves. While more data are needed, the correlational data and the evidence from carbachol stimulation indicate these neurons are the best present candidates for cellular initiators of PGO waves.



27.2 CROSS-CORRELATION OF PGO BURST CELL FIRING WITH EYE MOVEMENT POTENTIALS OF THE ALERT CAT. J. P. Nelson, R. W. McCarley and J. A. Hobson. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, Boston, MA 02115

PGO burst neurons are midbrain cells which fire in bursts of 4-6 spikes 12 msec before onset of ponto-geniculo-occipital (PGO) waves during REM sleep. We have shown that cells on one side of the midbrain fire when larger PGO waves occur in the lateral geniculate body(LGB) on the same side, but never fire when the larger wave occurs in the opposite LGB. They also fire preceding and during large rapid eye movements of REM sleep when they are to the ipsilateral side, but are almost always silent when the eye movements are to the opposite side. We have postulated that the burst cells act as output elements in the PGO generation system, and that during REM sleep they provide the forebrain visual system with information about the horizontal direction of upcoming REM's in the form of variation of PGO wave amplitude on either side of the brain.

We have thus far analyzed 11 of 44 burst cells in detail during wakefulness(W), using cross-correlograms(CC) of unit firing and averaged LGB and oculogram waveforms. During W these cells fire mostly single spikes with increased rates during periods of eye movement(EM) activity. Five of the 11 cells fired in relation to the LGB waves which often follow offset of saccades (eye movement potentials--EMP's). CC's of unit firing and EMP's showed that firing rates began to increase between 20 and 150 msec before onset of the EMP wave. The onsets were 20, 30, 30, 40, and 150 msec. The peak increase of firing rate over background levels ranged from 4 to 50 times, being for the individual cells 4, 6, 8, 10 and 50 times background.

Separate CC have been done on 3 cells for EMP's associated with rightward or leftward saccades. Two of these cells showed more increase of firing rate before EMP's associated with ipsilateral saccades than with contralateral saccades (7:4, 16:6 respectively), a finding of interest because it raises the possibility that waking EMP's may transmit information about EM direction.

The strong correlation shown here between firing of PGO burst cells and EMP's suggests that these cells likely play a role in generation of geniculate waves during wakefulness as well as during REM sleep. The cells on one side of the midbrain do not fire in unison in W as they do during REM sleep, but the more variable correlation in W is consistent with the greater variability of EMP's compared with PGO waves.

This research was supported by NIMH grant 2 RO1 MH 13923-13 and a RSDA to RWM.

27.3 COMPARISON OF THE PROJECTIONS FROM THE MESENCEPHALIC, ORAL PONTINE, CAUDAL PONTINE AND MEDULLARY RETICULAR FORMATION AND FROM THE LOCUS COERULEUS. T.Z. Yang and B.E. Jones (SPON: D.G. Lawrence). Lab. of Neuroanatomy, Montreal Neurological Inst., Dept. Neurology and Neurosurgery, McGill Univ., Montreal, Quebec, Canada H3A 2B4.

In order to assess quantitatively and qualitatively the efferent projections from the medial reticular formation and locus coeruleus in the rat, axonal transport of protein was studied by injection of ^{3}H-leucine (200μCi in 200μl, 40-60Ci/mM) into the following areas:mesencephalic, oral pontine, caudal pontine and medullary gigantocellular reticular formations and locus coeruleus. Two or seven days after injection, the rats were perfused and their brains processed either for autoradiography or liquid scintillation counting.

The mesencephalic reticular formation projected predominantly to the forebrain with a bilateral innervation to the following regions:basal forebrain, basal ganglia, entopeduncular nuc. subthalamic nuc., substantia nigra, zona incerta, and medial and intralaminar nuc. of the thalamus, the posterior nuc.,the pretectal area, the nuc. of the posterior commissure, and the interstitial nuc. of Cajal. In addition it sent bilateral widespread projections to the entire medial reticular formation of the brain stem and a small projection to the contralateral intermediate zone of the dorsal horn. The oral pontine reticular formation also sent significant though less dense projections to the same forebrain structures but more dense projections to the brain stem reticular formation. Caudally it projected the full length of the spinal cord, terminating predominantly in the ipsilateral intermediate zone of the ventral horn. The caudal pontine reticular formation sent a sparse ascending projection but provided a dense bilateral innervation to the brain stem reticular formation and vestibular nuc. It also provided the quantitatively most important innervation to the spinal cord, involving mainly laminae 7,8, and 9 of the ipsilateral ventral horn. The medullary gigantocellular reticular formation projected even more sparsely to the diencephalon but heavily innervated the brain stem reticular formation, the vestibular nuc., and the motor cranial nerve nuclei. Descending projections were bilateral onto the intermediate zone and lamina 9 of the ventral horns. In contrast to the reticular formation which thus provides a widespread but nonetheless differential innervation to the forebrain and spinal cord, the locus coeruleus innervates the entire central neuraxis including the cortex in a more diffuse and relatively homogeneous manner. (Supported by Canadian Medical Research Council Grant no. 6464).

27.4 STIMULATION OF MEDULLARY RETICULAR FORMATION DRIVES LUMBAR BACK MUCSLE EMG IN THE RAT. P.A. Femano, S. Schwartz-Giblin* and D.W. Pfaff. Rockefeller University, New York, NY 10021.

Previous studies have demonstrated that stimulation of neuronal activity within the pontomedullary reticular formation can exert both excitatory and inhibitory influences on motor mechanisms of the spinal cord via reticulospinal projections (see review by Peterson, B.W., Ann. Rev. Physiol., 41:127-140, 1979). For studying mechanisms of axial postural maintenance in the rat, we are investigating possible reticular influences on the lumbar axial musculature.

Adult female Sprague-Dawley rats were anesthetized with urethane and the axial muscles were exposed at vertebral levels L_2, L_4 and L_6. Recordings from motor units in either transversospinalis (TVS), medial longissimus (ML) or lateral longissimus (LL) muscle at each level were obtained by inserted pairs of twisted fine-wire tungsten electrodes fed directly into an LF356N FET as a first stage preamp. Bipolar stimulating electrodes consisted of a pair of twisted 75μ insulated tungsten wires. Electrodes were inserted stereotaxically into the medullary and pontine reticular formation ipsilateral and contralateral to the sites of EMG recording. Stimulation consisted of biphasic square wave pulses (leading phase cathodal) with a typical duration of 0.2 ms/phase. Frequency of stimulation varied from single pulses to trains of 1000 Hz, but typically trains of 200 Hz were used. Stimulus currents rarely exceeded 40μA. Conventional amplification, monitoring, stimulus, and recording circuits were used for on-line and post-experimental data analysis.

Stimulation of the medullary reticular formation ipsilateral to sites of motor unit recording elicited EMG driving at all vertebral levels investigated. Stimulation was especially effective in the region of nucleus reticularis gigantocellularis, Within this region effective currents were typically between 15μA and 25μA. Stimulation of the contralateral reticular formation at the same brainstem level could produce a strong inhibition of the EMG at currents comparable to those which elicited driving by ipsilateral stimulation. Repetitive stimulation of either side had a facilitating effect on the observed EMG responses. That is, a cumulative effect of repetitive trains of reticular stimulation occurred for both excitatory and inhibitory responses.

The results suggest that in the rat lumbar axial muscles receive a strong reticulospinal influence which could be important for the maintenance of posture and the initiation of certain behavioral responses.

27.5 PROJECTION FROM THE RETICULAR FORMATION OF THE MEDULLA TO THE FACIAL NUCLEUS. J. Courville, G. Goudreau*. Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal.

Injections of small volumes (0.1 - 0.2 µl) of ^{3}H-L-leucine (conc. 150 - 200 µCi/µl) in the reticular formation of the medulla and the autoradiographic method were used in 22 cats to demonstrate the presence and distribution of the projections to the facial nucleus and other motor nuclei of the caudal brainstem. The reticular formation comprises a medial portion which corresponds to nucleus gigantocellularis in the rostral half of the medulla and to nucleus ventralis in the caudal half of this region (Brodal, '57). The lateral portion corresponds to nucleus parvicellularis. This part of the reticular formation projects to the facial nucleus. The projection is dense ipsilaterally and less dense contralaterally. Different positions of the injection centers within that area demonstrate distributions with different densities in various subgroups of the facial nucleus. It is not possible, however, to demonstrate a precise correspondence between reticular regions and the nuclear subdivisions. Nucleus gigantocellularis does not project to the facial nucleus while the medial portion of the caudal medulla sends a moderately dense projection distributed in all subdivisions of the nuclei. The ipsilateral side is slightly more labelled than the contralateral one. Horseradish peroxidase injections in the facial nucleus confirm the position of the cells of origin of the projections in the lateral and in the caudal and medial parts of the reticular formation. Pars caudalis of the spinal trigeminal nucleus projects to the lateral subgroup of the facial nucleus, ipsilaterally. The efferent fibers from pars caudalis travel within the spinal trigeminal tract while reticulo-facial fibers course within the lateral part of the reticular formation. Projections to the motor trigeminal, hypoglossal, retrofacial and ambiguus nuclei also originate from the lateral reticular regions.

Supported by a grant from the Canadian Research Council to the Group in neurological sciences at Université de Montréal and grant MT-6722.

27.6 THE RETICULOSPINAL NUCLEI OF THE LIZARD AND RAT: A NISSL, GOLGI AND HRP COMPARISON. Donald B. Newman*, William L.R. Cruce and Rita Liu*. (SPON: R. Borke). Department of Anatomy, Uniformed Services University of the Health Sciences, Bethesda, MD, and Neurobiology Department, NEOUCOM, Rootstown, OH.

Present evidence (e.g., Cruce and Newman, '81) suggests that reptilian reticulospinal projections resemble those seen in mammals. Yet no one has compared reptilian reticular cell groups with those of mammals to ascertain whether these nuclei are similar in cytoarchitecture and neuronal morphology. Therefore, we have compared the organization of brainstem reticulospinal nuclei (RN) in Iquanid and Teid lizards with those of the rat using Nissl and Golgi techniques. In addition, we backfilled reticulospinal neurons with horseradish peroxidase (HRP) using large spinal injections and the tetramethyl benzidene (TMB) reaction. This enabled us both to precisely identify the location of reticulospinal cells and to compare their dendritic morphology in HRP and Golgi material. We found striking similarities. The rostral myelencephalic RN of the lizard can be subdivided into a dorsal portion (RID) vs. a ventral portion (RIV). RID contains large neurons with polygonal somata and dendrites which radiate in all directions. RIV contains neurons which possess fusiform somata and dendrites which course horizontally. Similarly, the rostral medullary RN of the rat can be subdivided into a dorsal portion (nucleus reticularis gigantocellularis) vs. a ventral portion (nucleus reticularis magnocellularis). Gigantocellularis, like RID in reptiles, contains large multipolar neurons whose dendrites ramify in all directions. Magnocellularis, like RIV in reptiles, contains neurons with fusiform somata and horizontally-coursing dendrites. The caudal metencephalic reticular field in reptiles (RM) resembles the nucleus reticularis pontis caudalis in the rat in that it also contains large multipolar neurons whose dendrites ramify in all directions. The dendritic arborizations of RM neurons, however, encompass a proportionately greater area of the brainstem than their counterparts in the rat. The rostral metencephalic RN of lizards (RS) resembles the nucleus reticularis pontis oralis of the rat in that it can be divided into a lateral area containing large cells (RSL) vs. a medial area containing mostly small cells (RSM). RSL cells of the lizard resemble the lateral nucleus reticularis pontis oralis cells of the rat in that the majority of their dendrites stream laterally as if to intersect the adjacent lateral lemniscus. Supported by USUHS Grant #919C07003 and NIH Grant #1R01.NS14346.

27.7 THE AFFERENT CONNECTIONS OF THE NUCLEUS VENTRALIS MEDIALIS THALAMI IN THE CAT,AS REVEALED BY THE HRP METHOD. J.Jiménez-Castellanos,Jr. and F.Reinoso-Suárez.Departamento de Morfologia.Universidad Autónoma de Madrid.Facultad de Medicina.Arzobispo Morcillo 2.Madrid 34.Spain.

The nucleus ventralis medialis thalami(VM)has been previously reported to provide an anatomical substrate for some nonespecific projection covering most of the cerebral neocortex.The aim of this repport is contribute to elucidate the origin of the afferent nervous impulses to the VM in the cat.Small amounts (25 nl)of a 16% solution of HRP(Sigma type VI)in distilled water were stereotaxically placed in the VM with a glass micropipette using an air-pulse delivery system.Forty eight hours postoperatively the cats were perfused and processed according to the method of Mesulam(1978)to reveal labeled neurons.The entire brain was surveyed for identifying HRP-labeled perikarya.At cortical levels labeled neurons were found in:gyrus proreus,sulcus praesylvius(medial and lateral banks and bottom),gyrus orbitalis gyrus frontalis,gyrus rectus,anterior limbic and cingular areae, gyrus suprasylvius(mainly in the anterior portion),sulcus ectosylvius anterior(both banks and bottom),gyrus sylvius anterior, sulcus rhinicus anterior(principally in the superior bank and bottom),sulcus cruciatus(mainly in the inferior bank and bottom) and sulcus rhinicus posterior.At subcortical levels the labeled neurons were situated principally in the claustrum,substantia innominata,nucleus entopeduncularis,amygdaloid complex,zona incerta,nucleus reticularis thalami,nucleus geniculatus lateralis (pars ventralis)and in dorsal,lateral and medial hypothalamic formations in the prosencephalon.The structures labeled in the brain stem were in all cases:substantia nigra,periaqueductal gray matter,mesencephalic and pontine reticular formations,deep layers of the superior colliculus,brachium conjunctivum area, locus coeruleus,nucleus reticularis gigantocellularis,nucleus spinalis nervi trigemini and deep cerebellar nuclei(mainly in the medial and lateral nuclei).These results show the forebrain as the main source of afferent connections to the nucleus ventralis medialis thalami.

28.1 NEUROCHEMICALLY IDENTIFIED RETINAL NEURONS AS PROBES OF VERTEBRATE PHYLOGENY. R.E. Marc. Sensory Sciences Center, University of Texas Health Science Center, Houston, TX 77025.

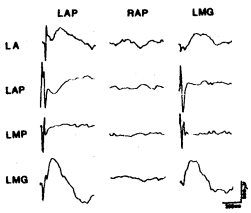
Two major uses of comparative neuromorphology are to investigate the validities of neural systems as mutual exemplars among vertebrates and to examine vertebrate evolutionary relationships. However, vertebrate phylogenies have rarely been evaluated at the level of neurochemically and morphologically identified neurons, though the primary unit of evolutionary change in the brain is indeed the neuron. Studying homologous neurons allows strong evaluations of phyletic models since neuron classes are generally robust characters not inclined to change dramatically except at major phyletic interfaces.

Using light and electron microscope autoradiography I have examined phylogenetic relations for identified GABA-ergic, dopaminergic and glycinergic retinal neurons in 36 species from 23 orders, and from all 7 classes. Each neurochemical class of cell shows either persistence or change that allows evaluation of events transpiring at different phyletic interfaces. GABA-ergic cone horizontal cells show continuity in all the modern "bony" groups(teleosts, holosteans, amphibians, reptiles, avians) except mammalians. This matches well with a model of mammalian evolution that posits a nocturnal or fossorial ancestor that lost or dramatically reduced cone vision. Since all GABA-ergic horizontal cells are cone-driven, their absence from mammalian eyes is consistent with the model. More evidence derives from the lack of homology between mammalian cones, which Walls (1943) considered to be secondarily derived, and all cones from other vertebrates. Dopaminergic neurons probe the osteichthyan/amphibian interface, where a major neural discrepancy exists: Anurans possess dopaminergic interplexiform cells as do modern teleosts, but urodeles possess, instead, a dopaminergic amacrine cell. The dopaminergic amacrine cell is the format found in urodeles, reptiles, avians, mammals and, significantly, the sarcopterygian fishes represented by the dipnoans, the lungfishes. The neurochemical and morphological organization of the retina of *Protopterus*, the African lungfish, is virtually identical to the retinas of urodele amphibians (*Necturus, Ambystoma, Amphiuma*), resurrecting the notion of Säve-Sodebergh (1934) that urodeles are the descendents of primitive dipnoans. That aside, my findings are in accord with the oft-suggested polyphyletic model of amphibian origins. Glycinergic amacrine cells appear to be archetypal in form and retinal distribution throughout the vertebrates, from Cyclostomata to Mammalia. They have apparently survived the events that drove the transformations of GABA-ergic horizontal cells and dopaminergic neurons.

28.2 FUNCTIONAL CONNECTIONS IN THE HUMAN LIMBIC SYSTEM. Michael Wang,* Charles L. Wilson, Thomas L. Babb, Eric Halgren and Paul H. Crandall. Brain Res. Inst., Reed Neurological Res. Cntr., and Dept. of Surg. (Neurol.), Sch. Med., UCLA, Los Angeles, CA 90024

In contrast to the animal literature, very little direct evidence exists on the functional pathways connecting structures within the human limbic system. The preliminary results reported here were obtained from 9 epileptic patients implanted bilaterally with chronic depth electrodes to localize temporal lobe seizure foci for surgical therapy. Sites included the anterior pes hippocampi (AP), middle pes hippocampi (MP), middle gyrus hippocampi (MG), posterior gyrus hippocampi (PG) and amygdala(A). These structures are homologous to ventral hippocampus, the temporal shoulder of dorsal hippocampus, entorhinal cortex, and basolateral amygdala, respectively. Bipolar recordings were from 40 uM platinum microwires which externded 5 mm beyond bipolar stimulating macroelectrodes stereotaxically placed under X-ray guidance within the same structure as the microwires. Single pulse, symmetrical, biphasic 100 usec square waves were delivered in turn, to macroelectrodes in each structure, and evoked field potentials were recorded from microwires in adjacent areas.

Results of tests in all electrode sites in 5 of the 9 patients indicate that the highest probability and lowest thresholds of response were from intrinsic macroelectrode stimulation within the same structure as recorded with local microwires. Next, in descending order of response probability came: ipsilateral response of amygdala to hippocampus, entorhinal cortex to hippocampus, hippocampus to entorhinal cortex and ipsilateral hippocampal sites to one another. In three cases hippocampal stimulation evoked responses in amygdala, and one amygdala site was responsive to entorhinal stimulation, but no entorhinal site responded to amygdala stimulation. Contralateral responses to stimulation of any limbic structure were totally absent. In the figure, single stimuli with a cathodal charge density of 7.0 uC/cm^2/ph were delivered to the sites across the top. The recording sites are labelled on the left, and responses are averaged from 4 stimuli. In response to LAP stimulation the shortest latencies are to intrinsic stimulation, then adjacent hippocampal (19 msec) and entorhinal cortex (25 msec) sites and longest, amygdala (37 msec). Contralateral response to RAP is absent.



Supported by NIH Grant NS 02808

28.3 ELECTRON MICROSCOPIC STUDIES OF THE PARABRACHIAL NUCLEI IN THE CAT USING HORSERADISH PEROXIDASE AND DEGENERATION METHODS: RECIPROCAL CONNECTIONS WITH THE AMYGDALA. Y. Takeuchi, J.H. McLean and D.A. Hopkins. Department of Anatomy, Dalhousie University, Halifax, Nova Scotia, B3H 4H7, Canada.

Recent anatomical studies have shown that the parabrachial nuclei (PBN) project to the amygdala which, in turn, projects back to the PBN. Initial studies have described the ultrastructure of four regions of the PBN (Takeuchi and Hopkins, Anat. Rec., 199: 252A, 1981) but there is no information on the synaptic relationships of these reciprocal projections. Therefore, in the present experiments, the ultrastructure of PBN projection neurons and amygdaloid afferents to the PBN were examined in the cat.

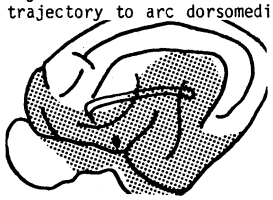
In order to identify the cells of origin of the PBN which project to the amygdala, horseradish peroxidase (HRP) was injected into the amygdala. After 2-3 days, cats were perfused with a 0.15M phosphate buffer containing 1.0% paraformaldehyde and 1.25% glutaraldehyde. Three-hundred-µm-thick sections of the PBN were first processed for HRP histochemistry using diaminobenzidine and then processed for electron microscopy. Retrogradely labelled neurons projecting to the amygdala were located mainly in lateral and ventral parts of the PBN. The labelled projection neurons were usually fusiform and ranged from 10-20 µm in diameter. They had a large nucleus which was often invaginated and had a moderately developed cytoplasm which contained many lysosomes.

In order to identify amygdaloid afferents, electrolytic lesions were made in the central nucleus of the amygdala. After 2 to 7 days, cats were perfused with the same fixative as in the HRP experiments. Degenerating axon terminals were found primarily in lateral and medial parts of the PBN and were characterized by swollen mitochondria and either round or pleomorphic vesicles in a dark matrix. Degenerating axosomatic terminals were occasionally found to contact soma of small-sized neurons particularly in the lateral part of the PBN. The majority of axodendritic terminals were 1-2 µm in diameter and were found mainly in lateral and medial parts of the PBN. The ultrastructural findings indicate that most small-sized neurons of the lateral and ventral PBN project to the amygdala. These neurons also appear to receive small numbers of axosomatic terminals from the amygdala but it remains to be determined to what degree they also receive axodendritic terminals. These reciprocal connections appear strongest in the lateral part of the PBN and provide further evidence for regional differences in the PBN.

Supported by the MRC of Canada and a Killam Postdoctoral Fellowship.

28.4 CORTICAL FIELD OF ORIGIN OF THE CAT'S ANTERIOR COMMISSURE. M. L. Jouandet. Institute of Anatomy, Univ. of Lausanne, 1011 Lausanne, Switzerland.

The extent of the neocortical field of origin of the anterior commissure (AC) of the cat, the cell types comprising this field, and the laminar and population distributions of these cells are not known. Following the complete transection, under deep Nembutal anesthesia, of the corpus callosum (CC) and hippocampal commissures (HC) of twelve cats, massive quantities of HRP (between 12 and 80 µL) were injected unilaterally in the right hemisphere in order to label completely the entire origins of the 3 branches of the AC in the left. Since the AC is the only interhemispheric telencephalic fiber system remaining following CC and HC commissurotomy, only the cells, fibers, and terminals of the AC should be labeled with HRP in the contralateral, uninjected telencephalon. Two additional cats, having their CC, HC, and AC aspirated, served as controls. All brains were cut coronally and processed by tetramethylbenzidine (TMB). HRP-labeled cells are found in the anterior olfactory nucleus, the prepiriform and piriform cortices, the nucleus of the lateral olfactory tract, the amygdala, and the olfactory tubercles. These findings agree with previous reports on other species. The neocortical field of origin of the AC is extensive. Deep layer V and VI polymorphic and pyramidal cells are apparent in high numbers in continuous laminae in the proreal, coronal, anterior ectosylvian, anterior sylvian, middle ectosylvian, posterior sylvian, posterior ectosylvian, and ventral portions of the posterolateral, gyri. More dorsal to a level horizontal to that at which the CC crossed the midline, the number of HRP-labeled cells drops off until only an occasional cell can be identified medially beyond the suprasylvian sulcus. The three major limbs, minor subsequent branches, and many individual axons of the AC system are labeled with HRP in the TMB-processed left hemispheres. Upon entering the hemisphere the posterior limb fibers sweep laterally to the ventral end of the external capsule and turn in tight bundles up into the external capsule. After leaving the dorsal end of the external capsule the axons then change trajectory to arc dorsomedially to recross the internal capsule at its dorsal end; arriving in the white matter just lateral to the dorsolateral tip of the lateral ventricle, the axons make sharp hairpin turns to then sweep directly lateral and fan out dorsally and ventrally into all those neocortical territories where HRP-labeled cells were found.



28.5 A MORPHOLOGICAL AND MORPHOMETRIC ANALYSIS OF THE SUBNUCLEAR STRUCTURE OF THE INTERPEDUNCULAR NUCLEUS IN THE RAT. G. S. Hamill* and N. J. Lenn. Dept. of Neurol., Univ. of Virginia, Charlottesville, VA 22908.

Nissl stained celloidin sections in three planes, 1μ plastic embedded sections, acetylcholinesterase (AChE) histochemistry, ^{3}H-leucine transport from injection sites in the habenular region and electron microscopy have been utilized to define the interpeduncular nucleus (IPN) and its major subdivisions in rat. Various parameters have been quantified using a Zeiss Videoplan image analysis system.

The cytoarchitectural boundaries of IPN are precisely congruent with the area labeled in the axoplasmic transport specimens. The volume of IPN so defined is 0.4 mm^3. Within IPN, there are 3 unpaired, median subnuclei: the rostral, central and caudal; and 3 pairs of bilateral subnuclei: the intermediolateral (IML), lateral and cap subnuclei. The myelin and AChE pattern, and crest synapse distribution suggest that IML consists of a rostral (IMLr) and a caudal (IMLc) division. The principal data are summarized in the Table.

Subnucl. Parameter	Rostral	Central	Caudal	IML (both)	Lateral (both)	Cap (both)
1. Volume(%IPN)	24	13	5	43	13	2
2. Cell diam.(μ)	8.13	11.53	--	12.3	13.3	12.8
3. Cells/area	18.5	8.33	--	12.8	4	--
4. Nissl stain	1+	3+	2+	2+	3+	4+
5. AChE stain	3+	2+	2+	1+	4+	2+
6. Density of label	3+	2+	--	2+	4+	--
7. Synapse type	S	--	--	Crest(IMLc)	--Dense-core	
8. Opiate recept.	3+	2+	--	0	1+	2+
9. Subst. P	--	--	--	Cell bodies	--	--
10. Afferents	Hab	Hab	DTN	Hab	Hab	Hab
11. Efferents	--	--	--	Hippocampus	--	--

2.p<.001 rostral vs all others; no other significant differences. 3. Denominator=7244μ^2. 4.-6. Rated 1+ to 4+. 7. Lenn, J.Comp. Neur.166,'76; Murray et al,J.Comp.Neur.187,'79. 8. Herkenham and Pert,Proc.Nat.Acad.Sci.77,'80. 9. Cuello et al, J.Comp.Neur.178,'78. 10. Hab=habenula; DTN=dorsal tegmental nucleus region, Herkenham & Nauta,J.Comp.Neur.187,'79;Contestabile & Flumerfelt,J.Comp. Neur.196,'81. 11. Baisden et al,Neurosci. Letters 13,'79.

The proposed scheme of subnuclei is based upon and supported by the above parameters. It is now clear that any detailed study of IPN will necessarily consider the subnuclear organization of this structure. Supported by NIH Grant # NS 16882.

28.6 DISTRIBUTION OF PRIMARY AFFERENTS TO THE OCTAVOLATERALIS AREA OF THE PIKE CICHLID. C.A. McCormick. Dept. of Anatomy, Georgetown University, Washington, D.C. 20007

The first order projections of the lateral line nerves were studied in the teleost fish Crenicichla lepidota using experimental degeneration methods. Either the posterior or the anterior lateral line nerve was transected at or proximal to its ganglion in a given specimen. Following survival times of 6-10 days at 28 C, brains were processed according to the Wittanen modification of the Fink-Heimer technique.

The posterior lateral line nerve enters the medulla as a single root just rostral to the entrance of the glossopharyngeal nerve and forms ascending and descending tracts positioned at the lateral edge of the medulla just ventral to the cerebellar crest. The single anterior lateral line nerve enters the medulla just caudal to the entrance of the sensory root of the facial nerve, and forms ascending and descending tracts which course ventral to those of the posterior lateral line nerve.

Some fibers in the ascending tracts of the posterior and anterior lateralis nerves terminate in the ipsilateral eminentia granularis of the cerebellum. The majority of primary lateralis fibers, however, terminate in two nuclei in the dorsal portion of the ipsilateral octavolateralis area of the medulla--nucleus medialis and nucleus caudalis. Nucleus medialis, which is the largest termination site of the lateralis nerves, is situated ventral to the cerebellar crest. Posterior lateral line nerve fibers terminate in the dorsal portion of this nucleus, while anterior lateral line nerve fibers terminate more ventrally. Some fibers in the descending posterior and anterior lateral line tracts terminate in the caudal-most portion of the dorsal octavolateralis area--nucleus caudalis.

In Crenicichla, the ventral portion of the octavolateralis area consists of five nuclei: the anterior octavus nucleus, nucleus magnocellularis, nucleus tangentialis, the descending octavus nucleus, and the posterior octavus nucleus. Preliminary studies indicate that all of these nuclei receive first order input from the eighth nerve. In addition to its primary eighth nerve input, nucleus magnocellularis also receives a light first order input from the posterior and anterior lateral line nerves, a connection similar to that seen in other fishes.

Supported by NINCDS 5 F32 NS06381-02 and NSF BNS77-26022.

28.7 PRIMARY PROJECTIONS OF THE LATERALIS NERVES IN THE SHOVELNOSE STURGEON, Scaphirhynchus platorynchus. J. G. New and R. G. Northcutt, Div. Biol. Sci's., Univ. Mich., Ann Arbor, MI 48109

Primary projections of the lateralis nerves were traced with HRP and Fink-Heimer methods. Adult sturgeon were anesthetized with MS222 and the anterior (ALLN) or posterior (PLLN) lateral line nerve exposed and unilaterally transected. A gelfoam pledget saturated with 40% HRP (Sigma VI) was inserted proximal to the transection in the HRP cases; the wound was packed with gelfoam and sealed with dental acrylic. After survival times of 6-16 days for the HRP cases and 14 days for the Fink-Heimer cases at 14°C, the animals were reanesthetized and perfused transcardially with phosphate buffer (ph 7.4) followed by 2% glutaraldehyde (HRP cases) or 10% formalin (Fink-Heimer cases). The brains were processed by a modification of the Mesulam HRP protocol using TMB as the substrate or by the Wiitanen modification of the Fink-Heimer method.

The ALLN of sturgeons possesses dorsal and ventral roots. Fibers of the dorsal root enter the medulla and form ascending and descending branches that terminate within the ipsilateral dorsal octavolateralis nucleus. Fibers of the ventral root of the ALLN, as well as fibers of the PLLN, enter the medulla ventral to the dorsal root of the ALLN where some of the fibers terminate among the dendrites of the magnocellular octaval nucleus. The bulk of the fibers form ascending and descending branches that terminate within the ipsilateral medial octavolateralis nucleus. A portion of the descending fibers continue more caudally to terminate in the ipsilateral caudal octavolateralis nucleus. Similarly, a portion of the ascending fibers continue more rostrally and terminate bilaterally in the cerebellar lateral lobes and granular layers of the corpus cerebellum. The dorsal root of the ALLN may possess additional projections, but experiments restricted to this root remain to be performed. The HRP cases also revealed retrogradely filled large neurons whose axons course peripherally in the lateral line nerves and are likely efferent to lateral line organs. These cells are situated in the medulla in the same rostrocaudal plane as the branchiomeric nuclei.

Thus there are marked similarities in the primary projections of the lateralis nerves in sturgeons and elasmobranchs, both of which possess ampullary electroreceptors; the direct cerebellar projections in sturgeons, however, appear to be unique.

This work was supported in part by NIH grants to RGN.

28.8 TECTAL AFFERENTS IN THE LONGNOSE GAR (HOLOSTEI). R. Glenn Northcutt. Division of Biological Sciences, University of Michigan, Ann Arbor, Michigan 48109.

Afferent pathways to the optic tectum of the longnose gar (Lepisosteus osseus) were determined by intratectal injections of HRP (Sigma VI). Volumes of 100-300nl of 20% HRP solution were delivered by micropipette pressure injections (3 cases), or the tectum was innoculated with HRP paste on the tip of a "00" insect pin (7 cases). Following survival times of 4-16 days at 27°C, the animals were reanesthetized and perfused transcardially with cold phosphate buffer (pH 7.4) followed by 2% glutaraldehyde in phosphate buffer. Brains were removed, embedded in 25% gelatin, and cut at 40μ on a sled microtome. Sections were reacted with o-dianisidine or tetramethyl benzidine following modified protocols of Coleman et al., 1976, or Mesulam, 1978.

Unilateral tectal injections resulted in retrogradely labeled cells in the following forebrain regions: ipsilaterally in the caudal portion of the rostral entopeduncular nucleus, anterior thalamic nucleus, ventrolateral and ventromedial thalamic nuclei, and periventricular pretectal nucleus; bilaterally in the rostral lateral zone of area dorsalis of the telencephalon, and in the central pretectal nucleus. At midbrain levels, retrogradely labeled cells were seen ipsilaterally in the torus longitudinalis, nucleus isthmi, and accessory optic nucleus; bilaterally in the torus semicircularis and a rostral tegmental nucleus. Pyramidal cells of the periventricular gray zone and fusiform cells of the central zone were also labeled in the contralateral optic tectum. Ascending tectal afferents from the brainstem arise bilaterally from the locus coeruleus, the superior, medial, and inferior reticular formations, and the nucleus of the descending trigeminal tract. Retrogradely filled cells were also observed in the inferior raphe nucleus, bilaterally in the eurydendroid cells of the cerebellum, and contralaterally in the medial octavolateralis nucleus and dorsal funicular nucleus and dorsal horn of the cervical spinal cord.

Analysis of these results and other connectional data for gars reveals that 1) There are two visual pathways to the telencephalon in these fishes, as in land vertebrates; 2) All pretectal nuclei except the superficial pretectal nucleus possess reciprocal connections with the optic tectum, thus suggesting that the superficial nucleus is not involved in tectal inhibition; 3) The gar tectum, like that of many other vertebrates, receives information from most sensory modalities that enter the brainstem.

(This work was supported by NIH Grant EY02485.)

28.9 ASCENDING AND DESCENDING SPINAL PATHWAYS IN THE PACIFIC HAGFISH. Mark C. Ronan* and R. Glenn Northcutt (SPON: M. S. Northcutt). Neurosciences Program and Division of Biological Sciences, University of Michigan, Ann Arbor, Michigan 48109.

Ascending spinal pathways and cephalic cell groups projecting to the anterior spinal cord in the Pacific hagfish, Eptatretus stouti, were examined with HRP histochemistry. Rostral cord lesions (5th-10th spinal segments), ranging in extent from hemisections to near transections, were made in seven adult hagfishes (29-41cm in length) and packed with gelfoam saturated with 40% HRP (Sigma VI). Animals survived 6-15 days in 14°C seawater. Transverse sections of the brain and rostral cord, 40μ thick, were processed according to a modification of the Mesulam, '78 TMB protocol. Staining of degenerating axons after rostral cord hemisections by the Wiitanen modification of the Fink-Heimer technique provided confirmation of ascending spinal pathways observed in HRP material.

The ascending pathways consist of a dorsal funiculus (DF) and a spinal lemniscus (SL). A large, well-defined DF ascends adjacent to the dorsal midline in the cord and then curves laterally in the diverging horns of the rostral medulla. The DF arches dorsally over the octavolateralis area and the trigeminal complex as it travels in the peripheral margin of the medulla before ending near its rostrolateral extent. The SL spans the ventral and lateral funiculi of the cord and ascends through the magnocellular divisions of the caudal and rostral medullar reticular formations. In the rostral medulla, fibers swing dorsomedially from the lateral SL and terminate in the ipsilateral caudal tectum.

Retrograde transport of HRP labels neurons in the nucleus of the MLF and mesencephalic reticular formations ipsilateral to the implant. In the medulla, HRP-filled cells of the rostral reticular formation included the entire ipsilateral and the anterior contralateral magnocellular divisions plus scattered cells of the ipsilateral parvocellular division. In the caudal reticular formation, magno- and parvocellular elements were labeled bilaterally with the ipsilateral side predominating in the latter division and the contralateral in the former, particularly in its posterior half. Large bipolar neurons in the ipsilateral octavolateralis area and numerous small cells in the perivagal nucleus were also labeled. Most filled cord cells were found in the intermediate contralateral spinal gray.

Pacific hagfish thus possess interstitiospinal and extensive reticulospinal pathways. A vestibulospinal system may be present. Ascending pathways include spinoreticular and spinotectal systems.

(Supported by NIH grant EY02485.)

28.10 CENTRAL PROJECTIONS OF THE OCTAVOLATERALIS NERVES IN GYMNOTIFORM FISH. Catherine Carr and Joanne Matsubara. Neurobiology Unit, A-002, S.I.O., UCSD, La Jolla, California,92093.

The afferent and efferent projections of the mechanoreceptive posterior and anterior lateral line nerves and the eighth nerve were investigated in two species of South American weakly electric fish (Gymnotiformes). The central cut ends of nerves were incubated in 30% horseradish peroxidase and reacted after a 3-10 day survival time using tetramethyl benzidine and Hanker Yates reagent as chromagens. Nomenclature was based on the work of McCormick (1981).

Mechanoreceptors of the posterior lateral line nerve (trunk) and the anterior branch of the anterior lateral line nerve (head) project topographically to the anterior lateral line lobe (ALLL), a probable field homologue of the medial octavolateralis nucleus, and to the caudal octavolateralis nucleus. Mechanoreceptive primary afferents also terminate on the large cells of the dorsal portion of the magnocellular octaval nucleus. Primary afferents send collaterals to the ementia granularis and the caudal lobe.

Eighth nerve fills produce terminal fields, from rostral to caudal, in the anterior octaval nucleus, the ventrolateral border of the mechanoreceptive ALLL, the magnocellular octaval nucleus, the tangential octaval nucleus, the descending octaval nucleus and the posterior octaval nucleus.The eighth nerve also projects to the ementia granularis of the cerebellum. Considerable overlap of eighth and mechanoreceptive lateral line afferents occurs at the ventrolateral border of the ALLL and adjacent dorsomedial border of the octaval column. There is no overlap between the ALLL and the tangential octaval nucleus.

Efferent cells of both the eighth and mechanoreceptive lateral line nerves are found bilaterally in a motor column which extends from caudal to the Mauthner cells to the level of the pacemaker nucleus. An additional small cluster of cells efferent to the lateralline are found closely apposed to the axons of the Mauthner cells at the level of eighth nerve entry. Only a small proportion of all the efferent cells are contralateral. Some project to both lateral line receptors and to the ear, as is supported by the observations that the same efferent cells appear to be backfilled by injections into either the lateral line nerves or the eighth nerve, and that an injection into the lateral line nerve produces a few well labelled fibers in the eighth nerve root.

This work was supported by NSF grant BNS76-20761 and NIMH grant PHSMH-2614904 to Walter Heiligenberg.

28.11 ELECTROSENSORY, AUDITORY AND LATERAL LINE NUCLEI IN THE MIDBRAIN OF A GYMNOTIFORM WEAKLY ELECTRIC FISH, STERNOPYGUS. J. Matsubara T.E.Finger, L. Maler, C. Carr. Scripps Inst. Ocean., UCSD, La Jolla, Cal. 92093; Dept of Anat, Univ Colo Med Ctr, Denver, Co. 80262; Dept of Anat, Univ Ottawa Fac Med, Ottawa, Canada, K1N9A9

The octavolateralis system of teleosts is composed of the lateral line, auditory and vestibular sensory systems. In the Gymnotiformes, weakly electric fish of South America, the lateral line system includes both mechanosensory and electrosensory modalities. The primary afferent fibers of the mechanoreceptive, electroreceptive and inner ear sense organs enter the brain via the anterior lateral line nerve (electroreceptive and mechanoreceptive fibers), the posterior lateral line nerve (mechanoreceptive fibers) and the 8th cranial nerve (vestibular and auditory fibers). The first-order termination sites of the octavolateralis system are segregated on the basis of modality. The electroreceptive input projects to the posterior lateral line lobe, mechanoreceptive input projects to the anterior lateral line lobe and the 8th nerve inputs project to a collection of 8th nerve nuclei (Maler et al 1974; Carr and Matsubara, in prep.).

In catfish, the second-order octavolateralis nucleus in the midbrain, the torus semicircularis, is also segregated on the basis of modality (Knudsen, 1977). However, in gymnotiforms the torus semicircularis is a complex laminated structure and the relationship between the electrosensory and other modalities has been unclear.

Horseradish peroxidase (HRP) was used as an anterograde and retrograde tracer to determine connections of the various octavolateralis nuclei in Sternopygus. Injections were made in the anterior lateral line lobe (ALLL), the octaval nuclei and various regions of the torus semicircularis (TS). These injections reveal two distinct regions of TS: a ventral nucleus which receives bilateral input from the mechanosensory lateral line and the octaval nuclei, and a laminated dorsal nucleus which receives bilateral input from the electrosensory system via the posterior lateral line lobe (Carr et al submitted). Furthermore, within the ventral nucleus there exists some segregation of mechanosensory lateral line and octaval inputs: efferents to the rostral ventral TS arise largely from the anterior octavus nucleus whereas efferents to the remainder of the ventral TS arise mainly from the crest cells of the ALLL. In addition to the projection to TS, the ALLL projects to the deep layers of the optic tectum and receives input from granule cells of the caudal cerebellum as well as from cells of the ventral region of nucleus praeementialis.

28.12 RETINAL PROJECTIONS IN THE GREEN SUNFISH: A CASE OF HOMOPLASY. Ann B. Butler and R. Glenn Northcutt. Dept. Anat., Georgetown Univ., Washington, D.C. 20007 and Div. Biol. Sci., Univ. of Michigan, Ann Arbor, Mi. 48109.

Eight adult green sunfish, Lepomis cyanellus, received unilateral intraocular injections of tritiated proline (spec. act. 139 Ci/mmol, conc. 50 μCi/μl) under MS222 anesthesia. After 1,3, 6,12 and 35 days, animals were reanesthetized and perfused. 15μ sections were coated with Kodak NTB3 and exposed 45 days at 7°C.

After complete decussation of fibers in the optic chiasm, two distinct fascicles enter the contralateral suprachiasmatic nucleus after arising from the medial edge of the marginal optic tract (MaOT). At more caudal levels, the axial optic tract divides into 3 main components: a medial fascicle that innervates the contralateral preoptic area (PO) and then redecussates to innervate the ipsilateral PO, a ventral fascicle that bilaterally terminates in the anterior tuberal region of the hypothalamus, and a lateral component that rejoins the MaOT at the level of the pars magnocellularis of the superficial pretectal nucleus (SPt). As the MaOT courses caudally it divides into dorsal (DOT), ventral (VOT) and medial (MOT) optic tracts. The MOT courses toward the periventricular cell groups of the diencephalon where rostrally it terminates in the anterior (A), ventrolateral (VL) and ventromedial (VM) thalamic nuclei and in a dorsal portion of the preoptic area. More caudally, the MOT terminates in the periventricular pretectal nucleus (PPt) and posterior tuberculum and contributes fibers to the deep white zone of the optic tectum (TeO) and posterior commissure (PC). As the MaOT is traced caudally it first gives off terminals to the pars parvocellularis of the SPt and then divides into DOT and VOT with most fibers coursing around or through the pars magnocellularis of the SPt. The DOT and VOT terminate in nucleus corticalis and the central pretectal nucleus and enter TeO to distribute fibers to the deeper portions of the marginal layer, the superficial white and grey zone, and the deep white zone. At more caudal levels, VOT contributes fibers to a basal optic nucleus, an accessory optic nucleus, VL, VM, the periventricular pretectal nucleus (PPt) and to the PC. Fibers of the MOT and VOT cross in the PC to innervate the ipsilateral deep white zone of TeO, PPt, VL, VM and A. Thus, the sunfish possesses bilateral primary retinofugal projections to the diencephalon and tectum; however, the ipsilateral projections decussate in the posterior and preoptic commissures rather than in the optic chiasm, suggesting that these ipsilateral pathways are homoplastic to the ipsilateral retinofugal pathways of other vertebrates.

28.13 LOCALIZATION OF ENKEPHALIN-LIKE IMMUNOREACTIVITY IN THE BRAIN OF THE LAMPREY, M.R. Gold and T.E. Finger, Depts. of Physiol. and Anat., Univ. Colo. Med. Sch., Denver CO 80262

Enkephalin-like immunoreactivity (ELI) has been reported in the nervous system of a wide variety of vertebrates. In the few amniote species examined, there appears to be marked similarities in the distribution of immunoreactivity. In order to assess the consistency of these patterns throughout the vertebrate phylogeny, we examined the distribution of ELI in a species of lamprey. The brain and pituitary of adult brook lampreys, Lampetra lamottei, were removed from the braincase and fixed by immersion in periodate-lysine-paraformaldehyde solution for 2-6 hours. Following wash in phosphate buffer, the tissue was sectioned in the transverse plane and reacted with unlabeled L-enkephalin antiserum (supplied by R. Miller). Both fluorescence and PAP techniques were used. All immunoreactivity was abolished by preabsorbing the antiserum with L-enkephalin (10 μM).

As in other vertebrates, immunoreactive somata and fibers occur in discrete areas throughout the length of the neuraxis. In the brainstem, a substantial plexus of ELI fibers courses through the ventralateral portion of the medullary neuropil. Immunoreactive fibers in this plexus turn dorsolaterally to end in the vicinity of the dendrites of the vagal and facial, but not trigeminal, motor nuclei. A second immunoreactive fiber bundle is located just ventral to the MLF in the rostral rhombencephalon. In addition, ELI fibers and cell bodies are located in the vicinity of n. solitarius and comm. nuc. of Cajal. Scattered ELI fibers enter the cerebellum. Throughout the metencephalon and mesencephalon ELI fibers run adjacent to the ependyma. Both the optic tectum and torus semicircularis show a laminar pattern of ELI fibers. None of the large identifiable reticulospinal neurons exhibit ELI.

In the prosencephalon, a dense plexus of ELI fibers extends through out the ventromedial hypothalamus and preoptic area. ELI somata occur throughout the hypothalamus. Both the median eminence and intermediate zone of the pituitary exhibit heavy ELI. Comparatively less ELI is present in the dorsal thalamus although substantial numbers of ELI fibers occur in portions of the habenular complex. In the telencephalon, ELI fibers are present mostly in ventromedial portion but certain pallial fields also receive a significant ELI input.

Comparison of these findings with previous reports indicates substantial similarities in the distribution of ELI among widely divergent vertebrate classes. This suggests marked conservation of enkephalinergic systems throughout the vertebrate phylogeny. Accordingly, peptide localization may prove to be a powerful means to indicate homologous systems.

28.14 CONNECTIONS OF CEREBRAL CORTEX IN THE TURTLE (PSEUDEMYS SCRIPTA ELEGANS). P. Desan*. (SPON: R. Baughman). Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The afferent and internal connections of the turtle cerebral cortex were delineated by anterograde and retrograde transport methods. This cerebral cortex is divided into four rostrocaudal strips, termed lateral, dorsal, dorsomedial and medial cortex. Injections of tritiated proline in the olfactory bulb label a dense plexus of afferent terminals in the superficial 100μ of the entire lateral cortex on both sides of the brain. Large injections of tritiated proline in the thalamus label a similar superficial lamina in dorsal cortex. After intraocular injections of tritiated proline, such labeling is restricted to a lateral, histologically distinct subdivision of dorsal cortex, presumably reflecting the transneuronal transport of the amino acid through a visual relay nucleus in the thalamus.

Injections of 15% HRP/2% lysolecithin or 2% wheat germ agglutinin-HRP conjugate (Sigma L-2384) were made across the rostrocaudal extent of dorsal cortex. These injections retrogradely label cell groups of the lateral thalamus adjacent to the optic tract: the nucleus ovalis and associated nucleus dorsolateralis anterior, the rostral and caudal parts of nucleus geniculatus lateralis. Rostral injections label caudal portions of this complex; caudal injections label rostral portions, in both ipsilateral and contralateral thalamus. Furthermore, injections in dorsal or lateral cortex label cells in medial cortex; injections extending into dorsomedial cortex label cells in medial and dorsomedial cortex on both sides of the brain.

Both types of HRP injections yielded vigorous anterograde transport. Olfactory cortex projects densely to a narrow superficial lamina of medial cortex, dorsal cortex projects to a deeper lamina of medial cortex, and injections extending into dorsomedial cortex additionally label the remaining deepest lamina of medial cortex (a similar pattern has been described in snake cortex- Ulinski, P.S., J.Morph., 150: 463-483, 1976).

These experiments suggest that visual and non-visual nuclei of the thalamus and the olfactory bulb project to different areas of the cortex, and these areas, with dorsomedial cortex, project convergently to medial cortex and receive reciprocal projections from it.

28.15 ANATOMY OF THE TRIGEMINAL MOTOR NUCLEUS OF THE TEGU LIZARD, G.A. Iwamoto and G.S. Throckmorton*, Dept. of Cell Biology, The Univ. Texas Hlth. Sci. Ctr., Dallas, TX 75235

Previous studies (Throckmorton, Archs Oral Biol 25:225-233 1980 and Bramble, Amer Zool 20:931 1980) have shown that jaw and tongue movements during the chewing cycle in reptiles are remarkably similar to those of mammalian species. Reports on several mammalian species (See Matsuda et al Neurosci Lett 8:1-4 1978) have shown a characteristic topographical organization within the trigeminal motor nucleus. Our investigation was undertaken to determine if a similar nuclear organization was also present in the lizard. Adult tegu lizards were anesthetized with ketamine hydrochloride (80 mg/kg) and sodium pentobarbital (15 mg/kg) and the muscles of the trigeminal nerve exposed. Injections of a 10% solution of horseradish peroxidase (Sigma Type VI) were administered in 1 μl aliquots (5-15 μl total per individual muscle) to all trigeminally innervated muscles on one side followed by injection of a selected muscle on the contralateral side. Selected muscles included: Superficial Portion of the External Adductor, Pterygoideus, Middle Portion of the External Adductor and Pseudotemporalis. The animals were re-anesthetized after a survival period of 48-72 hrs and perfused with 0.4 paraformaldehyde 2.5% glutaraldehyde following a saline wash. The brainstems were removed and following a 12 hr post-fixation period, placed in 30% sucrose-phosphate buffer for 48-96 hrs at 4°C. The brainstems were cut in 50 or 100 μm transverse sections, reacted with tetramethyl benzidine, counterstained with Neutral Red and microscopically examined. Labeled cells ranging from 15-50 μm were noted as to size and location. In agreement with Ebbesson (Brain Res 5:178-206 1967) it was found that the trigeminal motor nucleus may be grouped at least into major dorsal and ventral divisions. The muscles were represented as follows: the Superior Portion of the External Adductor occupied much of the ventral division with Pterygoideus occupying a smaller area on the ventral aspect of this division. Remaining portions of the External Adductor occupied the dorsomedial aspects of the nucleus comprising some of the dorsal division. Finally, Pseudotemporalis is represented in the most dorsomedial portion of the dorsal division. Comparisons with results from mammalian species suggest similarities in distribution of motor neurons between lizards and mammals for the following muscles: Superficial External Adductor-Masseter, Pterygoideus-Medial and Lateral Pterygoid muscles, Middle External Adductor and Pseudotemporalis-Temporalis. The data suggests that the anatomical organization of the trigeminal nucleus of the lizard is similar to that of mammalian species and may indicate that the neural apparatus controlling mastication had an early phylogenetic origin. This study was supported by NSF Grant No. DEB78-05330.

28.16 THALAMOCORTICAL ORGANIZATION IN TWO LIZARDS. Laura L. Bruce and Ann B. Butler. Dept. Anatomy, Georgetown Univ., Washington, DC 20007.

Thalamic projections to three divisions of telencephalic cortex were studied with retrogradely transported wheat germ agglutinin - horseradish peroxidase complex (Sigma WGA-HRP Type VI). In two lizards, Iguana iguana and Gekko gecko, crystals were deposited into the medial cortex, the dorsal cortex, and into a rostral area which included the lateral cortex and the pallial thickening. After six day survival periods, the animals were perfused and the tissue was processed according to the deOlmos and Heimer protocol (Neurosci. Lett., 1977). The characteristics of the retrogradely labeled cells were identical in both species.

Depositions of HRP which were confined to the medial cortex resulted in retrogradely labeled cells limited to the large-celled portion of the nucleus dorsolateralis anterior (DLA) of the thalamus. Labeled cells were present bilaterally in equal numbers. After depositions of HRP confined to the dorsal cortex, retrogradely labeled cells were observed only in the small-celled portion of the DLA. Slightly more labeled cells were present ipsilaterally than contralaterally. When depositions of HRP were confined to the lateral cortex and the pallial thickening, a small number of heavily labeled cells were present in the large-celled DLA, principally the ipsilateral side. The small-celled DLA contained lightly labeled cells bilaterally, possibly due to incorporation of HRP by broken fibers of passage. A small number of lightly labeled cells were present ipsilaterally in the dorsomedial nucleus and the perirotundal cell group. Labeled cells were present throughout the ipsilateral nucleus intercalatus. This nucleus was also labeled after HRP injections restricted to the pallial thickening and the dorsal ventricular ridge. Nucleus intercalatus receives a retinal projection from the contralateral eye in both iguana and gecko (Butler and Northcutt, Brain Res., 1978). Thus the pallial thickening is the recipient of a retino-thalamo-cortical pathway.

29.1 ONTOGENETIC DIFFERENCES IN THE RESPONSE OF THE CHOROID PLEXUS pH TO ACETAZOLAMIDE. Conrad E. Johanson and Zahra Parandoosh*. Dept. Pharmacology, Univ. of Utah, Salt Lake City, UT 84132

The carbonic anhydrase (CA) in choroid plexus (CP) tissue may participate in the regulation of pH of the CP-CSF system. A previous study of adult rats (Johanson, The Pharmacologist 21, p. 242) demonstrated that the CA inhibitor, acetazolamide, 20 mg/kg I.P. for 1 hr, markedly elevated the pH of the lateral ventricle choroid plexus (LVCP), from 7.0 to 7.5. We have expanded the investigation to include immature rats, and fourth ventricle choroid plexus (4VCP) as well as LVCP.

Immature Sprague-Dawley rats, 1 and 3 wk, were etherized and bilaterally nephrectomized and injected I.P. with DMO (dimethyloxazoladinedione), as tracer ^{14}C (20 $\mu C/100$ g) and as carrier (15 mg/kg). After 1 hr, samples were taken from arterial blood (AB), cisternal cerebrospinal fluid (CSF), and choroid plexuses. The pH of AB was analyzed on an IL 213, and the pHs of CSF, LVCP and 4VCP were calculated from the steady-state distribution of ^{14}C-DMO. Means (± SEM) for n = 6 are given below for control (C) and treatment (T), 20 mg/kg acetazolamide.

	pCO_2	pH values:			
	AB	AB	CSF	LVCP	4VCP
1 wk (C)	29(1)	7.43 (.03)	7.41 (.03)	7.05 (.07)	7.21 (.04)
1 wk (T)	47(5)*	7.18 (.03)*	7.24 (.06)*	7.03 (.05)	7.24 (.08)
3 wk (C)	22(1)	7.52 (.02)	7.44 (.02)	7.11 (.04)	7.25 (.04)
3 wk (T)	38(1)*	7.30 (.02)*	7.45 (.04)	7.30 (.04)*	7.33 (.02)*

Each asterisk denotes $P < 0.05$ by t test.

For the first time, control pH values are presented for the immature CP. The 1-wk rat LVCP, across which there is negligible turnover of CSF, has a control pH (7.05) not significantly different from that previously determined in adults. Moreover, choroid cell pH in 4VCP is consistently 0.15 pH unit greater than in LVCP. In 1-wk rats, acetazolamide does not alter cell pH. However, in 3-wk animals the CA inhibitor significantly elevated cell pH in both LVCP and 4VCP. The magnitude of the acetazolamide-induced change in cell pH in 3-wk rats (0.1 to 0.2 pH unit) was less than the corresponding induced change noted previously in adult rats (i.e., 0.5 pH). The increase in CP pH occurred in spite of a marked elevation in arterial pCO_2, and it is likely due to a build-up in the concentration of OH^- and HCO_3^- subsequent to acetazolamide effects on choroid cell function. Acetazolamide treatment did not alter CSF pH in the 3-wk rats; however, CSF pH was not effectively buffered in the 1-wk animals. This work was supported by USPHS Grant 1 R01 13988, NINCDS and by a RCDA to C.E.J.

29.2 SALICYLATE EFFECTS ON ORGANIC ACID HERBICIDE TRANSPORT BY CHOROID PLEXUS. C. S. Kim,* L. A. O'Tuama* and C. R. Roe* (Spon. G. D. Frye) Univ. North Carolina Sch. of Med., Chapel Hill, NC 27514 and Duke Univ., Durham, NC 27706.

We have shown that the uptake of 2,4-dichlorophenoxyacetic acid (2,4-D) by adult rabbit choroid plexus (CP) is saturable, energy and temperature dependent (Kim et al., Soc. Neurosci. Abs. 6:291, 1980) and have also described differential effects of salicylate and acetaminophen on the uptake system. The present study was undertaken to investigate whether these drugs also have differential effects on neonatal rabbit CP and to study interaction of salicylate metabolites with the carrier. Lateral and fourth ventricular CP (LVCP, FVCP) of 3 day and 30 day old rabbits were incubated for 10 min in control and experimental media containing ^{14}C-2,4-D 0.02 μCi/ml (sp. act. 28 mCi/mmol). The uptake of ^{14}C-2,4-D at 10 min was reduced by 52% and 66% respectively in FVCP and LVCP of neonatal rabbits incubated with 10^{-3} M sodium salicylate (SS) ($p < 0.01$). However, treatment with acetaminophen at the same concentration did not alter ^{14}C-2,4-D uptake by either LVCP or FVCP of neonatal rabbits. The major metabolite of salicylate, salicyluric acid (SU) has stronger inhibitory effects than its precursor salicylate. ^{14}C-2,4-D accumulation was reduced 66% and 84%, respectively, in adult FVCP and 53% and 83%, respectively, in LVCP incubated with SU (10^{-4} M, 10^{-3} M) ($p < 0.01$, $p < 0.001$). Gentisic acid was the weakest inhibitor of uptake. Recent studies suggest that high pesticide exposure and salicylate consumption contribute to the pathogenesis of Reye's syndrome (RS) (Starko et al., Peds. 66:859, 1980). This finding strengthens the view that embarrassment of cellular energy-linked functions is a critical event in the development of RS. This study suggests that salicylate intoxication to CNS function via impairment of the organic acid transport system in CP can provide a direct mechanism for the development of encephalopathy in RS. Supported by USPHS Grant HD-03110.

29.3 INSULIN EFFECTS ON SODIUM TRANSPORT BY CHORIDE PLEXUS. Yoshitaka Saito* Helen Wong and Ernest M. Wright. Dept. of Physiol., UCLA School of Medicine, Los Angeles, Ca. 90024.

CSF secretion by the choroid plexus is driven by Na/K pumps in the brush border membrane. Since little is known about the control of CSF secretion we have studied the effects of insulin on the Na pump in the frog choroid plexus.

Tissues were loaded with ^{22}Na in K-free, cold buffer solution. The efflux of ^{22}Na from the plexus was monitored at room temperature and the rate constant (k) was estimated by the method of Keynes (J. Physiol. 178:305, 1965). The pump component was obtained from the change in rate constant induced by the addition of 2 mM KCl to the Ringer solution (Δk). Ouabain (1 mM) completely blocked this K-induced Na efflux. Na pump rate ($\Delta k \times (Na_i)$) was a sigmoidal, saturable function of intracellular Na (Na_i) and extracellular K (K_o) concentration. The data suggested that the pump has two sites for K_o and three sites for Na_i. The K_m's and V_{max}'s were 1.1 mM and 7 mM and 8 μmoles/cm^2·h and 13 μmoles/cm^2·h for K and Na transport, respectively.

Addition of insulin (10^{-7}-10^{-5}M) to the washout medium significantly stimulated sodium pumping by 24-140%. This hormonal effect on the Na/K pump was also monitored by transepithelial Na flux measurement. We observed that insulin (10^{-6}M) increased net sodium secretion. Insulin (1×10^{-7}M) increased the guanylate cyclase activity of the epithelium by 109%, while there was no substantial change in adenylate cyclase activity. Furthermore, we found that addition of dibutyryl cyclic-GMP (1~3 mM) increased the Na pump rate by 42~219% while the effect of dibutyryl cyclic-AMP was marginal.

These results suggest that Na secretion by the choroid plexus is modulated by insulin via effects on Na/K pump, and the stimulatory effect of insulin may be mediated by increases in intracellular cyclic-GMP levels.
Supported by a grant from the USPHS (NS09666).

29.4 STUDIES OF THE BLOOD RETINAL BARRIER IN RATS WITH INHERITED RETINAL DYSTROPHY. Ruth B. Caldwell, Lou G. Boykins* and Barbara J. McLaughlin. Department of Anatomy. University of Tennessee Center for the Health Sciences, Memphis, TN 38163

Retinal degeneration in the Royal College of Surgeons rat occurs between 12 and 70 postnatal days with a gradual decline in phagocytic activity by the defective pigment epithelium (PE) as the photoreceptors degenerate. Another change in the dystrophic retina which can be attributed to a defect in the PE cell layer is a breakdown in the blood-retinal barrier. Between 72 and 116 days, the PE cell junctions, which form part of this barrier, become permeable to extracellular tracer (Bok, 1979) and corresponding intramembrane changes in cell junction structure are observed (Caldwell et al., 1981). In this study we have used tracer and freeze-fracture techniques to study the progression of these changes during retinal degeneration in dystrophic and normal rats from 3 wk to 1 1/2 years old. Eyecups were incubated with horseradish peroxidase (HRP) (Sigma, Type VI, 20%) for 30 min-1 hr and processed for EM. The other eyes were prepared for freeze-fracture. As early as 6 wks, PE cell junctions become permeable to HRP. By 72 days there are striking changes in PE cell junctions. Numerous annular gap junctions which are thought to be a means of disposing of cell junctional membrane (Albertini et al., 1975), are seen in the PE cytoplasm. In addition, some PE cells appear to have detached completely from each other while others remain joined but their junctions are displaced from their normal position. In these abnormal areas, HRP bypasses the cell junctions and is present on the baso-lateral membrane surface of some PE cells. Freeze-fractured tight junctions between normal PE cells are found to consist of 8 to 12 anastomosing ridges on the cytoplasmic membrane leaflet (P-face) and 8 to 12 complementary grooves on the external membrane leaflet (E-face). Gap junctional aggregates of hexagonally packed P-face particles and complementary E-face pits are enclosed within the tight junctional strands. In dystrophic rats younger than 42 days old, all PE junctional areas are indistinguishable from those of normal retinas. After 113 days dramatic alterations are observed: the tight junctional strands appear unraveled and to be broken up into short segments; the number of strands and the number of gap junctions are often reduced; and gap junctions are no longer encircled by the tight junctional strands and exist as isolated particle aggregates. In summary, our results show that permeability changes in the blood retinal barrier between PE cells occur as early as 42 days. These changes in PE cell junction permeability are found before any changes in junctional intramembrane structure are discernable by freeze fracture. Supported by USPHS EY 02853.

29.5 ASSESSMENT OF NEURAL TRANSPORT OF LOW DOSE INORGANIC LEAD. L. A. O'Tuama*, C. S. Kim* and R. N. Johnson* (Spon. P. Morell). Univ. N. Carolina Sch. of Med., Chapel Hill, NC 27514.

Concerns about possible effects of "low level" exposure to toxic metals, e.g., lead (Pb) (McCabe, Env. Health Perspect., 29: 29, 1979) indicate a need for detailed information on the neural distribution of such compounds in tracer amounts. These studies are complicated by the low entry rate of toxic metals into brain (O'Tuama et al., Toxicol. Appl. Pharmacol., 36:1, 1976). Arterial integral analysis (Blasberg, Radioscience 14:335, 1979) allows highly sensitive measurement of cerebrovascular permeation of tracers whose flux from plasma to brain corresponds to model assumptions. These assumptions include first-order transfer from plasma to tissue, initial permeation into a tissue space permitting free diffusion and final location in a tissue compartment whence no back-flux occurs. We have tested this model in the study of distribution of tracer amounts of inorganic Pb in peripheral and neural tissues. Young adult rabbits received radiolabeled $Pb(NO_3)_2$ [^{210}Pb] by iv bolus (1.2 μCi/kg; S.A. ≥ 1 mCi/mg). Serial arterial plasma ^{210}Pb activity was sampled from an arteriovenous anastomosis and compared with the activity in representative peripheral and neural tissues. The plot of the ^{210}Pb plasma concn. x time integral vs. tissue levels was linear for the peripheral organs, supporting model assumptions. Unidirectional rate constants for plasma-to-tissue transfer of metal ranged from 1.2 x 10^{-3} ml/g.min. (liver) to 2.5 x 10^{-3} mg/g.min. (bone). In contrast, for neural tissues, the integral vs. tissue plot was non-linear. The results show that plasma-to-neural transfer of tracer dose Pb involves mechanisms that are qualitatively different from those subserving uptake by peripheral tissues and appear substantially more complex than can be explained by a two compartment model. Preliminary analysis suggests that in brain there is a rapid initial uptake of metal followed by redistribution to peripheral organs. This pattern appears similar in several neural areas (cerebellum, caudate nucleus, occipital cortex, etc.) and may involve an anatomical structure common to all regions, e.g., the capillary endothelium tight junction. Supported by USPHS Grant ES-01141.

29.6 THE EFFECT OF LEAD ON CSF TRANSPORT IN THE ISOLATED SUPERIOR SAGITTAL SINUS OF THE DOG. J. D. Charlton*, S. L. Cookson*, N. E. Pederson*, R. N. Johnson and J. D. Mann. Dept. of Neurology, Univ. North Carolina, Chapel Hill, N.C. 27514.

We have previously shown that exposure to lead early in development results in impaired absorption of cerebrospinal fluid (CSF) in vivo. In the present study, we have assessed the effects of lead on CSF transport across the arachnoid villi in the isolated superior sagittal sinus of the adult dog.

Twenty adult mongrel dogs of either sex weighing 12.5 ± 2.8 kg were anesthetized with sodium pentobarbital. The superior sagittal sinus and a portion of the surrounding dura were removed from each animal and placed in cold, buffered artificial CSF. The superior wall of the sinus was opened longitudinally over a length of 2-3 cm and residual blood was removed. The sinus was mounted in a lucite chamber and perfused with oxygenated, buffered artificial CSF (10 mM glucose, 308 mOsm). The sinus was positioned to divide the chamber into two separate compartments (blood and CSF), with the sinus membrane providing the sole barrier between them. Pressure across the sinus was regulated by adjusting the relative heights of reservoirs of fluid circulating through either side of the chamber. A drop counter technique was used to measure the volume of CSF transported per unit time between compartments. Bulk flow was studied in response to changes in temperature, CSF composition, and differential pressure across the membrane. Movement of fluid into the CSF compartment from the blood side was negligible under all conditions studied.

Bulk transport of CSF to the blood side of the membrane was found to be both temperature and pressure dependent. Addition of uM quantities of KCN or ouabain significantly decreased transport. The addition of lead acetate (10-50 uM final concentration) resulted in a mean decrease of 37% (± 18% S.D.) in bulk CSF transport to the blood compartment as compared to baseline and Na acetate control conditions ($p < .001$). The effect was partially reversible when lead-free CSF was returned to the chamber. Nevertheless, lead clearly has an adverse effect on the bulk fluid transport capacity of tissues mediating absorption of CSF into the venous circulation. This study suggests that low level lead exposure results in a loss in intracranial pressure buffering capacity, thereby enhancing the risk for the development of intracranial hypertension and brain edema.

29.7 CHARACTERISTICS OF ZINC METABOLISM IN RAT BRAIN. E. J. Kasarskis* (SPON: A. C. Lastimosa). Dept. of Neurology, VA Hospital and Univ. Kentucky Med. Ctr., Lexington, KY 40536.

Zinc is the second most abundant trace metal cation in brain. However, the characteristics of zinc metabolism in the CNS have not been fully investigated to date. Zinc uptake and turnover in 7 brain regions, choroid plexus, and CSF have been determined and compared to plasma and non-neural tissues.

Groups of adult male Sprague-Dawley rats were maintained on zinc-adequate diets and received a single intraperitoneal injection of $^{65}ZnCl_2$ (25 μCi/100 g Body weight; 1.3 μCi/1 μg Zn). Representative animals were killed in groups of 3 at various times between 15 minutes and 28 days post-administration after pentobarbital anesthesia. The brain was perfused free of blood prior to dissection and assay of ^{65}Zn content.

Turnover of ^{65}Zn from plasma was rapid; less than 12% of the initial plasma concentration remained by 24 hrs. Uptake of ^{65}Zn by liver and other non-neural soft tissues was maximal by 6 hrs. In contrast, ^{65}Zn uptake into the CNS was exceedingly slow. Less than 0.4% of the administered dose was present in whole brain at 24 hrs. Moreover, the maximal accumulation of ^{65}Zn in whole brain did not occur until 7 days post-administration, remained relatively constant until 14 days, and declined slowly thereafter. The biological half-life of ^{65}Zn in brain varied from 13.0 days (optic nerve) to 26.6 days (hippocampus).

Initial transport into brain was greatest in cerebellum, optic nerve, and brainstem. Serial sectioning of brainstem revealed highest ^{65}Zn concentration at the level of the caudal IV ventricle. The concentration of ^{65}Zn in choroid plexus and the meninges was 10-100 fold higher than plasma throughout the 28 day period. Cerebrospinal fluid ^{65}Zn content averaged 0.5-1.5% of plasma and 9% of plasma ultrafiltrate (Pellicon PSAC membrane).

These studies demonstrate that the uptake and turnover of zinc in the CNS is protracted, especially when compared to metabolizable substrates. The rapid uptake of zinc by the choroid plexus suggests that it may be involved in zinc homeostasis within the CNS. The pattern of zinc metabolism in the CNS is qualitatively similar to other micronutrient cofactors. (Supported by a research grant from the Veteran's Administration and by USHS grant NS 16009).

29.8 EXPERIMENTAL SPINAL CORD TRAUMA: EARLY ALTERATIONS IN FLUID AND ELECTROLYTE LEVELS. NR Clendenon, WA Gordon* and JN Allen, Jr.* Neurochem Lab, Div of Neurol, Ohio State Univ, Columbus,O 43210

Edema of both gray and white matter was recognized as a prominent pathological finding in early morphological studies on experimental spinal cord trauma (Ducker TB et al, J Neurosurg 35: 700, 1971). Most biochemical studies of edema formation focused on intervals of 6 hrs or greater following impact injury. Yashon et al (J Neurosurg 38:693,1973) reported an average 2.6% increase in spinal cord water in trauma vs control samples as early as 5 min following a 300 g·cm impact injury to monkeys, reaching a maximum of 7.5% at 5 days. The present investigation used the rat model of cord injury and studied the sequence of edema formation within the initial 2 hrs following trauma.

Water and electrolyte levels of normal and traumatized spinal cord were assayed in laminectomized Sprague-Dawley rats weighing 250-300 gms using a section of thoracic cord approx 1 cm in length. Trauma was induced by applying a 90 g·cm force to the exposed cord by the weight drop method. Cord sections were cleaned of excess blood, weighed, dried at 95-100°C for 48 hrs and re-weighed. For electrolyte determinations, dried samples were homogenized in double distilled demineralized water. An aliquot, digested with concentrated nitric acid, was used for sodium and potassium determinations by emission flame photometry. Chloride was assayed using a protein-free filtrate of the remaining aqueous extract by an automated titration technique. Serum electrolyte assays followed established methods. Results were expressed as milliequivalents (mEq)/kg wet or dry weight of tissue and as mEq/l of serum.

Laminectomy alone produced a slight non-significant increase in tissue water and electrolyte levels over values obtained by the rapid removal method of DeSousa and Horrocks (Dev Neurosci 2: 115, 1979). Water content 5 min post trauma was not significantly different from laminectomized controls. Increased tissue water was evident by 10 min($p<0.05$) and continued to rise gradually throughout the period studied, reaching 4.5% of control at 120 min post injury. When tissue electrolyte levels were expressed on the basis of dry weight, a net gain in sodium($p<0.01$) and chloride ($p<0.001$) was evident by 15 min along with a slight but non-significant gain in potassium. Not until 30 min post injury was a significant decrease($p<0.02$) in net potassium observed, a time when serum levels were highest. Between 30 and 60 min, tissue sodium and chloride plateaued at levels approx 30% higher than laminectomized controls while potassium was 20% lower. These data suggest a vasogenic contribution to the edema formation occurring as early as 15 min post spinal cord injury and possibly a cytotoxic influence at later time intervals. (Supported by NINCDS #NS-10165).

29.9 DIETARY CHOLINE AND THE PERMEABILITY OF THE BLOOD-BRAIN BARRIER. R. Sankar*, B.A. Trommer*, K.L. Parrish, F.R. Domer and L. Wecker Depts. of Pharmacology, Tulane and Louisiana State Univ. Med.Ctrs. and Xavier Univ. College of Pharmacy, New Orleans, LA 70112.

We have examined the effect of dietary choline availability on the permeability of the blood-brain barrier (BBB) to a large molecular weight protein and a small anion by using radioiodinated serum albumin (RISA) and the ^{99m}Tc-pertechnetate anion(TcO_4^-), respectively. Male Sprague Dawley rats (final weight 250g) housed in groups of 2 and maintained on a 12 hour light/dark cycle with food and water available ad libitum were used for all studies. Rats were randomly divided into 3 groups and maintained for 12 or 24 days on: a) choline deficient chow (no free choline), b) basal choline chow (0.2% choline chloride) or c) choline supplemented chow (2.0% choline chloride). The rats were anesthetized with pentobarbital (60 mg/kg) and either RISA or pertechnetate was administered via the lateral tail vein.A cardiac blood sample was drawn 30 minutes after administration of the tracer , followed by perfusion with normal saline through the left ventricle to clear the cerebral vasculature. The brain was removed and the radioactivity in the brain was compared to that in the blood. Rats maintained on the 3 dietary regimens for 24 days did not exhibit any significant differences in the entry of RISA into the brain. The brain levels of the pertechnetate anion however, increased in the rats maintained on the choline deficient diet as compared to basal rats. Rats on the deficient diet for 12 days showed a 28% increase, while those maintained for 24 days showed a 50% increase increase in the brain to blood ratio of pertechnetate, indicating a time-dependency. Rats maintained on the choline supplemented diet did not exhibit significant differences in pertechnetate entry compared to rats on the basal diet. TcO_4^- is known to mimic I^- for many uptake processes and active removal of I^- from the CSF at the choroid plexus has been demonstrated. Our results indicate that dietary (chronic) choline deficiency leads to a compromised performance of this process. (Supported by NIMH grant # 33443.)

29.10 COMPARISON OF LIPID-MEDIATED BLOOD-BRAIN BARRIER PERMEABILITY IN THE ADULT AND NEWBORN BRAIN. L.D. BRAUN*, E.M. CORNFORD AND W.H. OLDENDORF (SPON: S.Diamond). Research Service, Brentwood VA Medical Center, Los Angeles, CA 90073 and Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

In many different membrane systems, oil:water partition coefficents of nonelectrolytes have been positively correlated with membrane permeability in a variety of in vitro studies. In this laboratory, it was demonstrated that measurement of brain uptakes could be correlated with olive oil:water partition coefficients (Oldendorf: Proc Soc Exptl Biol Med 147: 813, 1974) to extend this phenomenon to in vivo BBB function. Recently, we have demonstrated dramatically higher newborn brain uptakes for certain metabolites which cross the BBB by way of carrier-mediated systems as compared to the adult (Braun et al, J. Neurochm 34: 147, 1980). Preliminary studies also suggested brain uptakes of the anticonvulsants dilantin and phenobarbital was higher in the newborn than in the adult, and precluded a possibility of carrier-mediation. Because brain myelin content increases significantly in the neonatal period, the present study was undertaken to determine whether or not newborn brain uptakes of non-electrolytes could be correlated with octanol:saline partition coefficients. Brain uptake indices (BUI's) of cytosine, mannitol, urea, thiourea, ethylene glycol, propylene glycol, acetamide, methanol, ethanol, butanol, benzyl alcohol, phenobarbital, dilantin, antipyrine, caffeine and heroin were determined in the present study of newborn rabbits. Pardridge and Mietus (Endocrinology 107: 1705, 1980) have also determined newborn BUI's of estradiol and testosterone. Linear regression analyses indicated that the relationship of these 18 BUI's and octanol:saline partition coefficients (PC) in the newborn rabbit brain could be defined: (log BUI)x(Sq. root molec wt) = 6.3 (log PC) + 17, R= 0.86. In the adult rat BBB, on the basis of measuring BUI's of more than 45 compounds, and an almost identical relationship was derived: (log BUI)x(Sq. root molec wt) = 6.0 (log PC) + 14.5, R= 0.86.

Conclusion. These studies emphasize that despite developmental alteration in cerebral blood flow rates, and biochemical composition of the brain, in vivo function of the plasma: brain capillary interface is the same in the newborn and adult brains with respect to lipid-mediated penetration.

(This study was funded by the Department of Health, Education and Welfare under contract number NO1-NS-0-2332, and supported by the Veterans Administration.)

29.11 CHLORIDE MOVEMENT ACROSS THE BLOOD-BRAIN BARRIER: EVIDENCE FOR PASSIVE-DIFFUSIONAL TRANSPORT. Quentin R. Smith and Stanley I. Rapoport. Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore City Hospitals, Baltimore, Maryland 21224.

The mechanism of chloride transport across the in vivo rat blood-brain barrier was investigated to determine whether passive diffusion, facilitated diffusion, or active transport are involved in CNS Cl regulation. The concentration dependence of Cl-36 unidirectional influx (plasma to brain) and of brain chloride content was measured at the steady state after partial replacement of body Cl with nitrate. Briefly, Osborn-Mendel rats were anesthetized with 30 mg/kg Na pentobarbital. Plasma [Cl] was set at 50 ± 2, 72 ± 2, 97 ± 1 or 114 ± 1 mmol/l by peritoneal dialysis (3 cycles, 45 min/cycle) with rat artificial interstitial fluid containing 0, 50, 110 or 180 mmol Cl/l, respectively. Then, bilateral nephrectomy was utilized to maintain constant plasma [Cl] for 6 hr, during which time brain Cl content reached a steady-state distribution. At 1/2 hr prior to sacrifice, Cl-36 (6 μCi) and H-3 inulin (30 μCi) were injected into the femoral vein and plasma activity monitored until the rat was killed. Samples from 9 brain tissue regions, cisternal CSF, and plasma were analyzed for radioactivity and Cl content. When plasma [Cl] was varied over a 64 mmol/l range, changes in brain tissue Cl content were proportional to those in the plasma. In contrast, CSF [Cl]/plasma [Cl] decreased significantly from 1.62 ± 0.06 at 50 mmol/l to 1.21 ± 0.02 at 114 mmol/l. Cl-36 unidirectional influx from plasma to brain was linearly related to plasma [Cl] and extrapolated to the origin over a plasma [Cl] range of 50-114 mmol/l. Significant regional differences in blood-brain barrier permeability to Cl were detected in control rats. For example, the permeability surface-area product (PA) to chloride of cerebral cortex (1.68 ± 0.11 l/sec) was markedly less than the PA of cerebellum (3.03 ± 0.20), hippocampus (3.51 ± 0.43), and thalamus-hypothalamus (3.23 ± 0.25). The cisternal CSF PA to Cl was approximately 10 times greater than that of the cerebral cortex. In conclusion, the constancy of brain tissue Cl content/plasma [Cl] at the steady state and the linear relationship between Cl-36 influx and plasma [Cl] are consistent with passive-diffusional transport of Cl across the blood-brain barrier.

29.12 DEVELOPMENTAL CHANGES IN CALCIUM CONCENTRATION IN VARIOUS REGIONS OF THE RAT CNS, Scott A. Burton* and Conrad E. Johanson (SPON: S. Turkanis). Dept. of Pharmacology, Univ. of Utah College of Medicine, Salt Lake City, Utah 84132

Preparatory to an ontogenetic study of fluxes of radioactive Ca among various CNS compartments, we have analyzed the stable calcium content of cerebrospinal fluid (CSF), serum (SER), lateral ventricle choroid plexus (LVCP), fourth ventricle choroid plexus (4VCP), pineal body (PIN), cerebral cortex (CC), hippocampus (HIP), thalamus (THAL), cerebellum (CER), and medulla (MED) in infant (1 wk) and adult (8 wk) Sprague-Dawley rats. Blood taken from the inferior vena cava of lightly etherized rats was allowed to clot and then centrifuged to obtain serum. After exsanguination, CSF was taken immediately via puncture of the cisterna magna. Minced tissues were extracted for 2 days with 0.5 N HNO_3 and analyzed for Ca by atomic absorption. Mean values (± SEM), as mEq Ca/kg fluid H_2O (or kg wet tissue), for n = 6 are given below; because of developmental differences in tissue (tiss) H_2O content, Ca concentrations are also given per dry weight.

	One week	Eight weeks
SER	6.55 (.03)	6.03 (.02)
CSF	2.34 (.06)	3.36 (.03)

Total calcium in serum and CSF significantly decreases and increases, respectively, after 1 wk; CSF/SER Ca is greater in the adult (0.56) than in the infant (0.36).

	One week		Eight weeks	
	mEq Ca / kg wet tiss	mEq Ca / kg dry tiss	mEq Ca / kg wet tiss	mEq Ca / kg dry tiss
LVCP	2.29 (0.08)	13.45 (0.48)	1.84 (0.09)	9.20 (0.44)
4VCP	2.79 (0.13)	16.39 (0.76)	1.90 (0.05)	9.50 (0.23)
PIN	2.32 (0.15)	19.33 (1.25)	2.16 (0.05)	11.37 (0.26)
CC	2.12 (0.06)	18.74 (0.53)	2.39 (0.01)	12.58 (0.06)
HIP	2.05 (0.02)	18.14 (0.18)	2.45 (0.03)	12.89 (0.16)
THAL	2.10 (0.16)	17.50 (1.29)	2.38 (0.04)	11.90 (0.20)
CER	1.55 (0.05)	11.74 (0.38)	2.21 (0.02)	10.23 (0.09)
MED	1.68 (0.11)	12.44 (0.81)	2.48 (0.06)	9.65 (0.23)

In all regions analyzed, CP and brain tissue [Ca] (dry weight basis) is substantially greater in infants than in adults, particularly so (by 1/3) in 4VCP, PIN, CC, HIP and THAL. Since CSF [Ca], i.e., extracellular fluid [Ca], displays a trend with age opposite to that in tissue, the data strongly suggest that [Ca] in choroid epithelial cells and in brain cells (neurons and/or glia) of the rat undergo a significant reduction after 1 wk.

29.13 THE BLOOD-SPINAL CORD BARRIER FOLLOWING TRANSECTION IN THE RAT. Linda J. Noble* and D.S. Maxwell. Dept. of Anatomy, School of Medicine, UCLA, Los Angeles, CA 90024.

Following spinal transection in the rat, the blood-spinal cord barrier was studied at the ultrastructural level using Horseradish Peroxidase (HRP). Animals were sacrificed at 1 hour, 12 hours, and 3 days following surgery. Prior to sacrifice, HRP was administered intravenously and allowed to circulate 15-30 minutes. A 2 cm segment of spinal cord, distal to the transection, was removed and fixed by immersion. From the 1 hour and 12 hour timepoints, samples were processed by the method of Reese and Karnovsky. The tissue was examined electron microscopically. Vessels with reaction product were classified in 3 categories: Type I - no evidence of leakage but vesicles, containing reaction product, present in the endothelium, Type II - leakage of HRP into the basal lamina and surrounding interstitium without any apparent vesicles, Type III - presence of vesicles in the endothelium combined with HRP in the basal lamina and adjacent regions.

The present findings suggest barrier leakage at 1 and 12 hours which is not apparent at 3 days. In general, the vascular response was not consistent at each level and timepoint. In areas where leakage was noted, the endothelial tight junctions appeared intact. At 1 hour there was HRP in the endothelium, basal lamina and surrounding interstitium up to 18mm distal to surgical transection. Of the vessels analyzed, 56.5% were Type I, 22% were Type II, and 22% were Type III. At 12 hours, 75.5% were Type I, 2.0% Type II, and 22.4% were Type III. The preliminary evidence at 3 days demonstrates an intact barrier, although vesicles were present in the endothelium.

The barrier breakdown present at 1 hour and 12 hours following transection appears to be either absent or considerably diminished at 3 days.

Supported in part by MHTP Grant 1 T32 15345-03.

29.14 CEREBROSPINAL FLUID DYNAMICS IN THE CAT UNDER HALOTHAN AND PENTOBARBITAL ANESTHESIA. K.E. VanLandingham*, C.J. Maffeo*, H. Jackson, and A. B. Butler. Depts. Neurosurg., Anes., and Biom. Engr., Univ. Va. Med. Sch., Charlottesville, VA 22908.

Constant-flow manometric infusions into the subarachnoid space of the cat were used to assess the effects of Halothane@ and pentobarbital anesthesia on cerebrospinal fluid (CSF) dynamics. Animals were initially anesthetized with pentobarbital (30 mg/kg, i.p.) and atropine (.08 mg/kg, i.p.) and were maintained on either Halothane@ (.7%) or constant pentobarbital infusion (10 mg/kg/hr, i.v.). During each experiment, femoral arterial pressure was monitored, end-tidal CO_2 was maintained at 30 mmHg, and body temperature was regulated at 37.5°C. Following insertion of a 16 gauge needle into the cisterna magna CSF space, resting CSF pressure and steady-state pressures resulting from infusions of artificial CSF at flow rates of 40, 75, 150, and 400 µl/min were recorded and analyzed. CSF formation and resistance to absorption were calculated from the steady-state pressure/flow data.

The manometric data were fit to a logarithmic curve (pressure vs. log (flow)) resulting in correlation coefficients greater than 0.985. An analysis of variance (ANOVA) of the steady-state pressures did not show significant differences between the Halothane@ and pentobarbital groups. However, when the data were fit to a nonlinear model, differences in estimates of CSF production and resistance to CSF absorption at resting pressure were significant ($p<.05$). At resting pressure (30 to 80 mmH_2O), CSF production was calculated to be 20.9 µl/min (Halothane@) and 25.7 µl/min (pentobarbital), and resistance to CSF absorption was found to be 2.45 mmH_2O/µl/min (Halothane@) and 1.84 mmH_2O/µl/min (pentobarbital). At flow rates greater than 40 µl/min, differences in resistance were not significant.

In summary, we have shown that there is a significant difference in estimates of CSF production and resistance to CSF absorption at resting CSF pressure in the cat. At elevated CSF pressures (200 to 600 mmH_2O), however, estimates of resistance to CSF absorption are not significantly different between animals anesthetized with Halothane@ or pentobarbital.

(Supported by NIH grant NS155850).

29.15 BRAINSTEM INTRAPARENCHYMAL VASCULAR CHANGE FOLLOWING EXPERIMENTAL SUBARACHNOID HEMORRHAGE. J.T. Povlishock, D.S. DeWitt*, L.W. Jenkins* and D.P. Becker . Departments of Anatomy and Neurosurgery, Medical College of Virginia, Richmond, Va 23298.

In previous reports we have noted that mechanical brain injury results in widespread brain parenchymal and vascular change reflected in an increased vascular permeability to horseradish peroxidase (HRP) coupled with the generation of profound endothelial alteration. Furthermore, we reported that the post-traumatic hypertensive episode concomitant with an increased prostaglandin synthesis and free radical damage were responsible for the genesis of many of the observed changes. However, in that all the described phenomena were not adequately explained by these traumatically-induced factors, it was questioned whether traumatically-related subarachnoid hemmorhage could also contribute to the genesis of the described alterations. To explore this possibility cats received autologous arterial blood injected into the cisterna magna while the intracranial pressure was maintained within normal limits. Some cats received intravenous peroxidase prior to the cisternal infusion, while other cats received peroxidase delivered into the cisterna magna with the autologous blood. After variable survival periods ranging from 1 to 6 hours the animals were perfused with aldehydes, their brains were serially sectioned with a Vibratome and reacted for the visualization of the HRP reaction product. Alternate serial sections were then prepared for either light microscopy or transmission or scanning electron microscopy. With the infusion of autologous blood mixed with peroxidase, the protein was observed to pass through the glia limitans and reach the interstices of the brain stem parenchyma where its passage was much more pronounced that in the control situation. The luminal surfaces of the pial and superficial intraparenchymal vasculature demonstrated numerous attached leukocytes and some areas of increased vascular permeability to the intravenously injected HRP. Such change appeared consistent with the onset of an aseptic meningitis. Additionally deep within the brain stem parenchyma other microvessels demonstrated an increased vascular permeability to the intravenously injected HRP and the endothelia of such vessles demonstrated numerous microvilli vesicles, and luminal and abluminal pits as well as other forms of endothelial change. In that it was speculated that such intraparenchymal vascular change maybe associated with changes in cerebral blood flow several experiements were designed to assess blood flow via the use of radioactive microspheres. The correlation between the above described morphological changes and blood flow alterations will be presented, and their relation to mechanical brain injury will be discussed.

29.16 HYPOTHALAMIC NEURONAL NECROSIS IN NEONATAL CATS ADMINISTERED PHARMACOLOGIC DOSES OF MONOSODIUM L-GLUTAMATE. A. E. Applebaum, T. T. Daabees*, L. J. Filer, Jr.*, and L. D. Steginк*. Depts. of Anatomy and Pediatrics, U. of Iowa, Iowa City, IA 52242

Administration of large amounts of the dicarboxylic amino acids (glutamate and aspartate) produce hypothalamic neuronal necrosis in the infants of some animal species. While the neonatal mouse appears to be the most sensitive animal, lesions are not restricted to this species. We have examined the effects of monosodium L-glutamate (MSG) on the hypothalamus of the 8-day-old kitten.

MSG was administered either by gavage (n = 4) or intravenously (n = 4). Control animals received isotonic saline either by gavage (n = 3) or intravenously (n = 2). Blood samples were obtained (arterial catheter) at appropriate time intervals following MSG administration for amino acids, blood gas, and pH analyses. Animals were killed 5 hours after MSG administration by intracardiac infusion of a 2% glutaraldehyde--2% paraformaldehyde solution. Brains were removed, further fixed in the same solution, and embedded in either paraffin or plastic. Either 4 µm paraffin or 2 µm plastic serial sections were made through the hypothalamus and examined by light microscopy.

Neuronal damage was observed in the median eminence and arcuate nucleus of the hypothalamus after an oral dose of MSG at 4 g/kg body weight (20% w/v). However, the observed lesions were much less extensive than those observed in similarly treated infant mice. Damage was characterized by nuclear pyknosis and karyorrhexis. Mean peak plasma glutamate + aspartate concentration was 780 µmoles/dl (normal 9 µmoles/dl) 120 minutes after dosing.

After intravenous infusion of MSG (0.5 g/kg body weight; 0.4 ml/minute of a 1.67% solution, w/v) similar neuronal necrosis was noted. Mean peak plasma glutamate + aspartate concentration in these animals was 510 µmoles/dl 5 minutes after termination of infusion.

Administration of the large oral doses of glutamate produced metabolic alkalosis (pH 7.49 ± 0.03; pCO_2 - 35 ± 1 mm Hg; bicarbonate - 26.2 ± 1.8 mM; normal values 7.36 ± 0.01; 30 ± 1.5 mm Hg, and 16.6 ± 1.6 mM respectively). It is possible that this metabolic alkalosis affects the "blood brain barrier," facilitating dicarboxylic amino acid transfer and formation of CNS lesions.

These data indicate that the hypothalamus of the infant cat, like that of the infant mouse, but unlike that of the infant monkey, is sensitive to pharmacologic amounts of MSG.

29.17 RADIATION CONTROLLED FOCAL PHARMACOLOGY IN THE THERAPY OF EXPERIMENTAL EPILEPSY. M. P. Remler and W. Marcussen.* Department of Neurology, University of California, Davis, Veterans Administration Medical Center, Martinez, CA 94553.

Radiation controlled focal pharmacology is a method using intermediate dose radiation of a portion of the brain to break down the blood-brain barrier (BBB) followed by the administration of a drug which does not cross the normal BBB but which has a desired pharmacologic effect when it does cross the BBB. Therefore, the drug effects only the radiated portion of the brain. Cats with alumina-cobalt chronic epileptic foci were given IV Gama amino butyric acid (GABA) with no suppression of their EEG recorded computor analyzed epileptic spike frequency. Spike fequency ten minutes post infusion was chosen as the best indicator most sensitive of drug efficacy. When the focus received 6,000 rad of Bragg peak proton radiation there was still no significant change in spike frequency. Then, however, when IV GABA was again given, there was dramatic suppression of spike frequency. In every cat tested there was clear suppression of spike activity by the GABA at 9 days post radiation.

When the data from all cats are combined, each cat's GABA post radiation result is normalized against its own GABA before radiation. There is some suppression all during the first ten days post radiation. This suppression is maximum in the 7 to 10 day range. At the end of the week the suppression is so large, 87%, that despite the small number of cats involved the effect is statistically significant. The p value for the 9 day effect against preradiation controls is $<.1$ and for the combined 7 and 9 day effect $<.01$. Also, at 11 days the BBB is "closed" (meaning less than a 10% effect) with a $p<.01$.

29.18 AGE-RELATED ALTERATIONS IN BRAIN UPTAKE OF ANTICONVULSANTS AND DEVELOPMENTAL MODULATIONS OF BLOOD-BRAIN BARRIER PERMEABILITY TO METABOLITES AS AN INDICATOR OF CHANGING NUTRITIONAL REQUIREMENTS IN THE BRAIN. E. M. Cornford, L. D. Braun* and W. H. Oldendorf. Department of Neurology, UCLA School of Medicine, and Southwest Regional V.A. Epilepsy Center & Research Service, V.A. Medical Center, Los Angeles, CA 90073.

The intracarotid injection technique has been utilized to examine blood-brain barrier (BBB) function in studies of newborn (>24 hours), 7, 14, 21 and 28 day-old, as well as adult rabbits. The age-related modulations in BBB transport of adenine, arginine, choline, lactate and tryptophan are defined and demonstrated to be independent of each other. Lactic acid uptake was unusual in that the brain uptake index (BUI) was found to be greatest at 7 days post-partum. Elevated lactate uptake continues until 14 days and is then reduced. As indicated below, for all of the other metabolites examined, a maximal BUI was observed in the newborn brain and BUIs typically showed some sort of inverse relationship to animal age. The BUI of arginine is apparently halved in the first 7 days post-natally, and continues to decrease, reaching the value seen for the adult at an age of 21 days. In contrast, the brain uptake of adenine is unusual in that there appears to be a very gradual reduction in brain uptake occurring throughout the suckling period. A threefold decrease in the BUI of choline was observed during the first two weeks post-partum. Tryptophan uptake undergoes a fourfold reduction in the first four weeks post-natally. The uptake of butanol did not change appreciably over the range of ages examined. In contrast, brain uptake of the anticonvulsant drugs dilantin and phenobarbital was elevated during the first 14 days post partum, then declined to approach rates seen for the adult. The brain uptake rates of the metabolites which gain access by way of specific carrier mediated transport mechanisms are presumed to reflect nutritional requirements of the developing brain. Thus the present study indicates that the inclusion of adenine, arginine, choline, tryptophan and monocarboxylic acids such as lactate would be beneficial in clinical intravenous feeding of the neonate, to meet the apparent needs of the developing central nervous system.

(This study was funded by the Department of Health, Education and Welfare under contract number NO1-NS-0-2332, and supported by the Veterans Administration.)

29.19 EVIDENCE FOR PLATELET-MODULATED PROSTACYCLIN SYNTHESIS IN CEREBRAL MICROVESSELS. M. D. Ferrari*, J. A. Helpern* and K. M. A. Welch. Department of Neurology, Baylor College of Medicine, Houston, Texas 77030.

Several studies have reported that cerebral microvessels (CMV) have the capacity to synthesize prostacyclin (PGI_2) (Maurer, P., Moskowitz, M.A., Levine, L., and Melamed, E., Prostaglandins Med., 4:153-161, 1980; Rosenblum, W.I., and El-Sabban, F., Circ. Res., 43:238-241, 1978). The present paper describes the influence of aggregating platelets on this process.

CMV were isolated from the cerebellum and cortex of female gerbils (50-60 gm, N=15 per isolation) by albumin flotation and glass bead filtration. The isolate was then divided into four aliquots and incubated in Tris (pH=7.4, 100 µl per aliquot, 10-30 min). The supernatants and the CMV themselves were then tested for their influence on adenosine diphosphate (ADP)-induced platelet aggregation, performed in vitro in an aggregometer according to the Born technique. In five experiments, the CMV were preincubated in aspirin (200-400 µg/ml, 45-60 min), washed in Tris and then tested. All results were analyzed using paired t's.

The addition of untreated CMV to the cuvette prior to the addition of ADP (5 µM, final concentration) significantly inhibited platelet aggregation (mean per cent inhibition of control at 3 min [%MIC-3] $\pm$ standard deviation [S.D.]: 49 ± 30, $p<0.01$). In contrast, the addition of aspirin-pretreated CMV and the supernatants from the untreated CMV showed no significant effect (%MIC-3 $\pm$ S.D.: 25 ± 48, $p>0.2$ and 16 ± 23, $p>0.1$, respectively).

These results strongly suggest a triggered platelet-endothelial cell interaction and lend support to the recently described platelet-derived PGI_2 synthesis-stimulating factor, which is thought to be released during platelet degranulation (Coughlin, S., Moskowitz, M., Antoniades, H., and Levine, L., Stroke, 12:117, 1981, and personal communication).

30.1 BIOSYNTHESIS OF MET^5- AND LEU^5-ENKEPHALIN IN BOVINE ADRENAL MEDULLA: DIFFERENTIAL EFFECTS OF TRYPSIN INHIBITORS

I. Lindberg*, H.-Y. T.Yang* and E. Costa (SPON: J.Dahl) Lab. Preclinical Pharmacol.,NIMH, St.Elizabeth's Hospital, Washington D.C. 20032

The adrenal medulla has been shown to contain not only met^5- and leu^5-enkephalin (met-enk and leu-enk), but a variety of enkephalin-like peptides. It has been suggested that some of these larger enkephalin-like peptides function as precursors to met-enk and leu-enk. In this study, the formation of met-enk and leu-enk from high molecular weight enkephalin-like peptides was investigated. A soluble protein fraction was prepared from lysed chromaffin granules and rendered free of met-enk, leu-enk, and other low molecular weight enkephalin-like immunoreactivity by ammonium sulfate precipitation and dialysis. This preparation was found to produce low molecular weight enkephalin-immunoreactive peptides when incubated at 37°C. Through the use of HPLC, the production of authentic met-enk and leu-enk as well as of other unidentified low molecular weight enkephalin-like peptides was confirmed. This result suggests that the granule preparation contains both the enzymatic activity and the substrate required for the production of met-enk and leu-enk. The effect of various trypsin inhibitors on the the production of low molecular weight met-enk and leu-enk immunoreactivity was also tested. N-α-ρ-tosyl-lysyl chloromethyl ketone and p-amino benzamidine partially inhibited the production of leu-enk immunoreactivity but were without effect on the production of met-enk immunoreactivity. Conversely, soybean trypsin inhibitor was much more effective in inhibiting the production of met-enk immunoreactivity than of leu-enk immunoreactivity. The effectiveness of these trypsin inhibitors suggests that some of the enzymes involved in the biosynthesis of met-enk and leu-enk may be trypsin-like in nature. An account of the progress made in purifying enzymatic activities involved in the production of met-enk and leu-enk will be presented.

(Supported in part by NIMH Postdoctoral Fellowship #IF32MH08539-01 to I.Lindberg).

30.2 METABOLISM OF Tyr-Gly-Gly-Phe-Met-Arg-Phe BY DIPEPTIDYL CARBOXYPEPTIDASE.

An-Zhong Zhang and Erminio Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Since the chemical characterization of enkephalins, many different forms of enkephalin like peptides having molecular weight larger than enkephalin have been detected in various tissues. Some of the high molecular weight forms were found to have opioid activity and others were devoid of such activity. Whether the high molecular weight forms are related metabolically to enkephalins is not clear at present. In this study, conversion of Tyr-Gly-Gly-Phe-Met-Arg-Phe (heptapeptide) to [met^5]-enkephalin was studied. The heptapeptide was readily metabolized by a dipeptidyl carboxypeptidase prepared from striatum. The enzymatic products analyzed by HPLC include [met^5]-enkephalin, Tyr-Gly-Gly and Arg-Phe. The conversion of the heptapeptide to [met^5]-enkephalin was inhibited by some dipeptidyl carboxypeptidase inhibitors such as o-phenanthroline, Phe-Ala and SQ 20881. Interestingly, the SQ 20881, an angiotensin converting enzyme inhibitor, was found to have no effect on enkephalin inactivating dipeptidyl carboxypeptidase. Chloride ion, which is known to be essential for angiotensin converting enzyme activity, did not activate the conversion of the heptapeptide to [met^5]-enkephalin. With SQ 20881, it will now be possible to study whether the release of Arg-Phe from the heptapeptide is an activating or an inactivating process. Whether there is a specific dipeptidyl carboxypeptidase for conversion of the heptapeptide to [met^5]-enkephalin still remains to be established.

30.3 BOVINE CHROMAFFIN GRANULES CONTAIN AN ENZYME AND A PRECURSOR WHICH GENERATE METHIONINE ENKEPHALIN IN VITRO.

C.M. Troy* and J.M. Musacchio. Dept. of Pharmacology, New York Univ. Med. Ctr. New York 10016.

Reports that the bovine chromaffin granules contain enkephalins and their precursors indicate that the biosynthetic enzyme(s) could also be present in these secretory granules. An enzyme has been isolated from these granules which cleaves methionine enkephalin from its precursor.

The chromaffin granules of bovine adrenal medulla were isolated by a modification of the method of Smith and Winkler (Biochem J. 103: 480-482, 1967). The enkephalin precursors and their converting enzyme were found in the soluble lysate of the granules. Sephadex G-100 column filtration of the soluble lysate allowed identification of enkephalin precursors by trypsin digestion of fractions, followed by radioreceptor assay (RRA) with neuroblastoma x glioma cells for opiate-like activity. The fraction corresponding to a molecular weight of ~ 22,000 daltons was chosen to monitor the activity of the endogenous enzyme. This precursor was selected because it yielded the largest amount of opiate-like activity upon trypsin digestion. The enzyme was isolated in the void volume of a Sephadex G-200 column separation of the soluble lysate. The activity is not lysosomal in origin: an acid phosphatase profile of the sucrose density gradient used for the final purification of the granules indicated a complete separation of the lysosomes from the chromaffin granules. The enzyme has trypsin-like activity, as determined by the cleavage of the artifical substrates, benzoyl DL-arginine p-nitroanilide hydrochloride (BAPNA) and ^{3}H-N-tosyl-L-arginine methyl ester (^{3}H-TAME). An optimum activity at pH 7.5 was found using ^{3}H-TAME and ^{14}C-methemoglobin as proteolytic substrates. Incubation of this endogenous enzyme with the enkephalin precursor resulted in the production of methionine enkephalin. The incubation was carried out at 37°C, pH 7.5, in the presence of 190 mM Tris Acetate, 20 mM $CaCl_2$, 1 mM dithiothreitol. Opiate-like activity was easily detectable by RRA after four hours incubation, with maximum yield after twenty hours. The reaction was stopped by heat inactivation of the enzyme. The digestion product was identified as methionine enkephalin by high performance liquid chromatography (HPLC) on a Waters reverse phase C_{18} column combined with assay of fractions by RRA. This was confirmed by radioimmunoassay with a specific antibody for methionine enkephalin. All opiate-like activity applied to the HPLC column was recovered as methionine enkephalin. The presence of this converting enzyme with the precursors and products in the chromaffin granules indicate that this enzyme could be important in the biosynthesis of the enkephalins.

CMT was supported by MSTP grant GM07038, JMM by NIH grants DA02013 and MH17785.

30.4 EVIDENCE FOR MULTIPLE FORMS OF BETA-ENDORPHIN-RELATED SUBSTANCES IN THE PITUITARY OF THE REPTILE, ANOLIS CAROLINENSIS.

R.M. DORES* (SPON: W.J. BETZ). Dept. of Physiology, Univ. of Colorado School of Medicine, Denver, CO 80262.

At least four forms of β-endorphin have been isolated from the intermediate lobe of the mammalian pituitary (Smyth and Zakarian, 1980, Nature 288,613-615). These forms differ in the degree of proteolytic cleavage of the C-terminal region and the presence or absence of α,N-acetylation. β-Endorphin(1-31) has full opiate bioactivity; β-endorphin(1-27) has equal or diminished activity, depending on the bioassay system; the α,N-acetylated endorphins are completely inactive. To determine if these post-translational events occur in a lower vertebrate, single intact Anolis carolinensis intermediate pituitaries were incubated for 24 h in complete DMEM containing [^{3}H]tyrosine. The tissue was acid extracted in the presence of protease inhibitors, and an aliquot was immunoprecipitated with affinity purified antibody to the N-terminal region of β-endorphin. The immunoprecipitate was dissociated and fractionated by gel filtration (Sephadex G-75, 10% formic acid). Three peaks of radioactivity were isolated. Sequential immunoprecipitation experiments with affinity purified antisera to the N-terminal region of ACTH and to β-endorphin indicate that the first radioactive peak (K_d=0.12) represents the common precursor for the αMSH-like and β-endorphin-like molecules of this species. The second peak (K_d=0.40) eluted close to β_m-lipotropin. The third peak (K_d=0.68) eluted close to β_m-endorphin. This latter peak was concentrated and fractionated by ion exchange chromatography (sulfopropyl Sephadex, 50% acetic acid). This column was eluted with a linear NaCl gradient (0.05 M to 0.55 M) and at least four peaks of radioactivity were isolated: Peak 1, 0.27 M NaCl; Peak 2 0.33 M NaCl; Peak 3, 0.38 M NaCl; Peak 4, 0.42 M NaCl. The peaks of Anolis β-endorphin did not co-elute with β_c-endorphin(1-31), β_c-endorphin(1-27) or the α,N-acetyl derivatives. An aliquot of each of these peaks was analyzed on a Sephadex G-50 column in 6 M guanidine-HCl; Peak 1 was smaller than β_m-endorphin-(1-31) while Peaks 2,3,4 were about the size of β_m-endorphin (3400 daltons). These reptile β-endorphin-like substance are being further characterized by analyzing proteolytic digests.

Supported by NIH grants Am-19859, -18929, -06363, and NS-02083.

30.5 MULTIPLE FORMS OF B-END IN CNS: REGIONAL DIFFERENCES AND EFFECT OF STRESS. H. Akil, H-L Lin,* Y. Ueda,* S. Lax, M. Walker,* and S. Watson (SPON: H. Akil). Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109.

Previous work by our group and by others (Smyth and Zakarian, Mains and Eipper) has shown that multiple forms of B-Endorphin exist in mammalian CNS. We have shown that the naturally occuring form B-END (1-27) is 10 times less potent than B-END (1-31) at the opiate receptor. N-acetylation leads to a thousand fold decrease in binding potency. Thus it is critical to determine the ratios of the several forms of B-END in various tissues. We find that rat intermediate lobe synthesizes primarily N-Acetyl-B-END (1-27), while the anterior lobe stores mostly the opiate active B-END (1-31). Recent studies in brain show that B-END (1-31) is predominant in rat hypothalamus, although the other forms are detectable as well. Unidentifiable B-END-like immunoreactivity also exists in hypothalamus (and not in pituitary). Studies of the forms of B-END in terminal regions (such as thalamus and midbrain) are currently in progress. Behavioral manipulation, such as stress, alter both pituitary and brain B-END. The effect of such manipulations on the mulitple forms is being examined. While changes in total immunoreactivity are reliably found, it seems more important to determine changes in ratios of active to inactive forms of B-END, allowing for a more dynamic measure of the activity of the system.

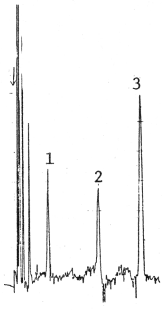
30.6 PARTIAL PURIFICATION AND CHARACTERIZATION OF A NOVEL HUMAN ENDORPHIN FROM CEREBROSPINAL FLUID. B. E. Miller, J.J. Lipman, S. Karkera*, R. Winfield*, W.L. Byrne, K. Mays*, and W.C. North* Depts. of Biochemistry and Anesthesiology, Univ. of Tenn. Ctr. for the Health Sci., Memphis, Tenn. 38163.

For the past three years our laboratory has been engaged in qualitative and quantitative analysis of endorphins contained in human cerebrospinal fluid (CSF). We have identified and routinely measured twelve endorphin components from both chronic pain and pain-free patients. Endorphins were defined as those components capable of displacing ^{3}H-dihydromorphine from homogenized mouse brain in a radioreceptor assay (RRA). One particular endorphin, Peak B, was best correlated with the pain status of the donor chronic pain patient and was also present in larger quantities in the pain-free patients. Peak B, as well as the other CSF endorphins, was initially determined as follows: whole CSF was passed through an Amicon PM-10 filter, the filtrate was lyophilized, this material was resuspended in 0.2 N acetic acid and loaded atop a Sephadex G-10 column and eluted in the same solvent, column fractions were lyophilized and assayed for endorphin activity with the mouse brain homogenate RRA. Based on its G-10 elution position, Peak B does not coelute with any of the structurally identified endorphins. Further characterization was performed using G-10 purified Peak B. This material was found to produce a naloxone-reversible dose-dependent inhibition of the electrically stimulated contractions of both the guinea pig ileum and the mouse vas deferens preparations. Peak B was also shown to produce a potent naloxone-reversible analgesia after intracerebroventricular (i.c.v.) injections into mice assayed by the mouse tail immersion test (48^{o}C). Additionally, HPLC on a reversed phase (Water's μBondapak C-18, eluant: ammonium acetate pH 4/ acetonitrile) column in conjunction with the RRA showed that Peak B's activity was found in a single peak which coeluted with leu enkephalin. However, this endorphin did not coelute with leu enkephalin on G-10. Finally, the biologic activity of Peak B was found to be resistant to trypsin and alpha chymotrypsin (34^{o}C, > 6 hr. incubations),i.e. these enzymes did not change Peak B's activity on the mouse vas deferens assay.

It is likely that Peak B is identical with the major component in Terenius and Wahlstrom's Fraction I endorphin (1975) and possibly also to the humoral endorphin described by Sarne, Azor and Weissman (1978). In conclusion, we believe that Peak B is a potent biologically active endorphin that is chemically different from any hitherto structurally identified endorphin.

30.7 A NEW LC-EC METHOD TO SEPARATE AND QUANTIFY ENDOGENOUS OPIATE PEPTIDES. D. Rodd*, L. H. Fleming*†, E. A. Stein and N. C. Reynolds, Jr.†. Dept. of Biology, Marquette University, and †Sect. of Neurology, Univ. of Wisconsin, Sch. of Med., Milwaukee, WI 53233.

Following the discovery and subsequent neuroanatomic localization of the endogenous opiate peptides (endorphins), research interest has focused on their role in normal physiology as well as pathologic conditions of the brain. To perform these experiments, it is first necessary to be able to measure levels of these peptides in brain with a highly specific yet sensitive procedure. Radioimmunoassay (RIA), while very sensitive, is limited by potential cross-reactivity with other closely related peptides. Liquid chromatography (LC), in contrast, is capable of separating these peptide species but using standard UV detection, lacks the sensitivity necessary to quantify biologically relevant samples. We report an LC technique coupled with electrochemical detection which enables the separation and detection of three principal endorphins, methionine and leucine enkephalin and β-endorphin from small brain samples. Our procedure involves a simple brain extraction technique followed by peptide separation on a reverse phase column with an isocratic buffer system. The peptides can be separated in a relatively short time with a sensitivity in the pmolar range. A typical chromatogram is shown. LC results have been verified from collected separated peptides. This simple procedure allows for the simultaneous measurement of changes in the concentration of these endorphins following various physiologic and pharmacologic manipulations. (Supported in part by NIDA grant #DA02334 and The Scholl Foundation.)



Chromatograph of Endorphin Standards

1) Leucine Enkephalin, 41.6 ng

2) Methionine Enkephalin, 41.6 ng

3) β Endorphin, 5.2 ng

30.8 GAMMA ENDORPHIN-LIKE PEPTIDES IN THE PITUITARY AND BRAIN OF THE RAT. M.B. Chapman* and D.M. Dorsa* (SPON: W. Stahl). GRECC, VA Medical Center, Seattle, WA 98108.

Experiments wherein tissue proteolytic enzyme activity has been inactivated prior to tissue disruption have suggested that alpha-endorphin (αE, BLPH 61-76) may exist only as an artifact of extraction procedures. In the present study we have examined the effect of enzyme inactivation on the content of β and gamma endorphin (γE, BLPH 61-77)-like peptides in brain and pituitary tissue of the rat.

Eight male rats were killed by decapitation and their hypothalami and pituitaries were removed and placed into 300 μl 0.1N acetic acid at room temperature (n=4) or into boiling acetic acid (n=4) for 15 min. The samples were then sonicated, aliquots taken, then centrifuged and aliquots of the supernatant were lyophilized. β and γ endorphin were measured using sensitive (4 and 2 pg/tube) and specific radioimmunoassays for these peptides. The results expressed in ng peptide/mg protein ($\bar{x}\pm$S.D.) were as follows:

	βE-Like Immunoreactivity	γE-like Immunoreactivity
Hypothalamus		
Non Boiled	0.400±0.083	0.18±0.09
Boiled	0.56±0.10	0.056±0.19
Pituitary		
Non Boiled	430±94	34.7±10.2
Boiled	829±105	104.3±26.6

When 500 ng of βE was added to pituitaries prior to boiling and sonication no increase in RIA-γE was noted indicating the effectiveness of boiling in preventing proteolysis. The decrease of γ-E like peptides in brain tissue and concomitant βE increase with boiling suggest the importance of this inactivating procedure for endorphin measurements. However, in contrast to αE, γE-like peptides persist in measureable quantities following this procedure indicating that their presence in brain tissue is not artifactual. In the pituitary both β and γE increased with boiling, suggesting that γE is not only present in pituitary tissue, but may itself be rapidly cleaved by proteases released during the extraction procedure, possibly to αE. Processing of βE appears to differ in the brain and pituitary. In brain the βE to γE cleavage may be a first step to inactivation of opiate-like activity. Alternatively, since γE-like peptides have been reported to possess neuroleptic-like properties, they may be synthesized as modulators of the function of dopamine neuronal systems.

31.1 B-ENDORPHIN AND a-MSH IN THE RAT BRAIN: A COMPARATIVE IMMUNOCYTOCHEMICAL ANALYSIS. H. Khachaturian, K. Tsou,* and S.Watson (SPON: H. Khachaturian). Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109.

The opioid peptide B-endorphin (B-END) and the neurointermediate lobe hormone a-MSH originate from a common precursor molecule, pro-opiomelanocortin (POMC), synthesized both in the pituitary and hypothalamic arcuate nucleus. Both peptides have been extensively mapped in the CNS by immunocytochemical methods. Recently Watson and Akil (Brain Res., 182:217, 1980) have shown that a-MSH and B-END occur in the same arcuate neurons, and further, have discovered a second a-MSH system (a-2) in the hypothalamus. It appears that the a-2 neurons do not produce, at least in detectable amounts, any other product of the POMC molecule, including B-END. Thus far, it has not been possible to separate the two hypothalamic systems with several antisera against a final common product, a-MSH. Fibers originating from the arcuate B-END/a-MSH neurons project throughout the hypothalamus, amygdala, nucleus accumbens, septal nuclei, periventricular thalamus, periaqueductal gray, and as far caudal as the level of the locus coeruleus and medullary reticular formation. Additionally, fibers originating from the a-2 neurons project to the hippocampus, caudate and cerebral cortex.

Immunocytochemical studies of B-END vs. a-MSH were carried out in male Sprague-Dawley rats, some of which were treated with colchicine to enhance cell-body visualization. B-END cells appeared to be restricted primarily to arcuate nucleus although peri-arcuate cells were also present. In contrast, three a-MSH cell groups could be delineated. One group corresponded to the arcuate B-END cells in serial section analysis. The other two groups (i.e., a-2) were composed of widely scattered neurons starting at mid-hypothalamic level. The more medially located a-MSH neurons were scattered in the periventricular regions and the dorsal part of the ventromedial nucleus. The laterally located a-MSH neurons were scattered in the lateral hypothalamic area and some were medially apposed to the optic tracts. Also many cells surrounded the forniceal columns. More caudally, some neurons appeared to be in the ventral region of the zora incerta. Preliminary cell counts revealed that the total number of a-MSH neurons (a-2) exceeds the total number of B-END neurons. Other studies are under way to determine the comparative distributional patterns of B-END and a-MSH fibers.

31.2 DYNORPHIN IMMUNOCYTOCHEMISTRY: PRELIMINARY DISTRIBUTION AND RELATIONSHIP TO VASOPRESSIN. S. Watson, H. Akil, G. Nilaver, E. Zimmerman, T. van Wimersma Greidanus,* A. Goldstein. Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109. (SPON: S. Watson).

The opioid peptide dynorphin has been extracted from bovine pituitary preparations and shown to be a potent opiate peptide. The partial sequence of dynorphin (1-13) is different from existing opioid peptides. After the development of antersia against dynorphin, RIA studies indicated a heterogeneous distribution in brain and pituitary. We began the immunocytochemical study of its distribution in rat CNS using antisera primarily against the C terminus of the peptide (i.e., the non-leucine enkephalin region). Some studies were carried out with diluted crude serum and some with affinity purified antiserum. All data were validated with affinity purified sera. The immunohistochemical demonstrations were blockable by dynorphin(1-13) but not by met- or leu-enkephalin, B-endorphin, aMSH, AVP or oxytocin.

Dynorphin immunoreactivity (DYN-ir) was detected in posterior pituitary but not anterior or intermediate lobe. Its pituitary levels were comparable to those for leucine-enkephalin - using antisera and separation techniques which can separate leu-enkephalin from dynorphin (HPLC/RIA). In hypothalamus, dynorphin has been localized in the magnocellular neurosecretory cells of the supraoptic and paraventricular nuclei. Serial section analysis using vasopressin (AVP) and dynorphin antisera clearly demonstrate that these two peptides are in the same cells. No relationship to oxytocin has been detected. Homozygous Brattleboro rats (with no detectable AVP) continue to show DYN-ir in their magnocellular neurons. The DYN-ir cells are the non-oxytocic cells.

It is suggested that dynorphin might be an active neurosecretory substance, vulnerable to the same physiology and pharmacology as AVP. It is further suggested that DYN is under separate biosynthetic control from those seen with AVP. The remainder of the CNS distribution of dynorphin is under study.

31.3 DYNORPHIN IMMUNOREACTIVITY IN TOAD (BUFO MARINUS) SPINAL CORD, BRAIN AND NEUROINTERMEDIATE LOBE, R. I. Cone and A. Goldstein. Addiction Research Foundation, Palo Alto, CA 94304.

Dynorphin is a highly potent opioid peptide, initially purified from porcine pituitary extracts. Dynorphin 1-13 (D1-13; YGGFLRRIRPKLK) contains the leu-enkephalin sequence at the NH_2 terminal, and is as potent as natural dynorphin in the guinea pig ileum bioassay. Using a highly specific antibody (Lucia) raised against thyroglobulin-conjugated D1-13, immunoreactive dynorphin (ir-DYN) has been found in pig, beef and rat pituitary and rat brain and spinal cord. In the rat, ir-DYN is found in highest concentrations within the neurointermediate lobe (NI), spinal cord and hypothalamus (Proc Nat Acad Sci 77: 6207, 1980).

We now report on the presence of ir-DYN in 1 M acetic acid extracts from toad (Bufo Marinus) spinal cord, brain and NI. Tissue concentrations of ir-DYN in spinal cord and brain were 330 and 510 fmol/mg protein, respectively. The highest concentration of ir-DYN was found within NI (50 pmol/mg protein or approximately 5 pmol total). In comparison to values reported for the rat, the tissue concentrations in toad spinal cord, brain and NI were 2 - 3 fold higher.

The size distribution patterns of ir-DYN were also examined in toad spinal cord, brain and NI using Sephadex G-50 gel permeation (0.1 M acetic acid; 0.15 M NaCl; 0.1% triton X 100). There appear to be considerable differences in the size distribution patterns of ir-DYN from region to region. For example, in spinal cord, most of the ir-DYN eluted in the void volume (apparent M_r greater than 30,000) with smaller amounts of ir-DYN eluting either coincident with cytochrome C (apparent M_r of 11 - 12,000) or following elution of ^{125}I-β-endorphin (I-END). In the brain, ir-DYN eluted in two major peaks, one coincident with cytochrome C and a second following elution of I-END (apparent M_r of 2 - 3,000). A third, smaller peak of ir-DYN eluted before I-END (apparent M_r of 4 - 6,000). In the NI, most of the ir-DYN eluted following I-END, with a small amount of ir-DYN eluting coincident with cytochrome C. These regional differences suggest that the toad may prove to be an interesting model for studying different molecular weight peptides containing dynorphin immunoreactivity.

Supported by research grant DA-01199 and NIDA post-doctoral training grant DA-07063-05.

31.4 DEVELOPMENT OF MET-ENKEPHALIN IMMUNOREACTIVITY IN ORGANOTYPIC EXPLANTS OF FETAL MOUSE SPINAL CORD AND ATTACHED DORSAL ROOT GANGLIA. J. Groth*, A. Chalazonitis†, E.R. Simon and S.M. Crain†. Depts. of Psychiat. & Pharmacol., N.Y.U. Med. Sch., N.Y. 10016; †Dept. of Neurosci., Albert Einstein Coll. Med., Bx., N.Y. 10461.

Sensory-evoked synaptic network responses generated in dorsal-horn regions of organized fetal mouse spinal cord explants with attached dorsal root ganglia (DRGs) are selectively depressed by opiates and opioid peptides (Crain et al, Br.Res.'77,'78). Binding assays of cord-DRG explants show high levels of opiate receptors in dorsal cord tissue, and even higher in the neuritic outgrowth of isolated DRG cultures (Hiller et al, Br.Res. '78). Naloxone often enhances the dorsal-horn responses in DRG-cord explants even without prior opiate exposure, suggesting the presence of opioid inhibitory control systems. We have now attempted to study the development of enkephalinergic neurons in these cultures using radioimmunoassays (RIAs).

Cross-sections of fetal mouse cord with pairs of attached DRGs were explanted on collagen-coated coverslips and maintained for 2-4 wks in vitro (i.v.). NGF was added to the medium (Eagle's MEM, with human placental serum and chick embryo extract) during the 1st week i.v. (300 B.U./ml) to insure good survival and maturation of the DRG neurons (Crain and Peterson, Br.Res.'74). Prior to RIAs, the cultures were rinsed for 15 min in Hanks' BSS, and the cord explants were surgically separated from the DRGs with neuritic outgrowth. Groups of 8-15 cord explants or DRGs with outgrowths were pooled in glass microhomogenizers, boiled in 0.2 ml of 0.1N HCl for 15 min to inactivate endogenous peptidases, and stored at -70°C. The tissues were then thawed, homogenized, centrifuged, and the supernatant was incubated for 24 hrs at 4°C with diluted met-enkephalin (ME) antiserum and ^{3}H-ME. Bound ^{3}H-ME was counted after removal of free ME with charcoal (Yang et al, Neuropharm.'77). No ME immunoreactivity (IR) was detected in cord-DRG explants freshly dissected from fetal mice (N=6). During the 3rd wk i.v. moderate levels were detected ranging from 60-200 picrogram/cord explant (N=4), 50-140 pg/pair of DRGs with total outgrowth (N=4), and 85-160 pg/whole cord-DRG culture (N=3). During the 4th wk i.v. higher levels of ME-IR were found, ranging from 140-835 pg/cord explant and 270-800 pg/pr of DRGs with outgrowth (N=7 in each). The levels of ME-IR were much lower when cord and DRG tissues were grown as separate cultures for 3-4 wks i.v. The high levels of ME-IR in the DRGs + outgrowth of DRG-cord cultures are consonant with immunocytochemical evidence of ME in adult rat DRG neurons (Itoga et al, Acta Histochem.'79). The possible roles of opioids in DRG as well as in cord neurons requires further analysis. (Supported by NIDA research grant DA-02031 to S.M.C. and E.J.S.)

31.5 IMMUNOCYTOCHEMICAL LOCALIZATION OF OPIOID PEPTIDES IN NORMAL AND DIFFERENTIATED NEUROBLASTOMA X GLIOMA HYBRID CELLS NG108-15

K. M. Braas*, D. C. U'Prichard, G. V. Childs* (SPON: L. E. Roel) Northwestern Univ. Med. Sch., Chicago, IL 60611, Univ. of Texas Med. Branch, Galveston, TX 77550.

The presence of endogenous opioid peptides has been demonstrated in Neuroblastoma x Glioma hybrid NG108-15 cells (Glaser et al Eur. J. Pharm.65:319, 1980). Recently, we described immunocytochemical staining of select cells in these cultures with anti-Met^5-enkephalin (ME) and anti-Leu^5-enkephalin (LE) (Braas et al, J. Histochem. Cytochem. in press, 1981). In order to investigate the possibility that the state of differentiation may account for this variability in staining, we now compare the enkephalin stain between normal cells and cells induced to differentiate with dibutyryl cyclic AMP (dBcAMP) treatment. Cells at an initial plating density of 4000 cells/cm^2 were cultured in Leighton Tubes or 25cm^2 flasks with Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% newborn calf serum, hypoxanthine, aminopterin, and thymidine. Two days after plating, experimental cultures were treated with complete medium containing 1mM dBcAMP for one to five days. Control cells were cultured in complete medium without dBcAMP. The cells were rinsed with DMEM, fixed for 1 hour at room temperature with 2.5% gluraraldehyde, washed, and stained with 1:10,000 anti-ME or anti-LE for 48 hours using the peroxidase-anti-peroxidase immunocytochemical technique (Braas et al, J. Cell Biol. 87:173A, 1980). 25-30% of the volume fraction of control cells stain for enkephalin-like immunoreactivity, localized in rounded or neurite-like cells either singly or in small clusters. After 5 days of treatment with dBcAMP intense stain increased to 60-70% of the cellular volume fraction. The stain is found throughout the cytoplasm, elongated processes, and cytoplasmic droplets adhering to these cells. If these cultures are further treated for 60-96 hours with 10μM arabinosylcytosine (Ara-C), the proliferating undifferentiated cells are killed and a pure culture of differentiated cells is obtained which stains intensely for enkephalin. Specificity tests included solid phase immunoabsorption to remove the antibodies from the antiserum to avoid the potential binding of enkephalin to cellular binding sites. Staining was abolished when cells were incubated with antiserum preabsorbed with enkephalin conjugated to Sepharose 4B beads. No stain was present when primary antiserum was replaced by diluent buffer or 1:10,000 normal rabbit serum. These results indicate that the immunocytochemical staining for enkephalin can be correlated to the state of differentiation induced by dBcAMP treatment. Supported by ACS-IN-112 (K.M.B.), PHS-DA-02763 and NS-15595 (D.C.U.) and RCDA-HD-00935 (G.V.C.).

31.6 DYNORPHIN-LIKE IMMUNOREACTIVITY IN BOVINE ADRENAL MEDULLA.

R. Day*, D. Denis*, J. Barabé*, S. St-Pierre*, S. Lemaire. Département de Pharmacologie, Centre Hospitalier Universitaire Sherbrooke, Sherbrooke, Québec, Canada.

Dynorphin-like immunoreactivity was examined in bovine adrenal medulla and isolated chromaffin cells. Using antisera raised against dynorphin-(1-13) (DYN-(1-13)), a sensitive and highly specific radioimmunoassay was developed. Five female rabbits (R31-R35) were immunized with a mixture of DYN-(1-13): methylated bovine serum albumin, (weight ratio: 7 to 1). In this mixture DYN-(1-13) was not covalently linked to methylated bovine serum albumin but rather adsorbed on its ionized surface, thus confering the necessary protection to the peptide for immunogenicity. Several useful sera were obtained by this method, but one with good sensitivity and high titers was chosen (R31D). This antisera bound 50% of ^{3}H-DYN-(1-13) (50 Ci/mmole; NEN) at a dilution of 1:5000. Displacement from the antibody of labelled DYN with unlabelled DYN-(1-13) began at a concentration of 10^{-10} M and was complete at 10^{-7} M. Various fragments: DYN-(1-6), DYN-(1-7), DYN-(1-8), DYN-(1-9), DYN-(1-10), DYN-(6-13), and related peptides: leucine-enkephalin-DYN-(1-5), methionine-enkephalin, β-endorphin, cross-reacted with insignificant percentages, (0.01%-.0003%). Thus a nearly intact antigen was required for recognition by the antiserum. Using this antiserum, acid extracts of bovine adrenal medulla and isolated chromaffin cells were shown to contain 28.5 and 88.0 fmoles of immunoreactive (ir) dynorphin per mg, respectively. The concentration of dynorphin in the chromaffin cells (4.2 pmole/10^6 cells) corresponded to 1/1.4 of the concentration of leucine-enkephalin, as determined in this same extract by leucine-enkephalin radioimmunoassay. Various secretagogues that have been shown to release ir-leucine-enkephalin were also demonstrated to induce the release of ir-dynorphin from the chromaffin cells. These data suggest a neurohormonal function for dynorphin at this level.

31.7 LOCALIZATION OF INCREASED HIPPOCAMPAL LEUCINE ENKEPHALIN-LIKE IMMUNOREACTIVITY FOLLOWING HILAR LESIONS IN THE ADULT RAT.

C. M. Gall, N. Brecha, K.-J. Chang and H.J. Karten. Depts. of Neurology and Neural Biology and Behavior, SUNY, Stony Brook, N.Y. and Wellcome Research Lab., Research Triangle Park, N.C.

It has been reported that a variety of seizure producing treatments (intraventricular kainic acid, ECS, isoniazid) induce an increase in hippocampal enkephalin content (Hong et al, Nature, 128:231, 1980). We report here that hippocampal enkephalin-like immunoreactivity is also dramatically elevated following the placement of small hilar lesions and that in this instance, as well as following kainic acid, the increase in immunoreactivity is primarilly localized within the mossy fiber system.

Small unilateral electrolytic lesions were placed in the hilus of the dentate gyrus of adult rats under ketamine/rompin anesthesia. Two days later the level of leucine enkephalin-like immunoreactivity was assayed and found to be elevated by over 200% within the contralateral hippocampus. Phenobarbital anesthesia reduced but did not eliminate this increase.

Immunocytochemical analysis revealed similar changes in the pattern of hippocampal enkephalin-like immunoreactivity following the hilar lesion and intraventricular kainic acid injection. In both cases no new immunoreactive staining patterns (absent in untreated rats) were seen. Rather, there was a modest bilateral increase in immunoreactivity within the lateral entorhinal cortex and subiculum and a very dramatic increase in immunoreactivity within the mossy fiber system. A higher than normal proportion of the dentate gyrus granule cells were seen to be immunoreactive in the treated rats as well. The lesion induced effects appear not to be directly attributable to deafferentation because 1) the range of the increase (throughout the full septo-temporal extent of both hippocampi) dramatically exceeds the zone of deafferentation and 2) fimbrial transection, creating similar but more extensive deafferentation than the contralateral hilar lesion, does not induce a similar increase in immunoreactivity.

We therefore have a paradigm in which plasticity in the level of enkephalin-like immunoreactivity has been demonstrated within an identified synaptic system. The increase in the number of granule cells seen to be immunoreactive indicates that within a population of neurons the full capacity to express enkephalin-like immunoreactivity may only be seen under special physiological conditions. Experiments are currently in progress to determine what physiological processes induce the observed immunoreactive changes and what consequence the increase has on mossy fiber function.

31.8 ENKEPHALIN-IMMUNOREACTIVE AMACRINE CELLS IN THE RETINAS OF SOME TELEOST FISH.

W.K. Stell, K.S. Chohan* and N. Brecha[1]. Lions' Sight Centre, University of Calgary Faculty of Medicine; SUNY, Stony Brook[1]; and Friday Harbor Laboratories.

Enkephalin-immunoreactive neurons occur widely in the central and peripheral nervous systems and as amacrine cells in the retina (PNAS 76: 3010, 1979; TINS: 292, 1980). Until recently little was known about their role in neural function. Newer studies, however, revealed multiple functional opiate pathways in goldfish retina (Neurosci. Abstr. 6: 613, 1980) and suggested that opiates act upon ON-centre ganglion cells by inhibiting GABA amacrines (Djamgoz, Stell, Chin & Lam, submitted for publication). These studies led us to search for the endogenous opiate neurons in the fish retina.

Goldfish (Carassius auratus), carp (Cyprinus carpio) and catfish (Ictalurus punctatus) were obtained commercially, and the marine teleosts pile perch (Damalichthys vacca), salmon (Onchorhynchus kisutch) poacher (Agonus acipenserinus), and rockfish (Sebastes caurinus) were obtained at Friday Harbor. Fish were decapitated, pithed and enucleated, and retinas were fixed, cryosectioned and FITC-stained by indirect immunofluorescence.

In goldfish and catfish, 6 primary antisera to met^5-enkephalin and 3 to leu^5-enkephalin (dilution 1:200) gave identical, positive results, controlled by preabsorption with synthetic peptide (100 mg/ml). In goldfish, very sparsely distributed neurites were stained throughout the inner plexiform layer (IPL), predominantly in its most distal and proximal levels. In catfish we stained a single class of cells with somata in the amacrine cell layer (ACL), their thick primary neurite descending and branching to form fine fibres in the innermost IPL. In the carp and marine teleosts only one antiserum to leu^5-enkephalin (Chang A-200) was used. The staining in carp was the same as in goldfish. In all four marine species we observed stained somata in the ACL and neurites in the IPL. The stained neurites were unistratified in the distal IPL in pile perch but multistratified or diffuse in the other marine species.

These observations show that enkephalin-immunoreactive retinal neurones, probably amacrine cells, occur widely among teleosts. Our data further support the presence of opiate pathways in teleostean retinas, while indicating that those pathways may differ substantially between species.

(Supported by grants from MRC (Canada) and USPHS).

31.9 ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL CHARACTERIZATION OF ENKEPHALINERGIC NEURONS AND SYNAPSES WITHIN THE PREOPTIC NUCLEUS OF THE GOLDFISH. R. Cumming*, T.A. Reaves, Jr. and J.N. Hayward. H. Houston Merritt Electron Microscopy Lab., Dept. Neurology and Neurobiology Program, Univ. North Carolina, Chapel Hill, N.C. 27514.

By light microscopic immunocytochemistry, using antibodies to (met^5)-enkephalin (ENK), we have previously shown that the goldfish preoptic nucleus (NPO) contains perikarya and processes of ENK neurons with anatomical and physiological connections to the neural lobe and with presumed neuroendocrine functions (PNAS 76: 6009 '79). We have sought to characterize the ultrastructure of ENK neurons in the NPO by pre-embedding electron microscopic immunocytochemistry.

Adult goldfish (Carassius auratus) were anesthetized, perfused intra-cardially with a paraformaldehyde-glutaraldehyde fixative, the brain removed and the hypothalamus vibratome-sectioned at 30 microns. We immunostained the sections with the peroxidase-anti-peroxidase technique and subsequently embedded them in Epon for ultramicrotomy.

Electron micrographs were taken throughout the rostro-caudal and dorso-ventral extent of the NPO. ENK immunoreactivity was localized in perikarya, dendrites, axons and axon terminals. We saw low level ENK immunoreactivity in granular (130-170 nm) and agranular form in perikarya and dendrites, while intense reaction product was observed in unmyelinated axons and axon terminals. ENK-labeled axon terminals contained predominantly small clear vesicles (SCVs, 35-45 nm) with scattered large dense-core vesicle (LDVs, 60-85 nm). Some ENK immunoreactive axon terminals possessed mainly LDVs. The LDVs showed labeling of vesicle membrane and core while reaction product was only associated with the periphery of the SCVs. The ENK-labeled vesicles were uniformly distributed throughout the terminal boutons, with occasional concentration of SCVs at synaptic contacts. ENK immunoreactivity was found at discrete regions on the neuronal membrane including points of synaptic contact and rarely at post-synaptic specializations. The external mitochondrial membrane also showed ENK-labeling. ENK-positive axon terminals formed single and multiple contacts with unlabeled dendritic shafts and spines. Axo-somatic ENK boutons were observed on small ($<10\ \mu m$) neurons with large nuclei and minimal cytoplasm located in parvocellular regions of the NPO.

We conclude that in the goldfish NPO the axon terminals of enkephalin-containing neurons form axo-dendritic and axo-somatic synapses on other neurons. These data suggest a neurotransmitter as well as a neuroendocrine function for opioid peptides in the teleost preoptic nucleus. (Supported by NIH Grant NS-13411 and a Neurobiology Fellowship to R.C.)

31.10 DYNORPHIN IMMUNOREACTIVITY IN MAMMALIAN SPINAL CORD AND DORSAL ROOT GANGLION. B. M. Cox, L. J. Botticelli and A. Goldstein. Addiction Res. Fndn. & Dept. Pharmacol., Stanford Univ., Palo Alto, CA 94304.

Dynorphin, a remarkably potent opioid peptide that contains leucine enkephalin as its amino terminus, was isolated recently from porcine pituitary extracts. The first thirteen amino acid residues are YGGFLRRIRPKLK. Dynorphin-(1-13) is as potent as natural dynorphin in the guinea pig ileum bioassay.

The regional distribution pattern of immunoreactive (ir-) dynorphin is different from that of enkephalin or any other known opioid peptide. The concentration is greatest in anterior and posterior aspects of the hypothalamus, with lesser amounts found in midbrain tegmentum. Lower levels are found in striatum, hippocampus, neocortex and cerebellum. In pituitary, ir-dynorphin is found predominantly in pars nervosa (Goldstein & Ghazarossian, 1980. Proc. Natl. Acad. Sci., 77: 6207).

We now report on the distribution and characterization of ir-dynorphin in the mammalian spinal cord and dorsal root ganglion (DRG). Concentrations are highest in the dorsal aspect of the spinal cord of both rabbit and rat (approximately 20, 5 and 1.5 pmol/g in dorsal cord, ventral cord and DRG, respectively, in both species). Levels of ir-dynorphin are relatively uniform over examined segments (C2-4 through S1-3) of rabbit spinal cord and DRG. Multiple unilateral or bilateral dorsal rhizotomy (C5-T1) in the rat did not affect levels of ir-dynorphin in spinal cord. As reported previously (Goldstein & Ghazarossian, 1980), mid-thoracic spinal transection was without effect. Gel permeation column chromatography (Sephadex G-50, 100 x 1.5 cm; 0.1 M acetic acid, 0.15 M NaCl, 0.1% Triton X-100) of rabbit dorsal and ventral spinal cord and DRG extracts revealed three immunoreactive components.

These observations suggest that ir-dynorphin is distributed in a regionally specific fashion in spinal cord and DRG. The neuropeptide appears, most probably, to be contained in short axoned neurons. We surmise this potent opioid peptide may participate in the processing of sensory information in spinal cord and DRG.

31.11 SCANNING ELECTRON MICROSCOPY OF RAT THIRD VENTRICLE AFTER ACUTE ENDORPHIN INJECTION TO LATERAL VENTRICLE: MACROPHAGE-LIKE CELL RESPONSE. L.C. Saland, E. Ortiz* and A.T. Munger*. Department of Anatomy, University of New Mexico School of Medicine, Albuquerque, NM 87131.

The ventricular system of the brain is a common site for introduction of opiate peptide molecules (endorphins) in many studies of analgesic and behavioral effects in animals and, more recently, via lumbar puncture in man. Acute effects of endorphins may in part be a function of local cellular responses, including ependymal absorption or transport. We have examined the surface of the third ventricle superior to the hypothalamic median eminence (HME) after single acute injection of synthetic ovine β-endorphin, human α-endorphin (courtesy of Dr. N. Ling) or met-enkephalin into the lateral cerebral ventricle (LCV). Young adult male Sprague-Dawley rats received 20ug (in 15-20ul saline) β- or α-endorphin or 100ug met-enkephalin (in 15-20ul saline) to the LCV while awake into previously implanted stainless steel cannulas. Controls received 15-20ul saline alone. 45-60 minutes after injection, animals were lightly anesthetized with ether, then perfused through the heart with saline followed by 1% paraformaldehyde-2.5% glutaraldehyde in 0.075M cacodylate/HCl buffer, pH 7.2, at room temperature. Brain tissue (HME and adjacent hypothalamus) was prepared routinely for scanning EM, and examined with an ETEC autoscan. The ependyma of most control rats exhibited smooth surfaces above the HME, although a few showed occasional neuron-like or macrophage-like supraependymal cells (SEC). β-endorphin-treated rat HME contained numerous free macrophage-like SEC similar to those found in studies of animals with intracerebral infections, or occasional neuron-like cells. Animals treated with α-endorphin or met-enkephalin exhibited occasional macrophages, but appeared instead to have more prominent neuron-like supraependymal cell clusters similar to those observed in rats after peripheral p-chloroamphetamine injections (Saland and Munger, 1981, Brain Res. Bull., in press). Observations suggest that specific opiate peptides as β-endorphin introduced in the cerebrospinal fluid may "attract" macrophages from intracerebral or blood-borne sources. The occasional appearance of SE "neurons" may reflect a cellular response to changes in composition of cerebrospinal fluid. Supported by NIDA grant DA-02269 and NIH RR-08139.

31.12 ENKEPHALINERGIC MECHANISMS IN THE COCHLEA. D.W. Hoffman,* R.A. Altschuler, and J. Fex. LNO, NINCDS, NIH, Bethesda, MD 20205.

Efferent fibers of the olivocochlear bundle terminate under both inner and outer hair cells of the organ of Corti. Although their function is not clear, these efferents may participate in hair cell function, ototoxic mechanisms, and attentional processes. While previous research has supported a cholinergic mechanism at the terminals of these fibers at the bases of hair cells, this laboratory has recently shown the presence of met-enkephalin-like immunoreactivity in the efferent fibers and terminals in the cochlea (Fex and Altschuler, PNAS, Feb., 1981). Further evidence by high performance liquid chromatography (HPLC) and radioimmunoassay (RIA) for the presence of immunoreactive substances in cochlear homogenates and HPLC fractions has also recently been presented (Hoffman et. al., Trans. Am. Soc. Neurochem., March, 1981). In the present study we have further defined the enkephalin-like immunoreactivity in the cochlea and have accumulated evidence supporting receptor mediation of enkephalinergic function in this organ.

Receptor binding was assayed in cochlear homogenates by a filter technique using GF/B filters. ^{3}H-naloxone and ^{3}H-etorphine were each used as ligands, and both were found to bind stereospecifically to cochlear homogenates, as defined by the difference between binding in the presence of 10 µM levorphanol and dextrorphan. The binding of these ligands appears to saturate. The effect of Na^+ on binding of agonists and antagonists was not determined after it became apparent that NaCl (100 mM) enhanced binding of ^{3}H-naloxone to GF/B filters in the absence of tissue.

Identification of immunoreactive substances in the cochlea by HPLC-RIA has been extended by adoption of rapid freezing of whole cochlea in liquid Freon, followed by lyophilization. The freeze-dried organ may then be dry-dissected into constituent tissues. Antisera raised in our laboratory have been carefully characterized as to titer and cross-reactivity, and identification of peptides of interest may be made both by retention time in HPLC and by reactivities to several antibodies of different specificities.

31.13 LIGHT AND ELECTRON MICROSCOPIC FEATURES OF IMMUNOREACTIVE LEU-ENKEPHALIN IN THE MONKEY HYPOTHALAMUS. I:PARAVENTRICULAR NUCLEUS.

M. DiFiglia, N. Aronin, J. Carey*, M.J. Breslow*, and J.B. Martin.
Dept. of Neurology, Mass. General Hosp., Fruit St., Boston, MA.

Neurons and terminals containing immunoreactive (IR) leu-enkephalin (leu-enk) were identified in the monkey (M. cynamologous) hypothalamus. Vibratome sections were incubated in leu-enk antiserum (BioFlex) and then processed by the immunoperoxidase technique. Light microscopy revealed labeled cell bodies (with colchicine pre-treatment) in numerous regions of the hypothalamus. Many leu-enk somata (15-30 μm) were present in the dorsal and posterior aspects of the paraventricular nucleus (PVN) and more laterally throughout the perifornical region ventral to the anterior commissure. Positive neurons (15 μm) were occasionally found in the vascular, medial PVN. Fewer immunostained perikarya (10-15 μm) were present in the lateral hypothalamic, periventricular, ventromedial and arcuate regions. IR leu-enk fibers were most numerous in the lateral hypothalamus and were also seen in the areas of cell body labeling, the supraoptic nucleus, and the external layer of the median eminence.

Electron microscopic examination of the dorsal aspect of the PVN revealed that leu-enk somata contained a deeply enfolded nucleus, well-developed endoplasmic reticulum and numerous large granular vesicles (LGV; 80-200 nm) which were heavily labeled with peroxidase reaction product. Leu-enk neurons were contacted by small boutons (0.5-1.0 μm) which contained clear round or pleomorphic vesicles and larger axon terminals (2 μm) with clear pleomorphic vesicles and LGV. Immunostained leu-enk dendrites had spines and contained clear vesicles and LGV filled with reaction product. The dendritic shafts and spines were postsynaptic to the same classes of boutons that contacted the cell body. IR leu-enk axons were unmyelinated, up to 0.3 μm in diameter, present in bundles of unstained axons of similar caliber, and gave rise to boutons (1.0 μm in size) that contained pleomorphic, clear vesicles (40 nm) and many LGV (80-200 nm). Reaction product deposited within the LGV and around the membranes of the smaller vesicles. Labeled boutons synapsed with unlabeled small dendrites, dendritic spines, the shafts of primary dendrites, and somata which were 15-20 μm in size. Most of the synapses appeared to be symmetric. The present results in monkey (1) show a distribution of leu-enk at the light microscopic level which is similar to that found in rat hypothalamus and (2) provide direct evidence at the ultrastructural level to support recent studies in vitro that enkephalins can markedly inhibit PVN neurons.

Supported by NIH grants #NS 16367, 5 F32AM06143-01, and AM 262-52.

32.1 THE ONTOGENY OF CHOLECYSTOKININ IMMUNOREACTIVITY IN VERTEBRATE BRAIN, Steven A. Goldman* and Bruce S. Schneider* (SPON: F. Nottebohm). Rockefeller University, New York City, NY 10021.

Cholecystokinin (CCK) is discretely localized in neurons and terminals of vertebrate brain, and may have a neurotransmittive function. We have previously demonstrated, by the use of radioimmunoassay in combination with regional brain dissection, that the development of CCK in rat brain occurs during the first postnatal month (Schneider et al, J. Clin. Invest. 64: 1348, 1979). To determine whether the appearance of CCK in discrete brain regions is associated with any particular aspects of brain histogenesis, we examined in detail the development of CCK immunoreactivity in the brains of several species. Two precocial species (guinea pig and chicken) were found to attain adult CCK concentrations in all areas (telencephalon, diencephalon, mesencephalon/tectum, and hindbrain) before the perinatal period. In contrast, the altricial zebra finch, like the altricial rat, manifested adult brain CCK concentrations only after several weeks of postnatal development. Each species' final brain CCK level was determined, however, not by its ontogeny, but by its phylogeny: both mammals showed high adult telencephalic CCK concentrations (rat, 550 ng CCK8equiv./g wet weight, guinea pig, 220 ng/g), while both birds showed lower adult telecephalic levels (chicken, 50 ng/g, finch, 60 ng/g).

Within any given species, the time course of development of brain CCK was essentially the same across all brain regions, despite differences in the adult CCK concentration from region to region. However, the patterns of a given species' CCK development were not always monotonically rising curves. Chick brain development in particular is marked by a perinatal rise in CCK concentration to levels far exceeding those of adult chick brain. Within the first month after hatching, CCK concentrations then declined to adult levels. We believe this effect to be due to a neurogenic, perinatal production of a relatively constant brain CCK store, followed by a subsequent dilution of this store by gliogenic and myelinogenic increases in brain weight. Correlation of our comparative ontogenetic data with known patterns of brain histogenesis demonstrate that CCK development comes after most known periods of neuronal proliferation, migration and axonal outgrowth, and occurs during or soon after local synaptogenesis. Sephadex G50 gel filtration disclosed no differences across the species or among different brain areas in the molecular forms of CCK. CCK-8 predominated with minor CCK-33 and void volume (pro-CCK) peaks. Finally, it was determined that duodenal CCK (largely CCK-33) appears much earlier than brain CCK in all species examined, indicating that the gut and brain CCK systems develop independently of each other.

32.2 THE DEVELOPMENT AND DISTRIBUTION OF SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE VISUAL CORTEX OF THE RAT. J.K. McDonald, J.G. Parnavelas, N.C. Brecha and J.I. Koenig*. Depts. of Cell Biology and Physiology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235 and Dept. of Neurobiology, S.U.N.Y., Stony Brook, NY 11794.

Using immunohistochemistry, we have examined the development of somatostatin-like immunoreactivity (SRIF-IMR) in the rat visual cortex, an area whose morphological development has been studied extensively. Sprague-Dawley albino rats of both sexes at 3,5,7,8,10, and 14 days of age as well as adult animals were used in this study. All animals were perfused with fixative containing 4% paraformaldehyde, 0.1M D,L-lysine and 0.01M Na periodate in 0.1M phosphate buffer. Coronal sections were cut at 30 µm and processed for fluorescence and PAP immunohistochemistry using conventional techniques. SRIF antiserum was raised in rabbits by J. Koenig and preabsorption with 10^{-4}-10^{-6}M synthetic SRIF (Peninsula) revealed no cortical staining.

In the adult, SRIF-IMR cells were observed in layers II-VI but were concentrated primarily in layers II & III and V. Layer I appeared to contain only labeled fibers. Labeled cells were almost exclusively non-pyramidal in morphology although a few pyramids were observed. The non-pyramidal cells were of the multipolar and bitufted varieties and their size and distribution in the cortex were similar to that observed in Golgi preparations (Parnavelas et al., 1977; Feldman and Peters, 1978). Particularly notable were the presence of large multipolar neurons in layer V and cells with horizontally oriented dendrites in layer VI.

At postnatal days 3 and 5, SRIF-IMR was confined to immature bipolar or multipolar neurons in the lower cortical plate. No positive fibers or cell bodies were observed in the upper cortical plate. At day 7, a few positive fibers were observed in layer I, but immunoreactive cell bodies were still present only in the lower cortical layers. At this and subsequent stages of development, non-pyramidal neurons with horizontally oriented dendrites were seen adjacent to the white matter. At day 8, SRIF-IMR cells appeared more differentiated and, for the first time, a few labeled cells were seen in layers II & III. At postnatal day 10, there was an increase in SRIF-IMR fibers in layer I as well as a greater number of non-pyramidal cells in layers II & III although the majority of immunoreactive cells remained in the lower cortical layers. A striking increase in the frequency of SRIF-IMR cells in the upper cortical layers was observed in the latter part of the second postnatal week, and at day 14 the morphology and distribution of the SRIF-IMR neurons were similar to that of adult animals.

Supported by NIH Grant EY02964.

32.3 SOMATOSTATIN (SOM)*, SUBSTANCE P (SP)*, ENKEPHALIN (ENK)*, AND 5 HYDROXYTRYPTAMINE (5HT)* IMMUNOREACTIVE ELEMENTS IN THE NEONATAL RAT SPINAL CORD, R.H. Ho, Department of Anatomy, The Ohio State University, College of Medicine, Columbus, Ohio 43210

The present account describes the distribution of SOM, SP, ENK and 5HT elements in the spinal cord of neonatal (Day 0-1 neonates) Sprague Dawley rats. Animals were perfusion fixed with Zamboni's solution and cryostat sections from representative spinal cord levels were processed by Sternberger's PAP technique. A moderate density of SOM fibers is present in the lateral funiculus, whereas only a small number are located in the dorsal and the ventral funiculi. Neuronal elements containing SOM are most numerous within the superficial laminae (presumptive laminae I, II and possibly III) of the dorsal horn. The outer portion of this region contains SOM varicosities whereas the inner portion also contains immunostained neuronal elements that resemble small perikarya. In addition, there is a widespread distribution of SOM immunoreactivity ventral to the superficial laminae. SOM immunoreactivity is localized within the cytoplasm that either partially or completely surrounds negatively stained nuclei. Thus, we interpret these neuronal elements to be SOM containing cell bodies. The perikarya are of various shapes and sizes and widely dispersed throughout the gray matter ventral to the superficial laminae. The cell density is slightly increased in regions lateral to the central canal and the ventral horn. The distribution of SP elements is generally similar to that described for the adult rat spinal cord. The major difference appears to be the presence of a moderate density of SP fibers in the dorsal funiculus of neonatal cords. The densest distribution of ENK is in the lateral funiculus, although some is present in the dorsal and ventral funiculi. ENK varicosities are present dorsal to the central canal and at thoracic levels, they are present in the presumptive intermediolateral cell column. In other gray regions, ENK varicosities are extremely sparce. 5HT elements are present in all areas of the spinal cord previously described in the adult animal. Control sera consisting of the various antibodies pretreated with the corresponding antigens failed to reveal any of the aforementioned immunoreactivities on adjacent and/or semiadjacent sections. In summary, the distribution of 5HT and SP are quite similar to that described in the adult. However, the localization of SOM and ENK are markedly different when compared to the adult. The functional significance of the abundant SOM cell bodies present during development remains to be determined. (We thank Dr. Robert Elde for the 5HT antibody. Supported by NIH NS-10165 and the Department of Anatomy, The Ohio State University).

* A substance's immunoreactivity is referred to by its name.

32.4 IMMUNOCYTOCHEMICAL LOCALIZATION OF AVIAN PANCREATIC POLYPEPTIDE-LIKE IMMUNOREACTIVITY IN THE HYPOTHALAMUS OF THE RAT. N. Brecha, J.P. Card and R.Y. Moore, Depts. of Neurology and Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, New York, 11794.

The distribution of avian pancreatic polypeptide-like (APP) immunoreactivity was studied in the rat hypothalamus using the indirect immunoperoxidase method. APP antisera was generously provided by J. Kimmel and cytochemical tests of antibody specificity included preabsorption of antisera with the APP antigen and by substitution of normal serum for the antibody. Some animals received an injection of colchicine into the lateral ventricle two days prior to sacrifice. Perikarya. Immunoreactive perikarya are present in the anterior and tuberal regions of the medial hypothalamus and in the lateral hypothalamic area. None are evident in the mammillary complex or posterior hypothalamic area. The largest numbers of immunoreactive perikarya are observed in selected nuclei of the mediobasal hypothalamus, particularly in the retrochiasmatic area and in the medial portion of the arcuate nucleus. A moderate number of immunoreactive neurons are evident in the ventral anterior hypothalamic area and scattered neurons are present in the medial preoptic area, periventricular nucleus, paraventricular nucleus, dorsal and ventral tuberal areas, dorsomedial nucleus, dorsal hypothalamic nucleus and in the zone surrounding the ventromedial nucleus. In the lateral hypothalamic area immunoreactive neurons are present along its entire rostro-caudal extent with the largest number evident from the level of the suprachiasmatic nucleus to the median eminence. Fibers. Immunoreactive axons are present in the organum vasculosum lamina terminalis, medial and lateral preoptic areas, the anterior and dorsal hypothalamic areas, the dorsomedial nucleus, and in the lateral hypothalamic area. Particularly dense plexuses of axons are demonstrated in the periventricular nucleus, the ventrolateral component of the suprachiasmatic nucleus, retrochiasmatic area, arcuate nucleus, and perifornical area. Scattered fibers are present in the subventricular zone of the median eminence. All of the magnocellular nuclei, supraoptic, paraventricular, circularis and tubermammillary, contain moderate numbers of immunoreactive axons. Few fibers are evident in the ventromedial nucleus or mammillary complex. These observations provide morphological evidence for the presence of systems of APP-immunoreactive neurons with a distribution differing from that of other known peptidergic systems in the rat hypothalamus. (Supported by USPHS Grant NS-16304 to RYM and by USPHS Postdoctoral Fellowship NS-06247 to JPC).

32.5 LOCALIZATION OF VASOACTIVE INTESTINAL POLYPEPTIDE-LIKE IMMUNOREACTIVITY IN IDENTIFIED NEURONS IN THE VISUAL CORTEX OF THE DEVELOPING AND MATURE RAT. J.G. Parnavelas, J.K. McDonald, C.-S. Lin and N.C. Brecha. Dept. Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235, and Dept. Neurobiology, State Univ. of N.Y., Stony Brook, NY 11794.

Using immunohistochemistry, vasoactive intestinal polypeptide (VIP)-like immunoreactivity was localized in the developing and adult visual cortex of the rat. Sprague-Dawley albino rats of various postnatal ages as well as adult animals were perfused with 4% paraformaldehyde, 0.1M D,L-lysine-HCl and 0.01M Na periodate in 0.1M phosphate buffer. Frozen sections were cut at 30 µm in the coronal plane, incubated in VIP antiserum and processed according to conventional immunohistochemical techniques. Preabsorption of the antiserum with 10^{-5}-10^{-7}M synthetic VIP (Boehringer-Mannheim) revealed no cortical staining.

Neurons which displayed VIP-like immunoreactivity comprised approximately 3% of the neuronal population in the visual cortex (area 17) of the adult rat. Their perikarya were located in layers II-VI but tended to be concentrated in layers II & III. All labeled neurons had the morphological characteristics of cortical non-pyramidal cells (Parnavelas et al., 1977) with the majority being of the bipolar variety as described in Golgi preparations (Feldman and Peters, 1978). Some multipolar non-pyramidal neurons were also present. Intraventricular injections of colchicine (50 µg colchicine in 10 µl saline) intensified the staining but did not reveal any cell types which were not observed in the visual cortex of untreated animals.

VIP-like immunoreactivity appeared to develop for the most part in postnatal life. At day 4, only a few immunoreactive cell bodies could be identified in the lower layers (V and VI) of the cortex. At day 6, immunoreactive cell perikarya were still present predominantly in layers V and VI although a very small number of neurons were seen in the upper cortical layers. The distribution of labeled cell bodies appeared quite different at the beginning of the second postnatal week when the majority were concentrated in the upper cortical layers. Although the distribution of immunoreactive cells at this time resembled that of adult animals, their morphology displayed immature features. It appears that the developmental changes observed in VIP-containing neurons in the visual cortex are reflected in the pattern of the morphological differentiation of these neurons.

We are grateful to Dr. John Walsh for providing the antiserum. The work was supported by NIH grant EY02964.

32.6 DISTRIBUTION OF SOMATOSTATIN IMMUNOREACTIVE NEURONS IN THE HYPOTHALAMUS OF THE RAT. R.Y. Moore, N. Brecha, J.P. Card and T. Yamada. Depts. of Neurology and Neurobiology, SUNY at Stony Brook, Stony Brook, NY 11794, and Dept. of Medicine, UCLA, Los Angeles, Ca.

The distribution of somatostatin-like immunoreactivity in neurons of the rat hypothalamus was studied using the indirect peroxidase-antiperoxidase method. Specificity was determined by pre-adsorption of antiserum with somatostatin. Perikarya. Immunoreactive neuronal cell bodies are found in two principal locations. The first is in the periventricular region, particularly in the anterior hypothalamus. Coextensive with this group cell bodies are present in the suprachiasmatic nucleus. The second is comprised of scattered immunoreactive perikarya present in the caudal anterior hypothalamic area, retrochiasmatic area, ventral tuberal area, perifornical area, caudal periventricular nucleus, ventral premammillary nucleus and in the tuberal area surrounding the ventromedial nucleus with scattered cell bodies present in that nucleus. No positive cells are present in the posterior hypothalamus or mammillary complex. Terminals. In the anterior hypothalamus scattered axons are evident in the organum vasculosum lamina terminalis. Dense axonal plexuses are present in the medial preoptic area, anterior hypothalamic area, and the rostral portion of the suprachiasmatic nucleus. Similarly dense plexuses are present more caudally in the retrochiasmatic area, ventromedial nucleus, arcuate nucleus and the ventral premammillary nucleus. The lateral hypothalamic area shows a scattered to moderately dense axonal plexus. No immunoreactive axons are evident in the supraoptic or paraventricular nuclei. Caudally, no immunoreactive axons are evident in the mammillary complex. Scattered axons are evident in the posterior hypothalamic area whereas the tuberomammillary and supramammillary nuclei show a more dense innervation. The pattern of immunoreactive somatostatin neurons differs from that of other peptidergic neuron systems in rat hypothalamus. (Supported by USPHS Grant NS-16304 to RYM and USPHS Postdoctoral Fellowship NS-06247 to JPC).

32.7 HIPPOCAMPAL NEUROPEPTIDES: DISTRIBUTION ACROSS SPECIES. G.E. Hoffman and S. Wray*. Dept. of Anat., Univ. of Rochester Sch. of Med. & Den., Rochester, NY 14642.

Recent evidence suggests an increasing role for neuropeptides in limbic system function. In certain instances the patterns of localization of the peptides has substantiated their functional role. Most investigations of neuropeptide localization in the hippocampus have been restricted to the rat or one of the other rodent species. However, striking differences in both hippocampal anatomy and function among species have been noted. Thus, a comparative investigation of the organization of somatostatin (SS), vasoactive intestinal polypeptide (VIP), LHRH and substance P (SP) in mouse, rat, rabbit and cat was conducted. The animals were perfused with neutral picric acid formalin and sectioned at 50 or 75 um on a vibrating microtome. The sections were processed using the unlabeled antibody enzyme method. SS neurons in the mouse were found mainly in the stratum oriens of the hippocampus proper and in the hilus of the dentate gyrus. The former cells gave rise to axons that coursed through many of the layers of the hippocampus to the stratum lacunosum. In general this pattern was consistent throughout the species examined. Likewise, the distribution of VIP neurons was consistent in the rat and mouse. Some of these neurons sent fine axons to the pyramidal layer much like basket cells. A few LHRH neurons were consistently observed in the hippocampus of the mouse but not the other species. Their random distribution suggested that these were stray cells of the septal LHRH populations. Nonetheless, in the mouse and in all the other species examined, sparse LHRH axons were observed scattered throughout the hippocampus. SP axons were rarely observed in the hippocampus of the rat and mouse. However, in the rabbit a moderate density of such fibers concentrated adjacent to the cellular layers of the hippocampus and dentate gyrus was observed. In the cat, these fibers formed a dense plexus. These results suggest that peptides such as substance P may underlie species differences in hippocampal function and further support a role for a variety of neuropeptides in limbic function. 32.8 PRODUCTION OF MONOCLONAL ANTIBODIES AGAINST VASOACTIVE INTESTINAL POLYPEPTIDE. Illana Gozes, Diane Barry*, Robert Benoit*, Fu-Tong Liu*†, David H. Katz*†, Robert J. Milner*, and Floyd E. Bloom. The Salk Institute and Scripps Clinic and Research Foundation†, San Diego, CA 92037.

Vasoactive intestinal polypeptide (VIP) was originally isolated from the intestine but has been subsequently shown to be widely distributed throughout the body, with a high concentration in the hypothalamus and cerebral cortex. In addition, this 28 amino acid polypeptide has been shown to be localized in and released from nerve terminals in the brain, suggesting that VIP may function as a neurotransmitter.

In order to integrate knowledge on the synthesis, localization, and the structure-function relationships of VIP we have prepared monoclonal antibodies against VIP. (Balb/c x A/J) F1 mice were injected intraperitoneally and subcutaneously with synthetic porcine VIP electrostatically complexed with methylated bovine serum albumin and emulsified in complete Freund's adjuvant. Mice were boosted intraperitoneally at 2 week intervals with the complexed antigen in aluminum hydroxide. The mouse with the highest antibody titer against VIP was boosted with antigen intravenously and intraperitoneally and sacrified 4 days later. Immune spleen cells were fused with SP2/0 tumor cells in the presence of polyethylene glycol and plated in 2500 wells. At 3 weeks 500 wells contained growing hybrid cells and of these 130 showed immunoreactivity against VIP as measured by a radioimmunoassay using ^{125}I labelled VIP. 32 hybridomas were stable after 8 weeks in culture.

We are presently using these antibodies to identify putative precursors for VIP. Preliminary results suggest that some of the anti-VIP positive hybridomas secrete antibodies that also recognize high molecular weight proteins which may represent VIP precursors. Fractionation of rat brain proteins by gel exclusion chromatography showed the presence of high molecular weight material having VIP-immunoreactivity detectable by radioimmunoassay. This finding has been corroborated by experiments using two conventional rabbit antisera against VIP. We are also using these antibodies to identify presumptive VIP precursors by in vitro translation of brain mRNA and molecular cloning experiments.

These experiments were supported by grants from the Sun Oil Company, Mobil Foundation, Inc., McNeil Pharmaceuticals, and USPHS grant AI-13874.

32.9 CEREBRAL CORTICAL GLYCOGEN METABOLISM REGULATION BY VASOACTIVE INTESTINAL POLYPEPTIDE (VIP).

Magistretti, P.J., Morrison, J.H., Shoemaker, W.J., Sapin, V.*, and Bloom, F.E. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, San Diego, California 92138.

The regulatory role of putative neurotransmitters on CNS energy metabolism has attracted increasing attention. To study such synaptic functions, we used a recently described, highly sensitive method (1), by which the effects of putative neurotransmitters on ^{3}H-glycogen levels newly synthesized from ^{3}H-glucose can be monitored. Mouse cortical slices (250 µm thick,) resuspended in a modified Krebs-Ringer bicarbonate buffer and preincubated for 15 min at 37°, were then incubated in the presence of ^{3}H-glucose (0.5Ci/mmol) for 30 min. At the end of that period, the synthesis of ^{3}H-glycogen reached a plateau, and drugs or vehicle were added for 15 min. The incubation was ended by rapid centrifugation. After sonication and recentrifugation, the ^{3}H-glycogen in the supernatant was separated from ^{3}H-glucose and other contaminants by ethanol precipitation on filter paper. Using this separation technique, the contamination by ^{3}H-glucose is < 0.5%. Filters were then counted in a liquid scintillation counter. Enzymatic hydrolysis of newly synthesized ^{3}H-glycogen was induced by VIP in a concentration-dependent manner. The EC_{50} for this effect was 30 nM. Consistent with a previous report (1), norepinephrine (NE) displayed a similar action, with an EC_{50} of 300 nM. The VIP effect was not mediated by a release of NE, since it was not blocked by noradrenergic antagonists and was still present in mice in which an 85% depletion of NE was induced by intracisternal 6-OHDA injections (2x25 ug). Interestingly, preliminary results show a decrease in ^{3}H-glycogen levels in these lesioned mice. Another cortical putative neurotransmitter, somatostatin, had no glycogenolytic effect; the possible action of other neuropeptides present in cerebral cortex on ^{3}H-glycogen metabolism is currently being investigated. This effect of VIP on cortical carbohydrate metabolism should increase the energy substrates available at the cellular level. Given the radial pattern of arborization of the intracortical VIP neuron, (see Morrison, J.H., et al., this volume) and the tangential intracortical trajectory of the noradrenergic fibers, a role of VIP in the regulation of energy metabolism within individual columnar modules in cerebral cortex may be envisaged, while that of NE may span adjacent columns.

32.10 THE IMMUNOHISTOCHEMICAL CHARACTERIZATION OF SOMATOSTATIN (SS) AND VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) NEURONS WITHIN THE CEREBRAL CORTEX.

J.H. Morrison, P.J. Magistretti, R. Benoit, and F.E. Bloom. A.V. Davis Center and Laboratory of Neuroendocrinology, The Salk Inst., San Diego, CA 92138.

Several laboratories have demonstrated biochemically that SS and VIP are present in the cerebral cortex. We have utilized specific antibodies to each of these peptides to visualize the VIP and SS-containing neurons within the cerebral cortex.

SS-positive cells are present throughout the cerebral cortex and hippocampus (principally CA1) and are particularly numerous in the pyriform cortex. In the neocortex, they are distributed in two major laminar bands, a supragranular band in layers II and III and an infragranular band in layers VI and deep V. Labelled cells are relatively rare in layers IV and superficial V. The cell bodies are variable in size and shape, but tend to be multi-polar and 12-20 µm in diameter. The dendrites are relatively short, and rarely extend more than 50 µm from the cell body in the plane of section (40 µm thick). Terminals are present in all layers, but are particularly dense in layer I.

VIP-containing cells are most numerous in layers II and III, but are present also in layers IV, V and VI. A fine plexus of terminal boutons is present in layers II-V. The cell bodies are generally ovoid and measure approximately 8-10 µm across and 15 µm in the radial axis. The VIP-positive neurons are radlally bi-polar, with a few major dendrites emanating from the superficial and deep poles of the soma. These major dendrites are generally beaded and can be followed for extremely long distances (up to 1 mm in a 40 µm thick section) and invariably are oriented perpendicular to the pial surface. The processes do not branch profusely and rarely extend for any appreciable distance in the tangential plane. Thus, an individual VIP-positive neuron may span the entire vertical thickness of the cerebral cortex, receiving synaptic input in all cortical laminae, and impinging upon other cortical elements in a narrowly defined, radial column. Given the effect of VIP on cortical carbohydrate metabolism (see Magistretti, et al., this volume), the VIP neuron may be an important component of the cortical column, modulating the availability of energy substrates as neuronal activity increases locally. The radial VIP system stands in striking contrast to the tangential noradrenergic system, which may also be involved in metabolic regulation, but has the capacity to intersect a longitudinal array of columns across a vast expanse of neocortex. Supported by USPHS Grants AA 07273 and AA 03504. PJM supported by Swiss NSF Fellowship.

32.11 IMMUNOCYTOCHEMICAL CHARACTERIZATION OF VENTRAL LATERAL GENICULATE NUCLEUS EFFERENTS TO THE RAT SUPRACHIASMATIC NUCLEUS.

J.P. Card, N. Brecha and R.Y. Moore. Depts. of Neurology and Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, New York, 11794.

Autoradiographic analysis of the efferent projections of the rat ventral lateral geniculate nucleus (vLGN) have demonstrated that the ventral aspect of the suprachiasmatic nuclei (SCN) receive a bilateral innervation which is most dense in the ipsilateral SCN (Swanson et al., 1974; Ribak and Peters, 1975). Moore et al. (1979) have demonstrated that this projection arises from a distinct lamina of cells at the dorsal limit of the vLGN. The present study demonstrates that the vLGN-SCN projection can be defined immunocytochemically following staining with antibody directed against avian pancreatic polypeptide (APP; generously provided by J. Kimmel). APP immunoreactivity was localized in brains of adult male and female rats using the indirect peroxidase antiperoxidase technique. Histochemical tests of antibody specificity included absorption of the antiserum with APP antigen and substitution of normal serum for APP antiserum. Within the rat SCN, APP immunoreactivity is restricted to varicose axons in the ventral and lateral aspects of the nucleus; the dorsomedial segment of the nucleus is totally devoid of immunoreactivity and immunoreactive perikarya are not present in any portion of the SCN. The immunoreactive axons in the ventrolateral component of the nucleus form an extensive plexus which is distributed in a pattern closely corresponding to the distribution of retinal and vLGN afferents to the SCN. Because of this similarity, both the retina and vLGN were examined as possible sites of origin for APP axons in the SCN. No immunoreactive perikarya are observed in the retina following immunoperoxidase staining for APP and neither unilateral nor bilateral enucleation causes an observable alteration in the pattern of APP axon distribution within the SCN indicating that the fiber plexus is not of retinal origin. In contrast, APP immunoreactive neurons are present in the same area of the vLGN in which retrogradely filled neurons are found after iontophoretic injection of HRP into the SCN. In addition, bilateral electrolytic lesions of the vLGN result in a total loss of immunoreactive axonal staining in both SCN while unilateral vLGN lesions cause a loss of immunoreactive fibers that is approximately twice as great in the ipsilateral SCN. These observations provide further information on the histochemical organization of the rat SCN and demonstrate that the vLGN projection to the SCN is chemically distinct from other afferents to the SCN. 32.12 MOTILIN RELATED IMMUNOREACTIVITY IN PURKINJE CELLS OF THE MAMMALIAN CEREBELLUM.

G. Nilaver*, R. Defendini*, E.A. Zimmerman, M.C. Beinfeld* and T. O'Donohue*. Lab. of Neuroendocrinology, Coll. of Phys. & Surg., Columbia Univ. New York, NY 10032, and Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

Motilin, a 2,700 dalton peptide initially isolated from porcine gut, has recently been demonstrated in the brain and anterior pituitary of several mammalian species, including rat, dog, monkey and man, by radioimmunoassay and immunocytochemistry. Reports of relatively high concentrations of this peptide in the cerebellum were of special interest since other peptides are known to be present in negligible concentrations in this part of the brain. We have localized motilin in the cerebellum using a rabbit antiserum generated against a synthetic porcine motilin-thyroglobulin conjugate. Immunoperoxidase labeling of 6 µm deparaffinized sections of rat, monkey and human cerebelli with the antiserum at a dilution of 1:1000 revealed intense "Golgi-like" reactivity in the cell bodies and processes of many, but not all, Purkinje neurons. Dendritic trees could be traced in their entirety, including terminal spines. Axons were traced through the granular layer and white matter to numerous terminals innervating cell bodies and proximal dendrites of the deep cerebellar nuclei. Other neurons and their processes in the cerebellum were not reactive. A few reactive neuronal perikarya were seen in the rat hypothalamus, as well as many fiber terminals in the median eminence. Immunoreactivity was also noted in anterior pituitary cells. Preabsorption of 1 ml of the final dilution of antiserum with 10 µg of synthetic porcine motilin completely abolished immunoreactivity in the hypothalamus and pituitary, whereas 100 µg of the antigen was required to significantly block staining in the Purkinje neurons. Furthermore, preabsorption of the antiserum with rat cerebellar extract completely blocked the staining in both hypothalamus and pituitary. Chromatography of the cerebellar and other brain extracts on Sephadex G50 revealed two immunoreactive peaks. One eluted soon after the void volume. The other eluted similarly to synthetic motilin. Reverse phase high pressure liquid chromatographic data as well as immunological data using region-specific antibodies, however, indicated that the material in cerebellum is distinct from synthetic porcine motilin. These results suggest that the Purkinje system of the cerebellum contains a substance immunologically related to, but not identical to synthetic porcine motilin. (Supported by the Parkinsons Disease Foundation, Columbia University.)

32.13 ULTRASTRUCTURE OF SUBSTANCE P AND METHIONINE-ENKEPHALIN IMMUNOREACTIVE NEURONS IN THE GLOMERULAR LAYER OF THE HAMSTER OLFACTORY BULB. Gail D. Burd, Barry J. Davis, and Foteos Macrides. Worcester Foundation for Experimental Biology, Shrewsbury, MA.

We have previously reported the presence of the methionine-enkephalin (MET) and substance P (SP) immunoreactive neurons in the hamster olfactory bulb (Soc. Neurosci. Abstr., 6: 244, 1980). The present investigation examined the ultrastructural features of the immunoreactive neurons located in the glomerular layer (GL).

Hamsters were anesthetized with Nembutal and perfused with a 2% paraformaldehyde and 0.08% picric acid fixative. The olfactory bulbs were cut at 20 µm on a Vibratome. The sections were incubated in primary antisera and processed with the unlabelled antibody enzyme immunocytochemical procedure. The sections were then placed in 1% paraformaldehyde and 3% glutaraldehyde, osmicated, dehydrated, infiltrated with Epon-Araldite, and flat-embedded.

MET-immunoreactive neuronal somata were numerous in the periglomerular region (PGR) of the GL. They were generally ovoid in shape and, from our light microscopic measurements, had major and minor diameters of 10 µm and 7 µm, respectively. A thin rim of perikaryal cytoplasm surrounded the nucleus which was generally spherical in shape and contained dense chromatin material and one or more nucleoli. MET-immunoreactive processes were also present in the PGR and within glomeruli. Based on the size and ultrastructural features of the somata and the distribution of the neuronal processes, the MET-immunoreactive neurons in the GL were identified as periglomerular cells.

SP-immunoreactive neuronal somata were also present in the PGR. They were larger and less numerous than the MET-positive somata. SP-positive somata were spherical or ovoid in shape and, from our light microscopic measurements, had major and minor diameters of 13 µm and 11 µm, respectively. Depending on the plane of section, the nucleus appeared to be ovoid or spherical in shape and was surrounded by a large or moderate perikaryal cytoplasmic area. No nuclear invaginations were observed. The chromatin material was generally evenly distributed throughout the nucleus and a nucleolus was occasionally observed. SP-positive processes were present in the PGR and within glomeruli. Synaptic contacts were present on SP-immunoreactive dendrites in both of these regions. Based on the size and ultrastructural features of the somata and the distribution of the neuronal processes, SP-immunoreactive neurons were identified as external tufted cells. However, the size and location of the SP-positive neurons are consistent with the interpretation that some short-axon cells might also contain SP.

32.14 ULTRASTRUCTURAL EXAMINATION OF SUBSTANCE P AND MET-ENKEPHALIN IMMUNOREACTIVE ELEMENTS IN THE RAT SPINAL CORD. J.C. Bresnahan, R.H. Ho, and M.S. Beattie, Dept. Anat., Ohio State Univ. Sch. Med., Columbus, OH. 43210

Following perfusion with 4% paraformaldehyde, sections from the spinal cord (8 rats) were cut on a vibratome. The PAP technique Sternberger was used to demonstrate met-enkephalin (ENK)* and substance P (SP)* on semi-adjacent sections. Sections were then osmicated, dehydrated, and flat embedded in Maraglas between sheets of smooth plastic for light microscopic observation prior to sectioning for the electron microscope.

LM observations of the distribution of SP and ENK in the osmicated sections corroborated published reports. Particularly noteworthy was the prominent staining of SP and ENK elements in the lateral spinal nucleus (LSN). Certain cells in this region were studded along their dendrites and somata with terminals that stained for either SP or ENK. Also of interest was the cytoplasmic labelling for SP or ENK of scattered cells, the laminar locations of which corresponded to previously published descriptions of labelled cells following colchicine treatment.

EM samples were taken primarily from cervical levels and from laminae I and II. Sections were systematically scanned and all labelled profiles were photographed. SP axons were small and unmyelinated. SP terminals had a mean diameter of 1.03 nm, and contained round, clear vesicles and dense cored vesicles (DCVs, mean no./term. = 2.2). The mean diameter of SP DCVs was 83.2 nm. The post-synaptic elements were small diameter dendrites and dendritic spines. Synaptic junctions were primarily assymetrical and often displayed subjunctional dense bodies. Lightly labelled somata and dendrites were also observed and on one occassion a labelled SP terminal was seen to synapse with a labelled dendrite.

ENK elements were small unmyelinated axons and terminals (mean diameter = .87 µm) with clear synaptic vesicles and DCVs (mean no./term. = 4.7). The mean diameter of ENK DCVs was 89.0nm. The post-synaptic elements were small diameter dendrites and synaptic junctions were symmetrical.

Comparing the SP and ENK terminals, the ENK population did not exhibit as many clearly identifiable synaptic junctions and contained more DCVs (U-test, $p < .01$), and these DCVs were larger than those present in SP terminals (U test, $p < .05$). Currently these studies are being expanded to include ultrastructural analysis of the LSN and laminae IX and X, as well as somatostatin elements. (Supported by Grants NS-14457 and -10165.)

*(A Substance's immunoreactivity is referred to by its name.)

32.15 IMMUNOCYTOCHEMICAL DOUBLE-LABELING FOR CHOLECYSTOKININ AND SOMATOSTATIN IN THE RAT HIPPOCAMPUS. R. S. Greenwood, K.K. Winstead*, Dept. Neurology and Neurobiology Program, University of North Carolina School of Medicine, Chapel Hill, N.C. 27514

Cholecystokinin-like (CCK-L) and somatostatin-like (SRIF-L) immunoreactivity has been found in rat hippocampal cells and fibers. Using the indirect immunofluorescent technique we elected to compare cellular localization of these peptides in the same hippocampal section. We incubated each septal hippocampal section with a primary antiserum to the COOH-terminal peptides of cholecystokinin and gastrin (Ab 4562**) and to a primary antiserum of somatostatin. Rhodamine-conjugated secondary antibody localized immunoreactivity with the first primary antiserum while fluorescein-conjugated secondary antibody localized immunoreactivity with the secondary primary antiserum. In an adjacent section we reversed the sequence of the primary antisera. This technique allows identification of those cells immunoreactive to the second primary antiserum alone. It does not identify cells immunoreactive to both antisera. We are exploring double-labeling techniques to identify these latter cells.

As in previous studies, CCK-L immunoreactive neurons were found in all layers of Ammon's horn and in the polymorphic zone of the dentate gyrus (Soc. Neurosci. Absts. 6:620, 1980). SRIF-L immunoreactive neurons were most numerous in the stratum oriens of Ammon's horn and the polymorphic zone of the dentate gyrus. Stratum oriens neurons with only SRIF-L immunoreactivity frequently appeared as small round cells with few processes. This cell type was generally located in the deepest part of the stratum oriens. The stratum oriens neurons with only CCK-L immunoreactivity varied in size and location but were usually larger and more superficial than SRIF-L immunoreactive neurons.

In the dentate few cells immunoreactive to only one antibody could be identified. Generally neurons with SRIF-L immunoreactivity alone were morphologically indistinguishable from those with CCK-L immunoreactivity alone. Usually neurons with only CCK-L immunoreactivity were found just beneath the granule cell layer. SRIF-L immunoreactive neurons were more evenly distributed in the polymorphic zone of the dentate.

We conclude that the distributions of CCK-L and SRIF-L immunoreactive hippocampal neurons are so distinct that even in those areas of the hippocampus where both types of immunoreactive neurons are found the two populations generally include dissimilar cells.

(**CCK-L antiserum a generous gift from Prof. Jens Rehfeld)

33.1 TRACING OF SUBSTANCE P AND ENKEPHALIN IMMUNOREACTIVE NEURONS PROJECTING TO THE GUINEA PIG INFERIOR MESENTERIC GANGLION: IMMUNOHISTOCHEMISTRY COMBINED WITH FLUORESCENT RETROGRADE LABELLING. C.-J. Dalsgaard*, T. Hökfelt*, L.-G. Elfvin*, L. Terenius* and P. Emson* (SPON: S. Vincent). Depts. of Anatomy and Histology, Karolinska Institutet, Stockholm, Dept. of Pharmacology, Uppsala University, Uppsala, Sweden and MRC Neurochemical Pharmacology Unit, Dept. of Pharmacology, Cambridge, United Kingdom.

The inferior mesenteric ganglion (IMG) of the guinea pig is rich in fibers immunoreactive to different neuropeptides such as substance P (SP), enkephalin (ENK), vasoactive intestinal polypeptide (VIP) and a cholecystokinin/gastrin-like peptide. To determine the origin of these peptidergic fibers a combination of fluorescent retrograde tracing and indirect immunohistochemistry was used, initially using SP and ENK antisera.

"True blue" (5 µl, 5%) or propidium iodide (5 µl, 3%) was applied to the IMG of adult guinea pigs. After four days the animals were perfused with ice-cold 10% formalin. Dorsal root ganglia (DRG) at levels L2 and L3 were dissected out and cut on a cryostat and the sections were examined in a Zeiss fluorescence microscope equipped with appropriate filter combinations. The same sections were then processed for indirect immunohistochemistry with antisera against SP and reexamined in the fluorescence microscope.

When photographs of the ganglia were compared some neurons containing the fluorescent tracer were SP immunoreactive. In addition there were some cell bodies labelled by the tracer only, as well as some substance P-positive perikarya containing no retrograde label.

A similar study was performed on the spinal cord aiming at identifying ENK-containing neurons projecting to the IMG. Application of fluorescent tracer in the IMG resulted in a labelling of cell bodies in the sympathetic preganglionic nuclei mainly in the L2-L3 segments. In order to achieve a sufficiently strong ENK immunoreaction in cell bodies of this region, the animals were treated intrathecally with colchicine 24 h before sacrifice. Following this procedure a large number of perikarya of the sympathetic preganglionic nuclei contained ENK immunoreactivity.

These findings indicate that the SP fibers in the IMG, at least in part, belong to primary sensory neurons at the lumbar level. The ENK-positive fibers may have their origin in the preganglionic nuclei of the spinal cord at the same level.

33.2 IMMUNOHISTOCHEMICAL STUDIES OF THE DISTRIBUTION OF SUBSTANCE P, SOMATOSTATIN AND CHOLECYSTOKININ IN RELATION TO THE SACRAL PARASYMPATHETIC NUCLEUS OF CAT. I. Lowe*, D. Blais*, O. Ronnekleiv, C. Morgan, I. Nadelhaft and W. de Groat. Dept. of Pharmacology, School of Medicine, Univ. of Pittsburgh and V. A. Medical Center, Pittsburgh, PA 15261.

Recent studies in our laboratory using retrograde and transganglionically transported HRP have demonstrated the projection of pelvic nerve visceral afferents into the vicinity of preganglionic neurons of the sacral parasympathetic nucleus (SPN). In the spinal cord the primary afferent axons were distributed first within Lissauer's tract (LT) from which collaterals extended through Lamina I around both sides of the dorsal horn to reach the intermediate gray matter. The lateral collateral projection (LCP) around the dorsal horn (DH) was very prominent and entered the dorsal band (DB) of the SPN (lamina V) as periodically arranged bundles of collaterals spaced at approximately 200 µm in the rostrocaudal direction. Relatively few collaterals entered the lateral band (LB) of the nucleus in lamina VII. Various peptides including substance P (SP) cholecystokinin (CCK) and somatostatin (ST) have been proposed as potential transmitters in primary afferent neurons. In the present investigation we have used immunohistochemical methods to study the distribution of these peptides within the sacral spinal cord and the relationship of the peptides to visceral afferent and efferent pathways as defined by the HRP technique. Cats were anesthetized and perfused with 4% paraformaldehyde. The spinal cord was removed and sectioned on a cryostat. Sections were processed according to standard techniques using the PAP method or the indirect immunofluorescence technique.

The distribution of SP and CCK in LT, the LCP and the SPN was in general similar to the distribution of pelvic nerve afferents with the exception that SP occurred also in the deeper layers of the DH (lamina II). Horizontal sections showed that in laminae I and V, SP and CCK terminals had a periodic distribution (interperiod distance approximately 200 µm). ST terminals exhibited a markedly different distribution with large numbers occurring in the LB of the SPN and in laminae II and outer III and fewer in the LCP (lamina I). Commonly, the region along the border between lamina I and II contained a low density of ST. All three peptides were present in the dorsal grey commissure and surrounding the central canal.

In summary, the localization in the sacral spinal cord of SP and CCK is very different from that of ST. The former correspond more closely with the distribution of pelvic nerve afferent projections. However, all three peptides were present in the region of the SPN and therefore should be considered as potential transmitters in the sacral autonomic pathways.

33.3 NON ADRENERGIC, NON CHOLINERGIC SECRETOMOTOR NERVES OF THE GUINEA PIG PANCREAS. J.S. Davison+*, G.T. Pearson*, J. Singh*, R.C. Collins* and O.H. Petersen*. Dept of Physiology The University, Dundee, U.K. (+ - Dept. Physiology, The University, Calgary, Canada). (SPON: G.E. Lucier)

Electrical field stimulation (FS) of isolated guinea-pig pancreatic segments evokes a tetrodotoxin sensitive release of amylase that is resistant to guanethidine and atropine, demonstrating the existence of non adrenergic, non cholinergic (NANC) secretomotor nerves. Stimulation of these NANC nerves is not associated with pancreatic acinar cell depolarization as is the case following cholinergic nerve stimulation. Moreover, FS in the presence of atropine has no effect on ^{45}Ca efflux from preloaded pancreatic segments. The NANC transmitter, therefore, appears to operate through an intracellular coupling mechanism other than calcium, since secretagogues such as Ach, which activate secretion via calcium, evoke ^{45}Ca efflux and membrane depolarization.

F.S. induces complex triphasic changes in endogenous cAMP and cGMP levels consisting of an initial rapid rise then fall in intracellular concentration followed by a slower rise to a secondary peak which then declines slowly. This triphasic response is also evoked by exogenous Vasoactive Intestinal Peptide (VIP - $10^{-7}M$). Since VIP also can induce enzyme secretion and V.I.P. nerves are present in the exocrine pancreas of many species, it should be regarded as a prime candidate for the unknown NANC transmitter released by F.S.

The time course of the change in cAMP levels is rather more rapid than that of the cGMP such that there appears to be a reciprocal relationship between the two nucleotides. This relationship might indicate that levels of one nucleotide might regulate the metabolism of the other.

33.4 CAPSAICIN-INDUCED SALIVATION IN RATS. P. J. K. Dobry and N. Masiques*. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Capsaicin, a releaser of substance P, was tested in a sialogogic assay adapted from S.E.Leeman and R.Hammerschlag (1967, Endocrinology 81:803-810). Male Sprague-Dawley rats (85-110 g) were anesthetized with 50 mg/kg sodium pentobarbital i.p. Control salivary rates were ≤2.0 mg/3 minute collection (measured as the increased weight of cotton balls placed into the rat's mouth immediately after saline injection). Test compounds in 0.9% saline were injected i.v. Statistical significance for sialogogia was determined by the Mann-Whitney U test, and for antagonism of sialogogia by Student's t test.

Over a 100-fold range of doses (0.1-10 mg/kg) capsaicin produced small but significant amounts of saliva (usually 4-9 mg/3 min., occasionally >20 mg/3 min.), much lower than the maximum produced by substance P (SP) (250 mg/3 min.). Salivary rate may have been limited by capsaicin's low solubility. Salivary rate in the second 3-min. period was less than half that in the first 3 min. and reached control rates by 9 min. (This was also true for salivation induced by small doses of SP.)

Capsaicin-induced salivation is antagonized by atropine sulfate, cyproheptadine HCl, and phenoxybenzamine HCl, but not by morphine sulfate, naloxone HCl, or propranolol HCl. SP-induced salivation is antagonized by none of these. Capsaicin (0.3-0.6 mg/kg) partially antagonized salivation induced by SP, but not by pilocarpine.

When administered in doses 6 min. apart, neither capsaicin nor SP showed tachyphylaxis in the salivary response.

Capsaicin produced a variety of overt reactions in the anesthetized rat. All rats given 0.01-10.0 mg/kg capsaicin flushed during or immediately after the injection. Almost all had irregular twitching of the tail and caudal body as if responding to a noxious stimulus or an analeptic. With increasing doses, an increasing proportion of rats had cyanosis, labored breathing, apnea, and a resultant need for resuscitation. Thirty-one percent of capsaicin-treated rats died during a saliva collection; data from these rats were not included in the analysis. Rats treated with high doses of SP showed flushing, cyanosis, deep and labored breathing, and apnea, but not twitching of the body.

In summary, capsaicin- and SP-induced salivation share some characteristics, but they respond differently to antagonists.

33.5 REGULATION OF AIIR IN THE RAT BRAIN AND UTERUS DURING THE ESTROUS CYCLE. F.M. Chen*, R. Hawkins*, and M.P. Printz* Dept. of Medicine Div. of Pharmacology, Univ. Calif. San Diego, La Jolla, CA 92093.

Angiotensin II (AII) is postulated to be involved in the CNS and peripheral regulation of blood pressure and water homeostasis. Reports indicate that estrus rats have decreased spontaneous and AII-induced drinking.[a] However, AII-induced uterine contractility displays increased sensitivity during estrus.[b] The present study was therefore designed to determine whether the AII receptor is regulated during the estrous cycle and to correlate any changes with the reported drinking variation and uterine response during the estrous cycle. Stages of the estrous cycle were determined by vaginal smear and organ size. AII receptor (R) determination was monitored by high affinity, saturable, specific AII binding. We found that AII binding in the uterus is highest on the day of estrus as compared to diestrus days. In contrast, in the brain, the olfactory bulb has significantly higher binding in diestrus than estrus. Other brain regions also show lowest binding during estrus and highest in diestrus, except the preoptic area in which the change is similar to that found in the uterus. In conclusion we found: 1) Rats drink less and have least AII binding in the brain during estrus; 2) Uterine AII binding is highest in estrus when the uterus is most sensitive to AII; 3) These data imply that brain AIIR and uterus AIIR are regulated separately. Furthermore, the reduced spontaneous and induced drinking, and augmented uterus contractility to AII can be explained by alterations of AIIR.

33.6 BOMBESIN-LIKE PEPTIDES: OXIDATION RESULTS IN LOSS OF BIOLOGICAL ACTIVITY. Terry W. Moody[1], Jacqueline B. Crawley[2] and Thomas L. O'Donohue[3]. [1]Dept Biochemistry, George Washington Univ. Sch. Med., Washington, D.C. 20037, [2]Clinical Psychology Branch and [3]Lab. Clin. Sci., NIMH, Bethesda MD 20205.

Bombesin (BN) represents one class of peptides which may function as a central nervous system (CNS) regulatory agent as it fulfills many criteria required for CNS transmitters. In particular, immunoreactive BN is present in discrete regions of rat brain, BN-like peptides are localized to synaptosomes and released from nerve terminals by depolarizing stimuli, high affinity binding sites for (Tyr^4)BN, a potent BN analogue, are present in rat brain and upon central injection, BN causes various biological responses such as hypothermia, hyperglycemia and analgesia with a similar structure activity relationship to that required for receptor binding.

Here endogenous rat brain peptides were extracted with acetic acid, fractionated by high pressure liquid chromatography and characterized by radioimmunoassay. Two major BN-like components were detected, fraction A which co-chromatographed with BN-sulfoxide and fraction B which coeluted with authentic BN. If the acetic acid used during the extraction process was deaerated extensively and purged with nitrogen before use, only fraction B was present. Therefore, endogenous BN-like peptides may be oxidized by air in the extraction solution. In an in vitro bioassay for BN, fraction A had no detectable biological activity, whereas fraction B was equipotent to BN. Also, synthetic BN-sulfoxide was characterized. The oxidized peptide was 60% as immunoreactive as BN; however, BN-sulfoxide was not a potent hypothermic agent upon central administration and was 30-fold less potent than BN in a brain radioreceptor assay. These data indicate that when BN-like peptides are oxidized, immunological activity is retained but receptor binding, as well as biological activity, is reduced dramatically. Therefore, oxidation of BN-like peptides may inactivate their function at the CNS synaptic level.

33.7

WITHDRAWN

33.8 A COMPLETE RENIN-ANGIOTENSIN SYSTEM IN NEUROBLASTOMA X GLIOMA HYBRID CELLS. M.C. Fishman, E. Zimmerman, and E. Slater*. Laboratory of Developmental Neurobiology, N.I.C.H.D., N.I.H., Bethesda, MD. 20205, Neurology Dept, College of Physicians and Surgeons, Columbia University, N.Y., N.Y. 10032, and Medical Services, Mass. General Hospital, Boston, Mass. 02114

All components of the renin-angiotensin system have been identified by enzymatic and immunocytochemical methods in a widespread distribution in brain (Hirose et al., Brain Res. 191:489, 1980) but it is not known whether they are neural in origin, nor whether the cascade is completed within the circulation or the cells. We have shown that mouse neuroblastoma X rat glioma (NG108-15) cells contain immunoreactive renin (34 pg/mg protein) and immunoreactive angiotensin II (AII) (62 fM/mg protein) as measured by radioimmunoassays, and converting enzyme and an angiotensinogen as measured by enzymatic assays. Immunocytochemistry by the peroxidase-antiperoxidase methods reveals renin and AII within essentially all of the cells, and both were distributed throughout the cell body and processes of each cell. Two methods to enhance differentiation--serum withdrawal (using a defined medium) and 1mM dibutyryl cAMP--cause an increase in renin concentration. The renin is in an inactive form, and becomes enzymatically active (generates AI) after exposure to trypsin. Trypsin activated plasma renin has been equated with a prorenin. We suggest that activation of intracellular renin may generate AII within nerve cells.

33.9 ENKEPHALIN-LIKE IMMUNOREACTIVITY (Enk-IR) IN RAT ADRENAL IS INCREASED BY NICOTINIC RECEPTOR BLOCKADE. Bohn, M.C., Kessler, J.A., Golightly, L.* and Black, I.B. Div. Develop. Neurology, Cornell Univ. Med. Coll., New York, N. Y. 10021

Recent studies have demonstrated that adrenal chromaffin cells contain both catecholamines and small peptides with opiate activity. While factors regulating catecholamine metabolism are well characterized, little is known about regulation of neuronal peptides. Employing an immunocytochemical approach, we have investigated various factors known to be important in the regulation of adrenal catecholamine metabolism for possible effects on Enk-IR.

In normal rats, only rare chromaffin cells were stained for Enk-IR. However, a dramatic increase in Enk-IR occurred following splanchnic nerve lesion as reported previously (Schultzberg et al., Neurosc.3, 1169, 1978). To determine whether this effect was mediated by nicotinic receptors, rats were treated with nicotinic-blocking agents. Both chlorisondamine and pempidine reproduced the effect of adrenal denervation, resulting in an increase in Enk-IR.

To ascertain the relationship of catecholamine (CA) metabolism to Enk-IR, we examined the effects of catecholaminergic agents. Enk-IR was increased 4 days after treatment with reserpine, a drug which depletes chromaffin vesicles of CA, and causes a reflex increase in presynaptic nerve activity. This effect was apparently not mediated solely by increased presynaptic nerve activity, since treatment with phenoxybenzamine or 6-hydroxydopamine, which also increase impulses to the adrenal, did not increase Enk-IR.

These studies suggest that levels of enkephalins and/or enkephalin-like peptides are normally depressed by presynaptic nerves acting via nicotinic receptor mechanisms. In addition, catecholamine depletion of chromaffin vesicles may influence enkephalin metabolism in the adrenal.

33.10 SECRETAGOGUES THAT ACT BY DIFFERENT MECHANISMS INDUCE SECRETION OF OPIOID PEPTIDES AND CATECHOLAMINES FROM CHROMAFFIN AND PHEOCHROMOCYTOMA CELLS. S.P. Wilson, R. Slepetis*, K.-J. Chang, N. Kirshner* and O.H. Viveros. Wellcome Research Laboratories, Research Triangle Park, NC 27709 and Department of Pharmacology, Duke University, Durham, NC 27710.

Opioid peptides (OP), including Met- and Leu-enkephalin, are stored with catecholamines (CA) in adrenomedullary chromaffin vesicles (Mol. Pharmacol. 16:1101, 1979). Consequently, OP and CA are co-secreted from the adrenal medulla (Adv. Biochem. Psychopharmacol. 22:191, 1980). We have used cultured bovine adrenal chromaffin cells to further explore the relationship between OP and CA secretion. Chromaffin cells, in culture for 4-10 days, secreted both OP and CA in response to stimulation with nicotine. The extent of both OP and CA secretion was concentration dependent with half-maximal and maximal secretion observed at 3 and 10 μM nicotine, respectively. Nicotine-evoked secretion of both OP and CA was dependent on the presence of Ca^{++} and was blocked by d-tubocurarine. Veratridine, K^{+} or Ba^{++} also stimulated the proportional secretion of OP and CA. Although the chromaffin cells preferentially secreted norepinephrine as compared to epinephrine, OP secretion was proportional to total CA secretion and not to that of either amine alone. OP secretion was also proportional to cellular OP content, i.e. reserpine-treated cells with twice the OP content of untreated cells secreted twice as much OP when stimulated with 20 μM nicotine. Hence, newly synthesized OP in chromaffin cells are stored in functional chromaffin vesicles.

Dissociated cells from a human pheochromocytoma tumor were also cultured (7-9 days) and the secretion of OP, endogenous CA and previously taken up [^{3}H]norepinephrine from these cells was examined. Nicotine, veratridine or Ba^{++} stimulated the secretion of OP, total CA and ^{3}H from the pheochromocytoma cells. Secretion of ^{3}H closely paralleled the secretion of OP, but secretion of endogenous CA was lower. Secretion of OP was more sensitive to stimulation by the calcium ionophore ionomycin than was secretion of CA. In the presence of 10 μM nicotine, the extracellular concentration of Ca^{++} required for maximum secretion was 0.2 mM for OP and 1.5 mM for CA and ^{3}H. As compared to the bovine chromaffin cells, veratridine was more potent, ionomycin less potent and nicotine equipotent in evoking CA secretion from the human pheochromocytoma cells. The results show that human pheochromocytomas secrete OP as well as CA and that there may be heterogeneous storage pools of CA and OP in cultured pheochromocytoma cells.

34.1 IS GABA-ERGIC MECHANISM RESPONSIBLE FOR ANTICONVULSANT PROPERTIES OF SODIUM VALPROATE? Michael S. Myslobodsky & Meir Morag* Psychobiology Research Unit, Department of Psychology, Tel-Aviv University.

A single dose of GABA-transaminase inhibitor, γ-vinyl GABA (GVG), administered to Wistar rats causes sedation and EEG synchronization reaching proportions of wave-spike activity (Myslobodsky et al., Pharmacol. Biochem. Behav. 11:483, 1979). Given that photically-induced sensory after-discharges (SAD) and the slow secondary negativity (SN) of the VEP faithfully reflect the degree of pro- and anti-convulsive action of various drugs, they were anticipated to undergo a facilitation after GVG treatment. Time-related two to three-fold enhancement of the SN and SAD area were obtained after 500 mg/kg (i.p.) of GVG. The changes seemed to parallel brain GABA increase. This effect was detectable at 1 hr, reached plateau at 3-4 hr and remained at this level 7 hr after GVG. Even about 24 hr after GVG, VEP components remained clearly hypersynchronized.

Sodium Valproate (VPA, di-n-propylacetic acid) which is also believed to block GABA-transaminase and succinic semialdehyde dehydrogenase causing GABA increase mostly in the nerve terminal compartment (Gale, K. & Iadarola, J.M. Science, 208:288, 1980) reduced SN amplitude by 70% when administered in a dose of 200 mg/kg (i.p.). It also totally eliminated SAD, when they were present, within 15-30 min. The recovery of VEP amplitude began at 3 hr. Given this finding it was anticipated that VPA would antagonise GVG-induced wave-spike discharges and paroxismally-enhanced SN and SAD. Indeed, VPA (200 mg/kg) administered 3 hr after GVG caused SN and SAD suppression within 15-30 min in all animals, this effect lasting about 2 hr. A typical GVG-hypersynchronized pattern of VEP recovered within the next 2-3 hr.

SN and SAD are believed to be organised by recurrent inhibition mediated by a pathway through axon collaterals and interneurons feeding back synaptic inhibition to the output and/or adjacent cells. VPA effects may be attributed to a disinhibitory action of a system located presynaptically on recurrent collaterals of the output neurons, or nerve terminals of inhibitory interneurons or both. Convulsant benzodiazepine, Ro 5-3663 (2 mg/kg, i.p.) which attenuates presynaptic inhibition (Schlosser, W. & Franco, S. J. Pharmacol. Exp. Ther., 211:290, 1980) potentiated SN-SAD within 1-3 min (the effect lasting 10-20 min) and partially antagonized VPA-induced SN-SAD suppression. These findings are interpreted as suggesting that VPA acts via a mechanism using a transmitter intimately connected to but not identical with GABA.

These findings also indicate that "GABA weakness" concept in epilepsy cannot be generalized to petit mal seizures.

34.2 FACILITATION OF THE NEUROCHEMICAL RESPONSE TO ANTIDEPRESSANTS BY ACTH AND YOHIMBINE. R. Duman*, J. Slopis*, D. Kendall* and S.J. Enna (SPON: B.T.Ho).

Numerous studies have suggested that the clinical response to antidepressants may be related to the drug-induced decrease in β-adrenergic and serotonin$_2$ (5-HT$_2$) receptor binding and function in cerebral cortex. This theory is partially based on the finding that the time (1-3 wks) necessary for observing a maximal reduction in receptor binding is quite similar to the delay observed in the clinical response. Recently it has been shown that the lag time for the receptor response can be significantly reduced if the antidepressant is co-administered with yohimbine, an α_2-adrenergic receptor blocker. In the present investigation, this drug interaction was examined further. For the study, male Sprague-Dawley rats (100-500 g) were treated chronically with yohimbine (2 mg/kg, b.i.d., s.c.) in combination with one of a number of antidepressant drugs (10 mg/kg, once daily, i.p.) and β-adrenergic and 5-HT$_2$ receptors in frontal cerebral cortex were quantified using receptor binding assays. As reported by others, this combination caused a more rapid decline in β-adrenergic receptors (3 days), though this was observed only with imipramine and DMI. However, yohimbine in combination with amitriptyline, iprindole and mianserin caused a more rapid (3 days) reduction in 5-HT$_2$ receptor binding, though no significant decrease in β-adrenergic binding was noted with these agents at this time. Since α-receptor antagonists are known to increase ACTH release and because this hormone has been shown to affect receptor site concentrations, the influence of ACTH on the drug-induced receptor changes was examined. Indeed ACTH (8 units/animal, once daily, s.c.) in combination with iprindole and mianserin reduced the number of 5-HT$_2$ receptors in 3 days. Like with yohimbine, only imipramine and DMI were able to reduce the number of β-receptors in this time period when administered with ACTH. These findings suggest that the more rapid onset in the antidepressant induced decrease in β-adrenergic and 5-HT$_2$ receptor binding observed with yohimbine may be mediated, at least in part, by an increase in the circulating levels of ACTH. If the receptor changes brought on by antidepressants are necessary for their clinical efficacy, then these results imply that the speed of onset in response may be a function of the hormonal state of the patient. (Supported in part by USPHS grants NS-13803 and NS-00335).

34.3 CHLORPROMAZINE BINDS TO AND INHIBITS CALMODULIN IN RAT BRAIN. T.L. WALLACE,* C.Q. EARL,* J.F. HABAS* AND B. WEISS, DEPT. OF PHARMACOLOGY, MEDICAL COLLEGE OF PA., PHILADELPHIA, PA 19129

Chlorpromazine (CPZ) and other phenothiazine antipsychotics inhibit the activity of calmodulin (CM) by binding to it in a Ca^{2+}-dependent, reversible manner. This binding can be made irreversible by irradiating CPZ and CM with ultraviolet (UV) light. When CPZ is irreversibly bound to CM, the activity of CM is irreversibly inhibited. These properties allowed us to investigate whether CPZ binds to and inhibits CM in crude preparations of brain where other naturally occurring brain constituents might offer competing binding sites for the antipsychotic. Rat caudate nuclei were sliced into 20 μ sections with a McIlwain tissue chopper. CPZ was added and irradiated with UV light (366 nm at 4°C). Tissues were then homogenized, boiled and dialyzed to remove unbound CPZ. CM activity in each sample was then determined from its ability to activate a CM-dependent form of phosphodiesterase. UV irradiation of tissues in the presence of CPZ resulted in an irreversible inhibition of CM activity. The concentration of CPZ required to produce 50% inhibition of CM was 10 μM. Complete inhibition was seen by 15 minutes. In the absence of CPZ, there was little or no effect on CM activity in samples irradiated for 15 minutes, although at longer times of irradiation there was significant inhibition of CM. Similar results were found using crude homogenates of brain or the 100,000 x g supernatant fraction. To demonstrate directly that the phenothiazine was bound to CM and to identify other possible binding sites, the 100,000 x g supernatant fraction of rat caudate nuclei and cerebral cortices were incubated with 20 μM CPZ (1 Ci/mmole) and irradiated with UV light for 30 minutes. The samples were dialyzed to remove CPZ and placed on SP-Sephadex columns (0.9 x 7 cm). Two-ml fractions were eluted sequentially using a discontinuous pH gradient, and each fraction was assayed for radioactivity and CM activity. Several peaks of irreversibly-bound ^{3}H-CPZ were found. In some of these peaks, the binding of CPZ was Ca^{2+}-dependent, whereas in others it was Ca^{2+}-independent. The Ca^{2+}-dependent peaks were associated with CM activity but peaks that showed Ca^{2+}-independent binding of CPZ were devoid of CM activity. These findings showed that photoactivated CPZ binds irreversibly to CM in the presence of other competing brain constituents, suggesting that this activator protein may be an endogenous phenothiazine binding site. These studies also showed that CPZ binds in a Ca^{2+}-independent manner to other materials in brain that do not possess CM activity.

34.4 LACK OF CORRELATION BETWEEN OPIATE-INDUCED BEHAVIORAL HYPERSENSITIVITY AND DOPAMINE RECEPTOR DENSITY. K.R. Carlson and T.F. Seeger*. Department of Pharmacology, University of Massachusetts Medical School, Worcester, MA 01605.

We examined the hypothesis that opiates, when administered chronically, increase dopamine receptor density in striatum and mesolimbic areas, thereby accounting for enhanced stereotypy and locomotion in response to dopamine agonists following chronic treatment. Each rat's striatum and mesolimbic area (n. accumbens and olfactory tubercle) was assayed separately with the object of correlating receptor density with the extent of behavioral change. Stereotypy (chewing) and locomotion (number of crossings of quadrants) in response to 0.5 mg/kg apomorphine were measured before and 2 weeks after a 3-week treatment with saline or methadone (10 increasing to 20 mg/kg/day s.c.). Each drug group was subdivided into those Ss which increased in the behavioral measures and those which decreased or showed no change, relative to pre-chronic drug behavior. Rats were sacrificed 24 hr. after the second apomorphine test, and specific binding of ^{3}H-spiroperidol to homogenates of each brain area was measured. Half the methadone group showed increases in chewing, as did a few saline Ss; the difference among the subgroups in duration of chewing was significant ($F=10.49$, $df=3,19$, $p < .001$). However, there was no difference among the subgroups in striatal receptor density ($F < 1.0$). Similarly, half the methadone Ss increased in number of crossings and none of the saline Ss did ($F=7.90$, $df=2,19$, $p < .005$), but there was no difference in mesolimbic receptor density ($F < 1.0$). The negative binding results were not attributable to inadequate specificity or sensitivity of the assay, since a 3-week treatment with 1.0 mg/kg haloperidol produced a significant 26% elevation in striatal receptor density, a value completely in line with other reports. We conclude that changes in dopamine receptor density do not account for opiate-induced behavioral hypersensitivity.

34.5 DEPRESSANT EFFECT OF TIMOLOL, A BETA-ADRENERGIC BLOCKER, ON NEUROMUSCULAR TRANSMISSION IN NORMAL AND MYASTHENIC MUSCLES. James F. Howard, Jr. and Bruce R. Johnson*. Department of Neurology, University of North Carolina, Chapel Hill, NC 27514

Timolol maleate, (Timoptic), used topically for the treatment of glaucoma, has been reported to acutely worsen the strength of a patient with myasthenia gravis (MG). The depressant action of this beta-adrenergic blocker on neuromuscular transmission was investigated in vitro in forelimb flexor digitorum longus muscles from normal rats and in intercostal muscle from normal patients and those with MG.

In rat muscles, Timolol in concentrations found in human plasma after ocular instillation and oral ingestion (5uM to 100uM) reversibly reduced the amplitude of miniature end-plate potentials (MEPP) and end-plate potentials (EPP) in a dose dependent manner. Rise times and half-decay times of these potentials were shortened following bath application of the higher concentrations. Similar results were found in normal human muscle.

In intercostal muscle from patients with MG, Timolol in concentrations of 10uM to 100uM also reversibly depressed MEPP and EPP amplitudes in a dose dependent manner.

These results demonstrate that Timolol maleate has a direct depressant effect on neuromuscular transmission at concentrations which are normally found in human plasma. This effect may account for the clinical worsening of strength which has been reported by a myasthenic patient after receiving this drug.

34.6 RDS-127: A POTENT NONHYDROXYLATED DOPAMINE AGONIST. S.P. Arneric*, D.B. Goodale, J.P. Long*, G.F. Gebhart, J.M. Lakoski, J. Mott*, C.F. Barfknecht*, (Spon: W. Steele). Dept. of Pharmacology, College of Medicine, and Div. Chem., Col. Pharm., University of Iowa, Iowa City, IA 52242

Responses indicative of dopamine (DA) receptor activation were studied in male Sprague Dawley rats following the administration of RDS-127 (2-N,N-di-n-propylamino-4,7-dimethoxyindane). To differentiate the site(s) of action where RDS-127 interact(s) with DA receptors, the potencies of RDS-127 were calculated in four models which are relatively selective for assessing pre- or postsynaptic receptor activity. Using the presynaptic model of Walters and Roth (1976, N-S Arch. Pharmacol., 296, 5), RDS-127 (0.05-12.8 μmol/kg, s.c.) dose-dependently inhibited the accumulation of DOPA concentrations in the caudate nucleus (ED_{50} = 0.15 μmol/kg) and the olfactory tubercle (ED_{50} = 0.93 μmol/kg). Pretreatment with haloperidol blocked the inhibition by RDS-127. In an electrophysiological model, single unit extracellular action potentials were recorded from neurons in the substantia nigra (SN). Recording from the SN permits the sampling of presynaptic elements in the pars compacta nigrostriatal units as well as postsynaptic elements of the pars reticulata units which are part of the striatonigral feedback system. RDS-127 decreased the firing of neurons in the pars compacta of SN (ED_{100} = 40 ± 10 nmol/kg, i.v., N=6); haloperidol reversed this suppression of unit activity by RDS-127. In contrast, the firing of units in pars reticulata of SN were either not altered, or increased in response to RDS-127 (40-400 nmol/kg, i.v.). The work of Strombom (1976, N-S Arch. Pharmacol., 292, 167) suggested that low doses of DA agonists activate presynaptic DA receptors to decrease locomotor activity (LA) and high doses activate postsynaptic receptor to increase LA. Low doses (0.05-0.2 μmol/kg) of RDS-127 produced a decrease and high doses (0.8-12.8 μmol/kg) produced a long-lasting (> 5h) increase in LA. Pretreatment with pimozide, but not metergoline, blocked the hyperactivity produced by high doses of RDS-127; α-methyl-p-tyrosine did not attenuate this response. In another postsynaptic model (Ungerstedt, 1971, Acta physiol. scand. 82, Suppl. 367: 69) RDS-127 produced contralateral rotational behavior in unilateral 6-hydroxydopamine produced lesions of SN (potency ratio to apomorphine = 0.13). Thus, the consistent findings between these different models indicate that RDS-127 is a direct acting dopamine agonist which in low doses preferentially activates presynaptic DA receptors. The absence of hydroxyl substituents on RDS-127 may account for its long duration of action. (supported by GM-22365 and NS-12114).

34.7 ERYTHROSIN B AND NA,K-ATPase: RECEPTOR-LIKE INTERACTIONS WITH BRAIN SYNAPTIC MEMBRANES. E.K. Silbergeld, S.J. Morris, and S.M. Anderson. Neurotoxicology, NINCDS, NIH, Bethesda MD 20205.

FD&C Red 3, tetraiodofluorescein, or erythrosin B (EB), interacts specifically and potently with Na,K-ATPase, inhibiting specific glycoside binding, ATP catalysis, and ^{86}Rb uptake (Silbergeld (1981) Neuropharm. 20: 87). In addition, EB acts on ATPase in brain, and not in red cell, myenteric plexus, or kidney cortex. Several reports suggest the existence of two enzymes in brain tissue, one of which is unique to the brain. Our results, using kinetic analyses of [^{3}H]-ouabain (OUA) binding and association-dissociation parameters, reveal two sites with Kd's of 1-2 and 80-140 nM. EB, in concentrations as high as 100 μM, only inhibits OUA binding to its high affinity site. [^{14}C]-EB binds saturably to crude synaptic membranes with an apparent Kd of 40-100 nM. It reaches equilibrium at 37° within 30 min. Like OUA, its binding is predominantly localized in the membrane fraction of purified synaptosomes: there are 217 fmol/mg protein EB binding sites; 714 fmol/mg protein OUA binding sites; and 10 μmol Pi liberated/20 min/mg protein of Na,K-ATPase activity. EB binding was compared to OUA binding: specific binding of both ligands is ATP-dependent. Both are displaced by unlabelled EB, rose bengal, diiodofluorescein, and eosin Y, while fluorescein and other derivatives do not displace either ligand. Neurotransmitters, such as GABA, dopamine, 5-HT, norepinephrine, and glycine, and neuroactive drugs, such as atropine, LSD, QNB, butaclamol, apomorphine, valium, and naloxone, also fail to displace either EB or OUA. However, although EB potently displaces OUA binding, none of the glycosides (ouabain, digitoxin, or strophanthidin) displaces EB. In further distinction, EB binding is not temperature sensitive, destroyed by boiling or by freezing and thawing of tissue. EB binding is enhanced by Rb and Cs, as compared to OUA binding, which is enhanced by Na and Li. Compounds which affect aspects of ATPase function -- ethanol, dithiothreitol, n-ethyl maleimide, oligomycin, tetrodotoxin, chlorpromazine, lead, ethacrynic acid -- do not displace EB. Vanadate, a known inhibitor of ATPase, weakly displaces EB binding (28 percent inhibition at 100 μM). These interactions of EB with brain tissue suggest the existence of a specific "receptor-like" recognition site which is associated with, but distinct from, such defined components of the enzyme as glycoside binding and ATP catalysis. The nature and function of this site is not presently known. Preliminary experiments with solubilized brain tissue ATPase provide evidence for separation of EB and OUA receptor sites, as well as further confirmation that EB binding is associated with ATPase activity.

34.8 BENZODIAZEPINE INHIBITION AND SELECTIVE BENZODIAZEPINE ANTAGONIST EXCITATION OF CA1 CELLS MEASURED INTRACELLULARLY IN THE HIPPOCAMPAL SLICE. P.L. Carlen, N. Gurevich, and P. Polc. Depts. of Medicine & Physiology, University of Toronto, Addiction Research Foundation and Playfair Neuroscience Unit, Toronto Western Hospital, Ontario, Canada; Pharma Research Dept., F. Hoffmann-La Roche & Co. Ltd., Basle, Switzerland.

Midazolam, a water soluble benzodiazepine, was applied by pressure ejection onto the somatic area of CA1 cells recorded intracellularly in constantly perfused guinea pig hippocampal slices. Threshold effects were noted at 10^{-10}M. Recordings were obtained from 21 cells with similar results for 10^{-9}M (10 cells) and 5 x 10^{-9}M (11 cells) midazolam doses. Within 1 to 2 minutes following drop application, hyperpolarization of 1 to 5 mV and decreased input resistance (10 to 50 %) occurred in 75% and 67% of cells respectively. Spontaneous activity, when present, decreased in 11/12 cells. IPSPs were increased in 14/18 cells. EPSPs were unchanged in 8 cells and slightly increased (15 to 30 %) in 4 cells. The afterhyperpolarization (AHP) following a train of 3 to 4 spikes elicited by a 100 msec constant current depolarizing pulse was augmented in 9/13 cells. The above effects lasted 10 to 20 minutes after drop application and were unaffected by the prior intracellular injection of chloride ions (3 cells). These preliminary results suggest that midazolam augments calcium mediated potassium conductance in CA1 cells.

RO14-7437 is a selective benzodiazepine antagonist which demonstrates potent inhibition of the specific high affinity binding of ^{3}H-diazepam to brain synaptosomal fractions. This compound, when applied by ejection onto the CA1 somatic layer using 10^{-9} and 10^{-8}M concentrations caused a depolarization (7/8 cells), increased input resistance (3/6 cells), increased spontaneous activity (2/3 cells), decreased IPSPs (4/7 cells) and decreased AHP (3/3 cells). EPSPs were unaffected. The above occurred in cells during midazolam-induced inhibition (4 cells). These excitatory affects also occurred in 4 cells not previously exposed to midazolam suggesting the possible existence of endogenous benzodiazepine ligands in the guinea pig hippocampus.

34.9 ^{3}H-CL 218,872 BINDING TO RAT BRAIN. A. Lippa*, B.J. Bradford*, D. Benson* and B. Beer. CVR-CNS Research, Med. Res. Div., American Cyanamid Co., Lederle Labs., Pearl River, NY 10965.

The development of novel triazolopyridazines (TPZ) which competitively inhibit ^{3}H-benzodiazepine (^{3}H-BDZ) binding has led us to investigate the binding of ^{3}H-CL 218,872, a representative TPZ. The binding of ^{3}H-CL 218,872 (specific activity 15 Ci/mole) was determined by a centrifugation method in both cerebral cortex and cerebellum. Clonazepan (1-10 µm) was used to determine non-specific binding which represented 60-85% of the total. In equilibrium binding studies, specific ^{3}H-CL 218,872 binding was saturable and temperature dependent. One component ($Kd_1 \approx 10$ nM) was observed in cerebellum while two components ($Kd_1 \approx 10$ nM and $Kd_2 \approx 200$ nM) were observed in cerebral cortex. BDZ inhibited ^{3}H CL 218,872 binding with potencies which paralleled their potencies in inhibiting ^{3}H-flunitrazepan binding. BDZ inhibitions conformed with the law of mass action. These findings suggest that ^{3}H-CL 218,872 specifically binds to and discriminates between BDZ receptor subtypes. This compound may be a useful probe for studying BDZ receptor heterogenicity.

34.10 BENZODIAZEPINES ANTAGONIZE THE EXCITATORY ACTION OF KAINIC ACID ON CA_1 HIPPOCAMPAL NEURONS: A MICROIONTOPHORETIC STUDY IN THE RAT. G. de Bonnel* and C. de Montigny, Institut P. Pinel and Département de psychiatrie, Univ. de Montréal, Montréal, Québec, H3C 3J7.

Diazepam (DZP) pretreatment reduces the neurotoxicity of kainic acid (KA); in the hippocampus, the CA_1 region is more effectively protected by DZP than the CA_3 region (Fuller and Olney, Neurosci. Abst., 5: 1880, 1979). The presents experiments were undertaken to determine if benzodiazepines antagonize the KA-induced excitation of pyramidal neurons in CA_1 and CA_3.

All experiments were conducted in urethane-anesthetized male Sprague-Dawley rats (250-350 g). Five barelled micropipettes were used for unitary recording and iontophoresis of the following solutions: KA (1 mM in NaCl 0,4 M; pH: 8), glutamate (GLU) (50 mM in NaCl 50 mM; pH: 8), acetylcholine (ACH) (20 mM in NaCl 0,2 M; pH: 4), chlordiazepoxide (CDP) (10 mM in NaCl 0,2 M; pH: 3), flurazepam (FLU) (10 mM; pH: 3). In a first series of experiments DZP or lorazepam (LOR) were injected intravenously during the activation of CA_1 or CA_3 pyramidal neurons by iontophoretic application of KA, ACH or GLU. In a second series, CDP or FLU were applied iontophoretically on CA_1 or CA_3 units activated with KA, ACH or GLU.

The intravenous administration of low doses of DZP or LOR (0.5-1 mg/kg) drastically reduced or abolished the KA-induced activation of CA_1 neurons but did not modify or only slightly reduced the excitatory effect of ACH and GLU. In contrast, the same doses of DZP or LOR had little or no effect on KA induced activation of CA_3 pyramidal cells.

Congruent results were obtained with iontophoretic application of CDP and FLU. Both drugs applied on CA_1 pyramidal neurons excited by KA produced a marked reduction of their firing rate, whereas applications of these drugs with the same currents had little or no effect on the same cells when activated by ACH or GLU. In CA_3, CDP and FLU were much less potent in reducing the excitatory effect of KA.

In view of the protective effect of DZP against the neurotoxicity of KA in CA_1, the antagonism of the neuroexcitatory action of this amino acid on the same neurons by DZP provides further evidence for the excitotoxic hypothesis. Accordingly, DZP has a lesser effect on KA-induced excitation in CA_3 where it does not afford protection against KA neurotoxicity. The differential effect of benzodiazepines on the action of KA in CA_1 and CA_3 suggests that this amino acid activates different types of receptors in these two regions. The blockade of the benzodiazepine-sensitive type of "KA-activated" receptors might contribute to the anxiolytic and/or anticonvulsant effects of these drugs. (Supported by MRC grant MA-6444 and a C.R.S.Q. fellowship to C. de M.).

34.11 PHENOBARBITONE BINDING SIES IN RAT BRAIN MEMBRANES, M. Willow,* G.A.R. Johnston and I.G. Morgan. Department of Pharmacology, University of Sydney, NSW 2006 and Department of Behavioural Biology, Australian National University, Canberra, ACT, 2601, Australia.

Radioligand binding studies have established that pentobarbitone and related barbiturates enhance GABA binding to synaptosomal membranes by increasing the affinity of GABA for its high-affinity recognition sites (Willow, M. and Johnston, G.A.R., Neurosci. Lett., 18:323, 1980). The present study has examined the characteristics of phenobarbitone binding to crude synaptosomal membranes isolated from rat brain in an attempt to elucidate molecular mechanisms underlying the interaction between barbiturates and GABA receptor/ionophore complexes.

Crude synaptosomal membranes were prepared according to methods previously described (Willow, M. and Johnston, G.A.R., Neurosci. Lett., 18:323, 1980). Phenobarbitone binding was determined by incubating the resuspended membrane material (1.0 mg protein/2 ml Tris-citrate buffer, 50 mM, pH 7.1) for 15 min at 4°C with 0.5 µM tritiated phenobarbitone (8.1 Ci/mmol) in the presence of varying concentrations of phenobarbitone. This was followed by centrifugation for 15 min at 48,000 x g av, removal of the supernatant and determination of the pelleted radioactivity.

Under the conditions employed, total and non-specific (in presence of 10 mM phenobarbitone) binding averaged 14,000 and 9000 c.p.m./mg respectively. Scatchard analysis suggests that there is a single class of binding sites of relatively low affinity (Kd 99.7 ± 8.1 µM, n=3) and high density (Bmax 810 ± 65 pmole/mg, n=3). Phenobarbitone binding is displaced by a number of substituted barbiturates with the following order of potency: methohexitone>thiopentone>butobarbitone>secobarbitone>amylobarbitone>pentobarbitone>phenobarbitone>barbitone>barbituric acid. For those barbiturates which possess anaesthetic/anticonvulsant properties, there is an excellent correlation ($P<0.001$) between the ability to displace phenobarbitone and the ability to enhance GABA binding. GABA, bicuculline methochloride, picrotoxinin, and diazepam were all without effect on phenobarbitone binding at 100 µM, suggesting that barbiturate binding sites are distinct from GABA recognition sites and ionophores.

34.12 CHRONIC TRICYCLIC ANTIDEPRESSANTS ALTER α_1- AND α_2-ADRENOCEPTOR RESPONSIVITY AS MEASURED BY THE EFFECTS OF SELECTIVE AGONISTS ON THE ACOUSTIC STARTLE REFLEX. M. Davis, D.B. Menkes, J.H. Kehne*, D.W. Gallager, and G.K. Aghajanian, Depts. Psychiat. and Pharmacol Yale Univ. Sch. Med., New Haven, CT 06508.

Biochemical, electrophysiological, and behavioral experiments suggest that chronic tricyclic antidepressant (TCA) treatment may depress central responsiveness to α_2-adrenergic agonists but enhance responsiveness to α_1-adrenergic agonists. However, this conclusion can only be inferred by comparison across studies that employ different drugs, doses, and methods of evaluation. This experiment evaluated how chronic TCAs would alter adrenergic sensitivity using a design where the effects of both types of agonists were measured on the same behavior in the same animal. The acoustic startle response was chosen since this reflex is depressed by systemic administration of the α_2-agonist clonidine and enhanced by intrathecal administration of the α_1-agonist phenylephrine. The action of both agonists can be blocked selectively by their respective antagonists (e.g., yohimbine or WB-4101).

Male albino rats were injected i.p. once a day with either saline, 10 mg/kg desipramine, 10 mg/kg amitriptyline, or 5 mg/kg iprindole. Two weeks later (24 hrs after the last saline or TCA injection) rats were given saline or 20 or 40 µg/kg clonidine and tested for acoustic startle over the next 40 min. Clonidine markedly depressed startle in rats pretreated with saline but had much less of an effect in rats pretreated with desipramine. However, this was peculiar to desipramine, since clonidine still markedly depressed startle in rats pretreated with amitriptyline or iprindole.

Following these treatments all rats were injected for another week with their respective TCA drugs. They were then implanted with intrathecal catheters and one day later infused with either 12.5 or 25 µg of phenylephrine directly onto the spinal cord. Phenylephrine increased startle in each of the groups over the 40-min test session. However, the magnitude of these effects were greater in rats pretreated with each of TCAs than those treated with saline. No correlation was found between the enhanced behavioral response to phenylephrine and receptor binding of the α_1-antagonist ^{3}H-prazosin in the spinal cord. In contrast, following denervation via intrathecal 6-OHDA a supersensitive behavioral response to phenylephrine did correlate with increases in ^{3}H-prazosin binding in the cord.

Taken together, the data suggest that different TCAs share in their ability to enhance responsiveness to the α_1-agonist phenylephrine but not in their ability to blunt the effect of the α_2-agonist clonidine.

34.13 SPECIFIC H^3-PENTYLENETETRAZOL BINDING IN THE RAT BRAIN. H. Lal, W. C. Davis* and M. K. Ticku. Department of Pharmacology, The Texas College of Osteopathic Medicine, Fort Worth, Texas 76107 and Department of Pharmacology, University of Texas Health Science Center, San Antonio, Texas 78284.

Although pentylenetetrazol (PTZ) produces pronounced neuropharmacological effects that include an induction of anxiety (for review see Lal and Shearman, Ann. Rep. Med. Chem. 15:51), convulsions, amnesia, and stimulation of brain cyclic AMP, attempts to demonstrate specific effects on brain neurotransmitters have met with only limited success. We, therefore, examined the possible ligand properties of PTZ in the rat brain fractions. PTZ was labeled by tritium gas exchange method and purified for the present study. When incubated with the brain membrane fraction, specific H^3-PTZ binding was only 10% of the total binding. However, solubilization of the mitocondrial plus microsomal ($P_2 + P_3$) fractions with Lubrol (1%) increased the specific binding of H^3-PTZ with signal to noise ratio of over 50%. Further fractionation of Lubrol extract through gel-filtration revealed that H^3-PTZ was bound specifically and in saturable fashion to a protein with approximate M. W. of 185,000 daltons. H^3-PTZ binding to Lubrol soluble protein was displaced by PTZ (IC_{50},10 μM), heptamethylenetetrazol (IC_{50},1 μM), 7-methyl-9-isopropyl-pentamethylenetetrazol (IC_{50},6 μM), 1-methyl-5-cyclohexyltetrazol (IC_{50},10 μM), 1,3-dihydro-5-methyl-2H-1,4-benzodiazepin-2 one or RO5-3663 (IC_{50},2 μM), ethosuximide (IC_{50},20 μM) and trimethadione (IC_{50},100 μM). Diazepam, flurazepam, GABA or (+) bicuculline failed to inhibit H^3-PTZ binding to the Lubrol soluble fraction at 10 μM concentration. There was no H^3-PTZ binding to 61,000 dalton fraction to which benzodiazepines specifically bind with high affinity.

34.14 MULTIPLE CENTRAL BENZODIAZEPINE RECEPTORS AND THEIR REGULATION BY GABA AND PYRAZOLOPYRIDINES. F.J. Ehlert*, P. Ragan*, W.R. Roeske* and H.I. Yamamura (SPON: N.W. Pedigo). Dept. of Pharm., Univ. of Ariz., Health Sci. Center, Tucson, AZ 85724.

Recent studies of the interaction of some triazolopyridazine and alkyl β-carboline-3-carboxylate derivatives with benzodiazepine (BDZ) receptors have provided evidence for multiple central BDZ receptors. In the present study, we have used propyl β-carboline-3-carboxylate (PCC) as a probe for investigating the heterogeneity of the BDZ receptor and its regulation by GABA and pyrazolopyridines.

The results of PCC/[^{3}H]PCC competition experiments on homogenates of the cerebral cortex of the rat brain revealed a small population of superhigh affinity BDZ receptors having a dissociation constant of 30 pM and a relative abundance of 3%. When measured by competitive inhibition of [^{3}H]flunitrazepam ([^{3}H]FLU) binding, the binding of PCC was generally consistent with that determined by direct measurements of [^{3}H]PCC binding and suggested the existence of two major populations of high and low affinity binding sites having dissociation constants of 0.54 and 10 nM and relative abundances of 52 and 45%, respectively. The effects of GABA on the binding of FLU at 37°C to the multiple BDZ receptors was determined by FLU/[^{3}H]FLU and FLU/[^{3}H]PCC competition experiments and by direct measurements of [^{3}H]FLU binding. In all experiments, a large GABA enhancement of FLU binding was demonstrable that was readily potentiated by chloride (100 mM NaCl). In contrast, no siginificant effect of GABA on the binding of PCC was detected by PCC/[^{3}H]FLU competition experiments or by direct measurements of [^{3}H]PCC binding when assays were carried out at 37°C in the presence of 100 mM NaCl. Studies of the effects of the pyrazolopyridine, tracazolate (ICI 136,753), on BDZ receptor binding at 0°C revealed that this compound enhanced the binding of [^{3}H]FLU in a chloride dependant manner whereas no such interaction was demonstrable for [^{3}H]PCC binding. The maximum enhancement of [^{3}H]FLU binding by tracazolate was approximately 50% with the ED_{50} for this effect being 0.3 μM. In summary, our results demonstrate that the binding of FLU to BDZ receptors is regulated by GABA and tracazolate in a chloride dependant fashion whereas the binding of PCC is not markedly altered under the same conditions (37°C, 100 mM NaCl). The differential effects of GABA and tracazolate on the binding of FLU and PCC may represent an important biochemical correlate for pharmacologically antagonistic effects of BDZ's and PCC.

35.1 DISTINCT POPULATIONS OF EXCITATORY AMINO ACID RECEPTORS REVEALED BY THE SELECTIVE DEPRESSANT EFFECT OF BARBITURATES.
V.I. Teichberg, N. Tal*, O. Goldberg*≠ and A. Luini*. Depts. of Neurobiology and Organic Chemistry≠, Weizmann Inst. of Science, Rehovot, Israel.

The use of selective antagonists of excitatory amino acids have allowed us to observe the existence in the rat striatum of at least four pharmacologically distinct populations of excitatory amino acid receptors, namely those for N-methyl-D-aspartate, (NMDA receptor), for quisqualate (Quis receptor), for L-glutamate and L-aspartate (Glu-Asp receptor) and for kainate (KA receptor). This finding has prompted us to investigate whether some of these receptors might be the site of action of some anticonvulsant, anaesthetic or antiepileptic drugs. Tested in a Na^+ efflux assay that we have recently developed (Luini, A., Goldberg, O., and Teichberg, V.I., PNAS, 78, May (1981)), at various concentrations in the 0.1 to 1mM range, barbiturates were observed to inhibit the increase in the specific $^{22}Na^+$ efflux rate produced in $^{22}Na^+$-preloaded striatal slices by Quis and KA but did not affect the responses to NMDA, Glu or Asp. At saturating conditions, the barbiturates behaved as partial blockers of the Quis and KA receptors and the following maximal extents of inhibition were observed: Thiopentone: 80%; Secobarbital: 75%; Pentobarbital: 55%; Amobarbital: 45%; Phenobarbital: 40%; Barbital: 10%. Chloroform at 10mM was also found to inhibit the Quis and KA receptors but it did not affect the responses to NMDA, Asp or Glu. The fact that the NMDA and Glu-Asp receptors are totally unaffected by barbiturates and chloroform suggest the existence of differences between the nature or the membrane environment of the ionophores coupled to the receptors of NMDA and of Glu-Asp, and those of the KA and Quis receptors. One may speculate that the barbiturates and chloroform act via the lipid bilayer to prevent an effective coupling between the receptor and the ionophore. The excitatory amino acid receptors were found to be unaffected by the two antiepileptic drugs, ethosuximide (used at 1mM) and diphenylhydantoin (used at 100μM) or the centrally acting muscle relaxant, mephenesin (used at 1mM) but the latter two drugs as well as the barbiturates were found to inhibit the increase in $^{22}Na^+$ efflux rate from striatum slices produced by 100μM veratridine. The data suggest that the action potential Na^+ channel is one of the targets of these drugs.

Supported by grants from the U.S.-Israel BSF. A.L. is an EMBO postdoctoral fellow.

35.2 EFFECTS OF ACIDIC EXCITATORY AMINO ACIDS ON ^{45}CALCIUM ACCUMULATION BY RAT STRIATAL SYNAPTOSOMES.
Konrad C. Retz, Alice C. Young and Joseph T. Coyle, Dept. of Neuroscience, Johns Hopkins Univer sity School of Medicine, Balto, MD 21205

The mechanisms whereby glutamic acid (GLU) and its conformationally restricted analogue, kainic acid (KA), produce neurotoxicity remain unknown. Recent studies have implicated influx of Ca^{++} ion as the mediator of agonist-induced myopathy of the cholinergic neuromuscular junction (J. Cell Biol. 82:811, 1979). Accordingly, we have examined the effects of GLU and KA on the uptake/accumulation of $^{45}Ca^{++}$ into synaptosomes prepared from the rat striatum. Unpurified synaptosomes in P_2 membrane fractions were prepared as previously described (J. Neurosci. Res. 4: 383, 1979) and resuspended in a Krebs-HEPES buffer (J. Biol. Chem. 252:2764, 1977) and preincubated for 5 min at 37°C under O_2. Drugs and the $^{45}CaCl_2$ (0.5-0.8 mCi/mmole) were added simultaneously; the reaction was terminated by adding 2.5-5.0 vol of ice-cold Ca-free buffer followed by rapid centrifugation. After a rapid wash of the pellet, it was solubilized in Protosol and ^{45}Ca was measured by liquid scintillation spectrometry. Unless specified all studies were conducted wih 5 mM K^+ ion present.

The uptake of Ca^{++} was biphasic in the presence of both 5 mM and 60 mM K^+ and consisted of an initial rapid phase within the first 30 sec. followed by a slower phase, apparently linear for 10 min. Incubation of the synaptosomes for 30 sec. in 60 mM K^+ stimulated Ca^{++} uptake by 40-50% and was not reversed by 5 μM tetrodotoxin (TTX). Veratridine, 100 μM, caused a lesser stimulation that was reversed by TTX. Calcium uptake in the presence of both 5 mM and 60 mM K^+ was inhibited by 20-30% when either 0.5 mM La^{+++} or 30 mM Mg^{++} were present; both ions are known to inhibit Ca^{++} transport (Phil. Trans. R. Soc. London B. 265:57, 1973). Glutamate, 0.1-10 mM, caused stimulation of Ca^{++} uptake with an apparent EC_{50} of 0.2 mM, and a maximal stimulation of 25-35% that was not reversible by TTX, in contrast to the stimu- lation produced by veratridine. An aspartate congener, 1 mM N-methyl-D,L-aspartate (NMDLA), also stimulated Ca^{++} uptake but to a lesser degree than did GLU. In contrast, KA usually produced no change or inhibition of Ca^{++} uptake at concentrations of 10-1000 μM reaching maximal values of 20% inhibition at 1000 μM.

Our preliminary studies indicate that two excitatory amino acids, GLU and NMDLA, stimulate the uptake of Ca^{++} by rat striatal synaptosomes. Although KA did not stimulate uptake under the present experimental conditions, it is possible that KA may mobilize intracellular Ca^{++} stores.

35.3 INTERACTION BETWEEN N-METHYL-D-ASPARTATE AND KAINATE RECEPTORS IN THE STIMULATION OF cGMP FORMATION IN MOUSE CEREBELLAR SLICES INCUBATED IN VITRO.
J. Ferkany, Ph.D., and J. T. Coyle, M.D., (SPON: L. Tune). Dept. of Neuroscience, Johns Hopkins University School of Medicine, Balto, MD 21205

Neurophysiologic and ligand binding studies suggest that the potent excitants kainic acid (KA), glutamic acid (Glu) and N-methyl-D-aspartic acid (NMDA) act at different neuronal receptors. The toxic effects of KA involve a coopertive interaction with endogenous excitatory neurotransmitters whereas its neuroexcitatory effects appear to be direct. In the present study, we have examined the effects of KA and Glu on the formation of cGMP in mouse cerebellar slices in the presence of an NMDA antagonist as a means of determining receptor interactions.

Adult male albino mice were decapitated, the cerebellum removed and sliced at 0.3 mm perpendicular to the pial surface. After 1 hr preincubation at 37°C in Krebs-HCO_3:-5% CO_2-95% O_2 buffer, the slices were transferred to fresh medium containing drugs and incubated for 15 min. The reaction was terminated by boiling the tissue in 50 mM Tris-HCl, pH 7.5 containing 0.5 M EDTA and cyclic GMP was measured in the extract by RIA.

Under these conditions basal levels of cGMP were 6 ± 1 pm/mgp; 60 mM potassium or 0.3 mM ouabain produce a 5-fold stimulation with maximal effects at 15 min. Kainic acid (EC_{50} = 180 μM) was ten-fold more potent than Glu (EC_{50} = 1.5 mM) but Glu (Δ_{max} = (+) 8.0 pm cGMP/-mgp) was more efficacious than KA (Δ_{max} = (+) 5.6 pm cGMP/mngp). Ibotenic acid failed to stimulate cGMP between 10 and 1000 μM.

When the putative NMDA antagonist, D-α-amino-adipate (DAA), (250 μM) was included with KA (500 μM), a significant increase in cGMP levels was observed with respect to KA only ($N = 11$; $p < 0.02$; ANOVA). The antagonist alone did not alter basal cGMP levels. This effect was specific to KA since DAA failed to alter the cGMP response of either Glu or Ibo.

To better define the interaction between KA and DAA, the effects of these drugs on the release of endogenous amino acids into the medium was assessed by an HPLC method. KA produced greater than a 200% increase in the release of both aspartic and glutamic acids ($p < .05$) but did not affect the basal release of glycine, glutamine or alanine. DAA alone did not significantly reduce the basal or KA induced amino acid release.

In summary, DAA markedly enhances KA induced stimulation of cGMP in adult mouse cerebellar slices. The results are consistent with the hypothesis that the direct action of KA on cGMP stimulation is adumbrated by neurotoxic effects produced by the release of an endogenous excitatory agent whose effects are blocked by DAA. The results support the existence of two separate receptors which are capable of neurotoxic interactions.

35.4 ALTERATIONS IN SYNAPTIC TRANSMISSION IN THE HIPPOCAMPAL SLICE PRODUCED BY THE IONTOPHORETIC ADMINISTRATION OF EXCITATORY AMINO ACIDS.
G.L. Collingridge and H. McLennan*. Dept. of Physiology, University of British Columbia, Vancouver, B.C., Canada.

We have recently observed that brief (eg. 10 sec) iontophoretic administration of kainic acid to the CA1 cell body region of the hippocampal slice preparation can produce a massive and prolonged (usually 15 min or more) potentiation of the population spike evoked by Schaffer collateral stimulation. In the present study the effects of various excitatory amino acids and other substances have been examined. Drugs were administered iontophoretically (0-100 nA, 10-120 sec) from 7 barelled microelectrodes, the centre barrel of which was used to record extracellular activity from the CA1 cell body region of rat transverse hippocampal slices. The Schaffer collateral pathway was stimulated with glass microelectrodes (0.1 or 0.2 msec pulses, 3-85 μA at 0.1 Hz).

During its administration, kainate produced an initial increase in the amplitude of the population spike and in the neuronal firing rate, followed by a decrease in the population spike and an increase in the late negative wave as the cells overdepolarized. The ensuing potentiation started immediately or up to 5 min after the end of the iontophoretic application, but in slices which did not potentiate (approx. 25%) recovery of the population spike from the depression could take up to 10 min. L-glutamate, L-aspartate and their more potent analogs N-methyl-DL-aspartate (NMA), quisqualate, D-homocysteate and (±)-ibotenate all produced qualitatively similar effects to kainate during their administration. On termination of iontophoresis it usually took 1-5 min for the population spike to recover to its initial level and this recovery appeared to correlate with the recovery of units from their overdepolarized state. With the analogs recovery could be followed by an increase in the population response, although this potentiation was considerably less than that produced by kainate.

Acetylcholine was a weaker neuronal excitant but often produced large increases in the population spike during administration with low doses but depressions with higher doses; whereas GABA depressed the response. No long lasting changes in the synaptic response were observed following the application of these agents.

These results demonstrate that kainate relatively selectively produces a long lasting potentiation of synaptic excitation in the CA1 region of the hippocampal slice. Preliminary studies have suggested that kainate also selectively potentiates for long periods the population spike recorded in the dentate gyrus in response to perforant path stimulation. Possibly these actions of kainate may be correlated with its neurotoxic effect and might explain the necessity for intact excitatory hippocampal afferents for the full development of this neurotoxicity.

35.5 IS γ-HYDROXYBUTYRATE AN INDEX OF GABAERGIC ACTIVITY? F. Cattabeni+, M. Eli+ and E. Coen+ (SPON: L. Beani), Inst. of Pharmacology, Univ. of Urbino and Inst. of Pharmacology and Pharmacognosy, Univ. of Milan.

The presence of γ-Hydroxybutyrate (GHB) in mammalian brain is now well established and it is presumed to be formed from GABA via succinic semialdehyde. Since GHB possesses pharmacological activities, much effort has been made in order to prove its physiological role within the CNS. However, no indications exist about the possibility to utilize GHB as an index of GABA-ergic functional activity. The experiments here described were performed in order to prove this hypothesis. Blockers of glutamate decarboxylase (isoniazide, 450 mg/kg i.p., 45 min.) reduce GABA levels in brain areas by 70%. Concomitantly, GHB is significantly reduced, although to a lesser extent (25%). Blockers of GABA-Transaminase (γ-acetylenic GABA, 100 mg/kg i.p., 2 hours) double GABA levels and decrease those of GHB. Sodium valproate (200 mg/kg i.p., 30 min and 1 hour), a compound which seems to block not only GABA transaminase but also the enzymes responsible for the degradation of succinic semialdehyde, induces an increase in both GABA and GHB levels. These findings clearly indicate therefore that GHB is formed by a great extent from GABA in the CNS and that drugs interfering with GABA metabolism alter GHB levels accordingly. Moreover, Pentamethylenetetrazole increases GABA levels in cortex but not in cerebellum of animals during convulsions (1 min and 30 sec after 100 mg/kg i.p.), whereas GHB is slightly but significantly decreased. After the convulsions have ceased, cortical GABA levels are returned to control values, whereas GHB levels are by 50% higher than controls. These data therefore indicate that during convulsions GABAergic activity is decreased, as indicated by lower GHB levels, whereas increased GABAergic activity, as indicated by higher GHB levels, could account for the disappearance of convulsions 20 min after Pentamethylenetetrazole treatement. These results further support the hypothesis that GHB could be considered an index of GABAergic activity and that Pentamethylenetetrazole acts through the GABAergic system.

35.6 GABA PRODUCES A BIPHASIC RESPONSE, AN INITIAL DEPOLARIZATION FOLLOWED BY A HYPERPOLARIZATION, WHEN APPLIED TO CAT VESICAL PELVIC GANGLIA. M.L. Mayer,* J.P. Gallagher, H. Higashi,* and P. Shinnick-Gallagher. Dept. of Pharmacology and Toxicology, Univ. Texas Med. Br., Galveston, Texas 77550, USA.

The action of GABA on parasympathetic neurons has been studied with intracellular techniques. When recordings were made with electrodes filled with potassium salts of impermeant anions bath applied GABA evoked a monophasic depolarizing response associated with a conductance increase. When electrodes were filled with permeant anion salts the GABA response became biphasic: initially the membrane depolarized by 10-20mV before rapidly repolarizing to a plateau value associated with a maintained conductance increase, presumably reflecting anion redistribution. The membrane then hyperpolarized and the conductance decreased to 26%-86% of resting values. On the rising phase of the GABA-induced depolarization, the cell fired action potentials, while during the subsequent hyperpolarization the electrical threshold required to fire the neuron increased. In cells that were spontaneously active, action potential generation ceased during the hyperpolarization. Muscimol and 3-APS were less effective in evoking the conductance decrease. Ion substitution experiments revealed no reduction of the hyperpolarizing response in calcium or sodium free media, while chloride reduction augmented both phases of the GABA response. Iontophoretically applied GABA did not evoke biphasic responses. Interaction between bath and iontophoretically applied GABA revealed no apparent reduction in the driving force for the iontophoretic response during the latter phase of the biphasic response to bath applied GABA. The physiological significance of this unusual GABA response is unclear. Supported by NIH Grant NS 16228 to P.S.-G. and a Harkness Fellowship to M.L.M.

35.7 ETHYLENEDIAMINE AS A GABA-MIMETIC. T.W. Stone, H.G.E. Lloyd*, M.N. Perkins*, M. Parker*, N.G. Bowery*, and D.R. Hill*, Dept. of Physiology St. George's Medical School, London SW17 and Dept. of Pharmacology, St. Thomas's Medical School, London, SW1, UK.

The simple diamine ethylenediamine, $NH_2.(CH_2)2.NH_2$, is often regarded as a pharmacologically inert carrier for theophylline, in the form of aminophylline. Having noticed that aminophylline induced the release of (^{14}C)-GABA from brain slices, we now present the following evidence that ethylenediamine (EDA) may act upon GABA recognition sites in the central and peripheral nervous system.

1. EDA causes an apparent release of (^{14}C)-GABA from preloaded slices of mouse cerebral cortex.
2. EDA inhibits significantly the uptake of (^{14}C)-GABA into cortical slices (23% inhibition at 1mM).
3. Applied by microiontophoresis, EDA is a powerful depressant of neuronal firing in vivo. This action is blocked by bicuculline in doses which also block GABA but not glycine. Strychnine blocks glycine but not EDA.
4. EDA depolarises sympathetic ganglia with a potency of about 0.05 relative to GABA. EDA and GABA dose response curves are parallel and both compounds are blocked by bicuculline.
5. EDA displaces (^{3}H)-GABA from $GABA_A$ sites on rat cortex synaptosomal membranes, with an IC_{50} of 5μM.

The neuronal depressant properties of EDA seen in electrophysiological experiments are shared by related compounds such as diaminopropane and N-methyl EDA, though these are less effective.

It is suggested that in view of its simple structure, lacking either a hydroxyl or carboxyl grouping normally considered essential for actions at GABA sites, EDA may prove a useful tool for probing GABA or bicuculline receptor mechanisms.

35.8 EFFECTS OF GABA ON HYPOTHALAMIC NEURONS: A NEUROPHARMACOLOGICAL STUDY. J.-T. Cheng*, F. C. Barone and M. J. Wayner. (SPON: R. T. Bartus). Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210.

Male rats were anesthesized with urethane and prepared for recording from neurons in the lateral hypothalamus (LH). Seven barrel electrodes were utilized to record simultaneously from and apply chemicals to single neurons. The center barrel and one outer barrel were filled with 2 M NaCl and used for neuronal recording and current balancing, respectively. The other outer barrels were filled with 2 M L-Glutamic acid, 0.5 M γ-Aminobutyric acid (GABA), 5 mM Picrotoxin, 5 mM Bicuculline, and 0.1 M Glycine HCl. After a stable discharge frequency was established chemicals were ejected microiontophoretically from the multibarrel electrodes. Dose effect relations were determined and control procedures were utilized to eliminate current and pH effects (Barone et al., Brain Res. Bull. 5: 325-332, 1980). Also, those regions which project to the LH and are known to contain GABA neurons (Barone et al., Brain Res. Bull. 7, in press), such as the reticular thalamic nucleus (Houser et al., Brain Res. 200: 341-354, 1980) and reticular zone of the substantia nigra (Fonnum et al., J. Neurochem. 29: 221-230, 1977), were stimulated, 0-500 μA 0.5 msec single pulses, in conjunction with neuropharmacological testing. Lateral hypothalamic neurons were very sensitive to GABA and relatively small ejection currents (0-5 nA) were required to eliminate completely neuronal discharges. Picrotoxin and Bicuculline when applied alone usually did not alter or slightly elevated neuronal discharge frequency. When these antagonists were administered prior to and during GABA ejection, the decreases due to GABA were attenuated. Glycine also decreased the discharge frequency of hypothalamic neurons but only at higher ejection currents and the effects could not be altered by Picrotoxin or Bicuculline. In some cases, the antagonists could partially block the decrease in hypothalamic neuronal activity induced by electrical stimulation of known GABA inputs. These data indicate the significance of GABA receptors in the LH and are consistent with the high GABA metabolic activity found in the LH (Fonnum et al., J. Neurochem. 29: 221-230, 1977) associated with GABA synapses in the medial forebrain bundle. (Supported by NIH Grant NINCDS USPHS No. 13543.)

35.9 CARRIER-MEDIATED RELEASE OF GABA FROM RETINAL HORIZONTAL CELLS. S. Yazulla and J. Kleinschmidt. Dept. Neurobiology and Behavior, SUNY StonyBrook, NY 11794.

GABA is very likely the transmitter of H1 horizontal cells in the goldfish retina. L-Glutamate (Glu) and L-aspartate (Asp) are candidates for the photoreceptor transmitter in goldfish, and as such would be expected to influence directly the synaptic release of GABA by H1 cells. The mechanism by which transmitter is released from H1 cells is unknown. We found by LM autoradiography that Glu, Asp and ouabain cause release of ^{3}H-GABA from H1 cells in a manner suggesting efflux through carrier-mediated transport.

Isolated goldfish retinas were preincubated in 200 µl of 0.72µM ^{3}H-GABA for 15 min, postincubated in 200µl of a variety of experimental media for 15 min, fixed and embedded in EPON. When preincubated in the light, goldfish retinas took up ^{3}H-GABA heavily into H1 cell somata and dendrites (HSD) as well as axon terminals (HAT). Postincubation of retinas, preloaded with ^{3}H-GABA, in 0.5 to 10mM Glu or 0.1 to 10mM Asp caused a dose-dependent loss of label from HSD and little loss from HAT. We found that this loss was not due to metabolic breakdown of ^{3}H-GABA nor to calcium dependent vesicular release. 0.1mM ouabain also released ^{3}H-GABA selectively from HSD. Further, 1mM nipecotic acid, a selective blocker of neuronal high-affinity GABA uptake, as well as lithium substitution for extracellular sodium, a condition which would fail to activate neuronal GABA uptake, both blocked ^{3}H-GABA uptake into H1 cells as well as Glu- or ouabain-induced release of ^{3}H-GABA from HSD preloaded with ^{3}H-GABA. These results suggest that ^{3}H-GABA is released from HSD via a sodium-dependent membrane carrier mechanism which can be activated by an increase in intracellular sodium concentration brought about by the opening of cation selective membrane channels by Glu or Asp or by blocking the sodium pump with ouabain. Furthermore, this carrier may be identical with the carrier responsible for uptake of ^{3}H-GABA into horizontal cells, and the direction of net transport of GABA may depend on the physiological state of the cell.

The differential release of ^{3}H-GABA from HSD and not from HAT implies that Glu and/or Asp receptors and sodium pump sites are restricted to HSD, i.e. the only part of the H1 cell known to release transmitter synaptically. Thus, carrier-mediated transport of GABA may be the mechanism by which H1 cells effect their localized synaptic actions.

35.10 GAMMA-VINYL GABA: PROLONGED EFFECT ON PICROTOXIN-INDUCED SEIZURES IN MICE. F.P. MILLER* AND J.I. ALLEN* (SPON:R.P. MAICKEL). Merrell Research Center, Cincinnati, OH 45215.

Gamma-vinyl GABA (GVG), a specific irreversible inhibitor of GABA transaminase (GABA-T), elevates whole brain GABA levels in mice (Jung, M.J. et al., J. Neurochem., 29:797, 1977). This effect persists up to 5 days after a single dose and has been shown to correlate with the degree of protection against audiogenic seizures in mice (Schechter, P.J. et al., Eur. J. Pharmacol. 45:319, 1977). The present study investigated the effect of GVG on seizures induced in mice with the specific GABA antagonist, picrotoxin (PIC) as a function of time after injection. Groups of 10 male, CD-1 mice (Charles River) were administered GVG at 1000 mg/kg i.p.. At 2, 4, 16, 24, 48, 65, 72, and 96 hours after GVG, PIC was administered at a dose of 2.5 mg/kg i.v. (CD98). In a group of 110 control mice, this dose of PIC caused seizures with a mean latency of 4.47 min. ± 1.85 S.D. Seizure reduction was considered significant if an individual mouse did not exhibit seizures for more than 8 minutes after PIC. At 2 and 4 hrs post-GVG, nearly all of the mice exhibited seizure latencies in excess of 8 min, in agreement with the results of Schechter et al. (Psychopharmacol. 54:149, 1977). This effect on seizure latency persisted, with significant increases in seizure latency being exhibited at 16 hrs (80%), 24 hrs (80%), 48 hrs (60%), 65 hrs (25%) and 72 hrs (11%) after GVG. No effect was seen at 96 hrs after GVG administration. These results illustrate a long-lasting effect of GVG on PIC-induced seizures, an effect which appears to mirror the long-lasting elevation of whole brain GABA concentration as reported by Jung, M.J. et al. (J. Neurochem., 29:797, 1977) following administration of a single dose of GVG.

35.11 EVIDENCE FOR MUSCLE RELAXANT ACTIVITY OF γ-VINYL GABA IN MICE. Gary D. Novack and Kathleen M. Owenburg*. Merrell Research Center, Cincinnati, OH 45215

A role for GABAergic drugs in amelioration of disorders of increased muscle tension has been suggested by Davidoff (Neurology 28:46, 1978). In addition, intracerebroventricular administration of GABA or baclofen, a GABA analogue, was shown to block morphine-induced Straub tail (ST) in mice (Ukai et al., Jap. J. Pharmacol. 26(S) 1189, 1976; Kameyama et al., Jap. J. Pharmacol. 28:249, 1978). ST has been shown to be blocked by a number of clinically effective muscle relaxants at doses which do not produce a loss of righting reflex (Ellis and Carpenter, Neuropharmacol. 13:211, 1974). Since γ-vinyl GABA (GVG) is an irreversible inhibitor of GABA-transaminase and raises CNS GABA levels in mice 5 to 8-fold after doses of 800 to 1600 mg/kg, i.p. (Jung et al., J. Neurochem. 29:797, 1977), we were interested in evaluating GVG as a possible muscle relaxant by assessing its ability to inhibit ST.

Groups of 10 mice were treated with either water or GVG, 200, 400, 800 or 1600 mg/kg i.p., at various intervals (1, 2, 4, 16, 24, 48 or 60 hr) prior to morphine sulfate, 60 mg/kg s.c. Mice were evaluated for ST in a quantal fashion 15 min after morphine. GVG inhibited ST at 2, 4, and 16 hr after dosing. The ED50's for this response were 1268, 796 and 1289 mg/kg, respectively. At the highest dose used, inhibition at 1 and 24 hrs was 30% and 10%, respectively. No inhibition was seen at 48 and 60 hrs.

The observed inhibition of ST was not due to direct narcotic antagonism, as GVG does not have naloxone-like activity in analgetic models. In addition, ST was inhibited at doses which did not elicit a loss of righting reflex. Therefore, the inhibition of ST by GVG seen in the present study is interpreted to be a muscle relaxant effect. The time to onset and peak effect of the ST blockade by GVG corresponds to that reported for elevation of whole brain GABA levels (Jung et al.). This suggests that the muscle relaxant effect of GVG may be related to its effects on the GABA system. Thus, GVG may be useful in the treatment of human muscle spasms.

35.12 FOMINOBEN: A NOVEL AMINO ACID ANTAGONIST. Herbert M. Geller and Frank Baldino, Jr. CMDNJ-Rutgers Medical School, Dept. of Pharmacology, Piscataway, NJ 08854.

Fominoben hydrochloride is a novel agent with the unusual composition of antitussive and respiratory stimulant properties. A recent report has emphasized the ability of fominoben to reduce the specific binding of benzodiazepines (BDZ) to central nervous system BDZ receptors (Antoniadis et al., 1980). In this series of experiments we examined the physiological actions of fominoben on neuronal activity and possible interactions of fominoben with inhibitory amino acids and BDZ on rat hypothalamic neurons grown in tissue culture.

The activity of single spontaneously active (or glutamate-driven) neurons was recorded extracellularly. Depressions of activity were elicited by local application of amino acids (GABA or glycine) or flurazepam, a water-soluble BDZ, as well as by focal electrical stimulation of the culture, which elicits a GABA-mediated inhibition. Reductions in activity were quantitated on line through the use of peri-event histograms. Fominoben was then perfused through the recording chamber at concentrations between 1-100 µM. Further histograms were computed to assess the efficacy of the locally applied agents during fominoben perfusion.

The major action of fominoben was to reduce or antagonize the actions of both amino acids and flurazepam. At 50 and 100 µM concentrations, fominoben attenuated the actions of GABA on all 14 cells on which it was tested, while 5 of 7 cells displayed a concomitant and smaller reduction in the efficacy of glycine. Electrically-induced inhibitions were also reduced at these concentrations. At 10 µM, fominoben reduced the efficacy of GABA in only 3 of 7 cells, and of glycine in 2 of 4 cells, and was able to antagonize the depressant effects of flurazepam in each of 3 cells. These changes were observed without any consistent actions on the rate or pattern of activity in the cultures.

In summary, fominoben antagonized depressions of firing elicited by both GABA and glycine, though it displayed a greater potency in antagonizing GABA. Flurazepam-induced depressions were also reduced. These actions thus bear significant resemblance to the actions of picrotoxin. A major difference is that fominoben is without effect on the rate or pattern of neuronal activity as is characteristic of high doses of amino acid antagonists. We hypothesize that this difference may be related to the absence of a convulsant action of fominoben. Thus, these interesting properties of fominoben hydrochloride may prove to be of use in further physiological and biochemical studies of the GABA-benzodiazepine-chloride ionophore complex. (Supported by NSF grant BNS 77-09241 and NIH grant NS 15468.)

35.13 THIP, GABA-TRANSAMINASE INHIBITORS AND BENZODIAZEPINES BLOCK A RESPONSE OF MUSCIMOL IN MICE. M. Krishna Menon. Psychopharmacol. Res. Lab., V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. of Psychiatry, UCLA School of Medicine, Los Angeles, CA 90024.

In a particular strain of mice, relatively high doses of muscimol (2-3 mg/kg, i.p.) caused myoclonic jerks of high frequency (peak effect 73 jerks/min). This response of muscimol was blocked in a dose-dependent manner by a GABA agonist 4,5,6,7-tetrahydroisoxazolo (5,4-c) pyridin-3-ol-hydrate (THIP). It was also observed that both γ-acetylenic GABA (100 mg/kg, i.p.) and γ-vinyl GABA (1500 mg/kg, i.p.) blocked the muscimol-induced myoclonic jerks, the intensity of which paralleled the elevation of brain GABA level. It seems that, in this particular strain of mice, muscimol or one of its metabolites possibly acts on certain specific binding sites in the CNS eliciting myoclonic jerks and that these receptor sites are different from those to which GABA or THIP binds with high affinity.

The benzodiazepines (i.p. 10 min prior) also blocked the muscimol-induced jerks in a dose-dependent manner. When compared with diazepam, their relative potencies to cause a 50 percent blockade of muscimol response were: diazepam = 1, medazepam = 0.24, oxazepam = 1.27, flurazepam = 1.90, lorazepam = 3.01, nitrazepam = 3.93, clonazepam = 33.14 and flunitrazepam = 116.00. If our earlier assumption that the muscimol-induced myoclonic jerks originate at the level of the spinal cord is valid, the present method seems to offer a convenient means to evaluate the inhibitory effects of benzodiazepines on the spinal cord. If so, the present results indicate the possible value of flunitrazepam in the management of neurologic disorders in which preferential action on the spinal cord is desired. Supported by the Veterans Administration.

35.14 BACLOFEN: A SELECTIVE DEPRESSANT AT SYNAPSES MADE BY CA3 PYRAMIDAL CELLS IN THE HIPPOCAMPAL SLICE. Brian Ault* and J. Victor Nadler. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

The anti-spastic drug, baclofen, has been proposed to act by interfering with excitatory transmission mediated by acidic amino acids. We have investigated the actions of this compound on transmission in slices of the rat hippocampal formation, where glutamate and aspartate are probable transmitters of several excitatory pathways.

(±)Baclofen (20 μM) strongly depressed extracellularly recorded synaptic responses of CA1 and CA3 pyramidal cells to stimulation of stratum radiatum (Schaffer collateral-commissural fibers) and responses of CA1 pyramidal cells to stimulation of stratum oriens. In contrast, responses of dentate granule cells to stimulation of perforant path or associational-commissural projections, responses of CA3 pyramidal cells to mossy fiber stimulation and responses of CA1 pyramidal cells to stimulation of temporo-ammonic fibers were little affected. Thus baclofen preferentially inhibited transmission at synapses made by axons of CA3 pyramidal cells. Although glutamate probably mediates transmission at these synapses, baclofen cannot be regarded as a blocker of glutamatergic/aspartergic transmission in general, since it failed to inhibit transmission at other such hippocampal sites.

The depressant action of baclofen was stereospecific. A threshold effect of (-)baclofen was obtained at 0.5 μM and 2.5 μM reduced the amplitude of the Schaffer collateral-commissural extracellular EPSP by about 50%. (+)Baclofen was two orders of magnitude less potent. The depressant action of baclofen on these synapses closely resembled, in potency and stereospecificity, its depression of spinal cord reflexes. Synapses made by axons of CA3 pyramidal cells may therefore serve as models for studying the mechanism of action of baclofen.

Baclofen has been proposed to act at bicuculline(BIC)-insensitive GABA receptors. We have therefore compared the effects of baclofen, GABA and the GABA agonists, 3-aminopropanesulfonic acid (3-APS) and imidazoleacetic acid (IAA), on the Schaffer collateral-commissural extracellular EPSP. GABA (3 mM), 3-APS (1 mM) and (±)baclofen (5 μM) similarly reduced the amplitude of this response. BIC (50-500 μM) only partially reversed the actions of GABA and 3-APS, whilst the response to baclofen was unaffected. IAA, which is thought to interact only with BIC-sensitive receptors, had relatively little effect on the extracellular EPSP, but depressed pyramidal cell firing. BIC (100 μM) reversed this action. These results are consistent with the hypothesis that baclofen inhibits excitatory transmission by interacting with a BIC-insensitive GABA receptor. (Supported by NIH grant NS 16064.)

35.15 NEUROPHARMACOLOGICAL CHARACTERIZATION OF A SELECTIVE TAURINE ANTAGONIST. G. G. Yarbrough, D. K. Singh* and D. A. Taylor. Merck Institute for Therapeutic Research, West Point, PA 19486.

6-Aminomethyl-3-methyl-4H-1,2,4-benzothiadiazine 1,1-dioxide hydrochloride (TAG), applied by microiontophoresis, caused a prompt and readily reversible antagonism of the inhibitory effects of taurine and β-alanine on rat somatosensory cerebral cortical neurons and cerebellar Purkinje neurons whilst not affecting the actions of γ-aminobutyric acid (GABA). TAG also consistently reduced, but did not abolish the synaptically evoked inhibitions of Purkinje cells produced by electrical stimulation of the cerebellar surface. On the isolated amphibian spinal cord (ASC), TAG caused a dose-related enhancement of the dorsal root-ventral root potential while not substantially affecting the dorsal root-dorsal root potential. Qualitative studies on the ASC showed that the depolarizing actions of taurine and β-alanine on the dorsal roots, but not those of GABA or glycine, were reduced by TAG. Somewhat surprisingly, TAG also offset the inhibitory effects on cortical cells and the dorsal root depolarizing actions of muscimol, 3-aminopropane sulfonic acid and piperidine-4-sulfonic acid, all of which have heretofore been considered as selective GABA agonists. Systemically administered TAG does not appear to penetrate the blood-brain barrier but intracisternal (i.cis.) injections in mice produced a dose-related behavioral excitation leading to marked clonus and death. Additionally, i.cis. TAG reduced taurine but not glycine-induced lethality in mice. These findings lend a substantial degree of credence to the repeated suggestions that taurine may subserve a neurotransmitter type function in the mammalian central nervous system. Furthermore, the availability of a relatively specific antagonist might reasonably be expected to facilitate efforts to elucidate the physiological functions of taurine not only in the CNS but in other organ systems in the body as well.

35.16 THE EFFECT OF HOMOCYSTEINE IN BRAIN. S.M. Wuerthele, W.J. Freed, B.J. Hoffer. Dept. of Pharmacology, Univ. Colorado Medical School, Denver, CO 80262, and Lab of Clinical Psychopharmacology, St. Elizabeth's Hospital, NIMH, Washington, D.C. 20032.

Homocysteine, a monocarboxylic sulfur-containing amino acid, produces convulsions in rats and mice when administered systemically (Sprince et al., Ann. N.Y. Acad. Sci. 166: 323, 1969). In order to evaluate its effect on the central nervous system directly, extracellular recordings were made from neurons in rat cerebral cortex, cerebellum and midbrain during local application of homocysteine by iontophoresis or pressure ejection. Homocysteine produced dose-dependent increases in the activity of 17 cells, while the activity of 5 cells was decreased. There was no regional specificity to these responses. When homocysteine and glutamate were ejected from different barrels of the same pipette, homocysteine was equipotent with glutamate in increasing neuronal activity. 3 of 4 cells inhibited by homocysteine were also inhibited by glutamate. Neither glutamate- nor homocysteine-induced excitations were affected by simultaneous application of magnesium, suggesting that these responses were the result of a direct action of the drugs.

Homocysteine can be methylated in brain ($^{5}NFH_4$homocysteine methylytransferase) and liver (betaine homocysteine methyltransferase, BHM) to form the nonconvulsive amino acid methionine. When applied locally, methionine had no effect on spontaneous activity. Betaine, an endogenous methyl donor derived from choline, blocks convulsions produced in mice by a number of systemically administered agents, including homocysteine (Freed et al., Epilepsia, 20: 209, 1979). The enzyme using betaine as a methyl donor (BHM) is not present in brain (Finkelstein et al., Arch. Biochem. Biophys. 146: 84, 1971); however, to determine if betaine had a direct effect, it was applied locally on central neurons by pressure ejection. When applied in this fashion, betaine reversed both homocysteine- and glutamate-induced increases in neuronal activity, while having no effect on spontaneous discharge. These results suggest that betaine's anticonvulsant properties are not the result of its action as a peripheral methyl donor. The fact that betaine derivatives are used as membrane solubilizers (Goenne and Ernst, Anal. Biochem. 87: 28, 1978) and that betaine antagonizes a number of different convulsants could suggest that betain's anticonvulsant effects are related to a direct action on membranes. Alternatively, since betaine blocks the excitatory response to glutamate, it is possible that betaine acts at the level of the glutamate receptor.

35.17 RETROGRADE TRANSPORT OF L-[^{3}H]PROLINE BY CORTICAL LAYER V PYRAMIDAL CELLS. Simon LeVay and Helen Sherk*. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

L-[^{3}H]proline has been used for many years as an anterogradely-transported neuroanatomical tracer. We were surprised to observe selective retrograde transport of this compound by giant layer V pyramidal cells in the visual cortex of the cat.

50μCi of L-[2,3-^{3}H]proline (S.A. 20-40 Ci/mmole), sometimes in combination with horseradish peroxidase (HRP), was injected into the pulvinar, superior colliculus (SC), a pontine visual area, four visual cortical areas, lateral geniculate nucleus (LGN) and claustrum. After a 1-3 day survival the animals were perfused with paraformaldehyde or glutaraldehyde and the brains frozen-sectioned and processed for autoradiography. Following injections in the pulvinar, SC and pons, giant pyramidal cells were labeled in layer V of several visual cortical areas including 17, 18, 19 and PMLS. The labeling extended into the apical and basal dendrites. Except after the pulvinar injection, there was no diffuse labeling of the cortical neuropil such as might have been produced by anterograde or transneuronal transport. Furthermore, in those cases where HRP was injected together with the [^{3}H]proline, the autoradiographically-labeled cells also contained HRP reaction product. It thus seems likely that their labeling resulted from terminal uptake followed by retrograde axonal transport. It may be that the same population of cells projects to all three targets.

The labeling was selective in three senses: 1) Other neurons projecting to the same injection sites (e.g. retinal ganglion cells and parabigeminal neurons after the SC injections) were unlabeled. 2) Other amino acids injected into the SC (L-[^{3}H]-glutamate, L-[^{3}H]leucine) were not transported to the cortex. 3) Cortical cells in other layers were not labeled when proline was injected into their appropriate targets (e.g. LGN, claustrum, associational and contralateral cortex).

The selective uptake and retrograde transport of tritiated amino acids (glycine, GABA, glutamate, aspartate) by different populations of CNS neurons has been taken as supportive evidence that these or similar compounds are used as neurotransmitters (Hunt et al., '77; Streit, '80; Baughman and Gilbert, '81). While there is no other evidence to implicate proline as the corticotectal neurotransmitter, the present finding suggests the possibility that it or a related compound may be involved in neurotransmission in this pathway.

35.18 UTILIZATION RATES OF PUTATIVE AMINO ACID NEUROTRANSMITTERS IN RAT CEREBELLUM. M.E. Freeman, J.D. Lane and J.E. Smith. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Glutamate (Glu) and gamma-aminobutyric acid (GABA) are thought to have a neurotransmitter role in the cerebellum. This study was initiated to determine the utilization rates of these and other amino acids in five regions of the rat cerebellum. Eight male F-344 rats were implanted with chronic jugular catheters and allowed to recover from surgery for 3-4 weeks, receiving periodic injections of saline through the catheter. 0.2mCi D-[U-^{14}C]-glucose was injected through the catheter either 60 (N=4) or 90 (N=4) minutes prior to sacrifice by total immersion in liquid nitrogen. The heads were removed and stored at -70°C. The cerebellum was removed at -20°C, cut into 0.5 mm saggital sections, and dissected into five regions: lateral cortex, deep nuclei, molecular layer, granular layer, and white matter. The tissue was homogenized in ice-cold 7 percent trichloroacetic acid. Content and specific activity of Glu, aspartate (Asp), GABA, glutamine (Gln), serine (Ser), glycine (Gly) and alanine (Ala) were determined by a previously described procedure (Freeman et. al., Anal. Biochem. 106:191-194, 1980). Levels of Glu, Asp, and GABA in the lateral cortex, deep nuclei, and molecular layer generally agree with previously published values (Rea et. al., Neurochem. Res. 6:31-37, 1981). Glu and Asp levels in the granular layer were significantly lower ($P < .001$, Student's t-test) than in the molecular layer; white matter levels were lower still ($P < .001$). GABA levels were significantly higher ($P < .01$) only in deep nuclei. The utilization rates were calculated from the fractional rate constants (K) which were determined from a semilogarithmic plot of the specific radioactivity at 60 and 90 min prior to sacrifice. $\text{Utilization}_A = K(\text{content}_A)$, where $K = \ln 2/t_{\frac{1}{2}}$. Asp and Glu rates of utilization were 2- to 8-fold higher than the control amino acid Ala. Glu utilization was significantly higher in the lateral cortex ($P < .01$) than in the other areas tested, supporting its proposed neurotransmitter role in this region. However, there were no significant differences in Glu utilization between the molecular and granular layers, suggesting possible involvement in both granular cells and parallel fibers. Asp utilization in the various regions was relatively similar to that of Glu, suggesting either a neurotransmitter role or a metabolic interrelationship with Glu. GABA utilization was significantly higher only in the deep nuclei ($P < .001$). These data support the proposed action of amino acids as neurotransmitters in the cerebellum. (Supported in part by USPHS Research Grant DA-01999-04).

35.19 NET CONSUMPTION OF AMINO ACIDS IN SELECTIVE REGIONS OF THE CNS IN INSULIN HYPOGLYCAEMIA. R. F. Butterworth, F. Landreville* and A. Merkel*. Lab. of Neurochemistry, Clinical Res. Inst. of Montreal, Montreal, Quebec H2W 1R7, Canada.

The neurological symptoms of hypoglycaemia have been suggested to reflect a depression of neural function in progressively descending levels of the CNS. Preliminary studies in our laboratory have indicated that certain modifications of glutamic acid, aspartic acid and GABA, amino acids essential to neuronal integrity, may be causally related to the neurological impairment associated with insulin hypoglycaemia since these changes were found to *precede* the appearance of symptoms (R. F. Butterworth and A. D. Merkel, Neurosci. Lett. 5: 446, 1980). The present study was undertaken to measure the net consumption of amino acids in specific regions of the CNS at various times during the development of insulin hypoglycaemia. Adult male Sprague-Dawley rats (180-200 g) were fasted 24 h., then administered insulin (NPH) 100 IU/kg, i.p. As blood glucose fell below 40 mg/100 ml, neurological symptoms (hindlimb weakness, mild catalepsy) appeared. More pronounced hypoglycaemia led to loss of righting reflex and convulsions. Amino acids were measured in discrete regions of the brain by the double isotope dansyl microassay previously described (Analyt. Biochem. 64: 389, 1975, J. Neurochem. 33: 575, 1979). No detectable consumption of *amino acids was detected in whole brain at times up to the onset of convulsive activity. However, the amino acid pool of cerebral* cortex and striatum decreased significantly by 1.7 μmole/g and 3.5 μmole/g respectively *prior to the onset of hypoglycaemic convulsions*. No changes were found at corresponding times in any other brain regions studied. These findings suggest that the neurological symptoms of insulin hypoglycaemia may be due, at least in part, to consumption of amino acids essential to neuronal function as alternative energy sources in selective regions of the CNS. That the amino acid pools in cerebral cortex and striatum are *selectively* decreased prior to hypoglycaemic convulsions is intriguing; it is precisely these regions of brain that have been shown to display the greatest signs of neuronal damage in insulin-hypoglycaemic rats and of patients dying in hypoglycaemia. (This work was supported by grants from the Banting Foundation, Toronto, and the United Cerebral Palsy Research and Educational Foundation).

36.1 PHYSIOLOGICAL AND ULTRASTRUCTURAL ALTERATIONS IN TRANSMITTER OUTPUT WITH DENERVATION AND OUABAIN AT LOBSTER NEUROMUSCULAR SYNAPSES. R.G. Chiang* and C.K. Govind. Scarborough College, University of Toronto, 1265 Military Trail, West Hill, Ont., M1C 1A4, Canada.

The single excitor motoneuron to the distal accessory flexor muscle on the walking legs of the lobster (Homarus americanus) forms high-output synapses amongst the distal fibers and low-output synapses amongst the proximal fibers (Meiss D.E. & C.K. Govind, 1979. J. exp. Biol. 79: 99-114). The transmitter release characteristics of these different synapses can be experimentally altered. Thus seven days after transecting the motor axon, the high-output synapses from the denervated muscle resemble low-output synapses from the control muscle on the contralateral leg. Conversely 10 Hz stimulation of the motor axon for 2 hr. in 10^{-4} M ouabain causes a significant increase in quantal release amongst low-output synapses as compared to their counter-parts on the contralateral side. Thus quantal release of transmitter is decreased by denervation and increased in the presence of ouabain.

Serial section electron microscopy of the physiologically identified synaptic regions in the denervated muscle showed a reduction in surface area of the terminals, synapses and presynaptic dense bars compared to the control contralateral muscle. In addition, there was a significant reduction in the size of dense bars per synapse. Comparison of the ouabain - treated synapses with their untreated counter-parts on the contralateral side showed no differences in the surface area of terminals and synapses, but an increase in the size of dense bars. Since the change in dense bar size is directly related to quantal output in both denervated and ouabain-treated muscles, the dense bars appear to be intimately associated with the release of transmitter. Whether they assist in the release of transmitter or are a by-product of transmission is unknown. They do however reliably measure activity at these lobster neuromuscular synapses. Supported by NSERC and MDA of Canada.

36.2 COMPARISON OF THE EFFECTS OF CYCLIC AMP AND NH_4^+ ON THE ELECTROPHYSIOLOGY OF THE VENTRAL WHITE CELL OF PLEUROBRANCHAEA. Rhanor Gillette. (SPON: L. Barr). Dept. of Physiol. & Biophys. and Neural & Behav. Biol. Program, Univ. of Illinois, Urbana, IL 61801.

The ventral white cell of Pleurobranchaea may be stimulated into prolonged, recurrent and endogenous burst episodes by food stimuli applied to the mouth of the animal (M. Gillette, this volume); these burst episodes drive multiple cycles of coordinated ouput in the feeding motor network (Gillette et al., 1980, J. Neurophysiol. 43:669). We have found that similar recurrent burst episodes may be stimulated both by cyclic AMP (Gillette et al., 1979, Neurosci. Abs.: 4) and by NH_4^+. A salient characteristic of stimulation by relatively low concentrations of cyclic AMP analogs and IBMX (10^{-5}-10^{-4} M) and NH_4^+ (15 mM, pH 7.5) is that the initially enhanced excitability of the cell progressively wanes in the continued presence of the agents. This is reflected in progressive increases in the interburst intervals. Agent washout is followed by pronounced decrease in excitability, which slowly recovers over 20-60 min.

In voltage clamp, triangular voltage ramps (-80-0 mv) reveal a negative slope region (NSR) between -35 to -25 mv in the IV curve induced by the agents, whose peak amplitude is greater on the down ramp than the up ramp, resulting in unconventional hysteresis. The NSR of the up ramp is reduced, and that of the down ramp abolished in nominally O-Ca^{++} saline. Analysis of current tails near V_K after depolarizing pulses shows relatively large slow inward tail currents with activation and decay times of seconds which are greatly reduced in O-Ca^{++} and Co^{++} salines. The amplitudes of such tails are markedly enhanced by both the drugs and NH_4^+; however while cyclic AMP-stimulated tail amplitudes decline slowly over 20-30 minutes after washout, the NH_4^+-stimulated tail amplitudes fall rapidly to control levels. The IV curves for cyclic AMP-stimulated cells also lose amplitude of NSRs only slowly. In contrast, the NSRs of NH_4-stimulated cells quickly decay after washout. It seems likely that the initial stimulation, slow waning, and post-washout depression of the cell excitability by NH_4^+ parallels rapid increase, slow recovery and post-washout undershoot of intracellular pH (Boron and DeWeer, 1976, J. Gen. Physiol. 67:91) and is in part due to accompanying changes in the slow inward current characteristics. It is hypothesized that increases in the Ca^{++}-activated K^+ conductance caused by intracellular Ca^{++} accumulation also contribute to the slow waning of excitability and post-washout depression for both cyclic nucleotide stimulation and NH_4^+. Supported by NSF-BNS-79-18329.

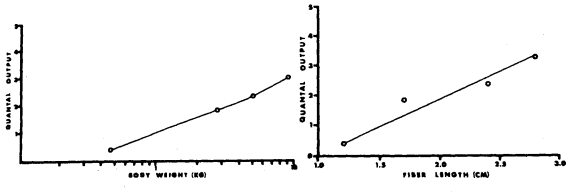
36.3 GROWTH OF LOBSTER NEUROMUSCULAR SYNAPSES: PHYSIOLOGY AND ULTRASTRUCTURE. D. E. Meiss, Dept. of Biology, Clark Univ., Worcester, MA 01610 and C. K. Govind, Division of Life Sci., Scarborough College, Univ. of Toronto, West Hill, Ontario, Canada M1C 1A4.

Neuromuscular synapses of the distal accessory flexor muscle (DAFM) of the lobster, Homarus americanus, form discrete populations which vary in transmitter release properties. The extremes are represented by low- quantal release synapses on proximally located muscle fibers and high-quantal release ones on the distally located fibers (Meiss and Govind, J. Exp. Biol. 79:99-114, 1979).

Growth of comparable low-output synapses was studied in lobsters of varying sizes in which there was an approximate 18-fold increase in body weight and a two-fold increase in muscle fiber length. Physiological properties of synaptic transmitter release were determined from focal microelectrode recordings at discrete synaptic regions. These analyses showed that transmitter quantal output increased proportionally with the logarithm of the body weight (Fig. 1A) and linearly with muscle fiber length (Fig. 1B).

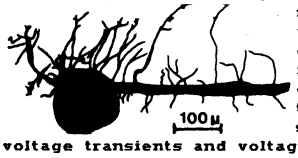
Serial thin section E.M. analysis (Govind and Chiang, Brain Res. 161:377-388, 1979; Govind and Meiss, Cell Tiss. Res. 198: 455-463, 1979) was done on physiologically identified synapses from the 0.5 kg and 5.0 kg animals. Synapses were characterized by a doubling in the mean size and the number of presynaptic membrane dense bars. Since these densities are regarded as active sites of transmitter release, their increase in size and number in the present study provides a morphological basis for the observed physiological increases in transmitter quantal output.

Fig. 1A Fig. 1B



36.4 **Aplysia BUCCAL GANGLION MOTORNEURONS: MORPHOLOGY AND ELECTROTONIC PROPERTIES.** **Katherine Graubard and William H. Calvin, Departments of Zoology and Neurological Surgery, University of Washington, Seattle 98195**

Many buccal motorneurons of Aplysia have large somata (150-250 mu), thick axons (15-20 mu), and a large number of thin to medium (1-10mu) processes leaving the axon to terminate in the neuropile within 350 mu. In addition, similar branches are often seen originating from the soma, a finding atypical of invertebrate neurons. Using two microelectrodes, current steps were applied and the voltage transients and voltage-current curve measured. The cells were filled with HRP or Lucifer and studied in whole mount. Electrotonic reconstructions (Rall 1959) yield estimates for membrane resistivities which are 10-100 times lower than the 500,000 ohm cm observed in abdominal ganglion (Graubard 1975). Retrograde voltage spread is 90-95%; indeed, the reversal for somatic ACh is within 90% of the chloride IPSP reversal potential (Gardner 1977).



A synapse at the tip of a thin process is nearly as effective in delivering current to the axon as is centrally-located synaptic input (Graubard and Calvin, The Neurosciences, Fourth Study Program, 1979). Whatever the membrane leakiness along the thin branch, the large central load will provide an easy path for the synaptic current; in this sense, the cell's geometry is the prime determinant of synaptic effectiveness, as seen from the axon, e.g., from the spike trigger zone. For synaptic output from a dendritic tip, however, neighboring inputs will be at least 20-40 times more effective than axonal inputs.

Voltage attenuation from tip to soma or axon was severe and could not be reduced by activating many inputs simultaneously (Turner and Calvin, Cell. Molecul. Neurobiol., 1981). The central load upon a dendrite is comprised of an irreduceable load (nonsynaptic membrane, such as the axon) and a load which can potentially be made invisible (simultaneous inputs to other branches preventing current flow into them). In lobster stretch receptors, most of the central load could be removed by activating other dendrites symmetrically. By reducing voltage attenuation, this greatly enhances the dynamic range compared to the one-input case, which has a limited current range between rheobase and saturation. In our buccal ganglion neurons, most of the central load is irreduceable, as it is dominated by the large axon. (NIH grants NS 04053 and NS 15697).

36.5 OPTICAL MEASUREMENT OF POTENTIAL CHANGES IN AXONS AND PROCESSES OF NEURONS OF A BARNACLE GANGLION. V. Krauthamer* and W.N. Ross* (SPON: S. Fraley) Dept. of Physiology, New York Medical College, Valhalla, N.Y. 10595.

Optical recordings of transmembrane voltages at multiple sites on single cells, combined with standard intracellular recording and staining methods, allows for an analysis of the regional properties of neurons. We have used this combination of techniques to examine cells of the supraesophageal ganglion of the giant barnacle, Balanus nubilus.

Ganglia were stained with one of several voltage-sensitive dyes, WW375, WW401, or NK2367 (see L.B. Cohen and B.M. Salzberg, Rev. Physiol. Biochem. Pharmacol. (1978) 83. p. 35. for review). The preparation was mounted on the stage of a Zeiss Universal Microscope and imaged with a x40 water-immersion lens onto a 6 x 6 square array of photodiodes, each element corresponding to 40 x 40 μm^2 in the object plane (A. Grinvald, W.N. Ross, and I. Farber, P.N.A.S. (1981) in press). Cells were impaled with a microelectrode and action potentials were evoked repetitively. The resulting changes in absorption, detected on each element at 750 ± 25 nm, were averaged on a laboratory computer. Optically detected action potentials could be seen without averaging from the cell bodies (typically 60 μm in diameter). Signals were also detected from antennular nerves and the cross-commissural connective. Extracellular recordings, Lucifer Yellow injections, and appropriate conduction times confirmed that the signals corresponded to action potentials propagating along single axons or large processes.

Similarly, when square hyperpolarizing current pulses were injected into the soma, optical signals corresponding to the electrotonic spread of these pulses were detected in axons over 500 μm away and in the commissural process. After correcting for distortions due to electronic filtering the optical records were compared with those predicted from a passive membrane model based on cellular geometry determined from Lucifer Yellow dye injections.

Supported in part by UPHS grant #NS16295 and the Irma T. Hirschl Foundation.

36.6 SURVEY OF APLYSIA BUCCAL GANGLIA NEURONS FOR NEUROTRANSMITTERS. J.K. Ono, Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

The bilateral organization of the buccal ganglion of the marine mollusc, Aplysia californica, and the information available about synaptic circuits of the ganglia make it an ideal preparation for extensive surveys of neurons containing specific neurotransmitters. The buccal ganglia consists of symmetrically paired hemi-ganglia containing neurons which have anatomical and functional counterparts in each hemi-ganglia. Some of these neurons have been identified by other investigators as motoneurons (B15, B16) or as interneurons (B4, B5, S1's) mediating a variety of synaptic responses. Acetylcholine (ACh) has previously been identified as the neurotransmitter used by certain motoneurons and interneurons (B15, B16, B4 and B5) in this preparation.

Techniques for isolating individual neurons and sensitive assays for ACh, histamine, octopamine, serotonin, and dopamine permit measurement of these amines in individual neurons or pooled groups of small neurons. Preliminary data indicate that aside from the previously identified cholinergic neurons, many other buccal neurons contain significant amounts of ACh. Maps indicating the location of various buccal neurons which contain significant quantities of transmitter substances will be presented. (Supported by N.I.H. grant #NS-15583).

36.7 PHYSOSTIGMINE PRODUCES PROLONGED CALCIUM DEPENDENT ACTION POTENTIALS IN LEECH NEURONS. J.Yang* and W.M.King* (SPON: C.M.Lent). Neurosciences Section, Brown Univ., Providence, R.I. 02912.

Physostigmine (eserine), known primarily for its reversible inhibition of acetylcholine esterase, was found to prolong action potentials in the Retzius cells of the segmental ganglia of the American leech, Macrobdella decora. This effect occurred over a period of 10-15 minutes at bath concentrations of 1-10mM; these concentrations are several orders of magnitude greater than that required for acetylcholine esterase inhibition. Exogenously applied ACH, 10^{-5}M, sufficient to cause membrane depolarization had little effect on action potential duration. A short duration stimulus evoked bursts of action potentials and trains of subthreshold responses and eventually a 30-50mV, 200-400ms duration prolonged action potential. The prolonged action potentials showed a early depolarization followed by a late plateau phase. Ionic substitution of Na with choline in the perfusion medium showed Na dependence of the fast phase. The longer slow plateau persisted in Na free solution when Ca was present at a concentration of 2mM. Raising the Ca concentration increased the threshold of the prolonged action potentials. At 10mM Ca, it was not possible to elicit a prolonged action potential; however, in preparations which showed spontaneous activity, long duration plateaus were observed despite the inability to induce such a response electrically.

Intrasomatic iontophoresis of physostigmine was not effective in prolonging the action potential.

Preliminary results indicate that physostigmine produces prolonged action potentials in leech Retzius cells and this effect resembles that of tetraethylammonium in the same preparation and occurs at similar doses.

36.8 THE ACTIVE ZONE AT APLYSIA SYNAPSES: INTRAMEMBRANOUS ORGANIZATION. C. H. Bailey* and M. Chen. Center for Neurobiol. and Behavior, Depts. Anat., Physiol., and Psychiatry, Columbia Univ., P & S, and the N.Y.S. Psychiatric Institute, New York, N.Y. 10032.

The vertebrate active zone is characterized by differentiated paramembranous appostions that are coextensive with regions of specialized membrane and vesicle accumulation. An inability to visualize this full complement of morphological specializations in the molluscan nervous system has resulted in confusion over the most basic aspects of synaptic architecture and has raised the possiblity of fundamental differences in synaptic structure and perhaps function between Aplysia and the vertebrates.

Recently we have used selective cytochemical techniques to demonstrate the presence of discrete active zones at Aplysia central synapses and to describe the organization of the presynaptic area (Bailey, Kandel and Chen, J. Neurophysiol., 1981). En face views at the level of the presynaptic membrane reveal oval-shaped discs containing dense projections that can exist in regular hexagonal networks remarkably similar to the precise grid described in vertebrates. In the present study we have extended this analysis by exploiting freeze-fracture techniques to examine the intramembranous architecture of specialized vesicle-release zones at Aplysia synapses.

Our preliminary results correlate well with the appreciation of the presynaptic area obtained by selective staining. In thin sections, Aplysia active zones are often characterized by apposed membranes that curve gently inwards towards the presynaptic element. Consistent with this configuration, freeze-fracture replicas reveal presumptive active zones as shallow indentations (P-face) or slight elevations (E-face) of the presynaptic membrane. These sites often appear restricted to varicose expansions. Within these regions the cytoplasmic leaflet of the presynaptic membrane displays varying numbers of intramembranous particles and small plasmalemmal pockets thought to represent points of vesicle fusion. We are currently examining synapses under conditions of maximal stimulation to determine the precise arrangement of these membrane deformations. Postsynaptic intramembranous specializations have been observed infrequently. This may be related to the lack of a well-developed postsynaptic density at Aplysia synapses. In one instance the tip of an invading postsynaptic spine contained a loose aggregate of large (~ 10 nm) intramembranous particles that corresponded in extent with the clustering of presynaptic vesicles. This arrangement appears to be very similar to that described at vertebrate excitatory synapses.

The findings from both cytochemical and freeze-fracture studies suggest that the organization of Aplysia and vertebrate active zones can be quite similar and argue against fundamental mechanistic differences in synaptic transmission between molluscan and vetebrate neurons. (Supported by an Irma T. Hirschl Career Scientist Award.)

37.1 LOCALIZATION OF VAGAL CARDIOMOTOR NEURONS IN NEONATAL PIG. D.A. Hopkins, P.M. Gootman, N. Gootman*, S.M. DiRusso* and M.E. Zeballos*. Dept. of Anatomy, Dalhousie University, Halifax, N.S. B3H 4H7 and Dept. of Physiology, Downstate Medical Center, Brooklyn, NY 11203.

The neonatal pig has been used extensively as a model for the postnatal maturation of the neural control of circulation (Gootman et al., Reviews in Perinatal Medicine, 1979). To date there have been no anatomical studies of the locations of cardiac preganglionic neurons in the pig. In the present study the distribution of the medullary cells of origin of the cervical vagus (N=3) and of physiologically identified cardiac nerves (N=6) has been studied in neonatal pigs ranging in age from one day to two months. Following anesthetization with sodium pentobarbital or halothane, the cervical vagus was exposed or a thoracotomy was performed and cardiac nerves were electrically stimulated to determine their function. The cervical vagus and cardioinhibitory nerves were injected with 5-20 µl of a 30% horseradish peroxidase (HRP) solution. After 1-3 days survival, transverse sections were cut through the medulla oblongata and processed for HRP histochemistry (Mesulam, 1978). In addition, the brain of a 7-day old piglet was embedded in paraffin and serial sections were cut and stained with cresyl violet or cresyl violet and luxol-fast blue.

After injections in the cervical vagus, retrogradely labelled neurons were observed in the ipsilateral dorsal motor nucleus (DMV), in and ventrolateral to the nucleus ambiguus (NA) as well as occasionally in intermediate regions between the two major nuclei. There were also small numbers of labelled neurons in the nucleus of the solitary tract. After injections in cardiac nerves the majority of labelled neurons were found in very distinct and tightly packed groups of neurons ventrolateral to the NA. Fewer were seen in the NA and scattered ventrolateral to the NA. Only small numbers of labelled neurons were present in the DMV. The distribution of labelled neurons after cardiac nerve injections appeared to be similar at each age studied. Comparisons of serial paraffin sections and labelled sections suggest that a morphologically distinct cardiac nucleus is present in the pig. The characteristic appearance and location of the nucleus make it ideal for further anatomical and physiological studies of cardiac preganglionic neurons. Supported by MRC of Canada, NLBI Grant HL 28064 and the American Heart Association, Nassau Chapter.

37.2 DISTRIBUTION WITHIN THE BRAINSTEM OF VAGAL AFFERENTS IN THE DOG. C.L. Chernicky, K.L. Barnes, J.P. Conomy and C.M. Ferrario. Division of Research and Department of Neurology, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

The distribution of vagal afferents was examined in the brainstem of 6 mongrel dogs (7-12 kg) with horseradish peroxidase (HRP) histochemistry. HRP was applied to the right or left nodose ganglion or the vagosympathetic trunk within 2 cm distal to the ganglion by either implantation of 30% HRP-acrylamide gel pellets or multiple microinjections of 30-50% HRP in TRIS buffer (pH 8.6). After 6-8 days the animals were anesthetized again (pentobarbital, 30 mg/kg, i.v.) and perfused transcardially with 1.0 L of normal saline (37°C) followed by 4.0 L of 5% glutaraldehyde in phosphate buffer (37°C) and a final wash of 2.5 L of cold sucrose buffer. The brainstem and ganglia were removed immediately and stored overnight in sucrose buffer at 4°C. Both the nodose ganglion and the brainstem (from C_2 to the caudal pons) were serially sectioned at 40-60 µm. Sections were processed for HRP histochemistry using tetramethyl benzidine (TMB) as the chromagen and examined for HRP reaction product with both bright and darkfield illumination.

The afferent fibers of the vagus nerve enter the dorsolateral medulla as a single bundle about 6 mm anterior to the obex. As the fiber bundle travels dorsomedially, afferents separate into a number of fascicles which reconverge and travel caudally in the solitary tract (TS). Labeled fibers exit the solitary tract throughout its rostral-caudal extent and are distributed within the following nuclei: the ipsilateral nucleus tractus solitarius (NTS), dorsal motor nucleus of the vagus (DMV), nucleus intercalatus (NI) and area postrema (AP). Fibers are also seen crossing in the nucleus commissuralis of Cajal and the commissure of the area postrema at the obex to enter the contralateral NTS and AP. The ipsilateral medial NTS and AP receive the heaviest projections of vagal afferents, while only moderate labeling is seen in the contralateral NTS and AP. No HRP reaction product was found in the contralateral DMV, NI or TS.

Although the distribution of the canine vagal afferents is similar to that in the cat, the heavy labeling in the area postrema more closely resembles that shown in the monkey.

Supported by grants from NHLBI #HL-6835 and the Reinberger Foundation.

37.3 CYTOARCHITECTURE OF THE RAT NUCLEUS TRACTUS SOLITARIUS: CATECHOLAMINES, BLOOD VESSELS AND PEPTIDES. L.Y. Koda, J.F. McGinty, E.L.F. Battenberg, and F.E. Bloom. The Arthur V. Davis Center, The Salk Institute, La Jolla, CA 92037.

Clinical and experimental evidence has implicated central monoamine and peptide systems in blood pressure regulation. Discrete monoamine and peptide terminal plexuses are located in pressor-related areas of the medulla, particularly in the nucleus tractus solitarius (NTS) and central grey. The NTS complex contains the A2 noradrenergic and more rostrally the C2 adrenergic cell body groups. In addition, various peptides implicated in autonomic function are found in the region of the NTS. The present study is aimed at mapping the distribution of blood vessels and of catecholamine- and peptide-containing cell bodies and terminals within the NTS. Sprague-Dawley rats (200g) were prepared for cryostat glyoxylic acid induced monoamine fluorescence (GIF) or immunohistochemistry. Where blood vessel distribution was examined rats were additionally perfused with 3-5 ml of ice-cold 0.2% pontamine sky blue in Ringer's solution. Coronal serial frozen sections were prepared through the NTS. The GIF cell bodies within the NTS complex were found caudal to the obex and are therefore considered to be the A2 cell body group as defined by Dahlstrom and Fuxe. The A2 cell body group is composed of 900 (890 + 43 n = 3) small to medium sized (20-30 µm diameter) neurons. In general, they are located on the dorsal and lateral edges of the dorsal motor nucleus of the vagus. They extend bilaterally from 200 µm to approximately 1600 µm caudal to the obex where they meet dorsal to the central canal and continue down the midline approximately 200 µm caudal to obex. The cell population is densest 600-1000 µm caudal to the obex where 15-20 cell bodies are found bilaterally in a 20 µm thick section. The NTS also contains a dense GIF terminal plexus. Serial sections of the GIF terminal plexus have been analyzed, and a detailed mini-atlas of the region developed. Blood vessel density has also been quantified over the NTS complex. Qualitative examination reveals that the NTS is less vascular than the surrounding central grey. Gamma-MSH immunoreactive (ir) fibers moderately innervate or pass through the NTS. Rostral to the obex the gamma-MSH ir are seen intermittently, but are mainly dorso-medial within the nucleus. Caudal to the obex, the fibers move ventrally and laterally to form a moderately dense plexus just lateral to the dorsal motor nucleus of the vagus (possibly in the nucleus intercalatus of Staterini). Gamma-MSH ir fibers continue just dorsal to the central canal into the spinal cord. The immunohistochemical distribution of other peptides e.g., enkephalin and VIP is now being added to the detailed NTS maps of catecholamines and peptides (USPHS grants HL25457 and MH 29466).

37.4 REGIONAL CHANGES IN GLUCOSE METABOLIC RATE IN CNS ELICITED BY ELECTRICAL STIMULATION OF THE NUCLEUS TRACTUS SOLITARIUS IN RAT. D.J. Reis, C. Iadecola*, S. Mraovitch*, L. Tucker* and D.A. Ruggiero. Lab. of Neurobiology. Cornell Univ. Med. Coll. New York, NY 10021.

The intermediate one third of the nucleus tractus solitarius (NTS) is a major site of cardiovascular integration. While major ascending projections of NTS have been mapped by traditional anatomical techniques (e.g. Ricardo and Koh, Brain Res. 153:1, 1978), polysynaptic pathways from the "cardiovascular NTS" have not. We have used the [^{14}C]-2-deoxyglucose method (2-DG) to map changes in metabolic rate (GMR) elicited by electrically stimulating vasodepressor sites in NTS. Rats were anesthetized with chloralose (40 mg/kg), paralyzed, and artificially ventilated with blood gases maintained. The intermediate third of lat. n. of NTS was stimulated at most sensitive sites with pulse trains (2 sec on/ 1 sec off, 20uA, 10Hz, 55 min). At onset of stimulation, AP fell to 61 $\pm$ 8 from 121 $\pm$ 5 mmHg (n=5; $p<.005$) stabilizing after 10 min at 93 $\pm$ 5 mmHg. 2-DG was administered 10 min after the start of stimulation, timed arterial samples withdrawn and animals killed 45 min later. Operated non-stimulated rats were controls. Densitometry was performed by a TV-based image analysis system. After NTS stim. (n=5), GMR significantly ($p<.05$) increased in 25 areas. In Group I (increase $\geq$ 40%), most pronounced increases (percent of control) were ipsilateral in: lat. n.of NTS (53%), lat. commissural n. of X (60%), lat. parabrachial n. (46%) paraventricular n. (37%), lat. hypothal. area (40%), n. stria terminalis (60%), and lat. preoptic area (40%). Contralaterally, GMR increased in all of the above areas except for portions of lat. NTS other than the mirror focus. In Group II (increase 20-40%) GMR was increased in n. ambiguus (20%), area postrema (37%) ventromedial (22%) and parafascicular thalamic n. (31%), zona incerta (33%) and central n. of amygdala (35%). Group III (GMR was unchanged) included parvocellular, gigantocellular, and vestibular nn., all adjacent to electrode sites, cerebellar nuclei, and medial parabrachial n. We conclude: (a) Stimulation of the cardiovascular NTS increases GMR throughout brain in regions primarily corresponding to anatomically defined monosynaptic projections. (b) The exceptions, e.g. thalamus and preoptic region, may represent polysynaptic spread. (c) The absence of changes in GMR in medial parabrachial n. suggests that 2-DG and anatomical data may differ. (d) The absence of stimulus spread indicates that the 2-DG method can be used in conjunction with electrical stimulation to map anatomical projections. (e) Information from cardiovascular afferents remains largely confined to interconnected systems mediating cardiovascular and visceral control.

37.5 DEOXYGLUCOSE MAPPING OF CENTRAL NERVOUS SYSTEM STRUCTURES DURING CENTRAL CHEMORECEPTOR MEDIATED HYPERCAPNIC RESPONSES IN THE RAT. C.V. Rohlicek*, J. Ciriello and C. Polosa*. Department of Physiology, McGill University, Montreal. Canada H3G 1Y6.

Physiological experiments suggest the presence of CO_2 receptors in the region of the ventral surface of the medulla. However, the actual anatomical structures associated with these receptors and the neural pathways involved in the respiratory and cardiovascular responses to activation of these receptors remain uncertain. In the present study, the deoxyglucose method was used to functionally map central structures activated by hypercapnia. Peripherally chemodenervated male Wistar rats anaesthetized with urethane were instrumented with femoral venous and arterial catheters and tracheal cannulae and allowed either to spontaneously breath room air or paralyzed and made hypercapnic by artifically ventilating with a gas mixture of 10% CO_2 and 90% O_2. In the latter group, the increased arterial pressure and electrical activity in the recurrent laryngeal nerve were used as indication of the activation of central chemoreceptors. [^{3}H]deoxyglucose (300-500 µCi/100g) was injected intravenously as a single bolus and after 45 min the animals were decapitated and the brains removed and quickly frozen on dry-ice. Serial transverse sections at 8µm were cut with a cryostat (-26°C) and one in every 10 was dried on cover glass and placed in contact with [^{3}H] sensitive film for 3-9 weeks. Autoradiographs were developed and analyzed for areas having the greatest metabolic activity as indicated by the density of photographic emulsion. Sections of the brainstem from hypercapnic rats, in comparison to those of the control rats, revealed marked increases in density bilaterally in the ventrolateral region of the solitary n. rostral to the obex, around the region of the n. retroambiguus, and in a region of the ventrolateral medulla extending rostrocaudally from the obex to the level of the intramedullary rootlets of the facial nerve. The cervical and thoracic cord of both the hypercapnic and control groups was more dense than the lumbar cord. In both groups the dorsal aspect of the dorsal horn and the region of the lateral horn, as well as lamina X in the thoracolumbar cord of the hypercapnic rats, were more dense than the surrounding grey matter. These data provide a functional map of central structures activated by hypercapnia suggesting that these structures are involved in the CO_2 responses of respiratory and sympathetic neurones.

37.6 IDENTIFICATION OF SPECIFIC CELLS IN THE CNS THAT ARE FUNCTIONALLY ACTIVE DURING CARDIOVASCULAR REFLEXES USING THE [^{14}C] DEOXYGLUCOSE TECHNIQUE.

D.R. Kostreva, and J.P. Kampine. Depts. Anesthesiology and Physiology, Med. Col. of Wis. and VA Med. Ctr., Wood, WI 53193

Recent CNS mapping studies of cardiovascular reflexes in our laboratory using the [^{14}C] deoxyglucose technique of Sokoloff, et al. (J. Neurochemistry 28:897-916, 1977) have demonstrated that functional metabolic activity increases substantially in specific nuclei within the CNS; i.e. nucleus tractus solitarius, nucleus ambiguus, external cuneate nuclei, inferior olivary nuclei, paramedian reticular nucleus, parabrachial nucleus, interpeduncular nucleus, hippocampus, and insular cortex, in response to stimulation of carotid sinus and vagal afferents. Although metabolic activity appears to be increased throughout an entire nucleus or region of the CNS, the localization of specific cells or groups of cells within a nucleus that are part of a specific reflex pathway cannot be obtained from gross observations of the autoradiographic data. Therefore, a technique has been devised to locate specific cells or groups of cells that are functionally and metabolically activated in specific reflexes. The frozen 20 um brain slices that are used to produce the autoradiographs are stained using a modified cresyl violet staining procedure and photomicrographs of these stained sections magnified 40X, 80X, or 160X are then montaged. The corresponding autoradiographs of the same sections are densitometerized using an aperature size of 100 um^2. An overlay of the numerical printout of the densitometer scan can then be photographically scaled on clear acetate to the same magnification as the photomicrograph of the stained section. The numbers with the highest values represent the areas of greatest metabolic activity. Therefore, since each number corresponds to an area 100 um^2, specific cells or groups of cells can be identified and functionally related to the reflex that was activated. Data obtained from serial brain sections using this type of analysis can be used to construct 3-dimensional plexiglass models of the cellular structure of various brain segments and specific nuclei. More importantly, specific cells or groups of cells within those nuclei that are involved in a specific reflex pathway can be identified. This method of analysis of [^{14}C] deoxyglucose data allows one to determine the physiological function of specific cells or groups of cells within the CNS. (Supported by NIH Young Cardiovascular Investigatator Grant HL 21042 and the VA Medical Research Service).

37.7 SUBNUCLEAR ORGANIZATION AND TOPOGRAPHY OF FOREBRAIN INPUTS TO THE NUCLEUS TRACTUS SOLITARIUS OF THE RABBIT. Gerald A. Higgins* and James S. Schwaber. Dept. of Anatomy and Neurobiology, University of Vermont School of Medicine, Burlington, Vermont 05405

Recently we have described in the rabbit direct projections from the central nucleus of the amygdala (CE) and bed nucleus of the stria terminalis (BST) that selectively innervate certain regions of the nucleus tractus solitarius (NTS) and dorsal vagal nucleus (DVN). Stimulation of the CE of the rabbit produces a profound, short latency decrease in heart rate that is mediated by the vagus nerve (Kapp et al, Soc.Neurosci.Abstr.,Vol.6,p.817, 1980). This effect may be mediated directly by forebrain inputs to vagal motoneurons, or indirectly by affecting baroreceptor afferents within the NTS. The aim of this report is to examine the morphological substrate for forebrain-visceral afferent interactions within the NTS.

Cytoarchitectonic studies show that the NTS of the rabbit is composed of eight distinct subnuclei: dorsomedial, commissural, intermediate, interstitial, lateral, medial, parvocellular and ventrolateral.

In initial experiments using standard neuroanatomical techniques, afferents were traced to the NTS from the CE, BST, aortic nerve (AN), carotid sinus nerve (CSN) and cervical vagus nerve (VN). The dorsomedial subnucleus contains medium-sized, fusiform cells, abundant fibers, and receives heavy projections from the CE, BST and AN, as well as inputs from the CSN and VN. The intermediate subnucleus is composed of a dorsal zone receiving VN input and a ventral zone receiving CE and BST afferents. The ventrolateral subnucleus contains medium and large-sized, darkly staining neurons and receives CE, BST, CSN and VN inputs. The medial subnucleus receives AN, CSN and VN afferents but is spared by CE and BST inputs. The interstitial subnucleus receives CSN and VN inputs. The lateral subnucleus and regions bordering the DVN and area postrema/IV ventricle receive CE and BST afferents. The commissural subnucleus receives minor projections from all these afferent sources. The parvocellular subnucleus receives VN input.

Additionally, regions of the NTS receiving forebrain inputs project to other cardioregulatory nuclei. For example, the dorsomedial, ventrolateral and ventral intermediate subnuclei project to the region of the intermediolateral cell column of the thoracic spinal cord. The ventral intermediate subnucleus, parts of the medial subnucleus and the NTS-DVN border region project to the BST. The NTS also projects to the vagal motor nuclei.

Forebrain inputs to regions of the NTS involved in cardiovascular regulation provide a substrate for early modulation of the baroreceptor reflex.

37.8 ULTRASTRUCTURAL LOCALIZATION OF SEROTONIN IMMUNOREACTIVITY WITHIN THE FELINE NUCLEUS TRACTUS SOLITARIUS. B. Maley and R. Elde. University of Minnesota Medical School, Minneapolis, MN 55455

In a previous account we have shown a differential distribution of serotonin (5-HT)-like immunoreactivity at the light microscopic level within various subdivisions of the cat nucleus tractus solitarius (NTS). The immunoreactivity in NTS appears as varicose fibers or punctate structures. Using a modification of the Sternberger peroxidase, anti-peroxidase (PAP) method we have identified 5-HT-like immunoreactivity at the ultrastructural level in the NTS.

Subsequent to perfusion of 4% paraformaldehyde-0.1% glutaraldehyde in 0.12M phosphate buffer, 100 µm coronal sections of the NTS were stained using rabbit anti-5-HT followed by the PAP procedure, reacted with 3-3'diaminobenzidine and hydrogen peroxide, osmicated, dehydrated and embedded in Spurr's resin. Absorption controls revealed the antiserum to be specific for 5-HT-like immunoreactivity. At the electron microscopic level the morphology of 5-HT-like immunoreactive varicosities was similar throughout all subdivisions of the NTS. Structures typically labeled within NTS measured less than 1 µm and contained a population of dense core vesicles and a variety of clear vesicles. The label was found to be distributed along the membranes of vesicles, mitochondria and the plasmalemma of the 5-HT varicosities. Although the labeled 5-HT varicosities were found to be distributed throughout the neuropil of the NTS, they were infrequently observed to be in synaptic contact with neuronal structures. When found in contact, 5-HT terminals were presynaptic to spines and dendrites of NTS neurons.

Results from this study indicate a distinctive morphology for 5-HT profiles in NTS. This sets them apart from substance P or methionine-enkephalin identified terminals which we have previously described for NTS. Furthermore the paucity of synaptic contacts involving 5-HT terminals suggests a modulator role for serotonin in NTS.

Supported in part by DA02148 and a Scholars Award in Neuroscience from the McKnight Foundation.

37.9 ULTRASTRUCTURAL LOCALIZATION OF MET-ENKEPHALIN, SEROTONIN AND SUBSTANCE P IN THE CAT INTERMEDIOLATERAL CELL COLUMN. V. Holets and R. Elde. Department of Anatomy, University of Minnesota Medical School, Minneapolis, MN. 55455

Met-enkephalin (ME), serotonin (5-HT) and substance P (SP) immunoreactive fibers are prominent in the intermediolateral cell column (IML) in the thoracic spinal cord of the cat, and are thought to play a role in the integration and control of the preganglionic sympathetic neurons. Using an immunohistochemical method to identify the ME, 5-HT and SP immunoreactive terminals in the IML of the cat at the electron microscopic level, the synaptic relationships of the three putative neurotransmitters with the IML neurons were investigated.

Pre-embedding staining for the localization of ME, 5-HT and SP immunoreactivity was accomplished using a modification of the Sternberger peroxidase, anti-peroxidase (PAP) technique. Adult cats were perfused with buffered 4% paraformaldehyde-0.1% glutaraldehyde, 100 µm transverse Vibratome sections of the thoracic spinal cord were cut, stained using rabbit anti-ME, -5-HT or -SP antisera, processed for the PAP procedure, osmicated, dehydrated and embedded in Spurr's resin. Specificity of staining was determined using antisera pretreated with the homologous antigens. The absorption controls indicated that the immunoreactivity observed was specific for each antisera.

ME and SP immunoreactive terminals have similar characteristics in IML. They measured 0.5-2 µm, and contained round clear vesicles (approximately 50 nm in diameter) and a few dense core vesicles. The ME and SP terminals were observed to make synaptic contacts with dendrites, dendritic spines and perikarya in IML. Reaction product was seen over the vesicles, as well as along the membranes of mitochondria and the plasmalemma of ME and SP positive boutons. The 5-HT immunoreactive terminals measured 0.2-1.5 µm, and contained large, dense core vesicles. They were found in apposition to IML neuronal elements, including cell bodies, dendrites and dendritic spines, but rarely formed synaptic contacts with these structures. The reaction product was observed over the vesicles and other cytoplasmic structures in the 5-HT positive terminals similar to that which was observed in the ME and SP terminals.

The presence of ME, 5-HT and SP immunoreactive terminals and synaptic contacts with IML neuronal elements suggests that these putative neurotransmitters may have a direct influence on the IML neurons in the cat thoracic spinal cord.

37.10

WITHDRAWN

37.11 ORGANIZATION OF CELLS GIVING RISE TO FIBRES TO THE STELLATE GANGLION IN THE CAT. S.B. Backman, J. Ciriello and J.L. Henry. Dept. of Physiology, McGill Univ., Montréal, Canada, H3G 1Y6.

While early anatomical and electrophysiological studies indicated that the cell bodies of sympathetic preganglionic neurones are located in the spinal intermediate grey region, recent HRP studies have demonstrated their organization to be more complex than previously thought. However, it remains controversial how far rostral these cell bodies extend and also what intraspinal path their axons follow before they exit from the cord. These controversies were approached in this study by using the retrograde transport of HRP combined with both a more sensitive method for the visualization of reaction product and longer survival times than previously used. Thirty µl of a 20-50 % solution of HRP in either distilled water or in 2% dimethylsulfoxide were injected into the right stellate ganglion. After survival periods of 45-120 hrs, 40 µm transverse, saggital or horizontal frozen sections were cut and processed according to the tetramethyl benzidine method of Mesulam (J. Histochem. Cytochem., 26:106-117, 1978). Labelled neurones were seen in segments C_7-T_8 predominantly ipsilateral to the site of injection in the main body of the lateral horn, the finger-like projections extending into the lateral funiculus, a thin band extending medially from the lateral horn and the region of the central canal. Additionally, a few labelled neurones were also observed ipsilaterally in the ventral horn of segments C_6-T_3 and others contralaterally near the central canal. Labelled neurones in the main body of the lateral horn of thoracic segments were in a single group whereas those in the cervical segments which appeared to belong to the main body were in 3 groups. In thoracic segments cells of the main body were spindle shaped and had their dendrites aligned primarily rostrocaudally whereas in cervical segments they were triangular and their dendrites were aligned mediolaterally. Cells medial to the main body were morphologically similar to those in the cervical segments. Dendrites of these medial cells extended laterally into the main body while others extended to either side of the central canal. The efferent path of most axons was along the lateral border of the ventral horn, some axons travelling first laterally through the dorsal part of the ventral horn to join the main bundle. With regard to the rostrocaudal paths of these axons, in experiments where the sympathetic chain was cut just caudal to the T_1 ramus, labelled neurones were observed to end abruptly at the caudal end of T_1 demonstrating that axons do not travel rostrally within the cord before their exit.

37.12 ASSOCIATION OF VASOACTIVE INTESTINAL POLYPEPTIDE-IMMUNOREACTIVE NERVE FIBERS WITH THE CARDIOVASCULAR SYSTEM OF GUINEA-PIGS. R.E. Papka*, N.G. Della*, J.B. Furness*, and M. Costa*. (SPON: J. Willoughby). Dept. Anat., Univ. KY, Lexington, KY 40536, Ctr. Neuroscience and Depts. Morph. and Physiol., Flinders Univ. of South Aust., Bedford Park, South Aust. 5042

Recent immunohistochemical studies have shown certain neuropeptides are widely distributed in the body. One of these, vasoactive intestinal polypeptide (VIP), can cause dilation of certain blood vessels. In spite of this fact there has not been a systematic study of the association of VIP-immunoreactive fibers with cardiovascular tissue. In the present work, the distribution of VIP-immunoreactive nerves was studied in the heart and blood vessels of guinea-pigs in whole mounts.

A double antibody labelling technique was used. Preparations were first exposed to antiserum raised in rabbit against authentic VIP, diluted 1:200. An FITC-conjugated sheep anti-rabbit antiserum at a 1:40 dilution was used as the second antiserum. The following tissues were examined: pericardium, atria, bicuspid valves, major arteries and veins and individual vascular beds, e.g. cerebral, uterine, mesenteric, renal and skeletal.

In the pericardium VIP-immunoreactive nerve fibers were quite sparse; individual, delicate varicose fibers were not necessarily associated with blood vessels. Immunoreactive fibers in the bicuspid valves formed a very fine plexus. In the atria such fibers were readily evident but did not form a definite plexus; the fibers were single or two fibers travelled together. Major elastic arteries had a sparse plexus of VIP-immunoreactive fibers which extended to the adventitia-media junction. The density of immunoreactive nerves varied in different regional vascular beds. Uterine arteries had a dense perivascular plexus of fibers (however, these fibers terminated 2.0-2.5mm proximal to the uterine wall). A substantial number of fibers were associated with cerebral vessels although they were fewer than those with the uterine arteries. A moderate perivascular plexus of fibers was present on the larger mesenteric vessels supplying the gut; however regional variation was noted in that the VIP-immunoreactive nerve fibers of arteries to the large bowel remained dense up to the gut wall whereas those around arteries supplying the small bowel progressively decreased in number until only a rare fiber was evident at the small bowel wall. Renal vessels and those in skeletal muscle (e.g. femoral artery) had only an occasional fiber associated with them. The present study was established that VIP-immunoreactive nerve fibers are widespread in the cardiovascular system and that there are marked differences in the density of innervation of different beds.

37.13 THE RETE MIRABILE: AN SEM/TEM STUDY. E. M. Burns, RSM, Ph. D., B. Braverman*†, M. D., T. W. Kruckeberg*, M. S., P. K. Gaetano*, A. S., G. D. Dobben*, M. D., and M. Shulman*†, M. D. Dept. of Nursing Science Laboratory, University of Illinois Medical Center, Chicago, IL 60612, and †Illinois Masonic Medical Center, Chicago, IL 60657.

In recent years the unanesthetized goat has been used as an experimental model for the study of cerebral circulation.

The flow of arterial blood to the goat brain is as follows: external carotid → internal maxillary → rete mirabile → internal carotid → circle of Willis → cerebral arteries. Ipsilateral cerebral blood flow can be measured after blocking all extracerebral branches of the internal maxillary artery, by an electromagnetic flow probe placed around the internal maxillary artery.

The rete mirabile consists of a subdural arterial network in the cavernous sinus. It is located intra-cranially on each side of the pituitary, within the sella turcica. The rete is thought to play an important role in cerebrovascular hemodynamics. Previous physiological, pharmacological and gross anatomic studies suggest that it is innervated via the sympathetic nervous system.

The purpose of this study was to investigate the fine structure of rete mirabile innervation.

By means of scanning electron microscopy (SEM) and transmission electron microscopy (TEM) we observed nerve tracts and neuro-effector junctions.

Nerve terminals contained numerous vesicles with electron dense cores approximately 86 nm in diameter as well as numerous spherical electron lucent vesicles approximately 53 nm in diameter. This evidence, although not conclusive, indicates the possibility of adrenergic innervation of the rete mirabile.

Technical assistance of I. Kairys and L. Vedegys, Dept. of Electron Microscopy, University of Illinois Medical Center, is gratefully acknowledged.

SYMPOSIUM

38 NEUROBIOLOGY OF DENDRITES. R. Llinás (Chairman; New York University Med. Ctr.), S. J. Redman* (Australian Natl. University), D. S. Faber (State University of New York at Buffalo), J.-P. Changeux* (Institut Pasteur).

This symposium concerns broad aspects of dendritic function and plasticity. It will cover the ionic basis for their electrical excitability, their role in neuronal integration, the electrophysiological modification which occurs in dendrites following axotomy, and dendritic growth and development in the central nervous system. In particular, electrophysiological properties of mammalian central neurons will be covered by Dr. Llinás. Emphasis on dendritic excitability and the ionic mechanisms involved in neuronal oscillation will be considered. Studies presented will relate to electrical activity in cerebellar, inferior olivary, and hippocampal neurons, with special reference to voltage-dependent calcium conductances and to the calcium-dependent potassium conductance which forms the basis for the dendritic spiking in these cells. Dr. Redman's topic will be concerned with the role of synaptic axo-dendritic input in neuronal integration, taking as a model his recent work on distribution of Ia terminals on mammalian alpha motoneurons. His research has dealt quite specifically with the correlation between the morphology of Ia inputs and the electrophysiological properties of the synaptic potentials evoked by these terminals. Dr. Faber will present results that elucidate some aspects of the regulatory mechanisms which follow Mauthner cell axotomy. The electrophysiological properties of Mauthner cell soma and dendritic membranes will be described in the context of three basic issues: (1) regulation and distribution of voltage-sensitive and transmitter-sensitive membranes, (2) the topographic localization of different afferent fibers to specific regions of the target neuron, and (3) interactions of discrete postsynaptic potentials. Dr. Changeux will consider the question of synaptically mediated depolarization of the dendritic processes in mammalian neurons. The topic will relate to those aspects of embryogenesis which may be important in stabilizing certain synaptic inputs and in allowing others to be selectively removed. In particular, the question of multiple innervation of climbing fibers on Purkinje cells during ontogeny and their reduction to a single terminal in the adult animal will be considered as one of the models in which selective stabilization is discussed.

40.1 MONOCLONAL ANTIBODIES LABEL SUBSETS OF AXONS IN THE CNS OF THE LEECH. S. Hockfield, B. Zipser and R. McKay*. Cold Spring Harbor Laboratory, Cold Spring Harbor, N.Y. 11724.

Monoclonal antibodies (mABs) have been generated against the CNS of the leech, Haemopis marmorata. Several of the mABs recognize subsets of neuronal cell bodies, axonal processes and axonal endings within the leech CNS. Each ganglion in the leech nerve cord is joined to the next by a large bundle of axons (the connective). While a segmental ganglion contains about 400 neurons, the connective between each neighboring pair of ganglia contains over 5,000 axons. This study examines the organization of axons in the connective using mABs.

mABs were generated by immunizing mice with homogenized leech CNS, fusing the mouse spleen cells with mouse myeloma cells and growing the resultant cell lines as monoclonal cultures. mAB binding to leech CNS was demonstrated immunocytochemically. Connectives were embedded in gelatin, sectioned (in cross section) and processed for immunocytochemistry. Sequential serial sections were treated with different mABs and either observed at the light level or further processed for electron microscopy.

Each of the mABs used in this study recognizes subsets of neuronal cell bodies in the leech CNS. Each also recognizes subsets of axons within the connective. Comparisons between adjacent sections processed with different mABs show that each mAB labels different subsets of axons. The connective is composed of two large lateral connectives and one smaller medial connective. Lan 3-9, a mAB that labels 10 neurons in the supraesophageal ganglion, labels large diameter axons in the medial connective throughout the length of the leech nerve cord. Lan 3-2, a mAB that labels the four nociceptive neurons in each segmental ganglion, labels several bundles of very small diameter axons in the ventro-lateral part of each lateral connective. Lan 3-6, a mAB that labels the pressure neurons and some small unidentified (as yet) neurons, labels a few bundles of axons in the medio-lateral part of each lateral connective with diameters slightly larger than those labeled by Lan 3-2. These positions and axonal diameters are essentially maintained throughout the entire nerve cord and are consistent between leeches.

These results demonstrate the usefulness of monoclonal antibodies for studying the leech CNS. Axons with stereotypical positions and morphology can be identified in the connective of the leech, much like neurons can be identified in each ganglion. The leech CNS, like the vertebrate CNS, contains consistently identifiable fiber tracts that may subserve specific functions.

40.2 MONOCLONAL ANTIBODIES AGAINST THE DROSOPHILA NERVOUS SYSTEM. S.C. Fujita‡ A. Ferrus‡ S.L. Shotwell‡ and S. Benzer‡(SPON: J.M. Nerbonne). Div. of Biology, California Institute of Technology, Pasadena, CA. 91125

Monoclonal antibodies against neural tissues have revealed extraordinary specificity (e.g.Zipser and McKay, Nature, 289, 549 (1981)). To apply this powerful technique to Drosophila, where genetic manipulation is feasible, we have established hybridoma lines that produce monoclonal antibodies binding to fly neural tissues.

Mice were immunized by injecting homogenates of brains cleanly dissected from freeze-dried flies. Standard technique was used for fusion with NS-1 cells. Culture supernatants were screened by indirect immunofluorescence on unfixed, frozen sections of fly heads.

Of 177 microtiterwells tested, 81 were positive for staining in some tissue in fly head sections. 61 stained the brain. Among the latter, 20 stained only the brain, while others stained also some other tissues (retina, muscle, hypoderm, etc.). 30 independent hybridoma lines were established by limiting dilution cloning. We describe here 4 examples of lines producing antibodies that bind to the central nervous system.

Antibody B7 intensely stains nerve fibers in the brain and thoracic ganglion, and all their major nerves such as the antennal and leg nerves. Fine fibers running between muscle cells, such as indirect flight muscle and proboscis muscle, are visualized. This antibody apparently stains axons only.

Antibody D10 gives intense and rather homogeneous staining in most neuropil regions of the brain and thoracic ganglion. In the lamina only a single layer of cell bodies stain. Weak staining occurs in the walls of the ventriculus and intestine; this may be associated with nerves innervating the intestinal muscles.

Antibody 2A1C stains the brain and thoracic ganglion to varying degrees in different regions. In general, the neuropil just beneath the cortex stains most. Major nerves stain less intensely, and weakly-staining fibers can also be seen in the retina, between muscles, and in the walls of the gut.

Antibody D12A gives fairly strong staining of fibers in the entire brain and thoracic ganglion, with regional variations of intensity. It also stains the major nerves with some fibers standing out brightly. Fine fibers are also seen between muscles.

An extensive set of such antibodies can be expected to be useful in studying development of the nervous system and in defining the anatomical and molecular defects in neurological mutants. (Supported by NSF grant PCM-7911771).

40.3 CELL-SURFACE SPECIFIC MONOCLONAL ANTIBODIES TO CHICK CILIARY GANGLION NEURONS. K.F. Barald. Neuroscience Program, Anatomy Dept. University of Michigan Medical School, Ann Arbor, Michigan 48109.

The ciliary ganglion of the embryonic chick is a parasympathetic ganglion of neural crest origin that contains two populations of neuronal cells both of which are cholinergic (CG neurons).

Monoclonal antibodies to these cells were produced by injecting individual mice with 1.2×10^6 cultured ciliary ganglion neurons. After 2 subsequent boosts with the same number of neurons, isolated spleen cells were grown for 4 days in the presence of a lawn of ciliary ganglion neurons and two mitogens, dextran sulfate and lipopolysaccharide (25 and 10 µg/ml respectively).

Hybridomas isolated after fusion of the spleen cells with an NS-1 parent myeloma line and subsequent cloning, produced monoclonal antibodies directed against ciliary ganglion neuronal cell surface. Two of the clones, designated CG-1 and CG-4 produce antibodies to ciliary but not surface or internal components of seven other neuronal populations from the embryonic chick or quail. These include spinal cord neurons (SC) and other parasympathetic neurons of neural crest origin. Neither antibody reacts with cell surface or cytoplasmic components of a variety of non-neuronal cells tested including skeletal muscle myotubes and myoblasts, or cultures of heart, liver, or "fibroblasts". Neither reacts with brain.

Another hybridoma clone, CG-5, produces antibodies that react with all neuronal cells but not non-neuronal cells tested. Antibody made by a fourth clone, CG-2 can be used to identify a small population of spinal cord neurons in addition to CG neurons.

The antibody made by clone CG-1 detects an antigen expressed in vitro by a small fraction ($\leq$5%) of cultured cranial neural crest cells from the embryonic chick isolated 31 hrs. after fertilization. The CG-1 antibody is cytotoxic for the crest cells it labels, as well as for the majority (>95%) of cultured ciliary ganglion neurons from embryos 8 days in ovo in the presence of complement and small amounts of antibody CG-4. In contrast, none of the cells from the trunk neural crest tested in vitro bound detectable amounts of either antibody. Neither antibody alone or in combination was cytotoxic for these cells in the presence or absence of complement.

Antibody CG-1 binds to chick ciliary ganglion neuronal cell bodies and neurites at all times tested in cell cultures isolated from embryos 7-18 days in ovo. None of the other neuronal or non-neuronal cells tested, with the exception of the ciliary ganglion neurons from embryonic quail, expressed the antigens at any time. This suggests that the neural crest contains a population of cells that can be distinguished early in development by its cell surface components.

40.4 MONOCLONAL ANTIBODIES AGAINST TORPEDO SYNAPTOSOMES. P.D. Kushner and L.F. Reichardt. Department of Physiology, University of California, San Francisco, San Francisco, CA 94143.

In order to gain a more thorough molecular understanding of synapses, their architecture, function and development, we have generated a library of monoclonal antibodies against the cholinergic synaptosome of the Torpedo ray electric organ. This organ, massively innervated by cholinergic terminals, is the purest source of synaptosomes of one transmitter type. Synaptosomes were prepared using standard isolation techniques modified to insure as pure a presynaptic fraction as possible (Hooper, Deutsch and Kelly, in prep.). Balb/C mice were immunized on days 1 and 22 IP with 50 ug protein and on day 59 IV with 20 ug protein. Fusion with NS1 cells and hybridoma selection with HAT medium were standard.

From one fusion 192 cell lines tested positive for binding to the highly purified synaptosomes, using the standard plate assay and an iodinated anti-kappa probe. Of these lines, 130 were cloned. Specificity tests, again using the plate assay, were performed in collaboration with R. Kelly. Homogenates of elasmobranch whole brain, electromotor nucleus, purified vesicles, and liver, revealed that most of the antibodies were nervous system specific: fewer than 10% bound liver and of these less than 5% cross reacted strongly with liver. Results indicated several different classes of antibodies, those binding only synaptosome and those binding other tissues in addition, for instance, vesicles, electromotor nucleus, etc.

Immunocytochemistry confirmed that most of the antibodies bound the innervated face of the electric organ. Likewise different binding patterns along this inenrvated face indicated different classes of antibodies.

With immunocytochemistry we have looked at the binding patterns of members of the library on a variety of frog and rat tissues, both central and peripheral to identify possible localization to synapses or cholinergic neurons. At the neuromuscular junction of the frog we see a variety of staining patterns. Some antibodies appear to be directed against a determinant within the terminal, others to a determinant in the muscle, others to both. The frog sympathetic ganglion with its well-defined regions of axosomatic synaptic contacts has been particularly useful in revealing interesting antibodies. Many of the antibodies cross react with the rat CNS and reveal distinctive patterns. For instance, there is a class of antibodies which stain the perimeters of the neurons of the dentate nucleus quite strongly.

We are currently identifying the antigens and specificities defined by the more interesting clones.

40.5 IMMUNOCYTOCHEMICAL LOCALIZATION OF CYTOPLASMIC ACTIN TO POST-SYNAPTIC STRUCTURES AT THE NEUROMUSCULAR JUNCTION (NMJ). Beverly W. Lubit, James H. Schwartz, and Zach W. Hall, Center for Neurobiol. and Behav., Columbia University, New York, NY 10032 and Div. of Neurosciences, Dept. of Physiol., Univ. of California, San Francisco, CA 94143.

Actins are ubiquitous, highly conserved proteins that fall into two classes: muscle actins and nonmuscle or cytoplasmic actins. Because actin is highly conserved, most antibodies to it cross-react extensively with all actins. However, an antibody to actin has been raised that has an unusual specificity: this antiactin recognizes cytoplasmic vertebrate actin but not skeletal muscle actin (1). It is therefore an ideal probe for studying the distribution of cytoplasmic actin in skeletal muscle. Previous immunocytochemical studies of human skeletal muscle showed that cytoplasmic actin is present and associated with membranes. Now we have investigated whether cytoplasmic actin is concentrated at or near the postsynaptic surface of the NMJ. Unfixed cryostat sections of rat diaphragm muscle were stained with rhodamine-labeled α-bungarotoxin to identify the endplate region and with purified antiactin which was subsequently detected with fluorescein-labeled second antibody. We have found that cytoplasmic actin or an actin-like molecule is concentrated at NMJs of normal and denervated adult rat muscle fibers. Its distribution corresponds exactly to the distribution of the acetylcholine receptors (AChRs). The high concentration of cytoplasmic actin in postsynaptic structures at the neuromuscular junction could be related to the clustering or anchoring of receptors. It could also serve to maintain the elaborately folded structure of the postsynaptic membrane. A thin layer of electron dense material has been described attached to the cytoplasmic face of the membrane and the underlying cytoplasm contains filaments which are thus far unidentified. To explore these possibilities, we studied diaphragm muscle at embryonic day 18, after receptors have clustered but before extensive folding of the postsynaptic membrane occurs, and at postnatal days 6 and 12, during the time that folds develop. We found cytoplasmic actin at all three developmental stages; its distribution in each case coincided with the distribution of the AChRs although the staining pattern at endplates became more complex with development. Thus the association of receptors with cytoplasmic actin exists prior to the development of the junctional folds. These results suggest that cytoplasmic actin may somehow stabilize AChRs in the postsynaptic membrane of the NMJ. Supported by grants from NIH, NSF and MDA.

40.6 MONOCLONAL ANTIBODIES WHICH RECOGNISE MEMBRANE GLYCOPROTEINS OF RAT NEURONAL CELL TYPES. C. J. Barnstable. Dept. of Neurobiology, Harvard Medical School, Boston MA 02115.

Monoclonal antibodies have been prepared against a slycoprotein fraction from rat cerebral cortex. A crude membrane fraction was dissolved in 2% sodium deoxycholate. Glycoproteins were isolated from the 6,000,000 g-min supernatant by affinity chromatography on a column of Lens culinaris (lentil) lectin-Sepharose 4B. BALB/c mice were immunised with this material and monoclonal antibodies produced by fusion of spleen cells with P3-NSI/1-Ag4-1 plasmacytoma cells.

The cell types recognised by the various antibodies have been investigated by immunocytochemical localisation at the light microscopic level. The biochemical identification of the antigens has been carried out by immunohistochemical labelling of glycoproteins separated by polyacrylamide gel electrophoresis and transferred onto nitrocellulose filters. The reactivity of the antibodies with cells in monolayer cultures set up from embryonic rat cortices will be presented and compared with the developmental expression of the antigens in vivo.

One antibody has been found that, in retina, specifically reacts with most of the cells in the ganglion cell layer. The identity of the retina cells has been studied by double-labelling experiments. Ganglion cells that project to the superior colliculus were labelled by retrograde transport of either granular blue or lucifer yellow-labelled wheat germ agglutinin. The fluorescing cells were compared with those labelled by antibody and were shown to form almost completely overlapping populations. Other experiments are in progress to determine whether the unlabelled cells represent displaced amacrine cells or ganglion cells that project exclusively to other brain regions.

Antibody 2G12 also reacts with living ganglion cells that have been dissociated from young retinas by digestion with proteolytic enzymes. Analysis of these dissociated cell preparations using a fluorescence activated cell sorter has been carried out and the use of this and other separation techniques compared for their ability to provide pure bulk preparations of ganglion cells. The results clearly show that antibody 2G12 represents a class of antibodies that can be used to isolate specific neuronal cell populations for a wide variety of chemical, pharmacological and physiological studies.

40.7 MONOCLONAL ANTIBODIES AGAINST CHOLINE ACETYLTRANSFERASE (ChAT): INTRASPECIES AND INTERSPECIES REACTIVITIES. Allan I. Levey* and Bruce H. Wainer. University of Chicago, Pritzker School of Medicine, Chicago, IL 60637.

Monospecific antibodies to choline acetyltransferase (ChAT), an enzyme specific to cholinergic neurons, should be useful for immunohistochemistry, purification of ChAT, and as molecular probes for studying the enzyme. We recently reported (Levey, A.I., Aoki, M., Fitch, F.W., and Wainer, B.H., Fed. Proc. 40: 270, 1981; Brain Res., in press.) use of the hybridoma technique to develop monoclonal antibodies to bovine ChAT. Immune Lewis rat spleen cells fused with the mouse myeloma cell line SP2/0 resulted in the production of two stable hybrid cell lines secreting monoclonal IgG2a antibodies reactive with bovine ChAT. We now report intraspecies and interspecies anti-ChAT reactivities of rat monoclonal antibodies secreted by the stable hybridoma cell line AB1. Antibody reactivity was measured by immunoprecipitation of enzyme in a double antibody assay. The amount of enzyme bound to antibody was calculated from measurements of enzyme activity remaining in the supernatants. Monoclonal antibody AB1 reacted equally well with crude soluble ChAT from bovine caudate nuclei and spinal cord, and with the two types of bovine caudate ChAT activity (Bov I and Bov II) resolved on CM-Sephadex ion exchange chromatography. Using bovine ChAT as a reference (100%), the following percent cross-reactivities were observed with ChAT obtained from each of the following species: Human, 69%; Ovine, 38%; Cat, 74%; Guinea pig, 84%; Mouse, 30%; and Rat, 0%. The effect of binding of monoclonal antibody AB1 in solution on enzyme activity was also measured. Aliquots of ChAT were incubated overnight in the presence of either AB1 or normal rat serum. The percent inhibitions observed were: Bovine, 0%; Human, 64%; Ovine, 0%; Cat, 22%; Guinea pig, 47%; Mouse, 38%; and Rat, 0%. The rank ordering of binding of AB1 to enzyme molecules from different species did not correlate directly with the rank ordering of the capacity to inactivate enzyme activity. These results can be used to operationally define two markers (binding vs. inactivation) which reflect interspecies differences in ChAT. The applicability of monoclonal antibody AB1 for immunohistochemical identification of cholinergic neurons in the appropriate species is presently being evaluated. 40.8 IMMUNOCYTOCHEMICAL LOCALIZATION OF RAT CHOLINERGIC NEURONS USING A RADIOLABELED MONOCLONAL ANTIBODY TO CHOLINE ACETYLTRANSFERASE. M. E. Ross, D.H. Park, G.N. Teitelman, D.J. Reis and T.H. Joh. Lab of Neurobiology, Cornell Univ. Med. Coll. New York, NY 10021.

We sought to develop a specific and sensitive method for immunocytochemical localization of choline acetyltransferase (CAT). We have produced radiolabelled monoclonal antibodies (Abs) to CAT in order to take advantage of their purity and specificity.

CAT was highly purified from rat striata (Park et al. Neurosci. Abs. 1981) and monoclonal Abs to CAT were produced by the similar manner as described elsewhere (Ross et al. Brain Res. 208: 431, 1981). Mouse lymphocytes, sensitized to CAT, were fused with murine plasmacytoma (NS1) cells. Four percent of hybridomas secreted CAT antibody, detected by an enzyme linked immunosorbant assay (ELISA). Hybridomas (CMCAT) were cloned by limiting dilution. The specificity of the Abs were established by the following criteria: (1) the Abs reacted on an ELISA with pure CAT as the antigen, but not with other proteins separated out during purification of the enzyme; (2) on immunoelectrophoresis, they produced a single precipitin arc against crude striatal homogenate; (3) using rabbit antimouse IgG, Abs precipitated CAT activity in vitro.

All monoclonal Abs, however, failed to localize CAT staining cells by the PAP technique. Therefore, a ^{3}H-labeled Ab was used for immohistochemical localization. A clonal line (CMCAT-11) Ab was radiolabeled in situ by culturing the hybridoma cells for 24 hours in media containing a mixture of ^{3}H labeled amino acids. Using the Ab, moderate to large size perikarya, dendrites and terminals were specifically labeled in characteristic cholinergic structures in both the fetal and adult rats. These included diaphragmatic neuromuscular junctions, anterior horn cells of spinal cord, and neurons of hypoglossal nucleus, pontine and medullary reticular formation and cerebral cortex. Thus, radiolabelled monoclonal autibodies to CAT were useful for the highly specific localization of cholinergic neurons in both PNS and CNS of rat.

Thus, cholinergic neurons in rat can be immunocytochemically localized with a high degree of specificity by use of a raido-labeled monoclonal antibody. Since this antibody can be used along with an indirect (e.g. PAP) method, it should provide a useful method for identification of two antigens in the same section.

40.9 DISTRIBUTION OF GLUTAMATE DECARBOXYLASE POSITIVE NEURONS IN THE RAT CEREBELLAR NUCLEI. E. Mugnaini and W. Oertel, Dept. of Biobehavioral Sciences, U.Conn., Storrs, CT 06268 and Lab. Clinical Sciences, NIMH, Bethesda, MD 20205

In addition to excitatory projection neurons, the cerebellar nuclei of the rat are thought to contain few short-axon neurons. Small neurons that take up exogenous ^{3}H-GABA (Chan-Palay, Cerebellar Dentate Nucleus, Springer, Berlin, 1977) may correspond to the local circuit neurons, which are seen after Golgi impregnation. In a recent immunocytochemical study using an antiserum to rat brain glutamic acid decarboxylase (GAD) and the unlabeled antibody enzyme method of Sternberger, we observed weakly GAD-immunoreactive small cells in the rat cerebellar nuclei. These data suggest the presence of a small population of GABAergic neurons in the rat cerebellar nuclei. In the present study on the rat, we analyzed the distribution of GAD-immunoreactive neurons in the four cerebellar nuclei using the same antiserum after colchicine treatment. Colchicine blocks axoplasmic transport of GAD and enhances somatal immunoreactivity (Ribak et al., Brain Res. 140:315-332, 1978). The animals were perfused, under sodium pentobarbital anesthesia, with a buffered aldehyde solution; Vibratome sections (25 μm) of the cerebellum were processed for GAD-immunohistochemistry as described elsewhere (Oertel et al., Neuroscience, in press). After topical application of colchicine (10-30 μg) stronger specific immunoreactivity was observed than after intraventricular injection (150-250 μg colchicine). With either procedure few GAD-immunoreactive neurons were found in the nucleus medialis, but an unexpectedly dense population of GAD-immunoreactive neurons appeared in the nucleus interpositus anterior and posterior and in the nucleus lateralis. In the latter, GAD-immunoreactive neurons predominated at the hilus. The dorsal part of the lateral vestibular nucleus contained scattered, small GAD-positive cells - a pattern, resembling that of the cerebellar medial nucleus. Preliminary studies indicate that a similar distribution of GAD-positive neurons is present in the cerebellar nuclei of the cat.

Thus, small neurons which are able to synthesize GABA and are presumably inhibitory, are unequally distributed in the four cerebellar nuclei and abound in the nuclei interpositus and lateralis. The possibility that some of the GAD-immunoreactive neurons are projection neurons will be discussed.

40.10 PENTAPEPTIDE PROCTOLIN (H-ARG-TYR-LEU-PRO-THR-OH): IMMUNOLOGICAL DETECTION AND NEURONAL LOCALIZATION. C.A. Bishop and M. O'Shea. Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637.

Proctolin (H-Arg-Tyr-Leu-Pro-Thr-OH) is a highly bioactive peptide and may be a neurotransmitter or neuromodulator. We have produced several proctolin antisera and applied them to detecting and localizing proctolin-like immunoreactivity (PLI) in the CNS of the cockroach, locust and other animals. Radioimmunoassay (RIA), capable of detecting 50 fmoles proctolin, was used to quantify PLI distribution. Immunocytochemistry (peroxidase-antiperoxidase or PAP technique) was used to determine the cellular localization of PLI in sectioned (6μm) and whole ganglia.

Results show that PLI is exclusively localized to neurons and moreover that the distributions of PLI as determined by RIA and immunocytochemistry are positively correlated. For example, in the cockroach, concentrations of PLI are highest in the genital ganglia (~0.8 pmoles/mg) and lowest in the cerebral ganglia (<0.05 pmoles/mg). The genital ganglia contains approximately 80 immunoreactive cell bodies and a widespread and dense distribution of arborizations and varicosities, but the cerebral ganglion contains less than ten immunoreactive cells and few varicosities.

We will describe the anatomy of the major components of the putative proctolin system in the cockroach and locust. Immunoreactive cell bodies, for example, are found in symmetrical pairs on the lateral margins in the cockroach abdominal ganglia. The lateral cell bodies appear either singly or in small clusters of 3-5 cells. An anterior lateral cluster consistently stains with the PAP technique and has contralaterally projecting immunoreactive axons. Immunoreactive cell bodies are also found close to the midline on the dorsal and ventral surfaces. Immunoreactive varicosities are distributed primarily in the dorsal neuropile and many of the neurons appear to have axons projecting to peripheral nerve roots and to other ganglia. A significant finding is that individual cell bodies occur in constant position from animal to animal. They are, therefore, potential subjects for an "identified neuron" approach to the function of a neuropeptide.

Results of a current developmental analysis of selected immunoreactive neurons and of a survey of invertebrate and vertebrate phyla for the presence of PLI will be reported.

41.1 EFFECTS OF LITHIUM ON MOTONEURONS, SYNAPTIC POTENTIALS, AND EXTRACELLULAR POTASSIUM IN THE ISOLATED FROG SPINAL CORD.
G. ten Bruggencate, P. Grafe*, M.M. Reddy* and J. Rimpel*
Department of Physiology, University of Munich, Pettenkoferstraße 12, 8000 München 2, F.R.G.

The mechanism of the therapeutic action of Lithium (Li) is still unclear. In order to obtain more information on the actions of Li upon neuronal excitability and ion concentrations, we carried out experiments in the isolated circumfused frog spinal cord using conventional intracellular recordings from motoneurons (MN) and both intra- and extracellular recordings with ion selective microelectrodes (ISMEs). The preparation is useful as it allows controlled variations of ion concentrations through the bath.

Application of LiCl in the bathing solution for 30-60 min (up to 15 mmol/l, 22°C) reduced the amplitude of polysynaptic postsynaptic potentials (poly- PSPs) evoked by dorsal root (DR) single shock stimulation (up to 30%). The effect was accompanied by an increase in spontaneous synaptic activity and an elevation of the extracellular potassium (K_e) with a maximum in deeper dorsal horn layers (upto 0.5 mmol/l). The elevation of K_e also occured in the presence of TTX (3 µmol/l), indicating that it was not the result of the enhanced spontaneous activity. The membrane potential of MN was only slightly depolarized by LiCl (upto 3 mV). Experiments with Li-ISMEs demonstrated that at a depth of 400 µm (= MN pool) steady state concentrations of Li_e were reached at about 60 min, and of Li_i between 60 and 120 min. The intracellular/extracellular concentration ratio in MN was 0.5-0.8.

In a further series of experiments, we tested the action of Li upon an acute load of the Na^+-K^+-pump evoked by repetitive activation of synaptic input. During repetitive stimulation of DR (10/s, 10s) MN depolarized and K_e rose. After the stimulation, a membrane hyperpolarization appeared while K_e was still elevated. This hyperpolarization seems to reflect the action of an electrogenic Na^+-K^+-pump. Single shocks to DR during this period induced poly-PSPs with a clearly increased amplitude. LiCl (15 mmol/l) as well as ouabain (10 µmol/l) reduced or abolished both the posttetanic membrane hyperpolarization and the posttetanic facilitation of poly-PSPs.

The results agree with an interaction of Li with the neuronal Na^+-K^+-pump in frog spinal MN, and additionally demonstrate consequences of this effect upon synaptic potentials. Although the blockade of posttetanic facilitation of poly-PSPs may be relevant to the clinical action of Li, it has still to be shown that corresponding effects occur at therapeutic concentrations in man.

41.2 NA^+/K^+ TRANSPORT IN RAT CEREBRAL CORTICAL SLICES: EFFECT OF ADRENERGIC AGENTS. P.H. Wu* and J.W. Phillis. Department of Physiology, College of Medicine, University of Saskatchewan, Saskatoon, Saskatchewan Canada S7N OWO

Norepinephrine hyperpolarizes central neurons. This hyperpolarization can be blocked by various adrenergic receptor antagonists and inhibitors of (Na^+,K^+)ATPase. A receptor-mediated activation of a membrane sodium pump has therefore been proposed as the basic mechanism by which norepinephrine exerts its central action. To gain further support for this hypothesis, the effect of norepinephrine on ion fluxes in brain slices was investigated.

Brain slices (0.35 mm thick) prepared by a McIlwain tissue chopper were incubated with ^{22}Na (2µCi/ml) for 30 min at 37°C in 5 ml Krebs improved Ringer 1 solution. After loading, the slices were rapidly rinsed in non-radioactive incubation solution. Subsequent efflux of ^{22}Na was monitored by transferring the slices at 5 minute intervals through a series of tubes containing non-radioactive incubation solution in the presence or absence of test drugs. Potassium uptake into brain cortical slices was carried out by incubating tissue with ^{42}K (0.2-2µCi/ml) and KCl to a final concentration of 5 mM for a period of 10 min at 37°C. After incubation and rinsing, the slices were dissolved and radioactivities were measured.

Norepinephrine (10^{-7}-10^{-5}M) increases the efflux of ^{22}Na from brain slices in a dose dependent fashion ($0.01>p$). ^{22}Na efflux and norepinephrine evoked ^{22}Na efflux were inhibited by ouabain (10^{-3}M). Phentolamine or propranolol partially but significantly *blocked norepinephrine evoked ^{22}Na efflux ($0.01>p>0.001$).* Norepinephrine enhancement of ^{42}K influx into rat brain slices was also a dose dependent response ($0.05>p>0.01$). Ouabain inhibited the rate of ^{42}K entry both in the presence and absence of norepinephrine. Propranolol and phentolamine effectively antagonized norepinephrine stimulated ^{42}K influx into brain slices. Norepinephrine did not alter the rates of influx and efflux of ^{22}Na and ^{42}K respectively. Various adrenergic agonists, including oxymetazoline, naphazoline, clonidine, tramazoline, methoxamine, phenylephrine, L-isoproterenol and methoxyphenamine were potent stimulants of ^{22}Na efflux from rat brain cortical slices. This facilitation of ^{22}Na efflux from brain slices by norepinephrine is stereospecific as demonstrated by the very weak effect of D-norepinephrine on ion fluxes. Our results are consistent with the hypothesis that norepinephrine hyperpolarizes central neurons by activating an ouabain sensitive, receptor-mediated, sodium pump. Supported by the Canadian Medical Research Council.

41.3 EFFECTS OF CATECHOLAMINES ON PRINCIPAL GANGLIONIC CELLS IN THE GUINEA-PIG INFERIOR MESENTERIC GANGLION. Stuart E. Dryer* and David L. Kreulen, Department of Pharmacology, University of Arizona, Tucson, AZ 85724.

Catecholamines have been shown to alter synaptic transmission in sympathetic and parasympathetic ganglia. The following experiments were performed to elucidate effects of catecholamines on the inferior mesenteric ganglion of the guinea-pig. Intracellular recordings were made from guinea-pig inferior mesenteric ganglion (IMG) in vitro. Synaptic potentials were evoked by stimulation of lumbar colonic, lumbar splanchnic, hypogastric and intermesenteric nerves with bipolar platinum electrodes. In 63% of cells tested superfusion with 10^{-6} M norepinephrine (NE) produced a 5-10 mV hyperpolarization that was slow in onset, reaching a maximum in about two minutes. This effect was not associated with a change in input resistance. In 12% of the cells tested there was a 5-8% mV depolarization with no change in input resistance. In 25% of cells tested 10^{-6} M NE resulted in no change in membrane potential or input resistance. In all cells tested dopamine (DA) 10^{-6} M or apomorphine 10^{-5} M produced no change in membrane potential or input resistance. These same cells did not respond to 10^{-6} M NE. These results suggest that NE modulates synaptic transmission in the guinea pig IMG.

41.4 DIAZEPAM AND (-)PENTOBARBITAL POTENTIATE INHIBITORY RESPONSES TO GABA IN CULTURED MOUSE SPINAL NEURONS BY CHANGING CHANNEL KINETICS. R.E. Study* and J.L. Barker, (Spon: J.D. Newman). Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, Md. 20205

Voltage clamp recordings from mouse spinal neurons grown in culture were used to study the mechanism by which diazepam (DZ) and (-)pentobarbital (PB) potentiate inhibitory responses to the amino acid neurotransmitter γ-aminobutyric acid (GABA). Fluctuation analysis and micropatch recording techniques have shown that the membrane mechanism underlying the inhibitory response to GABA in these cells involves the activation of two-state Cl^- ion channels (Nature 274 (1978) 596; Biophys.J. 33 (1981) 14a). Clinically relevant concentrations of both drugs (1-15µM DZ and 50-200 µM PB) were applied by passive diffusion or low levels of pressure (< 1 lb/in.^{2}). GABA was applied by iontophoresis. Standard fluctuation analysis methods were applied to potentiated GABA responses to estimate the electrical properties of the elementary ion channels underlying the responses. Current responses (ΔI) were associated with an increase in current variance (σ^2). σ^2 was directly proportional to ΔI with GABA alone and during potentiation by the drugs. The ratio $\sigma^2/\Delta I$, which allows estimation of the amplitude of an elementary current event, i, did not change during potentiation. Since neither drug changed the reversal potential of the inhibitory response to GABA, the results suggest that the conductance of the Cl^- ion channels is not altered by the drugs. Spectral analysis of current variance revealed that most power spectral density plots were well fit by a single Lorentzian equation, consistent with a model in which the variance reflects the activity of a population of ion channels whose durations are exponentially distributed with a mean duration, τ. τ was calculated from $\tau = 1/2\pi f_c$, where f_c is the half-power frequency of the spectrum. τ remained constant for responses to GABA alone. τ was either unchanged or increased slightly in responses potentiated by DZ, while it was consistently and markedly increased in a dose-dependent manner during potentiation by PB. However, the drug-induced changes in τ could not alone account for the augmentation. By taking into account the frequency of channel openings ν, which can be calculated from $\nu = \sigma^2/[i^2\tau]$, we have been able to account quantitatively for the potentiation. DZ increased ν while PB almost always decreased ν. Our results indicate, therefore, that DZ and PB potentiate GABA responses by changing channel kinetics rather than conductance, and they do so in different ways.

41.5 FLUCTUATION ANALYSIS CF DIRECT INHIBITORY EFFECTS OF DIAZEPAM AND (-)PENTOBARBITAL CN THE EXCITABILITY OF CULTURED MOUSE SPINAL NEURONS. J.L. Barker and R.E. Study* (Spon: J.H. Neale). Lab. Neurophysiology, NINCDS, NIH, Bethesda, Md. 20205

Intracellular recording methods were used to study the direct, inhibitory effects of the benzodiazepine diazepam (DZ) and the barbiturate (-)pentobarbital (PB) on the excitability of mouse spinal neurons growing in tissue culture. The drugs were applied by passive diffusion or by low levels of pressure (<1 lb./in^2) from blunt micropipettes containing known drug concentrations dissolved in the bathing medium. At clinically relevant concentrations (1-15μM DZ and 50-200μM PB) both drugs increased Cl^- ion conductance in some cultured neurons (8 of 65 cells studied with DZ and 10 of 33 cells studied with PB). In contrast, 10-50μM γ-aminobutyric acid (GABA) increased Cl^- ion conductance in every cell studied. The two-electrode voltage clamp technique using microelectrodes filled with 3M KCl was employed to study the membrane current responses evoked by the drugs. With the cell clamped to holding potentials over the range -50 to-90mV both drugs and GABA evoked inward current responses in a dose-dependent manner. The inward current responses were each associated with an increase in current variance. The drug responses and their associated variance were analyzed mathematically using a model which assumes that the macroscopic responses reflect the random variation in the number of open two-state Cl^- ion channels, as has been demonstrated for GABA responses in these cells (Nature 274 (1978) 596; Biophys. J. 33 (1981) 14a). Power spectral density plots of current variance were often well-fit by a single Lorentzian term of the form $S(f)/S(0) = 1/[1 + (f/fc)^2]$ where f is the frequency, S(f) is the spectral density at frequency f, S(0) is the zero frequency asymptote of the spectrum, and f_c is the corner, or half-power frequency. Such spectral behavior would be expected if the durations of the putative ion chanrel events activated by the drugs were exponentially distributed about a mean, τ and τ was inversely related to fc ($\tau = 1/2\pi fc$). τ s for DZ events were similar or slightly longer than τs estimated for GABA-activated channels on the same cells while τ s for PB were significantly longer than those estimated for GABA. Estimates of the average conductance of ion channels activated by the drugs did not differ significantly from those estimated for GABA-activated channels. The results suggest that these clinically important drugs can directly inhibit neuronal excitability by activating Cl^- ion channels much in the manner of a natural ligand like GABA. Although "GABA-mimetic", it is not clear whether the drugs utilize GABA receptor-coupled Cl^- ion channels.

41.6 d-TUBOCURARINE COMPETITIVELY ANTAGONIZES GABA IN THE HIPPOCAMPUS Frank J. Lebeda, John J. Hablitz and Daniel Johnston, Dept. of Neurology, Baylor College of Medicine, Houston, TX 77030

d-tubocurarine (dTC), when topically applied to the mammalian central nervous system, causes seizures. Since other convulsant agents are believed to antagonize γ-aminobutyric acid (GABA) mediated inhibition in the hippocampus, we examined whether dTC exerted its effects through a similar mechanism. We have demonstrated that dTC is a potent convulsant in hippocampal slices, suppresses spontaneous inhibitory activity and antagonizes GABA-mediated events.

Intracellular recordings were made from CA3 neurons in the guinea pig hippocampal slice preparation maintained in vitro. Either a 3 kHz single-electrode clamp system with 2 M Cs_2SO_4 microelectrodes or a standard preamplifier with 4 M KAc microelectrodes was used. GABA was iontophoresed onto locations proximal to the cell body layer using conventional methods. Tetrodotoxin (2 μM) was added to the perfusion medium during the GABA iontophoresis experiments.

When 50 μM dTC was added to the bathing medium, characteristic repetitive discharges were observed. These events occurred spontaneously and in response to orthodromic stimulation. Furthermore, these paroxysmal events fit all of the criteria for giant EPSPs (Johnston and Brown, Science 211: 294, 1981), including reversal in polarity at about 0 mV. Spontaneous inhibitory potentials were found to be blocked by dTC. In additional experiments, the effect of dTC on responses to iontophoretically-applied GABA were examined. Dose-response curves were plotted as the log of the charge delivered to the GABA pipette versus the % maximum decrease in input resistance. Bath-applied dTC (500 μM) produced an apparent parallel shift to the right in the GABA dose-response relation in a manner similar to, but less potent than, bicuculline methiodide (50 μM). In contrast, picrotoxin (500 μM) decreased the maximum response and increased the ED50 (dose producing a half-maximal response); this mixed form of inhibition (competitive and noncompetitive) has also been seen in lobster muscle (Constanti, Neuropharmacol. 17: 159, 1978). Finally, bath application of several cholinergic antagonists (atropine, scopolamine, gallamine, α-bungarotoxin or decamethonium) produced none of the field potential changes characteristic of dTC.

The present results suggest that dTC produces its excitatory effects by antagonizing a GABAergic rather than a cholinergic system, and that the three convulsants investigated interact with at least two different components associated with the GABA receptor/ionic channel complex in the hippocampus. (Supported by The Epilepsy Foundation of America and NS15772 and NS11535.)

42.1 DOPAMINE RECEPTORS AND ANTIDEPRESSANT DRUG ACTION. Tyrone LEE and Siu W. TANG. Department of Psychopharmacology, Clarke Institute of Psychiatry and Department of Pharmacology, University of Toronto, Toronto, Canada.

Antidepressants are effective blockers of transmitter uptake at synapses, e.g. noradrenaline and serotonin, and have been shown to induce beta-adrenergic receptor subsensitivity. However, Serra et al. (Life Sci. 25:415, 1980) and Chiodo and Antelman (Nature 287:451, 1980) have demonstrated that repeated antidepressant treatment in rats also induced subsensitivity of dopamine autoreceptors. In order to investigate the possible involvement of dopamine in antidepressant drug action, the effect of chronic treatment in rats of desipramine (DMI) and amitriptyline (AMT) on presynaptic dopamine receptors was studied.

Adult male Wistar rats (150-175 gm) were treated with either DMI (20 mg/kg i.p.) or AMT (10 mg/kg i.p.) once daily for 7 days. Control animals received equivalent volume of saline. All animals were sacrificed by decapitation 24 hours after the last dose. The brains were immediately removed, dissected and crude homogenates of the striatum were prepared. Presynaptic dopamine receptors were measured by using ^{3}H-dopamine (0.25-2.5 nM) and specific binding was defined by 1 μM apomorphine. The data were analyzed by Scatchard plots and the results were expressed as follows in density (B_{max}) in femtomoles/mg protein and affinity constant (K_D) in nanomoles/liter.

^{3}H-DOPAMINE	SALINE	DESIPRAMINE	AMITRIPTYLINE
B_{max}	68.2±4.8* (6)	72.8±3.1 (7)	74.4±2.9 (7)
K_D	1.74±.15 (6)	1.55±.09 (7)	1.75±.14 (7)

*Mean ± S.E.M.
Number of replicate assays are indicated in parentheses.

Under the conditions used in this study no significant difference in density or affinity of the presynaptic dopamine receptors was observed between the control animals and animals treated with antidepressants. However, dopamine may modify antidepressant action via different population of dopamine receptors with longer onset of action at a different locale of the rat brain. Such a possibility is being investigated.
(Supported by the Clarke Institute of Psychiatry.)

42.2 **EFFECTS OF N-ETHYLMALEIMIDE ON ^{3}H-SPIROPERIDOL BINDING TO RAT STRIATAL MEMBRANES.** Rita M. Huff and Perry B. Molinoff. Dept. of Pharmacology, Univ. Co. Health Sci. Ctr., Denver, CO 80262.

^{3}H-Spiroperidol (SPD) appears to bind to at least two types of striatal dopamine (DA) receptors, an adenylate cyclase linked subtype and a noncyclase linked subtype. Guanine nucleotides cause a 3- to 5-fold decrease in the affinity of DA receptors for agonists (Nature 275: 453, 1978). This decrease in affinity may reflect an interaction of one of the DA receptor subtypes with adenylate cyclase. A role for thiol groups in the binding of ^{3}H-DA to its receptors has been described (BBRC 96: 953, 1980). When incubations were carried out in the presence of N-ethylmaleimide (NEM), a sulfhydryl alkylating agent, a decrease in the specific binding of ^{3}H-DA has been observed. Pretreatment of striatal membranes with NEM also causes a dose dependent inhibition of DA stimulated adenylate cyclase activity (Fed. Proc. 40: 653, 1981). In the current study the possibility that NEM was selectively alkylating thiol groups associated with just one of the subtypes of DA receptors was examined. Membranes were prepared from rat striatum, incubated with NEM (10 μM - 1 mM) for 30 minutes at 37°, and then washed prior to being used in binding assays. The inhibition constant (K_i) for DA displacement of ^{3}H-SPD binding was increased up to 70-fold following pretreatment with NEM. The Hill coefficients for DA displacement of ^{3}H-SPD binding increased from 0.48 in controls to 0.94 with 1 mM NEM. The K_i values of other agonists, including N-propylnorapomorphine and apomorphine, were also increased in a dose dependent manner following treatment with NEM. Following incubation with NEM, however, GTP did not affect the K_i value for DA. Pretreatment with NEM also resulted in a dose dependent decrease in the density of ^{3}H-SPD binding sites (B_{max}); 10 μM NEM decreased the B_{max} by 15% and 1 mM NEM decreased the B_{max} by 42%. No change in the affinity (K_d) of the receptor for ^{3}H-SPD was observed after incubation with 10 μM NEM, but pretreatment with 1 mM NEM increased the K_d value by 2.5-fold. GTP did not alter the density or affinity of ^{3}H-SPD binding sites. The increases in the K_i values of agonists for ^{3}H-SPD binding sites following NEM pretreatment are greater than the increases in the K_i values observed in the presence of GTP. Thus, the effects of NEM on ^{3}H-SPD binding are not completely analogous to those of GTP. The K_i value for α-flupenthixol, an antagonist reported to be selective for cyclase-linked DA receptors, was increased 2-fold following incubation with 1 mM NEM. Similar results, however, were also obtained in studies using domperidone and bromocriptine, antagonists of noncyclase linked DA receptors. The findings do not support the hypothesis that pretreatment with NEM selectively alters DA receptors linked to adenylate cyclase.

42.3 ALPHA-ADRENOCEPTOR DEVELOPMENT AND HYPERLOCOMOTION IN YOUNG RATS. Elizabeth J. HARTLEY* and Philip SEEMAN. Dept. of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

Infant rats normally become hyperactive during the third week of life and this locomotor activity declines to adult levels by 25 to 27 days of age. Since the rise in locomotion has been ascribed to the development of the catecholamine system, we examined the development of post-synaptic alpha$_1$-adrenoceptors. We also measured the development of (pre-synaptic) alpha$_2$-adrenoceptors, since their maturation might inhibit or regulate the release of noradrenaline, accounting for the decline in locomotor activity. The alpha$_1$ sites were labelled by ^{3}H-WB-4101, the alpha$_2$ sites by ^{3}H-clonidine, and we used Wistar rat pup brain tissue homogenized in 50 mM Tris-HCl.

1. On the first day of life there were no detectable alpha$_1$ sites in the mesolimbic region, hippocampus, or frontal cortex. Rapid synthesis of these sites only commenced at day 4.
2. Although alpha$_2$ sites were detectable at birth, they lagged in development 1 week after the alpha$_1$ sites.
3. Only in the mesolimbic tissue did the ratio of receptor densities (alpha$_1$/alpha$_2$) parallel the locomotor development.
4. The results support Kellogg & Lundborg (1972) who proposed that adrenoceptors develop before dopamine receptors.
5. The early presence of alpha$_1$ sites also explains clonidine activation before day 14; the later onset of alpha$_2$ sites explains clonidine depression of activity after 21 days.
6. We conclude that the rise in locomotion at day 14 is associated with development of alpha$_1$ sites; the suppression of motion at day 28 is associated with the maturation of alpha$_2$-adrenoceptors in the nucleus accumbens of the mesolimbic region.

42.4 ^{3}H-LISURIDE, A POTENT DOPAMINERGIC ERGOT DERIVATIVE, LABELS D2-DOPAMINE RECEPTORS. P.F. Spano°, M. Memo°, F. Riccardi°, M. Carruba°, M. Trabucchi (Spon: I. Hanbauer). Dept. of Pharmacol., Sch. of Pharm., Univ. of Cagliari and Dept.s of Pharmacol., Sch.s of Pharm. and Med., Univ. of Milan, Italy.

Increasing evidence points to the existence of multiple receptors for dopamine (DA) in the CNS. On the basis of pharmacological and biochemical experiments we and others haved named central DA receptors D1 and D2. DA-D1 receptors are those coupled to adenylyl cyclase activity whilst DA-D2 are independent from the generation of cyclic AMP. We now report that lisuride, a potent dopaminergic ergot derivative unable to stimulate the formation of cyclic AMP, exhibits a specific binding in rat CNS. We found that ^{3}H-lisuride (26 Ci/mmol) binds to membrane preparation obtained from various dopaminergic regions. The binding appeared to be saturable, stereospecific and maximally enriched in the synaptosomal fraction. Scatchard analysis of binding data revealed receptor sites with high affinity (KDs from 1.4 to 1.9 nM) and a maximum capacity ranging from 70 to 281 pmol/mg prot. according to the various areas examined. Lisuride binding was higher in striatum and pituitary. Dopamine agonists and DA antagonists, including substituted benzamides, were potent competitors of lisuride binding in striatal and pituitary preparations. Most interesting, lisuride specific binding, contrary to ^{3}H-apomorphine binding, was not decreased in striatal membranes by guanyl nucleotides. This fact according to the present hypotheses would strongly suggest that DA receptors labelled by lisuride are not associated with adenylyl cyclase activity. Lesion studies which are now in progress in our laboratory seem to give further support to this hypothesis. In conclusion our data indicate that the characteristics of lisuride specific binding are compatible with the properties of a pharmacologically relevant DA receptor, possibly of the D2 type.

42.5 DOPAMINE RECEPTOR BINDING ON INTACT CELLS: ABSENCE OF A HIGH AFFINITY AGONIST STATE. D. R. Sibley, L. Mahan and Ian Creese, Dept. Neurosciences, Univ. Calif. San Diego, La Jolla, CA 92093.

Utilizing biochemical and pharmacological criteria, anterior pituitary dopamine (DA) receptors have been classified as belonging to the D-2 category of DA receptor subtypes. We have previously shown that the radiolabeled antagonist, ^{3}H-spiroperidol (^{3}H-SPIRO) and the agonist, ^{3}H-N-n-propylnorapomorphine (^{3}H-NPA) can label these D-2 DA receptors in bovine anterior pituitary membranes with high affinity. We now report that in intact bovine anterior pituitary cells there are no high affinity agonist binding sites as determined by ^{3}H-NPA binding or by agonist/^{3}H-SPIRO competition experiments.

^{3}H-SPIRO binding to intact cells is reversible, of high affinity, and saturable with Scatchard analysis indicating a homogeneous population of binding sites with a Kd of 0.21 ± 0.05 nM (n=3) and a Bmax of 9.0 ± 0.85 fmoles/10^6 cells (n=3). The stereospecificity and rank order of neuroleptic antagonists, catecholamines, and related drugs in competing for ^{3}H-SPIRO binding is indicative of a DA receptor. There is no high affinity, stereospecific or saturable binding of ^{3}H-NPA to these cells. In contrast, washed membranes prepared from these cells exhibit high affinity ^{3}H-NPA binding with a Kd of 0.25 ± 0.02 nM (n=3) and an appropriate pharmacological specificity.

In membranes prepared from either whole anterior pituitaries or from dispersed cells, agonist/^{3}H-SPIRO competition curves are heterogeneous with Hill coefficients <1. In the presence of guanine nucleotides, agonist/^{3}H-SPIRO curves are right-shifted and steepened with Hill coefficients =1. Computer analysis indicates that agonist/^{3}H-SPIRO curves in membranes are best explained by a two state binding model whereas in the presence of guanine nucleotides a one state model is sufficient to explain the data. Strikingly, in intact cells agonist/^{3}H-SPIRO curves have Hill coefficients =1 and exhibit affinities similar to the corresponding low affinity agonist binding state seen in membranes. Addition of guanine nucleotides does not alter the agonist/^{3}H-SPIRO curve in intact cells.

We hypothesize that high affinity DA agonist binding in bovine pituitary membranes does not represent a distinct DA receptor subtype but rather a transitional guanine nucleotide-sensitive, agonist-specific binding state of a singular D-2 receptor. In our model, endogenous or exogenous guanine nucleotides, in intact cells or membranes respectively, mediate an interconversion from the high to the low affinity agonist binding state thus effectively eliminating high affinity agonist binding as measured directly with ^{3}H-NPA or indirectly with agonist/^{3}H-SPIRO competition experiments. (Sup. by MH32990)

42.6 ASCORBATE ENABLES STEREOSPECIFIC DOPAMINERGIC RECEPTOR BINDING OF TRITIATED DOPAMINE AGONISTS. S. Leff, M. Hamblin, D.R. Sibley and Ian Creese, Dept. Neurosciences, Univ. Calif. San Diego, La Jolla, CA 92093.

Dopamine (DA) and other catecholamines oxidize readily. For this reason assay media used in early studies of DA receptor binding to membrane homogenates commonly included mM concentrations of the anti-oxidant ascorbic acid. Under these conditions extensive characterization of high affinity DA ^{3}H-agonist and ^{3}H-antagonist binding strongly suggests an association with DA receptors. Several recent reports have proposed that ascorbic acid at μM to mM concentrations may inhibit high affinity DA agonist binding to striatal membranes. Since these reports showed limited characterization of dopaminergic ^{3}H-agonist binding in the absence of ascorbic acid, we have further investigated the effects of ascorbate on DA receptor binding to membrane homogenates of bovine anterior pituitary and caudate and rat striatum.

Specific binding (determined using 10^{-6} (+)butaclamol as a blank) of the antagonist ^{3}H-spiperone was not significantly affected by ascorbate concentrations from 0.1μM to 10 mM except that concentrations of ascorbic acid >6 mM inhibit specific binding due to marked decreases in pH of the assay media. Dopaminergic ^{3}H-agonist specific binding (defined using blanks of (+)butaclamol at 10^{-6} M for ^{3}H-n-propylnorapomorphine [NPA] and 10^{-5} M for ^{3}H-apomorphine) was virtually undetectable in the absence of ascorbate. Specific binding increased with increasing ascorbate concentrations until a plateau was reached at 2-5 mM ascorbate.

While levels of total ^{3}H-agonist binding were markedly reduced in the presence of mM concentrations of ascorbate, ^{3}H-agonist binding in the absence of ascorbate was almost entirely non-stereospecific. Unlabeled DA at 10^{-5} M inhibited stereospecific and non-stereospecific ^{3}H-NPA binding to bovine striatal membranes in the presence and absence of ascorbate. These non-stereospecific binding sites were inhibited equipotently by other catecholamines such as norepinephrine, epinephrine and isoproterenol. Furthermore, DA inhibitable non-stereospecific binding failed to show a regional specificity suggestive of DA receptor binding.

Our results indicate that ascorbic acid or some other anti-oxidant must be present in in vitro assays of equilibrium DA receptor binding when using readily oxidizable agonists. We are currently investigating the effects of alkaline earth metals, anti-oxidants, and transition metal chelators on DA receptor binding. (Supported by MH32990)

42.7 STEREOSELECTIVITY IN THE BINDING OF (+), (-)2-HYDROXYAPOMORPHINE AND RELATED APORPHINES TO DOPAMINE RECEPTORS. G.W. Arana* and R.J. Baldessarini, Department of Psychiatry, Harvard Medical School and Mailman Research Center, McLean Hospital, Belmont, MA 02171; J.L. Neumeyer, V.J. Ram*, Section of Medicinal Chemistry, Northeastern University, Boston, MA 02115.

The potent DA agonists (-)2,10,11-trihydroxyaporphine [(-)2-hydroxyapomorphine (-)2-OH-APO] and (-)2,10,11-trihydroxy-N-n-propylnoraporphine (TNPA) were synthesized from the opioid thebaine. The enantiomer (+)2-OH-APO was synthesized from the aporphine alkaloid (+)bulbocapnine by a process which retained the chirality at the 6a carbon atom. Competition by these and other trihydroxyaporphines for binding of ^{3}H-labeled apomorphine (APO) (0.5 nM) was evaluated with a synaptosomal-membrane-enriched fraction (P_4) of calf caudate homogenates. Specific binding was defined by use of 6,7-ADTN (10 μM) as a blank to displace ^{3}H-APO. In competition for ^{3}H-APO binding, the more potent enantiomer of 2-OH-APO is the (-)isomer (IC_{50} = 10.0 nM) in comparison with (-)APO (1.0 nM); (-)NPA (2.5 nM); (±)NPA (5.0 nM); (-)TNPA (25 nM) and (-)2,10,11-trihydroxynoraporphine (30 nM). (+)2,-OH-APO had an IC_{50} value > 5,000 nM. These findings lend further support to previous studies in which it was shown that changes in the stereochemistry at the 6a carbon, the addition of a 2-hydroxy group and substitution of other alkyl side chains for the N-methyl group on apomorphine will have significant effects on the dopaminergic propreties of such aporphines.

42.8 INHIBITION OF R-(-)APOMORPHINE-INDUCED STEREOTYPIC ACTIVITY AND STRIATAL (^{3}H)-SPIROPERIDOL AND (^{3}H)-APOMORPHINE RECEPTOR BINDING BY S-(+)APOMORPHINE. W.H. Riffee, R.E. Wilcox, R.A. Reynolds-Vaughn*, and R.V. Smith. Coll. Pharm., Univ. Texas, Austin, TX 78712.

Although apomorphine exists in both the R-(-)- and S-(+)-isomeric forms, only R-(-)apomorphine (R-(-)APO) has previously been shown to have agonistic pharmacological activity. Initially, the ability of S-(+)apomorphine (S-(+)APO) to antagonize R-(-)APO-induced stereotypic cage climbing behavior in mice was investigated. Cage climbing was recorded continuously for one hour on videotape and subsequently the behavior was rated and the one min scores summed over 5 min periods for the hour. Studies using a racemic mixture of the two isomers showed that the presence of S-(+)APO produced a depression of the cage climbing behavior relative to that expected if S-(+)APO were merely inactive. In subsequent experiments, S-(+)APO was administered 1 min prior to the injection of R-(-)APO and dose and time-response analyses carried out. These studies demonstrated that the S-(+)isomer possesses no agonistic activity in the cage climbing model but that it acts as an antagonist. Doses of 30 mg/kg S-(+)APO which are well below toxic range of the drug depress the cage climbing behavior induced by R-(-)APO (10 mg/kg) by 50%. The time-response analysis showed a shift to the right in time of peak effect of R-(-)APO in the presence of S-(+)APO which may reflect a higher affinity of the R-(-)isomer for the receptor involved in the cage climbing behavior. In biochemical experiments the IC50 value for S-(+)APO inhibition of striatal (^{3}H)-spiroperidol (0.2nM) receptor binding was found to be 1uM vs. an IC50 value of 400nM obtained for R-(-)APO. The IC50 value for S-(+)APO inhibition of striatal (^{3}H)-apomorphine (2.0nM) binding was found to be 600nM vs. an IC50 value of 50nM obtained for R-(-)APO. (Supported in part by grants from NIMH (NM44332) and NINCDS (NS-12259).)

42.9 BEHAVIORAL SUPERSENSITIVITY BUT DECREASED STRIATAL (^{3}H)-SPIROPERIDOL RECEPTOR BINDING AFTER CHRONIC APOMORPHINE, N-n-PROPYLNORAPOMORPHINE, AND DEXTROAMPHETAMINE ADMINISTRATION. R.E. Wilcox, W.H. Riffee, R.A. Reynolds-Vaughn*, B.J. Leamons* D.M. Vaughn, and R.V. Smith. Coll. Pharmacy, Univ. Texas, Austin, TX 78712.

Several previous reports have demonstrated that chronic administration of direct and indirect acting dopamine agonists results in behavioral facilitation to challenge doses of dopamine agonists. In the present report, we sought to evaluate a possible mechanism for this response after chronic treatment with N-n-propylnorapmorphine (NPA), apomorphine (APO), and dextroamphetamine (AMP). Mice were administered (ip) NPA (30 mg/kg), APO (30 mg/kg), AMP (4 mg/kg) or saline once daily for two weeks. One, three or five days after the last chronic injection, the animals were tested for stereotypic cage climbing to challenge doses of APO. Separate groups of animals were sacrificed also at one, three and five days after the last chronic injection for assay of striatal (^{3}H)-spiroperidol receptor binding. APO-induced cage climb dose-response curves were shifted to the left at one three, and five days after chronic APO and NPA and three and five days after chronic AMP. In contrast, (^{3}H)-spiroperidol Bmax was slightly lower after chronic administration of APO and AMP and dramatically reduced (e.g. 30% at 3 days) in those mice treated with NPA. These results suggest that the relationship between APO-induced stereotypic activity and striatal neuroleptic binding may be neither as simple nor as direct after chronic drug administration as previously thought. (Supported in part by NIMH grant MH33442 and NINCDS grant NS-12259.)

42.10 STIMULATORY EFFECTS OF VARIOUS AGENTS ON THE BINDING OF ^{3}H-DOPAMINE TO NEOSTRIATAL MEMBRANE PREPARATIONS. Richard E. Heikkila, Felicitas S. Cabbat* and Lawrence Manzino*. Department of Neurology, College of Medicine and Dentistry of New Jersey-Rutgers Medical School, Piscataway, N.J. 08854.

It is now becoming increasingly apparent that certain reducing agents such as ascorbic acid can inhibit the specific binding of dopamine agonists and dopamine antagonists to neostriatal membrane preparations (e.g. Heikkila et al, Fed. Proc., 1981). During the course of studies with ascorbic acid, we tested the capacity of several drugs, all with varying oxidation-reduction potentials, for their capacity to inhibit the binding of ^{3}H-dopamine agonists and antagonists. To our surprise we found that one of these agents, potassium nitrite, did not inhibit, but in fact greatly stimulated the specific binding of ^{3}H-dopamine to neostriatal membrane preparations. This led to a search for other compounds that might also stimulate the binding of dopamine agonists. We found that several other agents including hydrogen peroxide, sodium nitrite, the diabetogenic agent streptozotocin, methyl nitrosourea, and potassium nitroprusside, in concentrations between 0.06 mM and 6 mM greatly stimulated the specific binding of ^{3}H-dopamine to neostriatal membrane preparations. As an example, 0.06 mM, 0.6 mM and 6 mM streptozotocin stimulated the specific binding of ^{3}H-dopamine by 27%, 229% and 465% respectively. The same three concentrations of sodium nitrite stimulated specific ^{3}H-dopamine binding by 25%, 63% and by 325% respectively. Current studies include a search to find other agents that similarly stimulate the binding of ^{3}H-dopamine, ways to counteract this stimulation of binding, as well as attempts to elucidate the mechanism of the stimulatory effects. Interestingly, several of the agents that stimulate the binding of ^{3}H-dopamine are also known to stimulate the activity of guanylate cyclase.

42.11 EFFECTS OF CHRONIC AMPHETAMINE OR PHENCYCLIDINE TREATMENT ON DOPAMINE AGONIST AND ANTAGONIST RECEPTORS: AMPHETAMINE BUT NOT PCP HAS DIFFERENTIAL EFFECTS. Harold A. Robertson, Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

There is now considerable evidence that chronic amphetamine treatment of rats (5 mg/kg, twice daily) produces down-regulation in the density of neuroleptic (3H-spiroperidol or D-2 dopamine) receptor sites. On the other hand, there is also evidence the same chronic amphetamine treatment produces a behavorial super-sensitivity to dopaminergic agonists such as apomorphine (Klawans and Margolin, Arch. Gen. Psychiat. 32: 725, 1975). In this study, we examined the effects of chronic d-amphetamine (5 & 10 mg/kg, i.p., twice daily) or phencyclidine (PCP) (5 mg/kg., i.p., twice daily) on striatal dopamine agonist (^{3}H-ADTN) and antagonist (^{3}H-spiroperidol) binding.

Male Wistar rats (200 g) were treated for 21 days and killed on day 23. Striata were pooled from 6-8 rats. Dopamine agonist binding was carried out using ^{3}H-ADTN, in an incubation mixture lacking ascorbic acid (ascorbate selectively destroys agonist binding sites). Displaceable binding was defined using 10 µM dopamine. Dopamine antagonist binding was determined using ^{3}H-spiroperidol and displaceable binding was defined with domperidone.

Chronic treatment with either d-amphetamine or phencyclidine produced a significant decrease in antagonist (^{3}H-spiroperidol) binding sites (Bmax) without affecting the affinity (K_D) of the site. In the same animals, there was an increase in specific ^{3}H-ADTN binding after amphetamine but not after PCP.

These findings indicate that the effects of chronic PCP are similar to those of amphetamine with respect to the neuroleptic or dopamine antagonist binding site but that PCP has little discernible effect on the dopamine agonist binding site. These findings may also clarify the apparent discrepancy between amphetamine's effects on receptor density and the effects on the response to dopamine agonists in vivo. Several groups have now suggested that the agonist and antagonist sites are distinct and separate. Our results suggest amphetamine at least can have a differential effect on the two sites. (Supported by the Canadian MRC).

42.12 MODULATION OF DOPAMINE RELEASE THROUGH ACTIVATION OF D_2 RECEPTORS IN THE ISOLATED RABBIT RETINA. M. L. Dubocovich* and N. Weiner. Dept. of Pharmacology, University of Colorado School of Medicine, Denver, Colorado 80262.

In the central nervous system, there is evidence for two subtypes of dopamine (DA) receptors: D_1 and D_2 (Kebabian and Calne, Nature 227, 93-96, 1979). The D_1 receptor is presumably linked to an adenylate cyclase system while the D_2 receptor is not. α-Flupenthixol and fluphenazine have high affinity for the D_1 receptor while S-sulpiride and metoclopramide are potent inhibitors of the physiological effects mediated by activation of D_2 receptors. In the retina of several species only the D_1 receptor has been described. Neither domperidone nor the benzamides: S-sulpiride or metoclopramide, inhibits the DA stimulated adenylate cyclase in this tissue (Redburn et al., Life Sci. 27, 23-31, 1980, Watling and Dowling, J. Neurochem. 36, 559-568, 1981). However, we have recently shown that S-sulpiride increases the calcium-dependent release of ^{3}H-DA from the isolated rabbit retina, presumably by blocking stereoselective DA autoreceptors (Fed. Proc. 40: 32, 1981). The aim of the present study was to investigate which subtype of DA receptor is involved in the modulation of DA release from the rabbit retina. The rabbit retina was isolated and labeled with 0.1 µM ^{3}H-DA (S.A:22.8 Ci/mmol). The tissue was superfused with Krebs solution and the calcium-dependent release of tritium was elicited by electrical stimulation at 3 Hz for 1 min at 20 mA, duration 2 msec. Two periods of electrical stimulation were applied (S_1 and S_2), separated by an interval of 40 mins. The percent of total tissue radioactivity released following the first period of stimulation (S_1) was: 2.25 ± 0.22%, (n = 12) and the S_2/S_1 ratio was: 1.12 ± 0.07, (n = 12). Both apomorphine (0.01 to 10 µM), and bromocryptine (0.01 to 1 µM) significantly decreased the stimulation-evoked release of tritium when added 20 mins before S_2. In contrast the DA antagonists S-sulpiride (0.01 to 1 µM), spiroperidol (0.01 to 10 µM), metoclopramide (0.01 to 10 µM), domperidone (0.01 to 10 µM) and R-sulpiride (0.01 to 1 µM), when added before S_2, increased in a concentration-dependent manner the release of tritium elicited by electrical stimulation. The concentration of the antagonists necessary to increase the stimulation evoked release of tritium by 50% were for (µM) : S-sulpiride, 0.0084; spiroperidol, 0.018; metoclopramide, 0.024; domperidone, 0.034 and R-sulpiride, 0.089. Domperidone and spiroperidol increased the spontaneous outflow of tritium at a concentration of 1 µM or higher. Neither stereoisomers of flupenthixol (0.01 to 10 µM) nor butaclamol (0.01 to 10 µM) modified the stimulation-evoked release of tritium from the rabbit retina, while fluphenazine significantly increased tritium release at 0.1 µM. These results suggest that the DA autoreceptors involved in the regulation of DA release from the rabbit retina possess the characteristics of a D_2 receptor. Supported by USPHS Grant NS 09199, NS 07927 and AA 03527.

43.1 CHARACTERISATION OF AN ENKEPHALIN ANALOG WITH SELECTIVE POTENT EFFECTS ON ANTERIOR PITUITARY HORMONES. J. Pless*, U. Briner*, H.H. Büscher*, F. Cardinaux*, W. Doepfner*, R.C. Hill*, R. Huguenin*, P. Marbach*, M. Markó*, R. Maurer*, D. Römer and L. Tolcsvai*, Preclinical Research, SANDOZ LTD., CH-4002 Basle, Switzerland.

A comparison in the rat of the properties of a series of mono- and poly-halogenated phenylalanine enkephalin analogs with the non-halogenated derivative FK 33-824 indicates that halogenation causes a selective and marked increase in the potency of the endocrinological properties of this group of compounds. In particular, the structure MeTyr-DAla-Gly-pF-MePhe-Met(O)-ol (200-999) is a very potent stimulator of prolactin and Growth Hormone secretion and inhibitor of Luteinising Hormone secretion and ovulation (ED50 for inhibition of ovulation = 0.07 mg/kg s.c.).

Detailed investigations of other pharmacodynamic effects of 200-999 show that it interacts with opiate receptors. In vitro, 200-999 displaces ^{3}H-naloxone from its binding site in rat brain homogenates to a high extent and it inhibits electrically-induced contractions of the isolated mouse vas deferens and guinea-pig ileum preparations. In vivo, 200-999 causes naloxone-reversible analgesia and it produces morphine-like physical dependence in the rhesus monkey when given by repeated i.v. infusion. However, in these tests the increased activity of 200-999 in relation to FK 33-824 is small when compared to the differences observed in the endocrinological potencies of the two compounds. RIA studies performed in the rat indicate that 200-999 penetrates the blood-brain barrier to a greater degree than FK 33-824 thereby offering a possible explanation for the more potent CNS properties of the halogenated analog.

43.2 ELECTROPHYSIOLOGICAL ANALYSIS OF THE INTERACTION AMONG PRODUCTS OF THE B-ENDORPHIN PRECURSOR. J.M. Walker,* H. Akil, and S. Watson (SPON: G.C. Quarton). Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109.

B-endorphin (B-END) arises from a 31K dalton glycoprotein termed pro-opiocortin. Other products of pro-opiocortin include one or more ACTH related peptides and a 16K dalton fragment which is under investigation. The discovery that these cells produce and package several biologically active peptides raised many new questions about the nature of synaptic transmission. In particular, the question of whether the effects of two such substances are antagonistic or co-operative is critical. We previously suggested the actions of B-END and several ACTH-like peptides appear to be similar because ACTH produces analgesia upon microinjection in the periaqueductal gray. However, in other systems ACTH antagonises the effect of morphine.

A more direct approach to this problem is to observe the effects of ACTH-like substances on single neurons receiving terminals from B-END-containing cells. The locus coeruleus is innervated by the hypothalamic arcuate neurons that contain both B-endorphin and some a-MSH-like material. Single cell recordings from these cells indicates that opiates depress their rate of firing. The questing as to the function of a-MSH in these cells remains open. We are studying the effects of centrally and peripherally administered MSH and ACTH-like substances on these neurons in order to determine how various products of pro-opiocortin interact upon release.

43.3 TOPOGRAPHY AND KINETIC ANALYSIS OF DISTINCT SUBCELLULAR CLASSES OF OPIATE RECEPTORS, B.L. Roth*, M.J. Laskowski and C.J. Coscia, Depts. Biochemistry and Physiology, St. Louis Univ. School of Medicine. St. Louis, MO 63104.

We have recently provided evidence which indicated that opiate receptors in rat forebrain may be located in two distinct subcellular loci. By several criteria, 60-70% of all opiate receptors were found to be localized in synaptic plasma membrane (SPM)-enriched fractions while 20-30% of the total opiate receptors were detected in smooth endoplasmic reticulum-golgi enriched fractions. Based on marker enzyme analyses, equilibrium density gradient ultracentrifugation, electron microscopy and sensitivity to guanine nucleotides, opiate receptor binding in smooth microsomes could not be accounted for by SPM cross-contamination. We now wish to present further information which strongly suggests that the two subcellular classes of opiate receptors are indeed distinct.

According to current concepts of membrane biogenesis, opiate receptors in smooth microsomes could be localized so that the recognition site for ligands is on the luminal surface. Assuming that the receptor is not a transmembrane protein, addition of low concentrations (20-100 µg/mg protein) of proteases should not perturb this "latent" receptor. When proteolysis was performed under iso-osmotic conditions (0.32 M sucrose, 40 mM KCl, 5 mM Hepes, pH=7.4), 60-80% of the receptors for [^{3}H]-naloxone were resistant to trypsin, α-chymotrypsin or pronase. As a positive control, SPM opiate receptors were almost completely destroyed under identical conditions. An enzyme located on the luminal surface, thiamine pyrophosphatase, was 90-100% latent to proteolysis in the absence of detergents. In the presence of 0.1% Triton X-100 and trypsin, pronase or chymotrypsin, however, this enzyme was 70% inactivated suggesting the occurrence of right-side out microsomes. The relative absence of a trans-membrane SPM marker-enzyme in this fraction indicates that these membranes are not inverted SPM's. These data support the notion that [^{3}H]-naloxone binding sites in microsomes are luminally localized and that the SPM binding sites are located on the extracellular surface of the membrane.

In kinetic studies with membranes isolated from calf caudate nucleus, we found that microsomal receptors for [^{3}H]-D-ala^{2}-D-leu^{5}-enkephalin exhibit faster rates of association and disassociation when compared with SPM receptors. In preliminary studies microsomal opiate receptors displayed relaxation times for association of 0.059 ± 0.01 min^{-1} while SPM receptors had relaxation times of 0.029 ± 0.002 min^{-1}. Taken together the kinetic and topographical data suggests that microsomal opiate binding represent a discrete subcellular population.

43.4 EFFECTS OF PHENCYCLIDINE (PCP) AND ITS DERIVATIVES ON ENTERIC NEURONS. A. R. Gintzler,* R. S. Zukin and S. R. Zukin Dept. Biochem. Downstate Med Ctr. Dept. Biochem. Albert Einstein Med Sch. Dept. Psychiatry, Mount Sinai Med Sch. N.Y.C.

The effects of PCP and related drugs on isolated intact segments of guinea pig ileum were determined. TCP, PCP and ketamine decreased the height of electrically-induced contractions (0.1 Hz) of intact segments of isolated guinea pig ilea. 30-40% of the inhibition of contraction height (0.1 Hz) was reversed by pretreatment with the pure narcotic antagonist naloxone. This naloxone reversible component showed cross tolerance with morphine. PCP pre-treatment caused a shift to the right in the dose respone curve to ACh that was not parallel with the control dose response curve. Thus PCP does not interact with the muscarinic cholinergic receptor in a strictly atropine-like competitive fashion. Binding sites for [^{3}H]PCP were detected in homogenates of the guinea pig longitudinal muscle-myenteric plexus preparation. The affinity constants and the rank order of potencies of various PCP derivatives competing with [^{3}H]PCP for binding suggests that these binding sites are very similar to those found in the central nervous system. These data suggest that the isolated guinea pig ileum may be used as an in vitro system for studying the mechanism of action of phencyclidines. Supported by Grants #DA02893 to ARG, DA01843 to RSZ, DA02587 to SRZ.

43.5 Thermodynamics of [^{3}H] Diprenorphine (DP) and [^{3}H] Etorphine (ET) Binding. R. Hitzemann, M. Goldsmith* and J. Curell*. Departments of Psychiatry and Pharmacology and Cell Biophysics, Univ. Cincinnati School of Medicine, Cincinnati, OH. 45267.

The hypothesis was tested that there are significant thermodynamic differences between [^{3}H]DP and [^{3}H]ET receptor binding. A whole rat brain membrane preparation, carefully stripped of endogenous opioids, was used to measure the equilibrium binding of [^{3}H]DP and [^{3}H]ET at 2°, 10°, 18°, 25°, 37° and 45°C. In (-) NaCl buffer, the Van't Hoff plots for [^{3}H]ET binding were linear over the range of 10° to 37°C and had a negative slope. In (+) NaCl buffer, temperature had no effect on K_A (H=0). NaCl significantly decreased the [^{3}H]ET K_D value below the (-) NaCl value only at 37° and 45°C. For [^{3}H]DP binding in both (+) NaCl buffer the Van't Hoff plots were linear over the range of 18° to 45°C and had a positive slope. NaCl significantly increased the [^{3}H]DP K_D at all temperature except 2°C; this effect was inversely proportional to increasing temperature. The equilibrium thermodynamic parameters at 37°C were as follows: (-) NaCl buffer - [^{3}H]ET-ΔG = -13.7kcal/mole, ΔH = + 2.5kcal/mole, ΔS= + 52.3 e.u.; [^{3}H]DP- ΔG = - 13.0kcal/mole, ΔH = - 8.4kcal/mole, ΔS = + 14.8e.u.; (+) NaCl buffer - [^{3}H]ET - ΔG = 13.5kcal/mole, ΔH=0, ΔS = + 43.5e.u.; [^{3}H]DP - ΔG = - 13.2kcal/mol, ΔH = - 9.8kcal/mole, ΔS = + 10.9e.u. The Bmax for both [^{3}H]ET and [^{3}H]DP significantly increased with increasing temperature in (-) NaCl buffer. In (+) NaCl buffer temperature had no effect on the [^{3}H]DP - Bmax. The [^{3}H]ET Bmax in (+) NaCl buffer progressively increased over the 2°C value at 10°, 18° and 25°C. However, at 37° and 45°C the Bmax values were not significantly different than the 2°C value but were significantly less than respective (-) NaCl values. Thus at 37°C both the affinity and Bmax for [^{3}H]ET binding were significantly decreased by NaCl. Overall, these results show that in comparison to [^{3}H]DP binding, [^{3}H]ET binding is significantly more entropy driven and that the availability of receptors for both ligands is temperature and ion dependent. Supported by NS-16061.

43.6 Phylogenetic Differences in Opiate Receptor Subtypes. M. Carroll-Buatti*and G.W. Pasternak (SPON: D. Rottenberg). Cotzias Lab. of Neuro-Oncology, Sloan-Kettering C.C. and Cornell University Medical College.

Both the subtypes and levels of opiate receptor binding differ between species. Rats have two major populations of ^{3}H-D-ala^2-D-met^5-enkephalinamide (3H-enkamide) binding sites: a high affinity site (K_D 0.2 nM) present in small numbers (Bmax 1.6 fmoles/mg tissue) and a low affinity site (K_D 3.3 nM) present at far greater numbers (Bmax 10.3 fmoles/mg tissue). Morphine binds very potently to the high affinity ^{3}H-enkamide site, displacing its binding with an IC_{50} less than 1 nM. In contrast, the low affinity site is far less sensitive to morphine and binds enkephalins much more potently. Naloxazone, an irreversible opiate antagonist, selectively inhibits the high affinity sites. Treatment of rat or turtle (Chrysemys scripta elegans) brain membranes with naloxazone in vitro lowers ^{3}H-enkamide binding by about 60%, while binding in frog membranes (Xenopus laevis) is depressed only 35% ($p<0.05$). The most striking differences were noted in goldfish membranes (Carassius auratus) where binding is virtually insensitive to naloxazone ($p<0.001$), suggesting the absence of high affinity sites. Since high affinity ^{3}H-enkamide binding is easily displaced by low morphine concentrations, displacement studies were performed in several species. Morphine significantly inhibits a portion of binding in both rat and turtle with an apparent IC_{50} of less than 1 nM in contrast to goldfish where no inhibition at these low concentrations is found. Goldfish binding is potently displaced by unlabeled D-ala^2-D-leu^5-enkephalin and by higher morphine concentrations (IC_{50} 5 nM), insuring the relevancy of binding. Finally, the saturation studies of ^{3}H-enkamide were performed in goldfish brain membranes. Unlike the curvilinear, two component Scatchard plots found in rat, goldfish have linear Scatchard plots describing a site (K_D 3.9 nM; Bmax 6.0 fmoles/mg tissue) whose affinity is very similar to the low affinity site in rat (K_D 3.3 nM). Thus, high affinity binding sites are more prevalent in higher species, correlating with their later appearance in ontogeny. The lack of high affinity sites in goldfish adds considerably to the hypothesis that high affinity sites represent a physically and pharmacologically distinct subpopulation of opiate receptors. The goldfish also offers a simple model for the examination of low affinity sites without the complicating binding to the high affinity receptors.

43.7 Mu and Delta Opiate Receptors in the CNS: A New Classification G.W. Pasternak, B.L. Wolozin*, A-Z Zhang. Cotzias Laboratory of Neuro-Oncology, Sloan-Kettering C.C. and Cornell U. Med. College

Binding studies in the CNS with ^{3}H-labeled opiates and enkephalins have suggested different types of sites for each class: mu (morphine) and delta (enkephalin). However, correlating these receptors with biochemically defined sites has remained difficult. Computer analysis of saturation studies have demonstrated high and low affinity ^{3}H-D-ala^2-D-leu^5-enkephalin (^{3}H-DADL: K_D 0.5 nM, Bmax 1.2 fmoles/mg tissue; K_D 5.2 nM, Bmax 11.0 fmoles/mg tissue) and ^{3}H-dihydromorphine(^{3}H-DHM: K_D 0.23 nM, Bmax 1.58 fmoles/mg tissue; K_D 2.9 nM, Bmax 5.84 fmoles/mg tissue) sites in rat brain. (Note that the term low affinity is a relative one. The K_D's remain under 10 nM.) Naloxazone selectively and irreversibly blocks the high affinity binding of both ligands. The mu peptide morphiceptin inhibits both ^{3}H-DHM and ^{3}H-DADL binding in a biphasic manner. The initial displacement of both ligands (IC_{50}<10nM) is abolished by naloxazone treatment of the membranes. Similar results are found displacing with morphine. Together, these experiments indicate that a mu peptide and a mu opiate bind with greatest affinity to the high affinity site of both ^{3}H-DHM and ^{3}H-DADL and strongly suggest that these ligands bind equally well and with highest affinity to the same site. However, the low affinity sites of ^{3}H-DHM and ^{3}H-DADL remaining after naloxazone treatment appear to be quite different. Morphine potently inhibits low affinity ^{3}H-DHM binding (IC_{50} 10 nM) but is quite weak against ^{3}H-DADL binding (IC_{50} 87 nM). Morphiceptin also displaces low affinity ^{3}H-DHM binding 250-fold better than low affinity ^{3}H-DADL binding. Conversely, D-ala^2-D-leu^5-enkephalin inhibits ^{3}H-DADL binding (IC_{50} 11 nM) far better than ^{3}H-DHM (IC_{50} 86 nM). Thus, the low affinity ^{3}H-DHM site selectively binds opiates and the low affinity ^{3}H-DADL site selectively binds enkephalins. In summary, these experiments define three general classes of opiate binding sites. Both ^{3}H-DHM and ^{3}H-DADL bind equally well and with highest affinity (K_D's 0.23 and 0.5 nM, respectively) to a discrete naloxazone sensitive receptor which mediates opiate, enkephalin, and beta-endorphin analgesia. Because of morphine's great potency at this site, we propose it be named mu_1. ^{3}H-DHM binds with slightly lesser affinity (K_D 2.9 nM) to a site which preferentially binds opiates, termed mu_2. ^{3}H-DADL binds with slightly lesser potency (K_D 5.2 nM) to a site which preferentially binds enkephalins. This latter site corresponds to the previously described delta receptors.

43.8 RECEPTOR BINDING STUDIES OF CNS KAPPA RECEPTORS. P.L. Wood. Douglas Hospital Research Centre, Verdun, Quebec, H4H 1R3.

Using rat brain membrane preparations, a unique kappa receptor was labelled with ^{3}H-ethylketazocine (^{3}H-EKC): KD = 3.45 nM, Bmax = 452 fmol/mg protein. Binding of ^{3}H-EKC to this site was potently displaced by kappa, partial mu and agonist/antagonist analgesics. Mu, delta, sigma and epsilon receptor agonists, however, were much less active at the kappa site. Representative K_I (nM) values for the mu, delta and kappa (^{3}H-Dihydromorphine/^{3}H-D-Ala^2-D-Leu^5-enkephalin/^{3}H-EKC) receptors were: morphine (1.3/26.1/696). D-Ala^2-D-Leu^5-enkephalin (8.3/1.6/113). β-endorphin (0.25/0.28/1835). SKF 10047 (1.4/5.0/24.1); EKC (4.1/7.6/4.7); buprenorphine (3.1/3.6/2.0); cyclazocine (0.2, 1.1, 5.0) and naloxone (1.4, 16.5, 11.1). Further studies of the inactivation of this ^{3}H-EKC binding site by N-ethylmaleimide demonstrated that kappa agonists but not mu or delta agonists could protect against receptor alkylation. Using such receptor inactivation protocols the specificity of purported kappa agonists was also examined and indicated that EKC but not MR-2034 possesses significant affinity for the delta receptor. In summary, our studies describe a kappa binding site which possesses a unique pharmacology and which can be selectively protected by purported kappa agonists from inactivation by alkylating agents. Therefore, our data support the concept of multiple opiate receptors and suggest that in addition to mu and delta sites a kappa receptor population is present in the rodent CNS.

43.9 DYNORPHIN-(1-13) CATALEPSY IS NOT MEDIATED BY A μ OPIATE RECEPTOR IN RAT BRAIN. B.H. Herman and A. Goldstein. Addiction Research Foundation, 701 Welch Road, Palo Alto, CA 94304.

In common with other opioids, lateral intraventricular (LV) administration of dynorphin-(1-13) induces catalepsy in the rat Herman et al., Life Sci. 27: 883, 1980). Naloxone was less effective in antagonizing the cataleptic effects of dynorphin-(1-13) as compared with D-Ala^2-dynorphin-(1-11) and Bc-endorphin, suggesting that catalepsy may be mediated by more than one opiate receptor in brain.

Evidence for a unique opiate receptor of dynorphin type in two peripheral tissue preparations has recently been provided (Wüster et al., Europ. J. Pharmacol. 62: 235, 1980; Chavkin & Goldstein, Nature, in press). We now report that μ opiate receptors in brain do not mediate dynorphin-(1-13) catalepsy, since no cross tolerance occurs between dynorphin-(1-13) and sufentanil (a specific μ receptor agonist).

Rats were made tolerant to sufentanil by chronic s.c. administration. Tolerance was assessed by comparing platform immobility (300-sec cut-off) and righting loss (60-sec cut-off) produced by a test dose of sufentanil (4 ug/kg) given before and after chronic sufentanil. Animals showing at least 50% reduction in both catalepsy scores were then tested with LV drugs. Controls were chronically administered saline. Scores are median times (sec). Independent groups were tested under each drug condition, and the same rats (N shown in parentheses) were tested for both catalepsy responses.

The table (platform immobility) shows that cross tolerance was obtained between systemic and central sufentanil, but not between sufentanil and dynorphin-(1-13). Indeed, dynorphin-(1-13) immobility was enhanced in sufentanil tolerant animals, and this effect is under further study. Similar results were obtained for righting.

	Test drug (LV)	
Chronic drug (s.c.)	Sufentanil (3.2 nmol)	Dynorphin-(1-13) (100 nmol)
Saline	300 (4)	119 (12)
Sufentanil	34 (7)	300 (8)
p	<.05	<.01

These data indicate that dynorphin-(1-13) catalepsy is not mediated by a μ opiate receptor.

Sufentanil was a gift from Janssen Pharmaceutica. Supported by NIDA grants DA7063 and 1199.

43.10 SPINAL CORD SEROTONINERGIC NEURONS: ACTIVATION BY MORPHINE IN THREE FUNCTIONAL REGIONS. J.W. Commissiong, Dept. of Physiology, 3655 Drummond Street, Montreal, Quebec, Canada, H3G 1Y6.

A part of the mechanism of morphine analgesia is thought to be mediated at the spinal level. The mechanism probably involves the activation of neurons in nucleus raphe magnus which project to the cord. An increased release and metabolism of serotonin (5-HT) in the cord, and consequently an increased production of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of 5-HT in the cord, would accompany such neuronal activation. The hypothesis was tested with regard to: 1) The specificity of morphine in activating serotoninergic, noradrenergic and dopaminergic neurons in the cord, and 2) The activation of serotoninergic neurons in three major functional regions of the cord. A gas chromatographic-mass fragmentographic method was used in which 5-HIAA, methoxyhydroxyphenylglycol (MHPG) and homovanillic acid (HVA), the major metabolites of 5-HT, norepinephrine (NE) and dopamine (DA) respectively, were determined from a single injection. The results obtained after the administration of 10 mg/kg s.c. of morphine for 1 hr are summarized in Table 1.

TABLE 1

REGION	5-HIAA nmol/g ± SD (N=5)		MHPG		HVA pmol/g ± SD (N=5)	
CERV.	CONTROL	MOR.	CONTROL	MOR.	CONTROL	MOR.
D. Horn	1.7±0.2	3.4±1.2*	1.5±0.3	1.4±0.2	399±82	329±59
V. Horn	1.2±0.1	2.5±0.8*	1.3±0.2	1.2±0.1	280±35	299±70
THOR.						
Z. Int.	1.6±0.3	3.9±0.9*	-	-	379±57	389±74

* $P < 0.01$ when compared with control.

The effect of morphine was dose-dependent and was reversible by naloxone (4 mg/kg i.p.). There were no consistent changes in the levels of 5-HT, NE or DA. Two conclusions follow from these results. 1) Of the three spinal monoaminergic neuronal systems, only serotoninergic neurons appear to be activated after morphine. 2) The activation of serotoninergic neurons is non-specific with regard to the functional region of the cord involved, since activation occurred to the same degree in the three functional regions studied. Much caution is therefore needed in the interpretation of results in which the analgesic affect of morphine is specifically correlated with the activation of serotoninergic neurons in the dorsal horn of the cord. (Supported by the MRC of Canada).

44.1 THE ROLE OF THE FRONTAL EYE FIELDS AND THE SUPERIOR COLLICULUS IN THE COMPUTATION OF RETINAL-ERROR AND EYE-POSITION INFORMATION. P.H. Schiller,* J.H. Sandell, and S.D. True*. (SPON:B. Dawson). Dept. of Psychology, M.I.T., Cambridge, MA 02139.

Recent studies have shown that in man and monkey the acquisition of visual targets by saccadic eye-movements is accomplished not only by relying on a retinal-error signal but also by utilizing eye-position information (1,2). Where these two signals are combined in the chain of events leading to a saccade is not yet clear, although it has been shown that both retinal-error and eye-position information are available at the level of the superior colliculus (SC) (3).

The aim of our experiment was to determine whether or not the frontal eye fields (FEF) and the SC are essential for computations based on both retinal-error and eye-position signals. To do this we used the Mays-Sparks paradigm (2). Monkeys were trained to acquire briefly flashed visual targets. Prior to the initiation of the saccade either the FEF or the SC was electrically stimulated to move the eyes, in total darkness, to a new location. Under such conditions animals corrected for eye displacement and reached the actual position of the already extinguished target, suggesting that both retinal-error and eye-position signals were utilized. We then removed the SC in some animals and the FEF in others. We found that following these ablations animals were still able to make proper corrections when the remaining structure was electrically stimulated. This, in combination with earlier work (4) suggests that the retinal-error signals supplied by either the SC or the FEF is combined with the eye-position signal at a station subsequent to the SC, probably somewhere in the brainstem.

44.2 PROJECTIONS FROM THE GRANULAR FRONTAL CORTEX TO BRAINSTEM OCULOMOTOR NUCLEI IN THE MONKEY. G.R. Leichnetz and R.F. Spencer. Department of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298.

We have previously described the origin, course and termination of projections from the granular frontal cortex to the superior colliculus (SC). However, HRP gel implants into subregions of the prefrontal cortex (PFC) in both old and new world monkeys also demonstrated corticofugal trajectories that were followed to the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), interstitial nucleus of Cajal, oculomotor nucleus, nucleus of Darkschewitsch, and rostral paramedian pontine reticular formation. But it was difficult to determine the specific subregions of PFC from which these anterogradely-labelled projections to specific nuclei originated.

Therefore, stereotaxic microinjections of brainstem preoculomotor nuclei were made to answer this question and to determine whether PFC subregions project to more than one, perhaps several, of these targets. Unilateral HRP injections into the oculomotor nucleus resulted in large numbers of retrogradely-labelled cells (60-80 cells in a single section) within the rostral bank of the arcuate sulcus and few, if any, on the crown of the prearcuate cortex. There was also a lightly-labelled and almost continuous stratum of layer V pyramidal cells on the dorsal convexity and medial prefrontal cortex from the lip of the principal sulcus to the cingulate sulcus. There were no labelled cells in the banks of the principal sulcus, inferior portion of the prearcuate cortex between the caudal principal sulcus and inferior ramus of the arcuate sulcus, or in the orbitofrontal cortex. Injection of the riMLF, on the other hand, resulted in only occasional retrogradely-labelled cells in the rostral dorsal convexity and medial prefrontal surface. Concentrations of cells were observed in the dorsal bank of the superior ramus of the arcuate sulcus which continued to its caudal terminus, and at these more caudal levels the densely-labelled cells were continuous with an almost uninterrupted stratum of layer V pyramidal cells which extended into the dorsal convexity of Area 6 and onto the medial surface to the cingulate sulcus, the abundance of which we attributed to probable spread of the injection into the subjacent dorsomedial red nucleus. Only an occasional cell was observed in the rostral bank of the arcuate sulcus, and again there were none in the banks of the principal sulcus or in the orbitofrontal cortex.

These preliminary results seem to suggest that prefrontal projections to the superior colliculus and oculomotor nucleus may arise from the same cortical area, but the projection to riMLF appears to come from a different region.

44.3 FRONTAL EYE FIELDS IN MONKEY: CLASSIFICATION OF NEURONS DISCHARGING BEFORE SACCADES. C. J. Bruce and M. E. Goldberg. National Eye Institute, NIH, Bethesda, MD 20205.

The frontal eye fields of the Rhesus monkey have been shown to participate in saccadic eye movements. Microstimulation evokes saccades and lesions impair the ability to make saccades. Neurons have an enhanced response when the monkey makes a saccade to a stimulus in the neuron's receptive field, but not when the monkey attends to the stimulus without making an eye movement. In order better to understand the role of the frontal eye fields in visually guided saccades, we studied the temporal discharge patterns of frontal eye field neurons in Rhesus monkeys performing tasks requiring visual fixation and saccades.

51% of neurons discharged before visually guided saccades to limited areas of the contralateral visual field. Of these presaccadic neurons, 23% were purely visual: they discharged in response to the stimulus and their discharge was unaffected by the presence or absence of eye movements to it. In contrast, 7% were purely motor. They did not respond to visual stimuli and when the monkey was induced to perform the necessary saccade in the dark (by omitting the target and rewarding the eye movement) these cells responded as briskly as when the animal made the same saccade to a visual target.

The largest number (70%) of the presaccadic neurons were visuomotor in that their discharge was affected by both visual stimululation and eye movements. Most visuomotor neurons gave vigorous responses when the monkey made a saccade to a visual target, but discharged much less to either the eye movement or the visual stimulus alone. The response began 100 msec or less after the visual target onset and continued through the saccade whether or not the stimulus was still present. For some neurons the response terminated sharply at or before the end of the saccade. For others it continued up to 200 msec longer.

Some visuomotor neurons began to respond before the saccade target onset if the task repeatedly required a certain saccade. This anticipatory discharge ceased when several trials not requiring the saccade were given.

We analyzed the effect of orbital position by requiring the monkey to make similar saccades from different orbital positions or to reach the same orbital position using different saccades. Each neuron studied discharged in association with a particular range of directions and amplitudes of eye movements, not to movements which achieved particular orbital positions.

These results are consistent with the hypothesis that the frontal eye fields provide subcortical structures with trigger and targeting signals for saccadic eye movements.

44.4 FRONTAL EYE FIELDS IN THE MONKEY: EYE MOVEMENTS REMAP THE EFFECTIVE COORDINATES OF VISUAL STIMULI. M. E. Goldberg and C. J. Bruce. National Eye Institute, NIH, Bethesda, MD 20205.

Man and monkey can make accurate saccades to briefly flashed targets present only before an intervening saccade. Such performance implies a dissociation of the direction of the evoked saccade from the retinal location of the target, and logically entails a vector subtraction of the intervening saccade from the retinal target location. We have previously described visuomotor neurons in the monkey frontal eye fields which discharge optimally before saccades to visual targets, We studied the response of these neurons while monkeys executed such double saccades in order to see how a dissonance between retinal stimulus location and required eye movement direction effects their discharge.

Monkeys previously trained on a simple saccade task were trained to make two successive eye movements to serially flashed spots each of which appeared and vanished before the monkey made the first eye movement. The second eye movement had coordinates which could only be calculated if the retinal location of the target were adjusted by the dimensions of the first eye movement. For each neuron studied we first determined its visual receptive field and the direction and magnitude of saccade associated with its optimal response. We then studied the same neuron in double jump experiments in which the stimuli were arranged either (1) that neither stimulus was in the receptive field of the neuron, but the second eye movement was the correct one, or (2) the second stimulus was in the receptive field of the neuron, but neither movement was correct.

Most visuomotor neurons gave a strong response during the right movement-wrong receptive field case. No neurons were more responsive in the right receptive field-wrong movement case than in a control task using the same stimuli without any eye movements. Since these neurons require visual input for their optimal responses, in the right movement-wrong receptive field case the visual input comes from an area of the retina not usually capable of driving the cell. These data suggest the critical signal from the frontal eye fields is not the retinal location of a target, but the movement that the target will evoke.

The frontal eye field also contains a class of neurons discharging after certain saccades. These postsaccadic neurons continue to discharge for up to several seconds after the saccade. If the animal makes a second eye movement, their discharge is immediately truncated so that they signal only the most recent saccade. We suggest that these neurons carry the information necessary for the remapping of the responses of the visuomotor neurons in the double saccade paradigm.

44.5 UTILIZATION OF AN EYE POSITION SIGNAL BY SACCADE-RELATED BURST NEURONS IN THE MONKEY SUPERIOR COLLICULUS. David L. Sparks and John D. Porter*, Dept. of Physiology and Neurosciences Program, University of Alabama in Birmingham, Birmingham, Al. 35294.

Recent studies (Mays and Sparks, Science, 208, 1980) provide convincing evidence that visual saccade targets are localized in a spatial, as opposed to a retinocentric, frame of reference. Computation of the vector of a saccade is based upon both retinal and eye position information. The present experiment is concerned with the question of where in the CNS retinal and eye position signals are combined.

Two rhesus monkeys with implanted eye coils were trained to look to brief (125 ms or less) visual targets for water reinforcement. Microelectrodes were introduced into the superior colliculus bilaterally and unit activity was monitored until a cell with saccade-related activity was isolated. On random trials, in the interval between target offset and saccade onset, electrical stimulation of the opposite colliculus drove the eyes to another position in the orbit. The monkey then made a short-latency compensatory movement of saccadic velocity to the location of the (now absent) target. On stimulation trials, the target coordinates were arranged so that the vector of the compensatory saccade was in the movement field of the unit being studied. Most units with saccade-related bursts also exhibited a burst prior to compensatory movements in their movement field. The discharge prior to compensatory saccades was generally reduced when compared to that observed for control movements. Burst neurons that did not fire before compensatory saccades were shown to require prior activation by a visual stimulus within their movement field (visually-triggered burst cells, Mohler and Wurtz, J. Neurophysiol., 39: 1976).

Saccades made to compensate for the stimulation-induced perturbation must be based upon a combination of retinal and eye position information. Accordingly, neurons which discharge prior to these compensatory saccades must be part of the neuronal circuitry after eye position and retinal signals have been combined. While we do not dismiss evidence that local feedback of an eye position signal is used to modify the output of pontine burst neurons (Van Gisbergen et al., J. Neurophysiol., 45: 1981), our data indicate that an eye position signal is also combined with retinal information at or prior to the level of the superior colliculus.

44.6 RESPONSE OF SUBSTANTIA NIGRA CELLS RELATED TO SACCADES TO REMEMBERED TARGETS. O. Hikosaka* and R. H. Wurtz (SPON: D. L. Robinson). Laboratory of Senosorimotor Research, National Eye Institute, NIH, Bethesda, MD 20205.

Cells in the pars reticulata of the substantia nigra of rhesus monkeys show high frequency, tonic discharges. Some of these cells show a response (decrease in discharge rate) during a visually guided saccade task in which the monkey makes a saccade to a currently present spot of light, and the decrease is coupled either with the stimulus onset or with the saccade onset (Hikosaka and Wurtz, Neurosci., 6:15, 1980). We found other types of cells which were characterized by: 1) weak or no response during a visually guided saccade task; 2) stronger response during a task which requires saccades to a previously present spot of light (delayed saccade task). In this delayed saccade task a spot of light (cue stimulus) is flashed for 50 msec while the monkey is fixating; this spot indicates the target for a subsequent saccade. When the fixation point goes off about 1 sec later, the monkey has to make a saccade (delayed saccade) to the no longer present spot of light; reward is given if the correct saccade is made.

The first type of cell decreased its discharge rate in response to the cue stimulus. This response was distinguished from a simple visual response because the response became much weaker or faded away when the task was changed so that the same spot of light was no longer the cue for the delayed saccade.

The second type of cell decreased its discharge rate in relation to the delayed saccade. The decrease in discharge rate started 50-200 msec before the saccade onset. Some of these cells showed no response during the visually guided saccade task although the resulting saccades were physically the same while others showed weaker response before visually guided saccades. None of these cells showed significant change in discharge rate in relation to spontaneous saccades made in the dark.

The third type of cell was characterized by the maintained decrease in discharge rate which started after the cue stimulus and ended with the delayed saccade.

All of these three types of cells showed the strongest decrease in discharge rate when the delayed saccade was directed to a part of the visual field contralateral to the substantia nigra studied.

These experiments suggest that the substantia nigra pars reticulata participates not only in the initiation of visually guided saccades but also in the initiation of saccades guided by short-term memory of target location.

44.7 AXONAL PROJECTION OF VISUAL-OCULOMOTOR CELLS IN THE SUBSTANTIA NIGRA TO THE SUPERIOR COLLICULUS. R. H. Wurtz and O. Hikosaka*. Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, MD 20205.

We have shown that cells in the lateral part of the pars reticulata in the monkey substantia nigra decrease their discharge rate in relation to saccades to real or remembered visual targets. This area roughly corresponds to the anatomically determined area which has a clear projection to the superior colliculus. The present study attempts to determine: 1) what type of pars reticulata cells project to the superior colliculus; 2) to which part or layer of the superior colliculus single pars reticulata cells project. We used microstimulation techniques to antidromically activate pars reticulata cells from a movable stimulating electrode in the superior colliculus of awake rhesus monkeys. We first inserted a fine tungsten microelectrode through a guide tube into the superior colliculus and determined the visual and oculomotor properties of cells recorded along the electrode track. This allowed us to determine the location of the electrode tip: from purely visual responses in the superficial layers and to purely motor responses in the deeper layers. Then we recorded single cells in the pars reticulata with another microelectrode and determined the relation of these cells to visual stimuli and to saccades to those stimuli. During recording of the single pars reticulata cells, we moved the electrode in the superior colliculus while applying single pulse stimuli. Many pars reticulata cells which decreased their discharge rate in relation to visual stimuli or saccades were activated antidromically from the ipsilateral superior colliculus. Antidromic responses were identified by: 1) fixed latencies to single and double pulse stimuli with a short interval; 2) collision with spontaneous spikes. We measured the threshold and latency for antidromic activation at 100 micron steps through the superior colliculus which yielded depth-threshold and depth-latency plots. Latency of antidromic response usually ranged between 0.7 and 1.3 msec. The depth-threshold plot typically showed multiple low threshold peaks of less than 20 uA. These peaks usually corresponded to the depths where visual-motor or motor cells were recorded. These multiple peaks indicate that the axons of pars reticulata cells arborize to several branches in the intermediate and deep layers and possibly terminate on some cells in these layers.

We suggest that pars reticulata cells which decrease discharge rate in relation to saccades to real or remembered visual targets have monosynaptic connection with superior colliculus cells which increase discharge rate in relation to visually or non-visually guided saccades.

44.8 BURST NEURONS IN THE MESENCEPHALIC RETICULAR FORMATION (MRF) ASSOCIATED WITH VISUALLY-TARGETED AND SPONTANEOUS SACCADES. David Waitzman and Bernard Cohen, Dept. of Neurology, Mount Sinai School of Medicine, New York, N.Y. 10029.

Single unit activity was recorded in the MRF of alert rhesus monkeys trained in a visual fixation/saccade task (Waitzman & Cohen, Neurosci., 5: 389, 1979). Sites of recording were identified both histologically and via microstimulation which produced characteristic fixed and variable amplitude saccades (Matsuo et al., Neurosci., 6: 15, 1980). Most MRF burst neurons began firing before contralateral spontaneous and task related saccades which brought the eyes to positions of fixation within ±30 degrees of the horizontal meridian. The number of spikes in the 32 msec period before the onset of movement was related to saccadic direction, not to the size of the horizontal component of movement. However, histograms ordered by size of horizontal component of movement, revealed that the highest peak firing rates were associated with saccades of specific sizes. For example, one group of cells had peak frequencies of approximately 600 Hz which occurred 15 msec before the onset of 2°-4° on-target saccades. These neurons also fired in association with larger on-target saccades but the peaks of firing were after the onset of movement. This group of neurons was active for 2°-4° spontaneous saccades but peak frequencies were about 300 Hz and occurred 1-2 msec before the onset of movement. Similar groups of neurons were identified which were most active prior to saccades in other ranges: 6° to 8°, and 10° to 12°. Another prominent feature of these neurons was the inhibition of firing that preceded off-target saccades to the ipsilateral side. During ipsilateral on-target saccades the neuron was not inhibited and spontaneous firing levels were maintained. In neurons associated with small (2°-4°) and medium (6°-8°) sized saccades the spontaneous level of firing increased during fixation of the target. These results demonstrate that the MRF has burst activity which leads spontaneous and visually-targeted eye movements. This lead activity contains information about the direction of the upcoming movement. MRF neurons that are excited to their peak firing rate before the onset of movement may help determine the size of the upcoming saccade. If the MRF affects the level of excitability of the saccade generating mechanism in the pons, then the reciprocal excitation and inhibition of MRF units during on- and off-target saccades could account for the production of contralateral saccades. During fixation the enhanced spontaneous firing rates in the MRF on both sides could provide damping activity that suppressed saccade generation in any direction.

44.9 NEURONAL CORRELATES OF VERGENCE EYE MOVEMENTS. Lawrence E. Mays. Department of Physiological Optics and Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

The oculomotor system which controls vergence eye movements is functionally and neurologically distinct from the conjugate control systems. Signals which control the angle between the eyes appear to be derived independently of conjugate signals and then combined with them at the medial and lateral rectus motoneurons.

The purpose of the present study is the identification of neuronal activity which may control disjunctive eye movements. Monkeys were trained to look at a small target light for a water reward. The horizontal and vertical positions of both eyes were measured using the search coil technique. By placing target arrays at near (19 cm) and far (83 cm) distances from the monkey it was possible to elicit convergence and divergence eye movements on command. Extracellular microelectrode recordings were made in pontine and midbrain areas during disjunctive and conjugate eye movements and fixation. Units were encountered near the oculomotor nucleus which had a firing rate closely related to the angle of convergence. The activity of these cells was unrelated to the direction of conjugate gaze. These responses are consistent with the expected characteristics of a vergence signal. However, the possible role of these units in other components of the near responses (e.g. accommodation) has not yet been determined.

44.10 SPATIAL COORDINATES OF VISUAL MESSAGES IN THE FLOCCULUS. J.I. Simpson, W. Graf* and C.S. Leonard* (SPON: R. Hess). Dept. Physiol. & Biophys., New York Univ. Med. Ctr., NY, NY 10016.

The visually modulated speed and rotation selective cells in the dorsal cap of the inferior olive project to the flocculus and can be divided into three classes according to eye dominance and the spatial orientation of the preferred axis of rotation. Since each Purkinje cell (P-cell) is synapsed upon by a single climbing fiber, each floccular P-cell can be assigned to one of three classes by determining the preferred axis of rotation of its complex spike (CS) response to visual stimulation. Collectively, the preferred axes of rotation, which bear a close resemblance to the principal axes of the semicircular canals, establish a natural or intrinsic reference frame potentially useful in the analysis of signal processing in the flocculus. In lightly anesthetized, immobilized rabbits we have extracellularly recorded the CS and simple spike (SS) responses of floccular P-cells to whole-world visual stimuli provided by a planetarium projector that produced a random spot pattern rotating about selectable axes. The responses of other neuronal elements were also recorded. Determination of the preferred axes of rotation for the CS responses confirmed that three basic classes of P-cells could be distinguished. In general, for a given P-cell the preferred axes of rotation for the CS and SS responses were similar. By far the most common relation between CS and SS responses was one of reciprocity, i.e. when CS activity increased SS activity decreased and vice-versa. A reciprocal relation seems not to be obligatory for the CS and SS activity of some cells increased and decreased together. While the SS responses are induced by retinal image slip, they likely represent a combination of retinal slip signals *per se* and signals related to aspects of eye movements consequent to the presence of retinal slip. In most P-cells with a binocular receptive field the spatial organization of both the CS and SS receptive fields was such as to prefer rotation rather than translation of the visual world. In a few cases, however, the sense of the direction selectivity of the SS response for each eye alone was such that translation would produce the greater modulation with binocular viewing. Responses with preferred axes similar to those of CS responses were also recorded from neuronal elements other than P-cells. In summary, the spatial organization of the visual world yielding preferred axes of rotation of floccular CS responses in vestibular coordinates is prevalent for SS responses. Supported by USPHS grant NS13742 and DFG grant Gr688/1.

44.11 VESTIBULAR CONTRIBUTIONS TO TARGET VELOCITY SIGNAL IN THE MONKEY VERMIS. David A. Suzuki* and Edward L. Keller. (SPON: E.Sutter). Smith-Kettlewell Inst. Visual Sciences, San Francisco, CA 94115.

The observation of retinal slip and smooth pursuit eye velocity-related Purkinje cell activity in lobules VI and VII, has raised the possibility of a neural target velocity correlate in the cerebellar vermis. The target velocity construct, however, requires the additional presence of a head velocity signal, the existence of which will be reported.

In order to clarify the sensory-oculomotor interactions occurring in the cerebellum, monkeys were trained to 1)suppress their vestibuloocular reflex (VOR), 2)track a small moving spot, and 3)fixate a stationary spot during movement of either a whole-field drum or a small test spot not associated with a reward. With these respective paradigms, head, smooth pursuit eye, and retinal slip velocity signals could be dissociated. Purkinje cells lacking vestibular inputs and exhibiting eye movement or eye movement plus retinal slip-related activites were observed, but this report will focus on the units exhibiting head velocity-related activity.

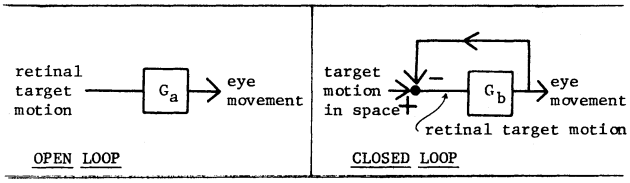
The majority of Purkinje cells receiving vestibular inputs exhibited peak firing rates during contralateral head rotations. Modulations in discharge rate were approximately in-phase with and increased in amplitude with head velocity. Some of these units also showed discharge modulations during pursuit eye movements with peak firing rates occurring with maximum contralateral eye velocity. Retinal slip velocity-related activity was observed in some units and peak activity occurred with contralateral visual stimulus movement. Thus, when head, smooth pursuit eye, and retinal slip velocity-related signals could be observed in the same Purkinje cell, peak firing rate was associated with head, eye, and image movement in the same direction (contralateral). This convergence of velocity signals implicates the presence of a neural correlate of a target velocity signal.

In a minority of the units demonstrating head velocity-related activity, peak firing rates occurred during ipsilateral head rotation. Of these units, some also exhibited pursuit eye and/or retinal slip velocity-related discharges. The eye and retinal slip-related activities usually exhibited peak firing rates during contralateral pursuit or visual stimulus movement. These units were, therefore, characterized by differing directional preferences for head and eye/retinal image movements. Such units could contribute to VOR or optokinetic functions.

The results suggest both the neccessity of broadening the label "vestibulocerebellum" to include the vermis and an involvement of vermal lobules VI and VII in the regulation of smooth pursuit eye movements.

44.12 SMOOTH PURSUIT EYE MOVEMENTS IN OPEN AND CLOSED LOOP: A LINEAR SYSTEM, ROUGHLY SPEAKING. Jordan Pola and Harry J. Wyatt. State University of New York, College of Optometry, NY, NY 10010.

Laboratory studies of the human smooth pursuit eye movement system have often been performed in the "open loop"; that is, with target motion (often sinusoidal) stabilized at the retina. In this situation, target motion at the retina, which is assumed to be the stimulus, is held constant regardless of the eye movements that result. In contrast, in the real world, a person generally makes pursuit eye movements in the "closed loop"; that is, target motion at the retina varies with the eye movement. The two conditions can be represented roughly as follows:



The open loop has significant experimental advantages; for example, gain and phase lag of the response (for constant stimulus frequency) may reflect system parameters and stimulus effectiveness. (Closed-loop gain and phase are often constrained to be near 1 and 0^{o} respectively). However, it is unclear whether the open-loop pursuit system tells us how the system performs in the real world. The relationship between open- and closed-loop performance is relatively simple for a linear system (G_a and G_b in the Figure are the same), but possible non-linear and volitional components of pursuit movements prevent us from assuming simple linearity.

We have measured open- and closed-loop pursuit movements for sinusoidal target motion, at frequencies 0.25-3.0 Hz and amplitudes $2\text{-}6^{o}$ peak-to-peak. Gain and phase lag were measured from the eye position record. (This entailed removing saccades from the records). The open-loop data were used to calculate closed-loop gain and phase lag for a linear system, and we compared calculated and experimental closed-loop results for each subject. We have observed a striking degree of correspondence between the linear prediction and the experimental closed-loop data. This suggests that (i) the steady-state pursuit system is approximately linear for small signals, and (ii) results from open-loop experiments have application in the real world.

45.1 METOCLOPRAMIDE INCREASES CANINE PLASMA β-ENDORPHIN IMMUNOREACTIVITY AND CORTISOL: EVIDENCE FOR SECRETION FROM PITUITARY INTERMEDIATE LOBE. B. Sharp*, E. Levin*, and J. Sowers* (SPON: D. Aures-Fischer). VA Wadsworth and Sepulveda Medical Centers and UCLA Dept. of Medicine, Los Angeles, CA. 90073.

Dopamine has been shown to inhibit the secretion of β-endorphin-immunoreactivity (β-EP-I) from the intermediate lobe of the pituitary, in vitro. The in vivo physiology of this modulation including its potential influence on the secretion of intermediate lobe β-EP-I into the systemic circulation has not been evaluated.

Metoclopramide, a specific dopamine receptor antagonist, was administered iv (2.5 mg) to 5 loosely restrained male mongrel dogs. Blood was drawn via an indwelling iv cannula at -30, -15, 0, +10, +20, +45, +60, and +90 min. In a second experiment, dogs were pretreated with dexamethasone 1 mg iv 120 min prior to metoclopramide. All plasma was extracted with talc and eluted with HCl+acetone, yielding recovery efficiencies of 60% and 30% for β-endorphin and β-lipotropin (β-LPH), respectively. β-EP-I was measured by an RIA which has equimolar cross-reactivity with β-LPH.

Following metoclopramide, basal β-EP-I levels increased from 16±2 pg/ml (mean±SE) to a peak of 68±16 at +10 min ($p<.025$). Thereafter, a steady decline to 27±5 at 90 min was observed. Cortisol increased from a basal of 3.3±0.5 µg/dl to 8.7±2.2 at 90 min ($p<.05$). Pretreatment with dexamethasone did not alter β-EP-I response but completely inhibited the cortisol response.

To further characterize the β-EP-I, 2 plasma pools were collected from 4 dogs prior to and 10 min following the administration of metoclopramide. The β-EP-I extracted from each pool was chromatographed on Sephadex G-50 gel, using a 0.9x60 cm. column at 4°C. RIA of the collected fractions showed 2 immunoreactive peaks which corresponded to the elution volume of β-LPH and β-EP. The basal β-LPH/β-EP ratio was 2.5 and the peak was 0.7.

Conclusions: The marked shift in the molar ratio of β-LPH/β-EP following the administration of metoclopramide is most consistent with secretion from the intermediate lobe of the pituitary since its β-EP-I content is predominantly β-EP rather than β-LPH. Furthermore, the rapid and significant rise in plasma β-EP-I following metoclopramide suggests that, at least in species such as the dog which have a well-defined pituitary intermediate lobe, the secretion of pituitary β-EP-I is tonically inhibited by endogenous dopamine. The differential effect of dexamethasone pretreatment on cortisol versus β-EP-I secretion suggests differences in the regulation of secretion from the two cell types which constitute the dog intermediate lobe; dopamine has not been shown to alter secretion by anterior lobe corticotrophs.

45.2 ANOMALOUS β-LIPOTROPIN CONTENT IN THE ANTERIOR PITUITARY OF BRATTLEBORO RATS:ABSENCE OF β-LIPOTROPIN. R. G. Allen*, J. C. Crabbe, Jr., J. Stack*, and N. D. Gaudette*. VA Medical Center and University of Oregon Health Sciences Center, Portland, OR 97201.

The biosynthesis and processing of corticotropin (ACTH), β-lipotropin (β-LPH), and β-endorphin in the rat pituitary are well understood. In the normal rat, the major protein containing the amino acid sequence of β-endorphin is β-LPH (MW approx. 14K). Since homozygous Diabetes Insipidus (Brattleboro) rats have been shown to lack functional vasopressin, as well as having reduced content of ACTH, it was of interest to us to investigate the forms of ACTH, β-LPH, and β-endorphin contained in anterior lobe tissue obtained from vasopressin deficient rats.

Anterior lobes obtained from Brattleboro rats were extracted in 30% acetic acid in the presence of protease inhibitors, lyophilized, and then fractionated by sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE). The gels were sliced, eluted, and assayed for β-LPH and β-endorphin immunoactivity. We found immunoactivity migrating on the gels only at the positions of the 31-35K common precursor to ACTH and β-LPH, and a very small amount of β-endorphin migrating at 3.5K daltons. Virtually no β-LPH was seen in these extracts.

In order to further assess this striking result we grew primary monolayer cultures of anterior lobe tissue taken from Brattleboro rats in the presence of radioactive methionine for periods of 2-48 hours. At the end of the incubation periods the cells were harvested and the extracts immunoprecipitated with affinity-purified antisera to ACTH, β-LPH and β-endorphin. The immunoprecipitates were then fractionated by SDS/PAGE, and the gels sliced, eluted and counted. Again, we found no intracellular β-LPH at any time period examined. Vasopressin added to the culture medium (10 ng/ml) for 24 hours did not cause β-LPH to appear in the cells. We conclude from these results that as well as a vasopressin defect, Brattleboro rats have a major defect in the processing and/or storage of β-LPH and β-endorphin derived from the common precursor to ACTH and β-LPH.

45.3 BETA-ENDORPHIN IMMUNOREACTIVITY IN RAT PLASMA: VARIATIONS IN RESPONSE TO DIFFERENT PHYSICAL STIMULI. G.P. Mueller. Dept. of Physiology, USUHS, Bethesda, MD 20014.

Recent findings in rats indicate that pituitary beta-endorphin (B-END) mediates, in part, the behavioral analgesia caused by certain forms of stress. Since the degree of analgesia produced depends upon the type of stress employed, it is possible that the amount of pituitary B-END released may also vary according to the particular stress experienced. To investigate this possibility, comparison of the effects of several types of stressful stimuli on plasma levels of B-END-like immunoreactivity (B-END-LI) was made in male rats. Treatments were: tail-flick and hot-plate nociception testing procedures, etherization and immobilization. Plasma levels of total B-END-LI were estimated by radioimmunoassay (Mueller, P.S.E.B.M. 165 75, 1980) and characterized by gel filtration chromatography (Sephadex G-50). The antibody used (C-55) recognizes B-END and beta-lipotropin (B-LPH) standards equally but does not cross react with N-terminal fragments of B-END (i.e. met-enkephalin and α-END). Continuous immobilization maximally increased circulating B-END-LI 10 fold by 10 to 30 min of stress. As compared to control values (.18±02 ng/ml) etherization for 90 sec increased plasma levels of B-END-LI 2.8, 5.0 and 3.1 fold by 5, 15 and 30 min respectively. Tail-flick and hot plate analgesia testing procedures both resulted in a doubling in circulating B-END-LI (.16±.03 ng/ml vs. .32±.18 ng/ml and .33±.06 ng/ml respectively), however, only the rise in response to hot-plate testing was significant due to the large variation in hormone values observed in the group subjected to tail-flick testing. Chromatographic analysis of B-END-LI in plasma pools revealed that about 70% of circulating B-END-LI in control animals co-chromatographs with B-END standard; the remaining 30% resembles B-LPH in molecular size. In response to stress (immobilization), both forms of plasma immunoreactivity were increased although a relatively greater rise in the form corresponding to B-LPH was observed. In stressed animals, 60% to 75% of circulating B-END-LI co-chromatographed with B-LPH standard. Together these data suggest that both B-END and B-LPH are secreted by the pituitary under basal and stimulated conditions. The increases in total plasma B-END-LI content observed in response to different stresses varied from 2 to 10 fold and these differences may indicate that the magnitude of a plasma B-END-LI response is directly related to the degree of trauma experienced.

45.4 THE SECRETION OF PITUITARY BETA-ENDORPHIN-LIKE IMMUNOREACTIVITY IS REGULATED INDEPENDENTLY BY DOPAMINE AND GLUCOCORTICOIDS IN THE RAT. J.M. Farah, Jr.*, D.I. Sapun* and G.P. Mueller (SPON: J.M. Sarvey). Department of Physiology, Uniformed Services University of the Health Sciences, Bethesda, MD 20014.

Recent in vitro studies indicate that several mechanisms probably control the secretion of beta-endorphin-like immunoreactivity (β-END-LI) by the rat pituitary. Dopamine acts directly on the pars intermedia but not the pars distalis to inhibit the release of β-END-LI. By contrast, glucocorticoids inhibit the spontaneous release of β-END-LI from pars distalis cells but is without effect on cells of the pars intermedia (see Eipper and Mains, Endo. Rev. 1:1, 80). The purpose of the present study was to examine the possibility that dopaminergic neurons and circulating glucocorticoids may regulate independently the pars intermedia and pars distalis secretions of β-END-LI in vivo. Accordingly, dopaminergic and glucocorticoid drugs were given alone and in combination to determine their effects on plasma levels of β-END-LI in male rats. Plasma β-END-LI was measured by RIA (Mueller, P.S.E.B.M. 165:75, 1980); the antibody used (C-55) recognizes camel β-END and human beta-lipotropin (β-LPH) equally but does not detect N-terminal fragments of β-END (met-enkephalin and alpha-endorphin). Administration of the dopamine receptor blocker, haloperidol (HAL, 2.5 mg/kg, ip) maximally increased plasma β-END-LI 3.4-fold over control values by 30 and 60 min after injection (.22±.04 ng/ml to .78±.15 and .71±.11 ng/ml respectively); by 3 h after HAL, plasma levels of β-END-LI had returned towards control values. Pretreatment with the dopamine receptor agonist, bromocriptine (5 mg/kg, ip, 2 h) completely prevented the release of β-END-LI in response to HAL. However, the HAL-induced increase in circulating β-END-LI was not affected by pretreatment with a dose of dexamethasone (50 µg/ml, ip, 4 h) known to completely prevent the stress-induced release of pituitary β-END-LI. Conversely, metyrapone (100 mg/kg, ip, 30 min), a blocker of corticosterone synthesis, increased plasma levels of β-END-LI 5-fold over control values (1.31±.32 ng/ml vs. .25±.03 ng/ml); this rise was unaffected by pretreatment (2 h) with either 1 or 5 mg/kg bromocriptine. The present results demonstrate that circulating β-END-LI in rats is acutely elevated by dopamine receptor blockade in a manner which appears to be independent of glucocorticoid influence on pituitary β-END-LI secretion. Conversely, the acute effects of glucocorticoid manipulations (dexamethansone and metyrapone) on plasma β-END-LI seem to occur independent of dopaminergic regulation. These findings are consistent with the view that dopamine neurons regulate β-END-LI release by the pars intermedia in vivo whereas the glucocorticoids inhibit the secretion of β-END-LI by the pars distalis.

45.5 ADRENERGIC REGULATION OF IMMUNOREACTIVE BETA-ENDORPHIN RELEASE FROM RAT PITUITARY. D.J. Pettibone and G.P. Mueller, Dept. of Physiology, Uniformed Services University, Bethesda, MD 20014.

Stimulation of α-adrenergic receptors by clonidine in vivo evokes the release of β-endorphin-like immunoreactivity (β-END-LI) into the circulation (ENDO, in press) probably by acting directly on cells of the par distalis (ENDO SOC abs, 1981). In this report, we further characterize the adrenergic control of β-END-LI release from rat pituitary in vitro and in vivo.

Enzymatically dissociated anterior lobe (AL) or neurointermediate lobe (NIL) cells from male, Sprague-Dawley rats were cultured for 5-9 days and then incubated for 2h in presence or absence of various drugs. Release medium was assayed for β-END-LI using an RIA for camel β-END (Mueller, P.S.E.B.M. 165:75, 1980). The RIA recognizes human β-lipotropin (β-LPH) and β-END equally but does not detect N-terminal fragments of β-END (enkephalin, α-endorphin). Incubation of AL cells with any of several α-adrenergic agonists significantly enhanced release of β-END-LI; α-methylnorepinephrine (10^{-6}M) from 0.80±0.06 to 1.44±0.16, methoxamine (10^{-5}M) from 2.20±0.12 to 5.58±0.62, clonidine (10^{-6}M) from 2.20±0.12 to 5.64±0.22 ng/plate. Mixed α-, β-adrenergic agonists such as norepinephrine (10^{-6}M) or epinephrine (10^{-6}M) also significantly enhanced release of β-END-LI from AL cells. The epinephrine-induced release (1.74±0.11 to 9.75±0.72 ng/plate) appears to be mediated by α-adrenergic receptors because phenoxybenzamine (10^{-5}M), but not propranolol (10^{-5}M), blocked the response.

Release of β-END-LI from NIL cells was not affected by clonidine (10^{-6} to 10^{-10}M) (ENDO SOC Abs, 1981), however β-adrenergic activation by isoproterenol (10^{-7}M) increased β-END-LI release from 20.18±2.32 to 39.02±1.69 ng/plate, an effect blocked by propranolol (10^{-5}M). Isoproterenol also released β-END-LI from AL cells but the concentration required was 100-fold greater than that which activated NIL release.

Intraperitoneal administration of isoproterenol (1 mg/kg) to rats increased plasma β-END-LI (0.38±0.03 to 1.83±0.19 ng/ml) 30 min post-injection. Treatment with propranolol (2 mg/kg, ip) 45 min before isoproterenol (200 µg/kg, ip) blocked the 3-fold rise in plasma β-END-LI, suggesting a β-adrenergic involvement.

These results demonstrate that α- and β-adrenergic activation releases β-END-LI from the pituitary in vivo and in vitro. Secretion of β-END-LI from AL or NIL cells in culture appears to be controlled predominantly by α- and β-adrenergic mechanisms, respectively. Together, these findings raise the possibility that blood-borne catecholamines may normally influence release of pituitary β-END-LI in vivo.

45.6 SEROTONERGIC NEURONS STIMULATE RENIN AND CORTICOSTERONE SECRETION VIA THE PITUITARY GLAND. L.D. Van De Kar*, C.W. Wilkinson*, M.S. Brownfield*, Y. Skrobik* and W.F. Ganong. Dept. of Physiology, University of California, San Francisco, CA 94143.

Brain serotonin has been shown to stimulate renin secretion in anesthetized dogs (Zimmermann and Ganong, Neuroendocrinology, 30:101, 1980). In conscious rats, the serotonin agonist quipazine and the serotonin releaser p-chloroamphetamine (PCA) caused an increase in both plasma renin activity (PRA) and corticosterone (Van De Kar et al. Neurosci. Abstr. 6:323, 1980). In order to identify the population of serotonergic neurons that stimulates renin and corticosterone secretion, the dorsal or median raphe nuclei were selectively lesioned by local injection of 5,7-dihydroxytryptamine (5,7-DHT) into desmethylimipramine pretreated rats. Two weeks later, the rats received saline or PCA (10 mg/kg i.p.) 2 hours before sacrifice. The PCA-induced increase in PRA was significantly inhibited by dorsal but not median raphe lesions. Combined dorsal-median raphe lesions also inhibited the rise in PRA caused by PCA. In contrast, the effect of PCA on plasma corticosterone was not inhibited by any of the lesions. This suggests that serotonergic neurons in the dorsal raphe mediate a stimulatory influence on renin but not corticosterone secretion.

In an effort to identify the pathways employed to exert this effect, rats were pretreated with the sympathetic blocker bretylium tosylate (10 mg/kg i.p.) 18 or 4 hours before sacrifice. This treatment did not prevent the effect of PCA on PRA and corticosterone. Adrenal enucleation performed 5 weeks before sacrifice, also failed to affect the PRA and corticosterone responses to PCA. Adrenalectomy, 70 hours before sacrifice, caused a significant increase in PRA and did not prevent the PCA-induced increase in PRA. The effect of PCA on PRA and corticosterone was completely abolished by hypophysectomy 22 days before sacrifice. These results suggest that the information from the central serotonin receptors is transmitted to the kidney via a factor that is secreted from the pituitary gland.

(Supported by USPHS grant AM06704, NIH postdoctoral fellowships to LDVDK and CWW, and a Giannini fellowship to MSB).

45.7 EFFECT OF CHOLINOMIMETICS AND CHOLINESTERASE INHIBITORS ON PLASMA BETA-ENDORPHINS. Edward H. Mougey* and James L. Meyerhoff. Dept. of Medical Neurosciences, Div. of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, D.C. 20012.

Cholinomimetic agents have been shown to release pituitary corticotrophins (1). Since corticotrophins and endorphins may share a common biochemical precursor (2), and since physostigmine is reported to have antinociceptive effects, we hypothesized that cholinomimetics or cholinesterase inhibitors might release pituitary endorphins. Accordingly, we have examined the effects of oxotremorine, nicotine, neostigmine, and physostigmine on plasma beta-endorphin immunoreactivity. Male albino Sprague-Dawley rats weighing 300 ± 10 grams were individually housed in a room with an ambient temperature of 23 ± 2°C and a 12/12 light/dark cycle (0700-1900 light). Food and water were available ad libitum. The rats were habituated to intraperitoneal injections of saline for 4 days and on the 5th day subjected to intraperitoneal injection of oxotremorine (1.2 mg/kg), nicotine (1.2 mg/kg), physostigmine (0.375 mg/kg), neostigmine (0.375 mg/kg) or saline. Ten minutes following injection the rats were decapitated, the blood collected in cold heparinized tubes, and centrifuged for 10 min at 4°C. The plasma was transferred to tubes containing traysylol and stored at -35°C. The samples were extracted to concentrate the immunoreactive fraction and then assayed for beta-endorphin immunoreactivity using antibody produced in rabbits in our laboratory. Significant increases in beta-endorphin immunoreactivity were produced by all four drugs. The finding of a response to neostigmine, which does not cross the blood brain barrier, suggests that direct effects on pituitary receptors must be considered along with several other possible mechanisms, including stress which has been demonstrated to release adrenocorticotropin and beta-endorphin concomitantly (3).

45.8 DESENSITIZATION OF THE ACTH RESPONSE TO EPINEPHRINE IN RAT ANTERIOR PITUITARY CELLS IN CULTURE. V. Giguère* and F. Labrie* (SPON: S. Radouco-Thomas), MRC Group in Molecular Endocrinology, CHUL, Québec, Canada G1V 4G2.

Recent data obtained in our laboratory show that ACTH secretion in rat anterior pituitary cells in primary culture is stimulated by highly specific α_1-adrenergic mechanisms. The ACTH response to epinephrine (EPI) is inhibited by the specific α_1-adrenergic antagonist prazosin at a K_d value of 0.06 nM while the α_2 antagonist yohimbine is 1,200 times less active. Many hormones which elicit a response in their target cells by initially binding to cell surface receptors have been found to decrease the magnitude of their responses during prolonged incubation. In order to examine the phenomenon of desensitization of the response to EPI in culture rat anterior pituitary cells, we have studied the ACTH response to EPI during prolonged incubation with the catecholamine. During a 3-h incubation period, rat anterior pituitary cells respond to increasing concentrations of EPI with a 10- to 12-fold stimulation of ACTH release at an ED_{50} value of 15 nM. First exposure of the cells to 1 µM EPI during 3 h leads to a decrease in the ACTH response to a second challenge with 30 nM EPI. Desensitization to EPI reaches a plateau at about 30% of the control stimulation after 2 h of preincubation. The desensitization by EPI is obtained at an ED_{50} value of 10 nM. The reduction of the ACTH response to EPI is not due to a decrease in pituitary cell ACTH content since EPI pretreatment reduces ACTH content by only 10%. We next studied the dose-response curves to EPI in control and 1 µM EPI-treated cells. The ED_{50} value for EPI stimulation of ACTH secretion is 3-fold higher in cells pretreated with the catecholamine while the maximal response to EPI is inhibited by 60%. When 1 µM phentolamine, an α-adrenergic antagonist, is present during preincubation with 1 µM EPI, no decrease in ACTH response to EPI is observed during the second incubation with EPI alone. Preincubations with phentolamine alone has no effect on a later stimulation by EPI, thus indicating that the occupancy of the α-adrenergic receptor is not sufficient to cause desensitization. When cells are preincubated for 3 h with 1 mM IBMX, a phosphodiesterase inhibitor, the ACTH response to 30 nM EPI is inhibited by 40%. The present data show that stimulation of the α_1-adrenergic receptor controlling ACTH secretion causes rapid desensitization to further stimulation by EPI. While α-adrenergic stimulation induces an almost complete inhibition of the response to a second stimulus, increased cyclic AMP levels induced by IBMX can also cause some desensitization (40%), thus suggesting that stimulation of cellular activity independant of receptor binding is also responsible for desensitization to specific stimuli.

45.9 ENKEPHALIN SYSTEMS IN THE MEDIAN EMINENCE OF THE MOUSE: EFFECTS OF NEONATAL MSG TREATMENTS. M.A. Romagnano, Theresa L. Chafel*, W.H. Pilcher* and S.A. Joseph. The Neuroendocrine Unit, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

The immunocytochemical distribution of enkephalin (Enk) was examined in the mediobasal hypothalamus of control mice and monosodium glutamate (MSG) treated mice using the unlabeled antibody enzyme method. Mice were neonatally treated with MSG according to the protocol of Pilcher (previously described). As adults, both control and experimental animals were perfused with Bouin's fixative, and the brains were serially sectioned at 50 μ on an Oxford Vibratome. Sections were immunocytochemically stained in Enk antiserum used at a dilution of 1:2000 (antiserum from Drs. Sundberg and Morris). Alternate sections were stained with ACTH antiserum to determine the extent of the lesion. We have previously shown that in the rat and mouse, the opiocortin bed nucleus is glutamate-sensitive and neonatal treatment with MSG destroys the cell bodies and fiber projections which normally stain with ACTH antiserum. In this study, only animals which demonstrated a complete lesion were used.

In addition to other areas which have been previously described (Wamsley et al., Brain Res., 190:153-173, 1980), Enk immunoreactive fibers in the mediobasal hypothalamus of control mice were found in the median eminence (ME). Both the internal and external zones of the ME contained numerous Enk fibers. In contrast, MSG-lesioned mice displayed a complete lack of immunoreactivity throughout the ME.

The presence of enkephalinergic fibers in the external zone of the ME in close proximity to portal vessels and loss of these fibers after MSG treatment suggests a possible role for enkephalin neuropeptidergic interaction with other neuroendocrine systems.

45.10 TIME COURSE FOR DEVELOPMENT OF INCREASED PLASMA CONCENTRATIONS OF CORTICOSTERONE FOLLOWING HIPPOCAMPECTOMY IN ADULT FEMALE RATS. M. M. Wilson, S. E. Greer*, and D. L. Keith*. Univ. of Portland and Univ. of Oregon Health Sci. Ctr., Portland, OR 97203

In a previous study, we observed increased basal PM plasma corticosterone (B) and ACTH concentrations in female rats whose hippocampus had been removed by suction (Wilson, M. M., et al., Brain Res., 197:433, 1980). There were no differences between hippocampectomized and cortex-lesioned controls in the AM and both groups showed AM-PM fluctuations indicative of an intact circadian rhythm. The increased PM basal samples were surprising because they have not been reported in numerous experiments on hippocampectomized rats. We tested the hypothesis that B concentrations did not increase until at least one month after surgery when neural reorganization has occurred. PM blood samples were obtained from adult female rats 8 days after they were housed in our controlled environment animal quarters (lights on 6 AM-6 PM). Rats were then assigned to intact (I), cortex-removed (CORTX) and hippocampectomized (HIPPX) groups by a randomized block design. Both dorsal and ventral hippocampus were removed by suction. In the CORTX control group, that portion of parietal cortex removed in the HIPPX groups was suctioned off to expose the dorsal hippocampus. Rats were housed 2/cage in a random order. No one entered the animal room for 24 hrs prior to the experiment. Experiments were done from 5:00-6:20 PM. Rats housed together were removed from the cage simultaneously and taken to an adjoining room where they were placed in jars saturated with ether until unconscious. Blood samples (1 ml) were drawn from the exposed external jugular vein within 3 min from the time the rats were first disturbed. Samples were collected weekly from 1-6 wks after surgery. All samples were run in the same radioimmunoassay for B to eliminate any effect of interassay variation. In hippocampectomized rats, plasma B concentrations were higher 1 wk after surgery than before surgery. Pre- and post-lesion values did not differ in the other groups. At 1 wk after surgery, there were no differences between groups in the PM plasma B concentrations. Corticosterone concentrations in the HIPPX group increased over the 6 wk post-surgery period with plasma concentrations at 5 and 6 wks higher than those at 1, 2, and 3 wks. Control groups did not vary with time. At 5 and 6 wks after surgery, PM plasma B concentrations were higher in HIPPX than in control groups. The results indicate that there is an immediate effect (within 1 wk) of removing the hippocampus on PM plasma B concentrations, but the full effects of hippocampectomy are not apparent until 5 wks after surgery.

45.11 SOMATOSTATIN RELEASE IN THE MEDIAN EMINENCE AS DETERMINED BY PUSH-PULL PERFUSION IN THE UNANESTHETIZED RAT. N.W. Kasting, J.B. Martin and M.A. Arnold*. Neurology Res. Lab., Mass. Gen. Hosp. and Harvard Med. Sch., Boston, MA 02114

Somatostatin is a tetradecapeptide known to inhibit the secretion of growth hormone (GH) from the anterior pituitary. Somatostatin is released from hypothalamic neuronal terminals in the ME where it reaches the anterior pituitary via the portal circulation. Research utilizing deafferentation techniques, lesions, or passive immunization with anti-somatostatin serum has indicated that somatostatin may have an important role in the rat in stress-induced GH suppression but its role in non-stress pulsatile GH release in plasma is not clear. It may function to decrease trough levels of GH. The present research was designed to investigate dynamic in vivo release of somatostatin from neuronal terminals in the median eminence (ME) in the unanesthetized, freely-behaving rat and to clarify the relationship of somatostatin secretion to plasma GH levels. To accomplish this goal, 300 g SD male rats were surgically implanted with chronic venous catheters and chronic intracranial guide cannulae directed towards the ME. After rats had recovered from surgery, they were placed in a sampling cage in which a spring-ball bearing assembly allowed the rats free movement and enabled tubing to pass out of the cage for sampling. Push-pull perfusion was used to evaluate immunoreactive somatostatin (IRS) release in the ME. Perfusion samples were collected at 15 min intervals and assayed for IRS by a specific and sensitive RIA. At the end of each 15 minute perfusion period a venous plasma sample was collected to be assayed for GH and prolactin (PRL). The experimental perfusion lasted for 4 h from 1000 h to 1400 h and the rats had free access to food and water. Results indicate that IRS is released in the ME in a pulsatile and episodic fashion with an inter-peak interval of about 1 h. Four hour determinations of mean plasma GH levels and mean IRS release showed a significant negative correlation. The results tended to cluster into two groups, one with low IRS release, normal pulsatile GH release and low PRL, and the other with high IRS release, low plasma GH levels and high PRL, indicative of a stressed animal. Peaks of IRS release often were concurrent with peaks of plasma GH. Gel chromatography indicated that the IRS was composed of several molecular weight species. These results suggested that somatostatin has an important role in stress-induced GH suppression and that there is also a short loop feedback of GH on somatostatin neurons. Furthermore, somatostatin appears to be released in several molecular weight forms, probably representing prohormone or precursor forms of the molecule.

45.12 MODULATION AND FUNCTIONAL ROLE OF GABA BINDING SITES AND UPTAKE SYSTEM IN RAT ANTERIOR PITUITARY. G. Racagni J.A. Apud, C. Civati, D. Cocchi+, V. Locatelli+ and E.E. Müller+. Inst. of Pharmacology and Pharmacognosy and Inst. of Pharmacology+, Univ. of Milan, Italy.

Evidence has been accumulated that γ-aminobutyric acid (GABA) plays a role in the regulation of anterior pituitary (AP) function and, particularly, of prolactin (PRL) release. In this context, we have presented data supporting the existence of a dual GABAergic control of PRL secretion in the rat; one stimulatory exerted on a central nervous system (CNS) site, and the other inhibitory, occurring at the level of the AP. Further, we have shown that GABA is present in the AP and derives from medio-basal hypothalamic (MBH) structures, which release the aminoacid into the hypophyseal portal vesvels. In this presentation, we report evidence on the measurement of GABA in the pituitary portal circulation and the existence at AP level of a GABAergic uptake system and different populations of GABA binding sites. GABA concentrations in the stalk blood were determined by a mass fragmentographic technique and the values are 677 ± 68 pmol/ml. GABA in the AP is taken up by an effective uptake system, temperature dependent. When AP homogenates were incubated at 15°C in a medium containing ^{3}H-GABA ($5 \cdot 10^{-8}$M) there was a rapid accumulation of radioactivity in the tissue, after 60 min. Previous studies by our group have indicated that AP does possess the enzymatic machinery to break down the aminoacid, i.e. GABA-T. The presence of this enzyme may account for the high doses of GABA required for significant inhibiting PRL secretion, we now report experiments performed on in vitro pituitaries in the presence of a specific GABA-T blocker, ethanolamine-O-sulphate, showing that GABA is able to decrease PRL release at lower concentrations (10^{-6}M). To characterize the pituitary GABA receptors, the binding of ^{3}H-muscimol (^{3}H-M) to crude mitochondrial AP membrane fractions, extensively washed with triton X 100, was examined. ^{3}H-M binding was saturable and occurred with a high (K_D= 2.8 nM and B_{max}= 45 fmol/mg prot) and low (K_D= 29 nM and B_{max}= 155 fmol/mg prot) affinity. Stereotaxic lesions at the level of MBH elicited a significant increase of the number of ^{3}H-M binding sites, suggesting that these receptors have become supersensitive. These results indicate that the inhibitory action of GABA at the pituitary on PRL secretion may represent a receptor mediated and a physiological action.

46.1 SYNAPTIC CONNECTIONS BETWEEN LEECH SWIM-INITIATING NEURONS AND THE SWIM CENTRAL PATTERN GENERATING CIRCUIT. Janis C. Weeks
Dept. of Biology, UCSD, La Jolla, CA 92093 (present address: Dept. of Zoology, Univ. of WA, Seattle, WA 98195).

Previously, swim motor neurons, pattern-generating "oscillator" interneurons and a single swim-initiating interneuron (cell 204) were identified in the leech (Ort et al. 1974; Friesen et al. 1978; Weeks & Kristan, 1978). Friesen and collaborators proposed a model for the swim central pattern generator (CPG) circuit involving the four oscillator cells, but more recent results (Weeks, in press) indicate that this description is incomplete and that other CPG cells must exist. In the present experiments, synaptic connections were sought between cell 204 and the oscillator cells, and between cell 204 and two newly identified CPG cells. These results provide the first indications of how the activity of swim-initiating cells causes activation of the rhythmic CPG circuit.

Pairwise intracellular recordings from cell 204 and oscillator cells revealed no synaptic connections in either direction. Cell 204 affects oscillator cells only insofar as its activity serves to evoke rhythmic swim motor output. Hence, cell 204 does not initiate swimming by way of effects on oscillator cells but rather must act via other CPG cells. Accordingly, new CPG cells were sought and two were identified and characterized.

Both new cells (cells 205 & 208) are unpaired intersegmental interneurons anatomically similar to cell 204. Cell 205 not only participates in pattern generation, but also has swim-initiating capabilities similar to those of cell 204 and is the first bifunctional swim cell of this type to be discovered. Cells 204 & 205 are not synaptically linked. The second new CPG neuron, cell 208, provides a major monosynaptic (as tested by TEA injection) source of rhythmic excitation to dorsal excitor motor neurons during swimming. Cell 208 is most interesting in that it is directly excited interganglionically by cells 204 & 205 and accordingly provides the first known link between swim-initiating cells and the CPG. Because of these inputs cell 208 is activated early on during swim initiation, unlike the oscillator cells which come on only at the onset of rhythmic motor bursts.

In other experiments both cell 205 and 208 were found to receive mechanosensory input. Cell 205 is polysynaptically excited by T (touch), P (pressure) and N (nociceptive) sensory neurons, and has a rectifying electrical connection with the multimodal giant fiber (S cell) system. Cell 208 is inhibited by P and N cells.

Friesen et al. (1978) J.exp.Biol. 75:25-43; Ort et al. (1974) J.comp.Physiol. 94:121-156; Weeks (in press) J. Neurophysiol.; Weeks & Kristan (1978) J.exp.Biol. 77:71-88.

46.2 MOTOR CONTROL IN THE LEECH: A NEWLY IDENTIFIED INTERNEURON SUBSERVING VENTRAL FLEXION. M.P. Nusbaum and W.B. Kristan, Jr., Dept. of Biology, UCSD, La Jolla, CA. 92093.

A new bilaterally paired intersegmental interneuron has been identified in the segmental ganglia of the gnathobdellid leeches Hirudo and Macrobdella. This cell, the Ventral Flexor interneuron (VF cell), when stimulated in brainless, semi-intact preparations causes the posterior end of the leech to flex ventrally and to one side. Stimulation of it's bilateral homologue causes the back end to flex to the other side. The anterior end of the leech shows no behavioral response to VF cell stimulation. These behavioral responses result from synaptic connections from the VF cells to the ensemble of identified motor neurons that innervate the dorsal and ventral longitudinal muscles. These are the muscles used by the leech for swimming and shortening, as well as for a ventral flexion. Each VF cell excites all of the ipsilateral ventral exciter motor neurons, and bilaterally inhibits the dorsal exciter motor neurons, in all ganglia posterior to it's own.

Serial VF homologues are weakly coupled such that an anterior VF cell excites a posterior VF cell, but there is no connection in the reverse direction. There is only weak electrical coupling between the bilateral VF homologues so that common presynaptic input is necessary to activate these cells coordinately. This suggests that the VF cells may be part of neuronal circuits for different behaviors, both local and whole-body.

Both VF cells receive bilateral mechanosensory and photosensory excitation, intra-and intersegmentally. Much of both of these sensory inputs are mediated by the multi-modal interneuron, the S cell. This cell receives strong mechanosensory and photosensory excitation and has a monosynaptic excitatory connection onto the VF cells.

There are also reciprocal inhibitory interactions between the VF cells and cells in the swim circuit. Depolarizing the swim-initiating interneuron, cell 204, results in a barrage of ipsp's in the VF cells. During swimming, the VF cells receive strong phasic inhibition. In turn, depolarizing a VF cell occasionally stops a swim.

Experiments are now under way to further elucidate this reciprocal inhibition, as well as to determine the contribution of the VF cells to natural behaviors.

This research was supported by PHS Grant NS14410.

46.3 Rate Modification in the Leech Heartbeat Central Pattern Generator. Edmund A. Arbas Biological Laboratories, Harvard Univ. Cambridge MA. 02138

The central pattern generator (CPG) which drives contractions of heart tubes in the leech, Hirudo medicinalis, is well characterized in terms of its neuronal elements, and the synaptic interactions which produce its basic output rhythm. Heart tube contractions are elicited by rhythmic bursts of action potentials from Heart Excitor (HE) motorneurons. The HE cell activity rhythm is controlled by cyclical barrages of inhibitory synaptic potentials from an ensemble of Heart Interneurons or HN cells. To understand the dynamics of the CPG further, I have examined several pathways through which the period of the rhythm is modified, using intracellular recording and electrical stimulation of neurons in isolated nerve cords as well as in semi-intact preparations in which only a few ganglia were dissected for recording.

I find that, in general, stimuli which increase motor activity also lead to decreases in the cycle period of the heartbeat CPG. Profound decreases in the burst period of HE cells (of up to 50%) are observed in specific association with swimming behavior. Such decreases are observed whether swimming is manifested "spontaneously" in semi-intact preparations, or elicited by mechanical stimuli applied to the body wall, electrical stimulation of nerve roots or swim-initiating interneurons (Weeks & Kristan 1978 J. Exp. Biol. 77;71-88).

The interaction between the swim system and the heartbeat CPG is, in great part, centrally mediated. Reductions in HE cell burst period are observed in the absence of peripheral feedback, on activation of the swimming motor program in isolated nerve cords. The reduction of HE cell burst period in every case reflects accellerated cycling of the HN cell ensemble.

46.4 LEECH HEARTBEAT: TIMING AND COORDINATION BY INTERSEGMENTAL INTERNEURONS. E.L. Peterson. Biol. Labs., Harvard Univ., 16 Divinity Ave., Cambridge MA 02138.

In each of the first 7 segmental ganglia of the leech Hirudo medicinalis there is a bilateral pair of heart interneurons (HN cells). These 7 pairs control the firing of the motor neurons which drive the rhythmic constrictions of the two lateral hearttubes. The 4 most rostral pairs constitute the heartbeat 'timing oscillator' by virtue of their capacity to reset and entrain the activity of all cells in the heartbeat system. The timing oscillation is generated in the following way. The interneurons originating in ganglion 3 (cells HN(L,3) and HN(R,3)) fire impulse bursts in antiphase, a relationship sustained by a balance between strong monosynaptic reciprocal inhibition and the endogenous properties of these two cells. Similarly cells HN(L,4) and HN(R,4) inhibit one another strongly and burst in antiphase. Finally a cell HN(1) or HN(2) both inhibits and is inhibited by the ipsilateral HN(3) and HN(4) cells. The apparent function of the connections between cells HN(1)/HN(2) and HN(3)/HN(4) is to phase-lock the oscillation of the HN(4) pair to that of the HN(3) pair thereby ensuring a coordinated output to the rest of the heartbeat system. Specifically, with each cycle the cessation of the HN(3) burst releases the ipsilateral cells HN(1) and HN(2) from inhibition. The resulting activity of the latter cells delays the ipsilateral HN(4) cell's burst sufficiently to hold cell HN(4) in its characteristic phase relationship to cell HN(3). Thus the timing oscillator can be viewed as a pair of oscillators--one the HN(3) cell pair, the other the HN(4) cell pair--coupled by the interganglionic coordinating interneurons HN(1) and HN(2). (Supported by NIH 1 RO1NS 15101-01 to R.L. Calabrese and a NATO postdoctoral fellowship to E.L.P)

46.5 SYNAPTIC RELATIONS UNDERLYING SWALLOWING AND REGURGITATION IN NAVANAX, AN OPISTHOBRANCH MOLLUSC. M.B.Zimering,* D.C.Spray and M.V.L. Bennett, Dept. Neurosci., Einstein Col. Med., Bx., NY.

Navanax inermis ingests prey by a rapid pharyngeal expansion mediated by radial muscles of the pharynx. Ingestion is followed by swallowing or regurgitation. Swallowing results from a wave of contraction that spreads anteroposteriorly along succesive bands of circumferential muscles of the pharynx (CMs). Regurgitation may result from a similar wave of contraction in the reverse direction, but more often it results from a simple, synchronous contraction of more caudal CMs.

CMs are controlled by neurons in the buccal ganglia,CMNs, which innervate distinct CM bands in specific regions of the pharynx. There are 7-8 homologous CMNs in each buccal ganglion; 4 controlling CMs in anterior, middle, midposterior, and posterior regions of the pharynx unilaterally (LUA & RUA, LUM & RUM, LUMP &RUMP, LUP &RUP), and 3-4 controlling CMs in similar regions bilaterally (LBA & RBA, LBM &RBM and/or LBMP & RBMP, LBP & RBP). The midposterior regions overlap with both the middle and the posterior regions. Electrotonic coupling occurs between at least 30 classes of CMN pairs; coupling coefficients were determined for each of these pairs ($n \geq 3$) and were as large as 0.25. Patterns of connectivity are as follows: within one ganglion CMNs innervating muscles unilaterally and bilaterally at the same level are coupled, except for UP and BP CMNs. CMNs innervating adjacent muscle groups are coupled except for BP CMNs. CMNs innervating nonadjacent muscles are at most weakly coupled. Between opposite ganglia corresponding CMNs generally are coupled except for UP CMNs (BP CMNs not tested), and noncorresponding CMNs are at most weakly coupled.

Electrotonically coupled CMNs can exhibit "effective sign reversal of coupling" when there is much inhibitory activity in them (Science 194: 1065, '76). CMNs which are not electrotonically coupled also can exhibit reversed coupling. Systematic investigation of reversed coupling ($n \geq 3$) showed bilateral symmetry between ganglia of interactions within each ganglion, but both classes of reversed coupling between corresponding CMNs on opposite sides (LUM & RUM, LUMP & RUMP) were stronger from left to right. U and B CMNs at the same level did not exhibit reversed coupling except for RUM and RBM where the relation was reciprocal. Other intraganglionic relations were strongly directional anteroposteriorly, with CMNs exhibiting reversed coupling with each CMN innervating muscles at more posterior levels, i.e. A to M, MP and P; M to MP and P; MP to P. These relations imply that under conditions of a high rate of background inhibitory activity depolarization and hyperpolarization of more anterior cells inhibits and excites respectively more posterior cells; actions presumably important in swallowing. In the absence of inhibitory activity, electrotonic coupling may facilitate regurgitation or pharyngeal emptying prior to the rapid ingestion phase. Supported (in part) by NIH grant 5T 32GM7288.

46.6 CONSEQUENCES OF ELECTRICAL COUPLING AND NON-SPIKING RELEASE OF TRANSMITTER FOR CIRCUIT ANALYSIS AND TRANSMITTER IDENTIFICATION. J.S. Eisen and E. Marder. Biology Dept., Brandeis University, Waltham, MA 02254.

Both electrical coupling and non-spiking transmitter release have been described in invertebrate and vertebrate nervous systems. However, the implications of these two phenomena for circuit analysis and transmitter identification have not been yet fully explored. In the stomatogastric ganglion of the spiny lobster, the 2 PD motor neurons are electrically coupled to the AB interneuron. Depolarization (with or without action potential activation) evokes a complex IPSP in another motor neuron, the LP. Action potentials in the LP cell evoke discrete IPSPs which can be recorded in both the PD and AB neurons. Based on these data alone, there are 9 possible alternative representations of the PD-AB-LP circuit. Therefore, we have used the Lucifer Yellow cell fill/kill technique (Miller & Selverston, Sci 206: 702-704, 1979) to selectively remove either the AB or the PDs from the circuit, and we have been able to eliminate 8 of the 9 alternative representations for the PD-AB-LP circuit.

When the AB neuron is killed, the PDs still evoke an IPSP in the LP. Likewise when both PDs are killed the AB alone evokes an IPSP in the LP. Therefore, the compound IPSP recorded in the LP under physiological conditions is due to transmitter released from both the PD and AB neurons. When the AB neuron is killed, LP action potentials still evoke discrete IPSPs in the PDs. However, when the PDs are killed, LP action potentials no longer evoke IPSPs in the AB, suggesting that the IPSP normally recorded in the AB cell is actually an electrotonic coupling potential from the PD. The PD-AB group also evoke IPSPs in another follower cell, the VD motor neuron. In this case, Lucifer fill/kill experiments indicate that the IPSP recorded in the VD cell is evoked predominately, if not completely, by AB-released transmitter.

Current evidence suggests that the PD and AB cells release different transmitters. Our data show that transmitter identification in any vertebrate or invertebrate local circuit containing electrically coupled neurons capable of non-spiking transmitter release is possible only if one knows, with certainty, which of a group of electrically coupled cells is actually releasing transmitter. Supported by NSF BNS-78-15399 and the McKnight Foundation.

46.7 MODULATION OF ELECTRICAL COUPLING AMONG CELLS WITH DIFFERENT POSTSYNAPTIC ACTIONS ON THE SAME FOLLOWER CELLS: A MODEL FOR "SYNAPTIC SWITCHING". E. Marder and J.S. Eisen. Biology Dept. Brandeis University, Waltham, MA 02254.

The stomatogastric ganglion of the lobster contains 2 PD motor neurons which are electrically coupled to the AB, an interneuron. In the previous paper (Eisen & Marder, above) we showed that the compound IPSP recorded in the LP motor neuron resulting from depolarization of the PD-AB cell group is due to transmitter released from both the PD and AB cells.

The 2 PDs and the AB together evoke a complex IPSP in the LP cell. This IPSP is multiphasic, containing an early picrotoxin-sensitive component which reverses at E_K, and a later, picrotoxin-resistant component which fails to reverse, even at membrane potentials 20 to 40 mV more hyperpolarized than E_K. We used the Lucifer Yellow cell fill/kill technique (Miller & Selverston, Sci 206: 702-704, 1979) to kill either the single AB cell or 2 PD cells. We found that after killing the 2 PD cells, the AB-evoked IPSP in the LP cell was picrotoxin-sensitive and reversed at E_K. After killing the AB cell, we found that the PD-evoked IPSP in the LP cell showed no apparent reversal potential, at cell membrane potentials tested (-40mV to -140mV) and was picrotoxin-resistant. Thus the PD and electrically coupled AB cells have remarkably different postsynaptic actions on the same follower cell.

The strength of the electrical coupling between the PDs and the AB appears to be influenced by inputs from the central nervous system (Ayers, personal communication). We predict that changes in this coupling provide a mechanism by which under some conditions the IPSPs in the LP cell will be 1) primarily evoked by the PDs 2) primarily evoked by the AB or 3) evoked by a combination of the two, with different consequences for the postsynaptic cell.

The PD neurons make cholinergic neuromuscular connections, while all present evidence suggests that the AB-transmitter is glutamate. In the special case, when the electrically coupled cells have different postsynaptic actions because they release different transmitters, our model predicts that a postsynaptic effect might switch from one mediated primarily by one transmitter to one mediated primarily by the other transmitter.

We suggest that neuronal circuits containing electrically coupled neurons capable of non-spiking transmitter release provide hitherto unexplored mechanisms for synaptic modulation and plasticity.

Supported by NSF BNS-78-15399 and the McKnight Foundation.

46.8 AN IDENTIFIED LOCAL INTERNEURON IN THE NEURAL OSCILLATOR OF CRAYFISH SWIMMERETS. D. H. Paul. Department of Zoology, University of California, Davis, CA 95616.

The swimmerets are paired appendages on the underside of the abdominal segments of crayfish. Each swimmeret is under the control of a neural oscillator in its own hemiganglion. The two oscillators in a ganglion can be coupled across the midline and to those of adjacent ganglia, so that when the appendages beat vigorously their movements are tightly coordinated. Using Lucifer dye filled microelectrodes to penetrate processes in the swimmeret neuropil, I have discovered six structurally and physiologically different local, nonspiking interneurons. There appears to be one of each type per hemiganglion. One of these, the MAIN cell - Medial (in the swimmeret neuropil), Axonless, InterNuncial cell - is an integral part of the swimmeret oscillator. It has a characteristic spontaneous behavior: abrupt hyperpolarizations caused by trains of IPSPs anticipate the onset of power-stroke bursts; the cell depolarizes as the IPSP frequency declines and it is relatively depolarized during return-stroke (RS) bursts as well as during tonic RS activity in non-bursting nerve cords. In silent preparations the MAIN cell's resting potential is -65 to -70 mV. During bursting it oscillates up to 10 mV around a -50 to -55 mV membrane potential. Injection of small depolarizing currents (≤1nA) stops bursting of all ganglia and drives tonically RS motoneurons. The reinstated bursting that begins following the depolarization is reset relative to the prestimulus pattern. The MAIN cell is dye- and electrically coupled to at least one, decussating RS motoneuron. When the nerve cord is not bursting, small hyperpolarizing currents (1nA) initiate and sustain the normal swimmeret bursting pattern in all ganglia; these hyperpolarizations also induce the usual patterning of IPSPs observed in this cell during spontaneous bursting. The MAIN cell is morphologically distinct from the other local interneurons by the shape, large size, and orientation of its integrating segment from which a characteristic array of primary branches extend dorsally (Fig. 1).

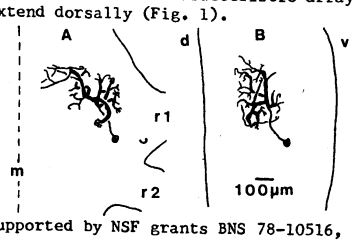

Fig.1. MAIN cell in right hemiganglion. A, dorsal aspect, B, sagittal view from right side. d, dorsal; m, midline; r1, root 1 (innervates swimmerets); r2, root 2; v, ventral.

46.9 CENTRAL CONTROL OF A RHYTHMIC INSECT BEHAVIOR WHOSE NEURAL ACTIVITY PERSISTS IN THE ISOLATED GANGLION. Karen J. Thompson, Department of Biology, University of Oregon, Eugene, OR 97403.

Movements corresponding to oviposition digging behavior are elicited upon transection of the ventral nerve cord in female grasshoppers. The terminal abdominal ganglion drives these movements and is capable of expressing oviposition motor output in the absence of sensory information.

All nerves of the terminal abdominal ganglion can be cut and the ganglion removed from the animal for extracellular ovipositor motor nerve recording. The pattern of activity in the isolated ganglion is found to closely resemble the naturally occuring one. This is true for burst period, spiking discharge frequencies, and for phase relationships among the four muscles of the ventral ovipositor valves.

The oviposition pattern generator appears to be under the control of more rostral ganglia. This control is thought to be inhibitory because cutting the ventral nerve cord anterior to the terminal abdominal ganglion is followed by continuous digging behavior. An attempt was made to mimic presumed higher center inhibitory control by electrically stimulating the cut connectives. Oviposition ceased during stimulation and for one to many cycles afterwards, depending upon the strength of the stimulation.

Intracellular recordings from motoneurons of a major ovipositor muscle, the depressor, show electrical activity consisting of membrane potential oscillations of approximately 6 s. periodicity. The motoneurons discharge with spiking activity at the peak of the depolarizing wave. Membrane potential changes were imposed on motoneurons to determine if they are involved in pattern generation. These motoneurons were hyperpolarized to suppress their discharge. This did not affect the timing of subsequent bursts. Thus, the depressor motoneurons do not appear to be an integral part of the pattern generator. Instead, pattern generator activity must depend upon interneurons.

46.10 FICTIVE SCRATCH AND FICTIVE FLEXION REFLEXES DISPLAY DIFFERENT MOTOR NEURON ACTIVITY PATTERNS IN THE TURTLE. Paul S.G. Stein, Gail A. Robertson* and Joyce Keifer*. Department of Biology, Washington University, St. Louis, MO 63130.

Gentle rubbing of specific regions of the shell in the low-spinal turtle will elicit a scratch reflex in which the foot reaches up and rubs against the stimulated site (Valk-Fai and Crowe, J. Comp. Physiol. 125:351,1978). The same stimulus will elicit a rhythmic motor program, termed the fictive scratch reflex, in an immobilized turtle (Stein and Grossman, J. Comp. Physiol. 140:287,1980). Gentle pressure applied to the dorsum of the foot will elicit a flexion reflex in which the foot withdraws from the location of the stimulus probe. The same stimulus will elicit a fictive flexion reflex motor program in an immobilized turtle. Electroneurographic recordings from muscle nerves and intracellular recordings from spinal motor neurons (MNs) reveal that these reflexes differ in their patterns of MN co-activation. This result indicates that the motor program responsible for the generation of the scratch reflex is different from that utilized for the flexion reflex in the turtle, Pseudemys scripta elegans.

The A1 phase of the fictive scratch is characterized by co-activation of MNs to iliotibialis (IT-KE), ventral puboischiofemoralis internus (VP-HP), and anterior iliofemoralis (AI-HP). These MNs maintain their activity until the middle or late portions of the A2 phase. During the A2 phase there is activation of MNs to femorotibialis (FT-KE) and ambiens (AM-KE). These MNs are active until the end of the A2 phase. Thus early in the A2 phase MNs to all five of these muscles are co-active. These MNs are inactive during the B phase of the fictive scratch.

In contrast, during the fictive flexion reflex MNs to AI-HP and VP-HP are depolarized and produce action potentials. At the same time, MNs to IT-KE, AM-KE and FT-KE are hyperpolarized. This demonstrates that the activation pattern produced during fictive flexion is different from that during fictive scratch. Therefore, in turtle, the synergies observed in the flexion reflex can not be utilized to construct a model of the scratch reflex program generator. Deliagina et al (J. Neurophysiol. 45:595,1981) have recently presented data which supports a similar conclusion in the cat. Sherrington (Quart. J. Exp. Physiol. 3:213,1910) claimed that a bipartite division of hindlimb musculature into flexors and extensors according to flexion reflex activation patterns can be utilized to describe the scratch reflex synergies in cat. This claim is not supported by the recent cat data and does not provide an adequate description of our turtle data. Supported by NIH Grant NS-15049 to PSGS and NIH Training Grant in Neurobiology NS-07071 to GAR.

46.11 SENSORY PATHWAYS ACTIVATING THE SCRATCH REFLEX IN THE TURTLE. Lawrence I. Mortin*, Joyce Keifer* and Paul S.G. Stein. (SPON: Viktor Hamburger). Department of Biology, Washington University, St. Louis, MO 63130.

Gentle mechanical stimulation of specific shell bridge regions (SP1, SP2 and SP3) of the low-spinal turtle, Pseudemys scripta elegans, elicits a rhythmic scratch reflex (Valk-Fai and Crowe, J. Comp. Physiol. 125:351,1978). This behavior can be monitored by electromyographic recordings (EMGs). Immobilized turtles produce a fictive scratch reflex which can be monitored by electroneurographic recordings (ENGs; Stein and Grossman, J. Comp. Physiol. 140:287,1980). Electrical stimulation of the carapace of a tortoise, Testudo graeca, excites cutaneous neurons in the shell (Rosenberg, Comp. Biochem. Physiol. 66A:227,1980).

We have implanted pairs of silver wires (4 mil) into shallow holes drilled into the shell bridge of low-spinal P. s. elegans at SP1, SP2 and SP3. Trains of electrical pulses (5-15 V, 1 msec pulses, 10-50 Hz for 50-500 msec) can elicit the goal directed scratch reflex as monitored by EMGs. Similar results have been obtained independently in Crowe's laboratory (personal communication). We have also found that this electrical stimulation will elicit a fictive scratch reflex. ENGs from segmental cutaneous nerves in the midbody region (D3-D6) reveal a temporally and spatially dispersed volley in response to each electrical pulse (4-22 msec latency range). This pattern of sensory activation remains the same when the nerve is cut central to the recording electrode. ENGs from cutaneous nerves D3 to D6 were used to map the dermatomes of the shell bridge. Each dermatome is directly lateral to the spinal root entry zone of its nerve. In the center of each dermatome mechanical stimulation excites only one cutaneous nerve; along the edges of each dermatome stimulation activates two adjacent segmental nerves ("overlap zone"). In general, the D3/D4 overlap zone contains SP3; the D4/D5 overlap zone contains SP2; and the D5/D6 overlap zone contains SP1.

The pathway of the central descending signal which initiates the scratch reflex was investigated with spinal cord hemisections at specific levels between D3 and D7. These resulted in the loss of scratch sensitivity in all ipsilateral shell bridge regions innervated exclusively by cutaneous nerves anterior to the cut. No contralateral loss of scratch sensitivity was found. The descending signal for the scratch reflex must run mainly ipsilaterally in the spinal cord. A similar result is seen in the cat, where the central pathway descends ipsilaterally in the caudal portions of the thoracic spinal cord (Deliagina, Neurophysiology 9:470,1977). Supported by NIH Grant NS-15049 to PSGS and NIH Training Grant in Neurobiology NS-07071 to LIM.

46.12 THE MARKOV ORDER OF INTERSPIKE INTERVALS RECORDED FROM RAT CEREBELLAR NEURONS: CORRELATIONS WITH MEASURES OF CENTRAL TENDENCY AND VARIABILITY. C. J. Sherry (Biology), W. R. Klemm (Veterinary Anatomy), and D. L. Barrow* (Mathematics), Texas A & M University, College Station, Texas 77843.

Interspike intervals (ISIs) were collected into a conventional non-sequential interval histogram. The histogram was then divided into thirds such that each third contained an equal number of ISIs. The first step was to have the computer determine if an interval belonged to the shortest, middle, or longest group and to code this relationship as a 1, 2, or 3, respectively. These numbers were then tallied into a series of conditional probability matrices, where the sequential relationships were specified as probabilities in a 'digram' matrix for 2 adjacent numbers through a 'pentagram' matrix for 5 numbers. The Markov order of each neuron was calculated using the Chi square statistic (Theoret. Biol. 29:427, 1970). The Markov order of each neuron was then tested for correlation with measures of central tendency (mean interval, median interval, modal interval, spikes per second) and variability (10-90 percentile range, 25-75 percentile range). The correlation coefficients were -0.56, -0.43, -0.26, 0.71*, -0.89*, and -0.62*, respectively. Multiple correlation methods were also used to determine the relationship between Markov order and mean-median (0.87*), 10-90 range-spikes per sec. (0.89*), 10-90 range-median (0.89*). (*indicates $p < 0.05$)

The neurons that were best described by an order 3 or 4 Markov process had very similar non-sequential distributions. For example, the average 10th percentile was 9.2 msec. (SD 1.6), the 25th percentile (18.2±1.8), the median (17.6±2.9), the mean (23.6±3.9), the 75th percentile (26.4±4.2), the 90th percentile (41.4±6.5), and the 75-90 percentile range (15.0±2.5). The neurons that were best described by an order 1 or 2 Markov process had a higher average median (56.7±53.8) and particularly a larger 75-90 percentile range (45.0±20.4).

This seems to imply that the 'memory' of the cerebellar neurons in this sample could extend to approximately 250 msec. (i.e. 90 percent of the intervals were 50 msec. or less and therefore, the duration of any group of 5 sequential intervals, on the average, should be 250 msec. or less). When the length of the longer intervals (i.e. the 75-90 percentile range) increases, the 'memory' of the system decreases.

47.1 DEVELOPMENT OF SPATIAL RESOLUTION AND CONTRAST SENSITIVITY IN MONKEY VISUAL CORTEX. Colin Blakemore* and François Vital-Durand* (SPON: Leo M. Chalupa). Univ Lab of Physiology, Oxford OX1 3PT, England and INSERM Unité 94, 69500 Bron, France.

Visual acuity improves gradually during the first year in baby monkeys (Teller et al, Vision Res, 18: 561, 1978) and there is a similar improvement in the spatial resolution of neurones in the lateral geniculate nucleus (LGN), from a maximum of 5 cycles/degree at birth to 35 c/deg in the adult. Surprisingly, LGN development is apparently entirely unhindered by visual deprivation (Blakemore & Vital-Durand, Trans Ophthal Soc UK, 99: 363, 1979).

We have now examined the maturation of spatial resolution and contrast sensitivity in the striate cortex of Old-World monkeys (mainly Erythrocebus patas). We recorded from neurones in the foveal representation from the day of birth to adulthood in normal and binocularly deprived animals, and stimulated the receptive fields with drifting gratings whose orientation and contrast could be varied, and whose spatial frequency, direction and temporal frequency of drift were under microprocessor control. In the newborn animal about half of all cells recorded showed some degree of orientation selectivity and these neurones were usually monocularly dominated. In visually-experienced animals, at all ages, the best cortical neurones had cut-off spatial frequencies similar to those for the best LGN cells; development of neural 'acuity' in the cortex normally parallels that in the LGN. As in kittens (Derrington, J Physiol, 276: 46P, 1978), contrast sensitivity was initially rather low and increased on average by a factor of 10 between birth and adulthood. Also, many cortical cells in young animals showed little low-spatial frequency attenuation and responded well to temporal modulation of the entire field. The narrowness of tuning for spatial frequency improved gradually during the first year of life.

By contrast with the LGN, deprivation seems to prevent all these maturational improvements in the cortex. With up to 130 days of binocular deprivation, cut-off spatial frequencies and contrast sensitivities of cortical cells remain at virtually the same levels as on the day of birth. These results suggest that there are two neural 'filters' for spatial information, one peripheral (perhaps in the retina) and one in the striate cortex, both maturing in parallel in the normal animal. The maintenance of maturation in the cortical 'filter' requires visual experience while that in the peripheral one does not.

47.2 STRUCTURAL DEVELOPMENT OF FUNCTIONALLY IDENTIFIED NEURONS IN KITTEN DORSAL LATERAL GENICULATE NUCLEUS (LGN_D). Michael J. Friedlander. Dept. of Physiology and Biophysics, University of Alabama in Birmingham, Birmingham, AL 35294.

Different physiological classes (W-,X-, and Y-) of $LGN_{(D)}$ neurons in the adult cat have characteristic morphological features[1,2]. Studies of $LGN_{(D)}$ neurons in young kittens (age 1-6 weeks)[3] suggest differential developmental rates for different physiological cell classes. The present study was designed to determine how the postnatal development of physiological and morphological properties of individual $LGN_{(D)}$ neurons are related.

Experiments were done on kittens aged 3-8 weeks. Single $LGN_{(D)}$ neurons were evaluated for receptive field center size, surround inhibition, temporal sensitivity, nature of response to standing and moving targets, linearity of spatial summation, and latencies to optic chiasm stimulation. Cells were then impaled with an HRP filled micropipette and injected intracellularly with horseradish peroxidase (HRP). Vibratomed sections were reacted with DAB-H_2O_2 and injected cells were drawn at 1000X.

Preliminary results indicate that some X-like and W-like cells have adult like dendritic morphology by postnatal age 3-4 weeks. However, some X-like cells (age 3-8 weeks) have morphological features different from those seen in the adult. These features include small dendritic trees symmetrically distributed about the soma, when viewed in the coronal plane. In some cases a very tangled dendritic arborization was seen. Some of these immature X-like cells have terminal swellings on their dendrites that are otherwise devoid of appendages. Too few Y-like neurons have been recovered for analysis, to date.

47.3 THE DORSAL LATERAL GENICULATE NUCLEUS OF THE NORMAL FERRET AND ITS POSTNATAL DEVELOPMENT. R.W. Guillery, D. Card Linden and Josephine Cucchiaro, Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637.

The anterograde transport of ^3H proline and horseradish peroxidase has been used to study the normal retinogeniculate pathways of ferrets from birth to maturity. In adults, the lateral geniculate nucleus (dLGN) shows a "carnivore" pattern, having layers A, A1, C, C1, C2 and C3, a medial interlaminar nucleus, and a well defined perigeniculate nucleus. At birth the dLGN is unlaminated and all parts are reached by afferents from both eyes. The larger crossed component extends from the optic tract well into the perigeniculate field while the smaller uncrossed component barely reaches this field. During postnatal days 1-3, the uncrossed fibers restrict their arbors to a small, posteromedial region (the precursor of the binocular segment of the nucleus) and subsequently the crossed fibers retreat from the region occupied by the uncrossed fibers. Between postnatal days 4 and 8, the field occupied by the ipsilateral component expands to form a major focus (lamina A1) and a minor focus (C1), but arbors of the crossed component still overlap the borders of lamina A1 and occupy all parts of lamina C1. The perigeniculate nucleus and the medial interlaminar nucleus become clearly distinguishable between days 3 and 8.

Between days 8 and 15, the cytoarchitectonic borders of layers A and A1 become clearly defined, but retinogeniculate axons still extend across the A/A1 border. These axons retreat to their appropriate layer after day 15, and the nucleus reaches its essentially adult structure by about day 28. Segregation of retinofugal axons in the C layers occurs after segregation in the A layers, but cells of the C layers show signs of cytological maturity earlier than those of the A layers. As the ipsilateral and contralateral components become segregated, the nucleus changes from a comma-shaped structure on the lateral aspect of the dorsal thalamus, to an "L"-shaped structure on the posterior aspect of the dorsal thalamus.

Our results show that the crossed and uncrossed inputs initially overlap. Segregation into distinct ipsi- and contralateral zones begins well before any visible cellular lamination occurs, but the process of segregation is not completed until well after the adult pattern of cellular lamination is formed. Thus the cellular and the retinofugal lamination probably represent separate developmental processes that are to some extent independent of each other.

47.4 INSIDE-OUT PATTERN OF NEUROGENESIS OF THE CAT'S LATERAL GENICULATE NUCLEUS. C.J. Shatz. Dept. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

The pattern of neurogenesis of the cat's lateral geniculate nucleus (LGN) was studied by means of ^3H-thymidine autoradiography. Neurons of the LGN are generated between embryonic day 24 (E24) and E31 (gestation is 65 days), with those destined for the A-layers generated prior to those for the C-layers (Hickey, '79). However, in the embryonic brain when the future C-layers first become identifiable on the basis of the pattern of retinogeniculate projections, they apparently lie external (lateral) to the prospective A-layers. This suggests that neurons destined for the C-layers must migrate through earlier-generated A-layer neurons en route to their appropriate position in the developing thalamus.

To verify this suggestion, fetuses were injected with ^3H-thymidine on E30 in order to label preferentially those cells destined to lie in the C-layers (Hickey,'79), and allowed to survive varying periods thereafter. That C-layer neurons were indeed selectively labeled by an E30 injection was shown in one animal which survived to 55 days postnatally. Another fetus survived 9 days, to E39. At this age, the LGN analage is an undifferentiated mass of cells and the C-layers are not evident from inspection of the histology or the retinogeniculate projection pattern (Shatz & DiBerardino,'80). However, labeled cells destined for the C-layers are found almost entirely along the medial aspect of the anlage, internal to a thick unlabeled cell margin. This margin presumably consists of earlier-generated neurons of the prospective A-layers. Two other fetuses injected at E30 survived to E54 when the C-layers, though not yet evident histologically, can be identified on the basis of the pattern of retinogeniculate input: they lie external to the A-layers along the posterolateral edge of the thalamus. As expected, the majority of thymidine-labeled cells were found within the C-layers.

This internal-to-external shift in the position of labeled cells seen between E39 and E54 suggests that a real through-migration occurs during histogenesis. Alternatively, the shift could result from a displacement of the entire LGN. To eliminate this possibility, an additional fetus was injected at E31 and killed at E47. Labeled cells in this case were seen embedded within the nucleus, confirming the suggestion that many of the neurons destined for the C-layers indeed migrate through the body of the nucleus.

The inside-out pattern of neurogenesis of the cat's LGN contrasts with the outside-in pattern found in the rhesus monkey (Rakic,'77). However, the cat's C-layers have no clear analogy within the monkey's LGN: perhaps this is a direct consequence of the difference in pattern of neurogenesis seen in the two species.

47.5 DIFFERENTIAL REDUCTION IN THE NUMBER OF IPSILATERALLY PROJECTING GANGLION CELLS DURING THE DEVELOPMENT OF RETINOFUGAL PROJECTIONS IN ALBINO AND PIGMENTED RATS. P.W. Land, K. Hargrove*, J. Eldridge* and R.D. Lund, Department of Anatomy, Medical University of South Carolina, Charleston, South Carolina 29425.

In adult albino rats, the uncrossed retinogeniculate and retinotectal projections appear markedly reduced when compared with pigmented animals. However, at birth these pathways appear quite similar in the two strains, occupying a much larger volume of the lateral geniculate nucleus (LGN) and superior colliculus (SC) than they do in adult (Land and Lund, 1979 Science, 205:698-700; Maxwell and Land, 1981 Anat. Rec., 199, #3) and it is not until 9-10 days after birth that conspicuous differences in the uncrossed pathways become evident. These observations allow the suggestion that the albino mutation results not in an initial "misrouting" of axons at the chiasm, but rather, a disproportionate loss of ipsilaterally projecting axons during early postnatal life.

In order to test this hypothesis, we examined the number and location of the ganglion cells of origin of uncrossed retinofugal projections in both newborn and adult rats of the Sprague-Dawley albino and Long-Evans pigmented strains. Animals received 3-4 injections (total volume 1-3 µl) of HRP, propidium iodide, True Blue or Nuclear Yellow (generously donated by Dr. H. Loewe) into one optic tract (and LGN). In some cases, each tract was injected with a different compound. Eighteen to 24 hours later, animals were perfused with 4% paraformaldehyde. The retinae were removed and either flat mounted and viewed with fluorescent illumination or reacted with diaminobenzidine and H_2O_2, flat mounted and viewed with bright field illumination. The number and location of labeled ganglion cells in the retinae ipsilateral to the injection were then plotted onto drawings of the retinae. In newborn rats of both strains, an average of 5643 ± 72 cells were labeled in the lower temporal crescent of the ipsilateral retina. Moreover, 886 ± 94 labeled cells were distributed throughout the remainder of the retina. In contrast, 1937 ± 394 ganglion cells were labeled in the lower temporal retina of pigmented adults with 163 ± 61 labeled cells occurring elsewhere in the retina while in albinos, 973 ± 236 and 49 ± 4 labeled cells were found, respectively, within and outside of the lower temporal crescent.

These results show that in both albino and pigmented rats there is a substantial loss of ipsilaterally projecting ganglion cell axons, with a more severe reduction of ipsilaterally projecting cells occurring in albinos. To what extent the reduction in ipsilateral projections in either strain results from ganglion cell death or loss of an uncrossed collateral of bilaterally projecting cells is currently under investigation. (Supported by USPHS Grant R01 EY 03447 and EY 03414)

47.6 STRIPE-REARING MODIFIES DENDRITIC MORPHOLOGY OF CELLS IN VISUAL CORTEX OF THE CAT. S.B. Tieman, K. Butterfield* and H.V.B. Hirsch (SPON: H. Tedeschi). Neurobiology Research Center, SUNY Albany, Albany, N.Y. 12222.

To determine whether selective exposure to lines of one orientation modifies the shape of the dendritic fields of cells in visual cortex, we examined the dendritic morphology of neurons in Area 17 of 4 normally-reared cats and 4 cats reared viewing only vertical lines or only horizontal lines. Kittens were placed with their mothers into a totally dark room before their eyes had opened. Beginning at 4 wks of age, the kittens were brought out for daily periods of exposure wearing masks that limited the vision of each eye to a field of 3 vertical lines or 3 horizontal lines. After a minimum of 150 h of exposure, the animals were deeply anesthetized and perfused with phosphate-buffered formalin. Blocks of visual cortex were removed, impregnated by the Golgi-Kopsch procedure, embedded in celloidin, and cut at 120 µm tangential to the pial surface. The sections were stabilized by the method of Geisert and Updyke (Stain Tech., 52:137, 1977) and counterstained with gallocyanin. Complete neurons from layers III and IV were drawn with the aid of a camera lucida, and the orientations of the dendritic fields were analyzed using Sholl diagrams. In normal cats, the distributions of the orientations of dendritic fields were fairly uniform, while in stripe-reared cats, the distributions were shifted toward horizontal or vertical. The direction of this shift varied with the type of cell and the experience of the cat. Thus, for spiny stellate cells in layer IV, the orientation of the dendritic fields matched that presented during rearing. The size of the shift was somewhat larger for the pyramidal cells than for the stellate cells. We suggest that the orientation preferences of stellate cells in layer IV are determined by the spatial arrangement of excitatory inputs, as proposed by Colonnier (J. Anat., 98:527, 1964), while the orientation preferences of pyramidal cells in layer III are determined by the spatial arrangement of inhibitory inputs, as suggested by Schiller et al. (J. Neurophysiol., 39:1362, 1976). Apparently both mechanisms of orientation selectivity can be modified by early visual experience, although the mechanism based on inhibition may be more modifiable than the one based on excitation. (Supported by PHS grants EY02609 to SBT and EY01268 to HVBH).

47.7 DEVELOPMENT OF RETINOGENICULATE SYNAPSES FOLLOWING VISUAL DEPRIVATION IN THE CAT. R.E. Kalil and G. Scott*. Depts. of Opthalmology and Anatomy, Univ. of Wisconsin, Madison, Wisconsin 53706.

In cats raised with monocular eyelid suture, neurons in the dorsal lateral geniculate nucleus (LGN) connected to the deprived eye develop abnormally. For example, cell bodies in deprived layers of the LGN fail to grow to normal size, while physiologically there is a reduction in the number of Y-cells that can be recorded from these laminae. Complete deprivation by dark rearing also disrupts normal cell growth in the LGN and decreases the percentage of Y-cells that are encountered. The basis for deficits such as these is at present unknown, but one possible explanation is that deprivation affects the formation of retinogeniculate synapses which leads to subsequent changes in LGN cell growth and function.

We have studied this question with the electron microscope in a series of cats monocularly deprived (MD) by eyelid suture at 7 days for periods that ranged from 1 to 32 weeks, and in two cats that were dark reared (DR) from birth for 42 weeks. Large area photographic montages were prepared from thin sections taken from the binocular segment of lamina A near the center of the LGN. Terminals from the retina that could be identified by standard criteria (RLP, Guillery '69) were scored quantitatively according to the number and pattern of synaptic contacts which they made. In MD cats, deprived and nondeprived laminae A were compared in each animal, whereas normally reared adult controls served for comparison with DR cats.

At each of the ages studied in MD cats, the development of RLP synapses appeared to be influenced little, if at all, by deprivation. In kittens 3 weeks old and younger, deprived and nondeprived retinal terminals made like numbers of simple axodendritic contacts almost exclusively. By 5 weeks, both sets of afferents also contacted vesicle containing postsynaptic profiles, and a small percentage of each were found in encapsulated synaptic zones. At later ages, deprived retinal terminals established patterns of mature synaptic organization at about the same rate as nondeprived terminals. Similarly, a comparison of RLP synaptic organization in 42 week DR cats with normally reared adults failed to reveal any consistent differences.

Keeping in mind the limits of the present analysis, these results indicate that visual deprivation produces no major changes in the ultrastructural organization of RLP synapses, nor the rate at which they develop. These findings suggest that in the LGN the relevant changes caused by deprivation may be biochemical in nature, or may involve alterations in synaptic patterns on a scale too large to be appropriate for study with the electron microscope.

47.8 NORMAL ORIENTATION AND DIRECTION SELECTIVITY AFTER MONOCULAR DEPRIVATION IN SIAMESE CATS. N. Berman and B.R. Payne. Department of Physiology/Biochemistry and Anatomy, The Medical College of Pennsylvania. Philadelphia, PA.

In normally pigmented cats total deprivation of pattern vision during development leads to a loss of orientation and direction selectivity of cortical neurons. This alteration in cortical receptive field properties occurs during a period when there is intense competition between the two eyes for cortical space. In normally pigmented cats, each cortex receives input from both eyes and therefore competition between the inputs from the two eyes is always a possible factor in the development of cortical receptive field properties. In Siamese cats, however, an abnormal crossing of retinal ganglion cell axons at the chiasm results in a visual cortex in which virtually all of the neurons are influenced only by one eye. This situation provides the opportunity to study how monocular deprivation affects cortical neurons when there is no competition between the input from the two eyes in the cortex.

Three Siamese kittens were monocularly sutured on the fourth day of life. 3½ to 9 months later the sutured eye was opened and single neurons were recorded in area 17 contralateral to the deprived eye. Five normally-reared Siamese cats were also studied. In both groups the cortical units had receptive fields in the region from 25° into the ipsilateral half-field to 30° into the contralateral half-field. In the normally reared Siamese cats, 83 percent of the units could be driven only by the contralateral eye. In the monocularly deprived Siamese cats, 81 percent of the units were driven only by the deprived (contralateral) eye. Thus, there was no significant increase in the effectiveness of the ipsilateral (experienced) eye in driving cortical neurons. In normally-reared Siamese cats 97 percent of the units were orientation selective, while in monocularly deprived Siamese cats, 91 percent of the units were orientation selective. Finally, in normally-reared Siamese cats 74 percent of the units were selective for the direction of stimulus movement, while in monocularly deprived Siamese cats 79 percent of the units were direction selective. Our results show that monocular deprivation has no effect on the development of receptive field properties of cortical neurons in Siamese cats. Our results suggest that the susceptibility to pattern deprivation which is present in normal cats depends on competition between the two eyes for cortical space during the early postnatal period.

47.9 AN ELECTROPHYSIOLOGICAL COMPARISON BETWEEN EXOTROPIC AND ESOTROPIC STRABISMUS IN CATS R. D. Freeman and T. Tsumoto, School of Optometry, University of California, Berkeley, CA 94720

Normally reared 3-week-old kittens were made exotropic (exo) or esotropic (eso) by tenotomy of medial or lateral rectus muscles, respectively. Six cats, three in each condition, were studied at ages from 4 to 7 months. The animals were anesthetized and paralyzed, and viewed a CRT screen. The deviating eye was repositioned mechanically with sutures, or with optical prisms so that the area centrales of both eyes were approximately centered on the CRT.

In the first study, visually elicited cortical evoked potentials (EP) were measured via skull electrodes during presentation of bright, high-contrast phase-reversing sinusoidal gratings. A computer averaged and performed harmonic analysis of data and controlled presentation of stimuli which were interleaved between right and left eyes. No substantial differences were found in wave forms, amplitudes, or latencies of the EP between normal and deviated eyes of exo cats. Spatial frequency-response functions were also similar but in one case, there was a slight reduction in low-frequency sensitivity. In the eso group, responses mediated by the deviating eyes were substantially reduced and spatial frequency response functions were particularly depressed at the low-frequency end. For all cats, spatial cut-off frequencies between deviating and non-deviating eyes were similar.

For the second study, bipolar stimulating electrodes were placed stereotaxically in the lateral geniculate nucleus (LGN) and optic radiation (OR), and hooked bipolar electrodes were positioned around each optic nerve (ON). A recording electrode was placed in area 17. As found previously, receptive field analysis showed that proportions of binocular cells were very low in all cases, but neither eye was significantly dominant. Of 208 cells studied in detail, approximately half responded to ON stimulation of the deviated or non-deviated eyes. Mean response latencies to right or left ON stimulation were similar in exo cats, but deviated eye latencies were significantly longer than those from the non-deviated eye in the eso animals. These differences applied to binocular as well as monocular cells. Conduction times between ON and LGN and between LGN and OR were also slower from deviated eso but not exo eyes. Interocular inhibition of the deviated by the non-deviated eye, as determined by ON stimulation with or without visual activation was generally stronger in the eso compared to exo cats.

Considered together, these results indicate that the effects of experimentally produced esotropia are physiologically pronounced compared to those from exotropia, and that peripheral as well as central pathways are affected. (EY01175)

47.10 MORPHOLOGY AND DISTRIBUTION OF RETINAL GANGLION CELLS PROJECTING TO THE LATERAL GENICULATE NUCLEUS (LGNd) IN NORMAL AND SIAMESE CATS, A.G. Leventhal, Dept. of Anat. Univ. of Utah, School of Medicine, Salt Lake City, Utah 84132.

Electrophoretic injections of horseradish peroxidase were made into physiologically characterized sites within the LGNd of normal and Siamese cats. Histochemical procedures used stained the cell bodies, dendrites and axons of retrogradely labeled ganglion cells. The regions of retina examined ranged from .5mm from the area centralis (a.c.) to the far periphery.

In normal cats, only α and β type ganglion cells are labeled by injections restricted to the A laminae. The α/β ratios (# labeled alpha cells/# labeled alpha+beta cells) resulting from injections into lam A increase from about .045 at .5mm from the a.c. to about .10 in the periphery. The α/β ratios observed outside of the a.c. following injections into different parts of lam A1 were about 15% lower at each eccentricity than those resulting from injections into corresponding parts of lam A. Also, outside of the a.c., α and β cells projecting to lam A1 (those in ipsilateral, temporal retina) are larger than those projecting to lam A (those in contralateral, nasal retina).

In Siamese cats, as in normal cats, only α and β cells are labeled by HRP injections into lam A or lam A1 and the relative numbers of α and β cells projecting to lam A are normal. However, α cells comprise an abnormally small proportion of ganglion cells projecting to the normal segment of Siamese lam A1. They range from 0% of labeled cells near the a.c. to only 4% of labeled cells in the far periphery of ipsilateral, temporal retina following injections into this region. In contrast, α cells constitute an abnormally large proportion of cells projecting to the abnormal segment of lam A1. As a result of injections into this region, they range from the normal value of about 5.0% of labeled cells .5mm from the a.c. to over 70% of labeled cells in the far periphery of contralateral, temporal retina.

Injections into the C laminae of the LGNd in normal and Siamese cats show that the morphological classes which project to these laminae in normal cats also project to these laminae in Siamese cats. Unlike in normal cats, however, examples of all of these morphological types are found far into the contralateral, temporal retinas of Siamese cats following injections into lam C1. Thus, it appears that all classes which project to the ipsilateral C lamina are effected by the Siamese abnormality.

The morphologies and sizes of cells belonging to the different classes of retinal ganglion cells in Siamese cats seem normal. There are no obvious morphological differences between the cells in temporal retina which project ipsilaterally (normally) and those which project contralaterally (abnormally).

47.11 PERIOD OF SUSCEPTIBILITY TO EFFECTS OF MONOCULAR DEPRIVATION: DIFFERENCES BETWEEN STRIATE AND EXTRASTRIATE CORTEX. Kim R. Jones*, Peter D. Spear, and Lillian Tong. Dept. of Psychology, Univ. of Wisconsin, Madison, WI 53706.

Previous studies of the critical period for effects of monocular deprivation have been confined exclusively to striate cortex. To assess the possibility that this period might be different for extrastriate regions, we monocularly lid-sutured kittens at various ages and compared the effects in striate cortex to those in the lateral suprasylvian visual area (LS) in the same animals.

Thus far, we have studied 16 animals, divided into groups of three lid-sutured at 4, 12, 18, and 26 weeks of age, and a group of four lid-sutured at 35 weeks. All kittens were monocularly deprived for a period of 4 weeks, at which time single-unit recordings in both striate and LS were made contralateral to the deprived eye. In each area, the ocular dominance distributions of from 19-62 cells (mean=35) were determined using hand-held stimuli, and compared to results obtained from three 39 week old normal kittens. Several procedures were employed to insure a representative sampling of ocular dominance. To record from as many ocular dominance columns as possible, penetrations in both areas were made tangential to the cortical surface. In addition, cells were sampled a minimum of 100 μm apart, and comparable visual field eccentricities (0°-20°) were sampled in each area.

Monocular deprivation at 4 weeks of age caused nearly all cells in both cortical areas to be driven exclusively by the nondeprived eye. In the 12 and 18 week old groups, this dominance decreased at about the same rate for both striate and LS cortex, so that at the latter age only about 40% of the cells in each area were driven strongly or exclusively by the nondeprived eye (OD classes 6 & 7). After this age, however, clear differences developed between the two areas. In both the 26 and 35 week old groups, the percentage of cells in OD classes 6 & 7 in LS cortex fell to an average of 13%, which was similar to that seen in normals. In striate cortex, results from the same animals were much more variable, with some ocular dominance distributions appearing normal and others very abnormal. In both age groups, however, the average percentage of striate cells in OD classes 6 & 7 remained above 40%, which was significantly different than the 15% seen in normal animals.

In summary, these results show that the critical period for monocular deprivation differs for striate and LS cortex, and that the effects are more prolonged in striate cortex than previously believed.

47.12 NOREPINEPHRINE IONTOPHORESIS IN CAT VISUAL CORTEX: A QUICK CHANGE IN OCULAR DOMINANCE.
Takuji Kasamatsu, Division of Biology, California Institute of Technology, Pasadena, CA 91125, U.S.A. and
Paul Heggelund* Neurobiology Laboratory, University of Trondheim, Dragvoll-Trondheim, Norway. (Spon: J. Brockes)

We have been studying roles played by norepinephrine (NE)-containing nerve endings in regulation of neuronal plasticity in cat visual cortex. Using NE iontophoresis in place of the continuous micro-perfusion method which was intensively used in our previous studies, we wanted to know how quickly changes in ocular dominance take place.

We first studied how responsiveness of individual visual cells changes during NE iontophoresis if their receptive fields are stimulated by appropriate visual stimuli. We found 3 populations of cortical cells during NE iontophoresis: an increase, a decrease or no change in their responsiveness to proper visual stimulation. About equal numbers of cells belonged to each of these 3 groups. In the majority of such cells that changed visual responsiveness during NE iontophoresis and that had measurable amounts of spontaneous activity, the ratio of visually evoked to spontaneous activity (signal-to-noise ratio) improved by NE. This improvement was independent of an increase or a decrease in responsiveness to visual stimulation. Secondly, there was a differential effect of NE on simple and complex cells. Although most simple cells (36 of 42) changed clearly their responsiveness during NE iontophoresis (either an increase or a decrease), the effects were seen in only one-third of complex cells (6 of 18). Finally, we noted an unusually high (N=60, 68%) sampling incidence for monocular cells in our samples which were derived from either visually normal kittens which were pretreated with 6-hydroxydopamine or a normal adult cat. A control animal which repeatedly received only current injections but not NE iontophoresis, however, showed the normal ocular dominance distribution with a high proportion of binocular cells. These results suggest that breaking up the normal convergence of visual axes, which was more or less inevitable in paralyzed preparations, induced stronger effects of "squinting" than usual on cortical binocular cells which had been plasticized by concurrent NE iontophoresis. This change in ocular dominance was observed within 24 hrs after the start of NE iontophoresis.

48.1 TESTOSTERONE REGULATES ACETYLCHOLINE RECEPTOR NUMBER IN TWO ANDROGEN SENSITIVE MUSCLES. A.L.Harrelson*,W.V.Bleisch and V.N.Luine, Rockefeller University,New York,N.Y. 10021

The "levator ani" (LA) of rodents and the syrinx of songbirds are examples of neuromuscular systems in which both the muscles and their motoneurons have high levels of androgen receptors. The muscles respond to castration with a decrease in weight, protein and acetylcholinesterase (AChE) activity (Tucek et al., 1976,J.Neurol.Sci.27:363 and Luine et al.,1980,Brain Res. 192:89). This led us to examine the response of acetylcholine receptor (AChR) number to changing hormone levels (Bleisch, this volume). In both muscles, AChR number decreases after castration of males and treatment with testosterone can increase AChR number. In the LA of 250 g male rats, 2 weeks of castration causes a 47% decrease in AChR number, from 2.79±.15pmoles/muscle to 1.49±.06 ($p<.005$). In contrast to other reports (Chin and Almon,1980, J.P.E.T. 212:553) we find no change in AChR number per protein (153±9fmoles/mg protein in intacts and 167±6 in castrates). After 1 week of castration, one week of testosterone proprionate (TP, 127ug/kg/day s.c.) increases AChR number by 29% over untreated castrates, from 1.47±.1pmoles/muscle to 1.86±.13(p .05). Again, there is no change in AChR number per protein, since these changes parallel changes in muscle protein. In contrast to AChR, total AChE activity is unaffected by these short treatments (6.58±.71 umoles substrate/hr/muscle in intacts, 6.74±.98 in castates and 7.04±.4 in TP treated castrates). Because muscle protein decreases markedly after castration, specific AChE activity is higher in treated and untreated castrates than in intacts (335±33 nmoles/hr/mg protein in intacts, 728±77 in untreated castrates and 665±42 in TP treated castrates,$p<.01$ and $p<.01$).

Unlike the rat LA, the syrinx of songbirds exists in both males and females. In zebra finches, this organ is sexually dimorphic, and there is also a dimorphism in the number of AChR in the syrinx (1069±69fmoles/syrinx in males and 280±19 in females,$p<.001$). AChR is also different on a per protein basis (771±61fmoles/mg in males and 623±29 in females, $p<.05$). After 23 days of castration, AChR number decreases in males by 42%, from 1276±72 fmoles/syrinx to 737±85 ($p<.005$). After 6 days of testosterone treatment (5mm silastic capsule), AChR number increases in intact females from 164±14 fmoles/syrinx to 470±83 ($p<.05$).

We believe that the LA and syrinx may provide novel model systems of defined synapses for the study of synaptic regulation in response to hormones.

This work was done in the laboratory of Dr. B.S. McEwen.

48.2 LAMININ AND OTHER BASEMENT MEMBRANE PROTEINS CODISTRIBUTE WITH ACETYLCHOLINE RECEPTORS ON THE SURFACE OF CULTURED MYOTUBES. M.P. Daniels, M. Vigny*, H. Bauer, P. Sonderegger*, and Z. Vogel. NHLBI; NIDR; and NICHD; N.I.H., Bethesda, MD. 20205.

The results of recent studies [Burden, S.J. et.al. J. Cell Biol. 82:412 (1979)] have suggested a role for the synaptic basal lamina in the postsynaptic organization of acetylcholine receptors (AChR). We now report a fluorescence microscopic study comparing the extracellular distribution of basement membrane proteins to the distribution of AChR in rat myotube cultures and in sections of rat diaphragm. We have used antisera against purified basement membrane proteins (kindly provided by Drs. G. Grotendorst, J. Hassel, H. Kleinman, M. Silver, and G. Martin) and fluorescein-labeled 2° antibodies. AChR distribution was visualized in the same cultures and sections with rhodamine-labeled α-bungarotoxin. In diaphragms of adult and 17 and 20 day-old fetal rats, immunoreactivities for laminin, fibronectin, heparan sulfate proteoglycan, collagen type IV and V all delineated the basement membranes of muscle, blood vessels, connective tissue, and Schwann cells. In contrast, laminin immunoreactivity on the surfaces of cultured rat myotubes was concentrated in regions of high AChR density (AChR aggregates). Most AChR aggregates were coextensive over at least part of their area with laminin aggregates. In addition, there was a much smaller number of laminin aggregates which were not coextensive with AChR aggregates. The remainder of the myotube surface was weakly stained. Concentrations of anti-heparan sulfate proteoglycan immunoreactivity were found within a majority of AChR aggregates, but the codistribution was less marked than with laminin. Staining with antisera against the other basement membrane proteins revealed much less codistribution with AChR. Detergent extraction of the myotubes in situ yielded cytoskeletons in which the laminin-AChR association was intact. When myotube cultures were treated with conditioned medium from cultures of NG108-15 neuroblastoma x glioma hybrid cells in order to induce a several-fold increase in the number of AChR aggregates [Christian, C.N. et.al. PNAS 75:4011 (1978)], the frequency with which AChR aggregates coincided with laminin aggregates was at least as high as in controls. The results of this study indicate a consistent and stable codistribution of laminin with AChR aggregates. In another study (Vogel, Z. et.al. These Abstracts) we have shown that laminin markedly enhances the AChR aggregating activity of NG108-15 cell conditioned medium. We therefore suggest that laminin plays a role in the neuronal induction of AChR aggregation.

48.3 THE EFFECT OF LAMININ, A BASEMENT MEMBRANE PROTEIN, ON THE CELL SURFACE AGGREGATION OF ACETYLCHOLINE RECEPTORS OF CULTURED MYOTUBES. Z. Vogel, M.P. Daniels, M. Vigny*, H.C. Bauer, P. Sonderegger*, and C.N. Christian*. Lab. of Biochem. Genetics, NHLBI; Lab. of Devel. Biol. and Anomalies, NIDR; and Lab. of Devel. Neurobiol. NICHD; NIH, Bethesda, MD 20205.

Recent studies have indicated that the synaptic basal lamina may contain material which induces the aggregation of acetylcholine receptors (AChR) at the former site of the neuromuscular junction during muscle regeneration, and that synaptic basement membrane preparations can induce AChR aggregation on cultured myotubes (1). The biochemical nature of the active materials in these preparations is unknown. In another study (2) we have shown that two basement membrane components, laminin and heparan sulfate proteoglycan, are largely codistributed with aggregated AChR on the surface of cultured rat myotubes.

Therefore, we have tested the effect of 3 purified basement membrane proteins, laminin, heparan sulfate proteoglycan, and collagen type IV, on the aggregation of AChR on cultured myotubes. Purified chick plasma fibronectin was similarly tested. The proteins (generously provided by Drs. J.R. Hassel, H.K. Kleinman, M. Silver and G.R. Martin) were added to primary cultures of rat myotubes or myotube cultures of the G8-1 muscle cell line, in the presence or absence of conditioned medium (CM) from NG108-15 neuroblastoma x glioma hybrid cell cultures (3). Of the proteins tested, only laminin consistently caused a significant increase in the number of AChR aggregates per myotube (A/M). A concentration-dependent increase in A/M over the range of 1-60 μg/ml of laminin was observed. Laminin markedly enhanced the AChR aggregation activity of NG108-15 cell CM. For example, 3.6 μg/ml of laminin caused a 100% increase in the A/M of G8-1 myotube cultures after 22 hrs, NG108-15 CM gave a 170% increase, and CM together with laminin gave a 600% increase. Similar results were obtained with primary rat muscle cultures. Results of immunoassays indicated that there was less than 5 ng/ml of laminin in NG108-15 cell CM. Thus, laminin itself does not appear to be the AChR aggregating factor found in CM (3). Conditioned medium, laminin, and the two combined all produced AChR aggregates of similar morphology, found on the sides and dorsal surfaces of the myotubes.

The results suggest that laminin itself can induce AChR aggregation on cultured myotubes, and further, that laminin plays a role in the induction of AChR aggregation by neuronal factors.

48.4 CELL-FREE EXTRACTS OF TORPEDO INCREASE SYNTHESIS AND CLUSTERING OF ACETYLCHOLINE RECEPTORS ON CULTURED CHICK MYOTUBES. Paul A. St. John, Joe A. Connolly* and Gerald D. Fischbach. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

Previous results from this laboratory have shown that cell-free extracts of the chick central nervous system, but not of dorsal root ganglia, can increase the number of acetylcholine receptors (AChR) and receptor clusters on cultured chick myotubes (Jessell et al, 1979, PNAS 76: 5397). These results suggested that the active substance might be unique to cholinergic neurons. The electromotor system of the electric ray, Torpedo californica, is embryologically homologous to the neuromuscular system and, since neuro-electrocyte synapses are cholinergic, provides a very rich source of cholinergic neurons. We have examined extracts of this model cholinergic system to determine whether they too can influence receptor number.

Tissues are homogenized in saline, then centrifuged at 10,000 x g for 20 min. The supernatant is centrifuged at 200,000 x g for 120 min to produce a high-speed supernatant (HSS) and a high-speed pellet (HSP), both of which are assayed. Extracts of the electric lobe and the electromotor nerves (both HSS and HSP) and the HSS of the electric organ increase the number of AChR on un-innervated chick myotubes to 1.7-4.2 times control values, as measured by the binding of ^{125}I-α-bungarotoxin (α-BGTX). The HSP from the electric organ contains many Torpedo AChR and if these are blocked with cold α-BGTX, the extract contains no apparent activity. Extracts prepared from the rest of the Torpedo brain or spinal cord also increase the number of AChR by 2-3 fold, but extracts of skeletal muscle or liver cause no increase.

Myotubes treated with extracts from the electromotor system are more sensitive to iontophoretically applied ACh, indicating that the additional toxin binding sites are indeed functional receptors. Labeling with a fluorescent conjugate of α-BGTX reveals that treated myotubes have several fold more clusters of AChR than control cells. At least part of this increase is explained by migration of pre-existing receptors: when AChR are prelabeled with fluorescent α-BGTX before extract treatment, extracts increase the number of fluorescent receptor clusters within 8 hrs. The extracts are not trypsin sensitive and retain most or all of their activity after heating at 95°C for 5 min. Gel filtration of the electric lobe HSS on Biogel P-150 reveals one peak of activity near the exclusion limit and a second peak of lower MW. Further characterization of these extracts is in progress.

Supported by a NIH postdoctoral traineeship (P.A.St.J.) and a MRC of Canada postdoctoral fellowship (J.A.C.) and by grants from NIH and the Muscular Dystrophy Association.

48.5 REGULATION OF FUNCTIONAL MUSCARINIC RECEPTORS ON CHICK CARDIAC CELLS IN CULTURE. R.E. Siegel* and G.D. Fischbach. Dept. of Pharmacology, Harvard Medical School, Boston, Mass. 02115

The presence of muscarinic binding sites on isolated chick heart cells has previously been demonstrated with two muscarinic antagonists, [^{3}H]l-quinuclidinyl benzilate ([^{3}H]lQNB) and [^{3}H]N-methylscopolamine ([^{3}H]NMS). Both atrial and ventricular cultures bound similar amounts of [^{3}H]lQNB and [^{3}H]NMS. In addition, [^{3}H]lQNB autoradiography showed that the binding sites were diffusely distributed on isolated cells from both regions (Siegel and Fischbach, Soc. Neurosci. Abstr., Vol. 6, p. 358, 1980). However, little is known concerning the relationship of the binding sites to functional muscarinic receptors. We have examined the sensitivity of atrial and ventricular cells, dissociated from 8-day embryonic chick hearts and maintained in culture for 2-3 days, to the cholinergic agonist, carbachol. The sensitivity of single cells or small cell clusters was determined by intracellular recording of the hyperpolarization produced by a known concentration of drug delivered by pressure ejection. Although both cell types have a similar density of [^{3}H]lQNB binding sites, 89% of the atrial cells (R.P. = 50 ± 8mV, mean ± s.d., n=18) hyperpolarize in response to 10^{-4}M carbachol but only 26% of the ventricular cells (R.P. = 52 ± 9mV, n=19) respond to the same concentration. Thus, the muscarinic binding sites are not correlated with functional receptors.

Saline extracts prepared from embryonic chick brain cause 4- to 5-fold increases in the number of nicotinic receptors and in the sensitivity to acetylcholine of skeletal muscle fibers in culture. These extracts had little effect on the muscarinic binding sites but enhanced the sensitivity of ventricular cells to carbachol. Addition of extract for 48 hours caused small increases (15-20%) in the [^{3}H]-NMS binding sites. In contrast, the number of ventricular cells responding to 10^{-4}M carbachol increased over 100%, from 26% in the control condition to 68% (R.P. = 52 ± 11mV, n=22) in extract-treated cultures. These studies suggest that muscarinic binding sites and functional receptors are regulated in different ways.

48.6 EVIDENCE FOR A SKELETAL MUSCLE PROTEIN THAT ENHANCES NEURON SURVIVAL, NEURITE EXTENSION, AND ACETYLCHOLINE (ACh) SYNTHESIS R. Glenn Smith* and Stanley H. Appel (SPON: Henry F. Epstein). Depts. of Biochemistry, and Neurology, and Prog. in Neurosci. Baylor Coll. of Med., Houston, TX 77030

The continued development of spinal motor neurons in culture requires either the presence of skeletal muscle in co-culture, or muscle conditioned medium. In this report, we describe the effect of a protein(s) extracted from muscle tissue on the differentiation and maintenance of dissociated spinal cord neurons.

Skeletal muscle from newborn Sprague-Dawley rats was homogenized in 3 volumes of phosphate buffered saline (PBS:pH 7.4) at 4° C, and centrifuged at 32,000g for one hour. The resulting supernatant(S_1) was recentrifuged to 100,000g for 2 hours, and S_2 dialysed against PBS overnight.

Spinal cord cultures were obtained from arachnoid-free ventral cord of stage 24-27 rat embryos. After dissociation, cells were plated(1.5×10^6 cells/dish) onto polylysine coated culture dishes. Cytosine arabinoside, or fluorodeoxyuridine(1×10^{-5}M) was added to the growth medium one day after cell plating, and was maintained in that medium until the muscle extract (MX) was added.

Within 3 days of application of MX (7.5%v/v,~450µg/ml medium) to cord cultures, neuronal and glial cells begin to associate into clusters. Concomitant with this change is (1) a 1.5 fold increase in cell survival, when compared to cultures without MX, (2) a >4 fold increase in the average number of neurites/neuron, and (3) a 3.5 fold increase in the average neurite length. The crude MX acts in a concentration dependent fashion(30-500 µg/ml). MX appears to maintain neuron survival for longer than 3 months, whereas, by that time in its absence, no neurons are detectable.

MX appears to have specific effects on motor neurons. The morphologic changes induced by MX are limited to ventral cord cultures, with no apparent result on cultured dorsal spinal neurons. Further, increases in ACh synthesis (see Vaca and Appel, this volume) and choline acetyltransferase (2.4 fold after 4 days) are observed upon addition of MX to ventral cord cells.

We have begun to characterize this activity. The substance is stable to freezing(-70° C) and lyophilization, and labile to heating(60° C,1 hr:$t_{\frac{1}{2}}$=25min.) and to trypsin. It is precipitated in a 35-60% $(NH_4)_2SO_4$ fraction with retention of activity, and has an apparent molecular weight of >40,000d as determined by gel filtration chromatography. The MX does not appear to act solely by altering cell-substratum attachment, nor does it cross react with antisera directed against β-NGF.

These data demonstrate that skeletal muscle from newborn rats possesses a protein(s) that enhances neuron survival, neurite extension, and ACh synthesis, as well as supporting glial proliferation. Supported by Hartford Foundation grant 470-G09281.

48.7 INDUCED RETARDATION OF OPTIC AXON INGROWTH RESULTS IN A DELAY IN TARGET NEURON DIFFERENTIATION. E.R. Macagno. Dept. of Biological Sciences, Columbia University, New York, N.Y. 10027

Groups of embryonic photoreceptors in one side of the compound eye of Daphnia were irradiated with a UV microbeam at a stage when the cells were post-mitotic but had yet to elaborate axons. Immediately after irradiation the embryos were placed under fluorescent illumination. On the average, 16 of the irradiated photoreceptors were killed by the exposure. Previous observations suggest that an approximately equal number were rescued by the post-irradiation fluorescent illumination. The schedule of differentiation of the rescued photoreceptors was affected such that their axons arrived at the target region in the optic lamina from 2 to 10 hours after they would have normally. Serial section electron microscope analysis showed that differentiation of laminar neurons contacted by the delayed axons was also delayed by a length of time corresponding to the delay in axon arrival. These and previous observations indicate that the differentiation of laminar neurons is triggered by contact with optic axons and can be initiated over a period of several hours after these cells become post-mitotic.

Supported by NIH Grant NS-14946.

48.8 ROLE OF NERVE GROWTH FACTOR FOR THE PRE- AND POSTNATAL DEVELOPMENT OF RAT DORSAL ROOT GANGLION NEURONS.

U. Otten, M. Goedert*, M. Schlumpf and W. Lichtensteiger.
Dept. of Pharmacology, Biocenter of the University Basel and Inst. Pharmacol. Univ. Zürich, Switzerland.

Sensory neurons in vitro require nerve growth factor (NGF) for survival during critical stages of their embryonic life. The investigation of the importance of NGF for the in vivo development of sensory neurons has been hampered by the lack of biochemical marker substances for these neurons. The demonstration that the undecapeptide substance P (SP) is present in sensory neurons indicates that it could be such a marker.

Administration of NGF to newborn and adult rats lead to an increase in SP content of sensory neurons including their central and peripheral endings. Moreover, retrogradely transported NGF is biologically significant, as shown by an increase in SP and general protein content of sensory ganglia from adult rats.

Administration of 50 mg/kg of purified anti NGF-antibodies to newborn animals produced a marked but reversible reduction in the SP content of sensory neurons. These changes were paralleled by similar changes in their central nerve endings in the spinal cord. Prenatal exposure of sensory ganglia to anti NGF-antibodies resulted in a marked reduction in the number of dorsal root ganglia neurons and in their SP content.

These results indicate that NGF is not only essential for normal postnatal development of at least SP-containing neurons but is also required for their survival during the prenatal period.

48.9 THE NERVE GROWTH FACTOR OF MASTOMYS NATALENSIS. T.L.J. Darling,* E.M. Shooter and D.J. Weiner*. (SPON: U.J. McMahan). Stanford Univ. Sch. of Med., Stanford, CA 94305 and Univ. of Pennsylvania, Sch. of Veterinary Med., Pennsylvania, PA 19174.

Nerve growth factor (NGF) is a peptide hormone which is necessary for the growth and maintenance of sympathetic and some sensory neurons. In the male mouse submaxillary gland, the biologically active protein, βNGF, occurs in a stable complex (7S NGF) with two other proteins and zinc ions. Little is known at the molecular level about mammalian NGF from any source other than the male mouse submaxillary gland, and the guinea pig prostate. The high levels of NGF in the glands of male mice is demonstrably a function of high levels of testosterone. The NGF of Mastomys natalensis, the multi-mammate rat of southern Africa, has been studied to determine its molecular properties. We confirm the original finding of Levi-Montalcini et al. that the submaxillary glands of both female and male Mastomys contain substantial amounts of NGF, in contrast to the situation for female mice and other female mammals. When measured by competitive radioimmunoassay (RIA) using rabbit IgG raised against mouse βNGF, the amount of NGF in the submaxillary gland of males (0.17 mg/gm wet weight) is equivalent to that in glands of females (0.13 mg/gm). When measured by the bioassay carried out with dissociated dorsal root ganglia neurons, the amount of NGF in glands of males (52 mg/gm) is again equivalent to that measured in glands of females (40 mg/gm). The disparity between the amounts of NGF detected by the two techniques prompted attempts to purify the NGF's from both glands. In each sex, 15-50% of the RIA activity is in a low molecular weight protein, and the remainder in a high molecular weight (HMW) form. Two monoclonal antibodies against mouse pNGF both cross-react with both NGF's of each sex. The low molecular weight form has an apparent molecular weight of 25,000 based on its behavior during gel filtration, and a sedimentation coefficient of 2.5S in sucrose density gradients. The HMW NGF of both males and females has an apparent molecular weight of 57,000 during gel filtration, significantly less than that of 7S NGF. Its sedimentation coefficient is 5.1S compared to a value of 6.9S for 7S NGF under the same conditions. The sedimentation properties of Mastomys HMW NGF remain constant through further purification by chromatography on DEAE cellulose. Examination of the partially purified HMW NGF by isoelectric focusing in the presence of urea on polyacrylamide gels reveals that a protein very similar in charge to βNGF has been co-purified with a second protein having an apparent pk of 4. After DEAE chromatography the specific biological activity of HMW-NGF is about one half of that of 7S NGF.

48.10 β-NERVE GROWTH FACTOR-LIKE MOLECULE IN HUMAN PLACENTA. Mark H. Grossman, Edward Hawrot, Michael Rosenberg* and Xandra O. Breakefield. Dept. Human Genetics and Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510.

β-Nerve growth factor (β-NGF) is essential for the maintenance and differentiation of sympathetic and sensory neurons. Little is known about human β-NGF due to the extremely low and variable levels that exist in most tissues (including human fibroblasts). β-NGF-like molecules were demonstrated in human placental tissue by radioimmune and receptor binding assays. Using a standard radioimmunoassay, homogenates prepared from the trophoblast portion of a term placenta were found to have 3.3 μg immunoreactive β-NGF per gm wet weight. This assay measures the ability of proteins in the homogenates to compete with purified mouse ^{125}I-β-NGF for antiserum prepared against purified mouse β-NGF. since other proteins in the homogenates may bind ^{125}I-β-NGF, the presence and quantity of a human β-NGF-like molecule was confirmed by a two site radioimmunoassay (Suda et al., 1978). In this assay purified antibodies prepared against mouse β-NGF are bound to poly-vinyl microtiter wells, then incubated with β-NGF standards or samples for 24 hrs, and then with ^{125}I-purified anti-β-NGF antibodies overnight. β-NGF-like molecules in human placental homogenates were further tested for their ability to compete with authentic mouse ^{125}I-β-NGF for binding to β-NGF receptors on rat PC12 pheochromocytoma cells. ([^{125}I-β-NGF]= 1 ng/ml; specific binding is that which was blocked by co-incubation with 10 μg/ml mouse β-NGF.) Immunoreactive human β-NGF molecules in human placenta were about one-fifth as effective as authentic mouse β-NGF in competing for receptor sites.

These studies support the findings of Goldstein et al. (1978) and Walker et al. (1980) of a β-NGF-like molecule in human placenta. This molecule is able to cross-react with some antibodies prepared against authentic mouse β-NGF and to bind to β-NGF receptors on rat pheochromocytoma cells. Due to the relatively high levels reported here, we are now using human placenta as a source of this β-NGF-like protein for characterization of the structure and comparison with mouse β-NGF by methods of immune-precipitation, gel electrophoresis and two-dimensional peptide mapping. (This work was supported by NIH grant NS17083 and by the Dysautonomia Fdn.)

48.11 SUBUNIT COMPOSITION OF NGF FROM HUMAN PLACENTA AT TERM. M. Blum*, C. E. Beck* and J. R. Perez-Polo (SPON: J.S.Kittredge). Department of Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, Texas 77550.

Nerve Growth Factor (NGF) has been isolated from several species including mouse, snake and the guinea pig. In each case the biological activity was found to reside in a basic protein with a molecular weight of about 26,000. Another more acidic protein, the γ subunit, which demonstrates arginyl esteropeptidase activity can also be consistently found associated with the biologically active subunit in a complexed form in all species studied. Only in the murine 7S-NGF complex has a third more acidic subunit, α, been demonstrated thus far. No known biological activity has been associated with the α subunit. In our laboratory we have isolated NGF from human placental tissue and once again found the biological activity to reside in a basic subunit with a molecular weight of about 28,000. Only after several unsuccessful attempts to promote the dissociation of the human NGF complex using treatments known to dissociate mouse 7S-NGF (M. Blum, C. E. Beck and J. R. Perez-Polo, Society for Neuroscience Meeting, 1980), were we able to dissociate the human complex and detect arginyl esteropeptidase activity. The difficulty we have encountered in dissociating the human NGF complex probably reflects a much greater affinity of the subunits for each other as compared to the murine 7S-NGF subunits which are easily dissociated. In addition to the γ and β subunits, we have immunological evidence for the presence of an α subunit in human NGF. Thus the human NGF complex appears to be similar to the mouse NGF in that it contains an α, β and γ although the subunits have a much greater affinity for each other.

48.12 FURTHER STUDIES OF THE EFFECTS OF MATERNAL ANTI-NGF ON THE DEVELOPING GUINEA PIG. E. M. Johnson, Jr. P. A. Osborne*, R. E. Rydel*, R. E. Schmidt and J. Pearson. Depts. of Pharmacology and Pathology, Wash. U. Med. School, St. Louis, MO and Dept. of Pathology, NYU Med. Center, New York, NY.

We have previously reported (Science 210, 916-918, 1980) that female guinea pigs (g.p.) immunized with mouse nerve growth factor (NGF) make antibodies against mouse NGF which cross-react with g.p. NGF. The antibody is transferred to the offspring in utero. Animals born to anti-NGF producing mothers showed a marked decrease in neuronal numbers in sympathetic, dorsal root, and trigemminal ganglia, but no decrease in nodose, ciliary or sphenopalatine ganglia. The offspring had gross sensory deficits. In the most severely affected litters the newborns invariably died within a few days of birth for reason(s) not yet understood. In these severely affected litters we find decreases of greater than 95% in the norepinephrine levels of heart and spleen and about 80% in small intestine. Thin sections of a mixed nerve (sciatic) showed an almost complete absence of small unmyelinated fibers. Despite the massive effects on sympathetic and DRG neurons, no adverse affects are seen in the developing adrenal medulla by either light microscopic or biochemical criteria. The severity of effects on the offspring of different female guinea pigs is highly variable. Effects as severe as those described above have been seen in the offspring of only 4 of over 25 guinea pigs immunized. The major source of variability appears to be the degree of cross reactivity of antibodies raised against mouse NGF with g.p. NGF. It is possible to produce guinea pigs with lesser degrees of sensory deficit and these animals will survive. These results demonstrate the potential usefulness of this approach. However, variability represents an impediment to the use of this experimental approach in the study of the biology of NGF. Possible approaches to resolving the problem of variability will be discussed. (This work was supported by the March of Dime Birth Defects Fdn., The Familial Dysautonomia Fdn, and NIH grant HL-20604. 49.1 COMPARATIVE MORPHOMETRIC ANALYSIS OF THE BASILAR MEMBRANE IN SELECTED MAMMALS AND ITS IMPLICATIONS TO AUDITION. G. Fred Ramprashad*, Jack P. Landolt, and Kenneth E. Money*. Dept. Zool., Univer. Guelph, Guelph, Ontario, Canada N1G 2W1 and D.C.I.E.M., Downsview, Ontario, Canada M3M 3B9

Serial sections and graphic reconstruction of the cochleae of the rabbit (Oryctulagus cuniculus), gerbil (Meriones unguiculatus), chinchilla (Chinchilla laniger), little brown bat (Myotis lucifugus), two-toed sloth (Choloepus sp.), and harp seal (Pagophilus groenlandicus) were used to study changes in width, thickness and cross-sectional area, and to derive an approximation of the "stiffness gradient" along the basilar membrane of these mammals. Moreover, a plot of the theoretical frequency distribution along the basilar membrane of these six species using Greenwood's formula (J. Acoust. Soc. Am. 33: 1344-1356 (1961)), showed that the frequencies to which these mammals were most sensitive tended to coincide with regions of morphological discontinuity as demonstrated by the stiffness gradient. Moreover, the density of afferent VIII-nerve fibers (as indicated by the density of the bipolar ganglion cells as a function of their location along the length of the cochlea), also coincided within this same region. These findings suggest that the morphological discontinuities, that are present within the basilar membrane, may alter its mechanical and vibrating properties, thereby facilitating a peripheral auditory fine-tuning-mechanism within the basilar membrane. (Supported by Defence and Civil Institute of Environmental Medicine Research Contracts 3278008/2SU78-00209 and 3279027/8SU79-00311.)

49.2 DIFFERENTIAL LABELING IDENTIFIES SUBPOPULATIONS OF SPIRAL GANGLION NEURONS AND COCHLEAR EFFERENTS AFTER AMINO ACID INCUBATIONS. Ilsa R. Schwartz and Allen F. Ryan*, Division of Head and Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024 and Otolaryngology Research Laboratory, UCSD School of Medicine, San Diego, CA 92103.

Label localization has been compared autoradiographically in various structures in the gerbil cochlea following in vivo perfusion with artificial perilymph containing micromolar concentrations of one of eight tritiated amino acids: l- and d-aspartic acid, l-glutamic acid, glycine, GABA, taurine, alanine, glycine and muscimol. Major findings include differential labeling of efferents under the inner hair cells as compared to the outer hair cell efferents with d-aspartic acid. Also, after incubation with taurine, about 5% of spiral ganglion neurons including the least myelinated cells were labeled much more heavily than the remaining 95%.

At the light microscopic level, efferents beneath the inner hair cells showed heaviest labeling after incubations with d-aspartic acid and GABA. These fibers were more modestly labeled after incubations with l-aspartic acid and l-glutamic acid. After GABA incubations, efferent terminals beneath the outer hair cells were also labeled. Tunnel crossing fibers were most heavily labeled after GABA incubations. Labeling of inner and outer hair cells was slight with all of the amino acids tested, but after alanine and glycine incubations the labeling was slightly greater in inner than in outer hair cells. After taurine incubation there was noticeably less labeling of hair cells than of surrounding supporting cells.

The glial cells around spiral ganglion neurons were most heavily labeled after incubations with GABA and showed a similar but lighter labeling after taurine. The glial cells around spiral ganglion neurons were also moderately labeled after d- and l-aspartic acid, l-glutamic acid and alanine. The spiral ganglion neurons themselves were modestly labeled after d-aspartic acid, l-glutamic acid, glycine, alanine and taurine, and even more lightly after GABA, l-aspartic acid and muscimol. Only after taurine incubations were any differences noted in the labeling of cells within the spiral ganglion neuronal population.

Electron microscopic studies are under way to confirm the identity of the labeled elements.

This study was supported by grants NS09823, NS10076, NS14503 and NS14945 from the NINCDS.

49.3 CELLULAR UPTAKE OF 2-DEOXYGLUCOSE IN THE COCHLEA. Allen F. Ryan* and Nigel K. Woolf (SPON: B. Pfingst). Otolarynology Research Laboratory, University of California at San Diego Medical School and San Diego VA Medical Center, San Diego, CA 92103.

The uptake of ^{3}H-2-deoxyglucose (2-DG) was examined at the single cell level in the cochlea of the mongolian gerbil. ^{3}H-2-deoxyglucose (New England Nuclear) was administered by intracardiac injection (167 µCi/100gm in 0.1 ml) to unanesthetized gerbils. The animals were immediately placed in a double-walled, sound-attenuated chamber for 1 hr, either in silence or exposed to wide band noise at 85 dB SPL. The cochleas were then removed, frozen intact in Freon 12 at -159 °C, lyophilized at -40 °C for 72 hr, vapor-fixed with osmium and acrolein, and embedded in plastic. Single-turn segments were sectioned at 1 µm and coated with dry emulsion (NBT2, Kodak) by a loop technique. Sections were exposed for periods varying from 3 to 6 weeks.

In the spiral ganglion, uptake of 2-DG was observed in both the neurons and their associated Schwann cells. In general, uptake of 2-DG was appreciably higher in the glial cell than in the associated neuron. Much less uptake was observed in the myelinated axons within the spiral ganglion. Wide band noise exposure increased the relative uptake of 2-DG in both neurons and glial cells of the spiral ganglion, when compared to other cochlear structures.

In the lateral cochlear wall, grains were spread uniformly through the cellular portion of the spiral ligament, but not in connective tissue elements. Uptake of 2-DG appeared to be uniform in the spiral prominence as well. However, the basal cells of the stria vascularis appeared to incorporate 2-DG at a higher rate than marginal cells.

In the organ of Corti, 2-DG uptake was subtantially lower than in the lateral wall structures or in the spiral ganglion. There appeared to be a slightly higher level of uptake in hair cells than in structural cells in some sections. However, longer exposure times will be necessary to confirm this observation.

It is concluded that the uptake of 2-DG in spiral ganglion reflects both neural and glial metabolism. Also, the metabolic requirements of both neurons and glial cells appear to increase during functional activation of spiral ganglion neurons by acoustic stimulation. The relatively low rate of 2-DG uptake in the organ of Corti is consistent with previous reports of a low metabolic rate at this site.

49.4 EVIDENCE FOR THE PROJECTION OF TYPE II SPIRAL GANGLION NEURONS TO THE COCHLEAR NUCLEUS IN THE CHINCHILLA. M. A. Ruggero and P. A. Santi. Dept. of Otolaryngology, Univ. of Minnesota, Minneapolis, MN

Two types of neurons have been identified in the cochlear ganglia of several mammalian species. The overwhelming majority of neurons (Type I) innervate the inner hair cells and degenerate upon transection of their central axons. The minority population (Type II) resists retrograde degeneration and apparently innervates only the outer hair cells. Because of their peculiar degeneration behavior, and because it has not been possible to trace their central axons, Spoendlin (Acta Otolaryngol., 1979, 87:381-387) has suggested that Type II ganglion cells do not project to the brain. In order to test this hypothesis we have studied the transport of horseradish peroxidase (HRP) from the cochlear nucleus to the cochlea. Two groups of chinchillas were used: the experimental group received HRP injections (30%, 0.3-0.8 µl) in the left cochlear nucleus; the second group, which served as a control, was identically treated, except that the HRP was purposefully spilled over the cochlear nucleus and at the entrance of the internal auditory meatus. After 24 hr survival, the animals were intracardially perfused with glutaraldehyde and the brains and cochleae were removed. After decalcification in EDTA and glutaraldehyde (18-72 hr) each cochlea was dissected so as to open Rosenthal's canal widely. Incubation in diaminobenzidine and H_2O_2 was followed by Epon embedding, sectioning (2 µm) and light staining with toluidine blue. Type I neurons are characterized by their pale nuclei and by a distinct perinuclear investment of Nissl substance. Type II neurons - less than 5% of the ganglion population - are smaller, their nuclei are relatively dark and have little perinuclear Nissl substance. They are almost exclusively located at the periphery of the ganglion, particularly near the intraganglionic spiral bundle. In the control animals HRP could be demonstrated in only a few ganglion neurons, apparently corresponding to labelling of a few axons in the cochlear nuclei. In the experimental group, there was substantial labelling of both Type I and Type II neurons. HRP reaction product was usually present in the form of granules scattered through the cytoplasm; granules tended to be smaller and fewer in Type II neurons. No HRP could be demonstrated in some Type II neurons, even when surrounded by well-labelled Type I neurons. We conclude that Type II ganglion cells do project to the brain, although their termination may not be identical to that of Type I cells. (Supported by NIH Grant NS12125).

49.5 A STUDY OF THE MECHANISM UNDERLYING THE DIRECTIONAL SENSITIVITY OF THE ANURAN EAR. Walter Wilczynski, Carl Resler*, and Robert R. Capranica. Sect. Neurobiol. and Behav., Cornell University, Ithaca, NY, 14853.

Recent work (Feng, J. Acoust. Soc. Am., 68:1107, 1980) has verified that auditory nerve fibers in frogs are highly sensitive to direction, demonstrating that the anuran has directionally sensitive ears despite lacking pinnae and a large, boney head. As the initial phase of a study to elucidate the mechanism of this directionality, we recorded single eighth nerve units in the leopard frog, Rana pipiens, via a ventral approach to the nerve. A movable speaker presented tones (200 to 1800 Hz) from different azimuthal positions in the free field while sound intensity at the eardrum was monitored with a condensor microphone. Unit responses as a function of sound direction were determined under two conditions. In one, the frog's mouth was opened to expose the Eustachian tubes, maximizing a pressure gradient across the tympanic membranes. In this condition, units were directionally sensitive at all frequencies such that a null, or area of least response, was present in the frontal field. In the second condition, the mouth remained open, but a clay and plastic cap molded to mimic the natural mouth spaces interconnecting the middle ear and nasal cavities was inserted and sealed with grease. This changed the directional characteristics of the units' response such that stimulation at low frequencies still yielded a null pattern, but stimulation above 600 Hz in general yielded a gradually decreasing response as the speaker was moved from the ipsilateral to the contralateral side of the animal. This phenomenon depended on the frequency of stimulation, regardless of the actual characteristic frequency of the unit, implicating a mechanical mechanism independent of hair cell physiology or position in the inner ear. The results also suggest that while a pure pressure gradient mechanism could account for low frequency directionality, other factors contribute to high frequency directionality. In order to determine what these factors are, and whether a pressure gradient is in fact involved in low frequency directionality, experimental manipulations of these two conditions, such as plugging the nares or Eustachian tubes, coupled with eighth nerve recording and concurrent laser interference measurements of tympanic membrane movement are now in progress. Preliminary results from these experiments suggest that while the anuran ear is directionally sensitive, if a pressure gradient mechanism is involved, it is not a dominant factor in determining the directional sensitivity of the anuran's peripheral auditory system.

Supported by NIH Fellowship NS 06237 to W.W. and NSF grant BNS 7706803 to R.R.C.

49.6 POSSIBLE FACTORS AFFECTING THE RESPONSE PHASE OF AUDITORY NERVE FIBERS. W.G. Sokolich*, D.R. Maceri*, and D. Strelioff. Div. Head & Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024.

In a previous comparative study in our laboratory, the time-locked responses of auditory-nerve fibers to acoustic sinusoids having frequencies between 100 Hz and 400 Hz were studied in gerbils and guinea pigs. It was found that the preferred response phase of fibers with CFs between 1 and 10 kHz varies in a systematic way with fiber CF in gerbils, but is relatively independent of fiber CF in guinea pigs. In the present study, preliminary data obtained from chinchillas indicates that a CF-independent response phase is atypical of preparations having the most sensitive whole-nerve and single-fiber thresholds. This observation suggests that the CF-independent response phase typical of less-sensitive chinchillas and of guinea pigs used in the previous study may be indicative of a traumatized preparation. The suggestion that even the slightest trauma could substantially affect the operation of the cochlea has rather unappealing implications concerning the validity of routinely-used procedures for making measurements of cochlear microphonics and basilar membrane displacement. Refinements in surgical procedures and controlled studies of the effects of various cochlear manipulations on the response phase of fibers in the most sensitive preparations will be required to place the issue of the sensitivity of the cochlea to insult on a more firm basis.

49.7 "^{3}H-GABA UPTAKE IN ISOLATED VESTIBULLARY CRISTAE OF CHICK INNER EAR". °G. Meza, C. Hernández$^+$ and M. Ruíz$^+$. °Dept. Neurociencias, CIFIC, UNAM and $^+$Dept. Histologia, Facultad de Medicina, UNAM, México 20, D.F.

Afferent neurotransmission in the vestibule of vertebrates is chemical in nature as indicated by considerable evidence. Although the identification of the neurotransmitter has been controversial, strong indication exists favoring GABA as the afferent neurotransmitter in the accoustico-lateralis system of amphibians and fish (Flock and Lam, Nature 249: 142-144, 1974). As this system is fairly constant in vertebrates, we would like to postulate that some similarities must exist amongst them, concerning the neurochemical correlates of neurotransmission. In a previous report (Meza, G. et al, Trans.Am.Soc.Neurochem. 12 (1): 256, 1981) we presented our findings of GABA synthesis as evidence for postulating its participation in the avian vestibule neurotransmission. As further support, in this communication we report the results of some experiments in which ^{3}H GABA uptake was investigated in isolated vestibule cristae of chick inner ear, since Na^+ and energy dependent high affinity transport has been shown to be the inactivating mechanism for GABA in SNC and it is proven to be a suitable criterion when pointing out a transmitter candidate.

For this purpose, ampullary cristae were dissected out from 1 day-old chicks and incubated with 0.5 uM ^{3}H GABA in a Krebs-Ringer-bicarbonate buffer (KRBB), pH 7.3, at various times at 37°C. Sodium-free experiments were performed in the same conditions, incubation buffer was Krebs-Ringer-HEPES, pH 7.3, in which Na^+ was substituted by choline. Temperature dependence was studied by incubation of the tissue in KRBB pH 7.3 at 4°C. Uptake was stopped by centrifugation and tissue was digested in NCS and the radioactivity counted in a Packard TriCarb Scintillation Spectrometer.

We found that 0.5 uM ^{3}H GABA can be accumulated twenty fold in an hour in a saturable manner by isolated cristae of chick inner ear; when incubation took place in the absence of Na^+ or at 4°C, it was inhibited by 90%.

These results indicate that GABA uptake found in isolated vestibullary cristae of chick inner ear shows the characteristics presented by the GABA transporting mechanisms in vertebrate CNS and although the cell responsible for this activity has not been yet identified, this transport might represent the inactivating mechanism for GABA and supports its participation in neurotransmission in the vertebrate vestibule.

49.8 ANATOMICAL AND PHYSIOLOGICAL CHARACTERISTICS OF HRP-LABELED PRIMARY VESTIBULAR NEURONS IN THE BULLFROG. S. Sitko,* V. Honrubia,* J. Kimm and I. Schwartz (SPON: J.M. Miller). Div. of Head and Neck Surgery, UCLA School of Medicine. Los Angeles, CA 90024.

Intracellular recordings were made in the VIIIth nerve of the bullfrog (Rana catesbiana) to measure the membrane characteristics and obtain records of spontaneous and evoked spike activity of primary semicircular canal afferents. Physiological stimulation of the canals was achieved by rotating the preparation on a servo-motor driven turntable with the animals' head centered in the rotational axis. The responses of each neuron to sinusoidal rotations at frequencies of 0.05 Hz, 0.5 Hz and 2 Hz and for impulsive accelerations of 400 deg/sec^2 were obtained. Membrane characteristics measured included the cell resting and action potential amplitude, cell input resistance and spike-activation threshold for applied currents. Physiologically characterized neurons were injected with HRP by applying pneumatic pressure and/or inotophoretic currents to the micropipettes containing 5% horseradish peroxidase in 1 m KCl. Following survival times of 12-48 hours, the VIIIth nerve and attached vestibular end organ was removed for histochemical processing using a diaminobenzidine procedure to visualize the HRP reaction product. Light microscopy was used to discern the anatomical features of the neurons and to trace their peripheral dendritic trajectories from the ganglion to their terminations in the crista. Our studies have revealed that the bullfrog's primary vestibular afferents are characterized by a broad range of soma and axon diameters which correspond to an equally broad range of spontaneous and evoked activity characteristics. The largest neurons had more irregular spontaneous firing rates and consistently exhibited the greatest gain and smallest phase shifts with respect to head acceleration. These neurons consistently terminated at or near the central region of the crista. On the other hand, the smallest neurons were characterized by having the most regular spontaneous discharge patterns the lowest gains and greatest phase shifts with respect to head acceleration. Our findings are thus consistent with the view that the anatomical features of the primary vestibular neurons are important in determining the neuron's physiological characteristics. In terms of response dynamics our observations indicate that the receptors in the frog's crista ampullaris are heterogeneous and differentially sensitive to a wide range of stimulus frequencies.

49.9 RESPONSES OF SEMICIRCULAR CANAL AND OTOLITH AFFERENTS TO LINEAR ACCELERATION. A.A. Perachio,[1,2] M.J. Correia,[1,2] T. Clegg*[1]
[1]Dept. of Otolaryngology, Univ. Texas Medical Branch, Galveston, TX 77550; [2]Depts. of Otolaryngology and Physiology & Biophysics, Univ. Texas Medical Branch, Galveston, TX 77550.

The traditional view that the semicircular canals are insensitive to linear acceleration has been challenged by evidence that canal afferent activity can be modified by static repositioning of the head with respect to the gravity vector (e.g., Estes, et al., J. Neurophysiol. 38: 1232-1249, 1975; Goldberg and Fernandez, Acta Otolaryng. 80: 101-110, 1975). This evidence was questioned as potentially artifactual since the internal auditory meatus was exposed by removal of overlying tissue allowing thermal gradients across the labyrinth to act as a caloric stimulus to the canals. Stereotaxic methods were used in urethane/ketamine anesthetized gerbils in which the brain and tissue surrounding the labyrinth were left intact. Five conditions of head tilt relative to the cardinal head axes were used. 0° tilt (lateral canal coplanar to the earth horizontal), ± 10° pitch angle, and ± 10° roll angle. Sixty vestibular afferents have been tested to date in 9 male gerbils. Of these, 41 were in ampullary nerves innervating the semicircular canals (16 lateral/25 anterior). A change of no less than ±10% in firing rate was considered to be significant. Among neurons with a coefficient of variation (C.V.) of less than 0.20 (n=24), thirty-three per cent of afferents from the semicircular canals exhibited a statistically significant change in firing rate as a result of head tilt. Neurons with a C.V. of greater than 0.20 also responded to tilt. Statistically significant changes in average firing rate occurred in a large percentage of this type of afferent. 91.1% responded to pitch tilt; 72.7% responded to roll tilt. Responses of canal afferents to head tilts were recorded in each of the 9 preparations. Bi-directionality of responses was consistently observed only for lateral canal afferents; firing rate increased when the nose was pitched up and decreased when the nose was pitched down. In contrast, no general characteristics could be identified for anterior canal afferents in terms of response directionality. For purposes of comparison, the responses of identified macular afferents to the same test paradigm were recorded. These afferents were so classified by their lack of response to angular acceleration about the vertical head axis. Macular afferents with a regular firing rate (C.V. = less than 0.2) were sensitive to the small angle head tilts; 88% responded. 83% of irregularly firing otolith afferents also responded to linear acceleration.

(Supported by NASA Contracts NAS9-14641, NS2-10502, Grant NAG2-26.)

49.10 SEISMIC SENSITIVITY IN VIIIth NERVE AFFERENT FIBERS OF THE WHITE-LIPPED FROG. E. R. Lewis and P. M. Narins. Electronics Research Laboratory, University of California, Berkeley, CA 94720 and Department of Biology, University of California, Los Angeles, CA 90024.

Seismic sensitivity (sensitivity to substrate-borne vibration) is known to reside in the inner ears of salamanders and frogs (D. W. Ashcroft & C.S. Hallpike, J. Physiol., 81:23P, 1934; R.J. Ross & J.J.B. Smith, Comp. Biochem. Physiol., 65A:167, 1980). The most acute seismic sensitivity reported for amphibian inner-ear afferents was found in saccular fibers of *Rana catesbeiana* (E.R. Lewis & R.A. Baird, Abstr. ARO Res. Mtg. 4:11, 1981). Those fibers exhibited thresholds in the neighborhood of 0.0001 g substrate acceleration, with best excitatory frequencies between 40 and 100 Hz; and their responses typically saturated at 0.0005 to 0.001 g. Field observations in the Luquillo Mountains of eastern Puerto Rico suggested that *Leptodactylus albilabris* (Günther), a terrestrial-breeding frog, might have even greater seismic sensitivity. Adults of this species cease calling at the slightest disturbance caused by a would-be observer, even when that observer apparently is not visible to the frog. To date we have recorded the responses of seven seismic afferents from the inner ear of *L. albilabris*, and each of those fibers exhibited sensitivity approximately ten-fold that of the *R. catesbeiana* saccular fibers. All seven exhibited thresholds in the neighborhood of 0.00001 g (with best frequencies between 50 and 100 Hz); and all seven exhibited saturated response at 0.00005 to 0.0001 g. On the basis of their position in the VIIIth nerve, we believe the seven fibers originated at the saccule; but confirmation of this awaits dye-injection studies.

Recordings were made in the VIIIth nerve between the brain and the intact otic capsule. To facilitate access to the nerve (via the roof of the mouth), the frog was mounted upside down, firmly attached to a small platform connected to an electromechanical vibration excitor. This apparatus was placed on an acoustically isolated vibration table, the surface of which exhibited ambient vibration with peak acceleration less than 0.000005 g. Sinusoidal vibrations were applied along the dorsoventral axis and measured by means of an accelerometer (B&K 4370) mounted to the surface of the small platform, immediately adjacent to the frog's head.

At 100 Hz, the peak-to-peak sinusoidal displacement was approximately 0.25 nm at the threshold for *L. albilabris* seismic fibers. This sensitivity is very nearly the same as the most acute displacement sensitivity determined behaviorally in fish (R. R. Fay & M.L. Patricoski, in Abnormal Animal Behavior Prior to Earthquakes II, U.S. Geol. Surv., Menlo Park, CA., p.63, 1980).

49.11 A MORPHOLOGICAL COMPARISON AMONG THE VESTIBULAR SEMICIRCULAR CANALS IN GUITARFISHES AND SKATE. R.F. Dunn and D.P. O'Leary. Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15213.

Striking morphological differences were present when the three semicircular canals were considered in terms of their: overall shape; major radii; length percentages of the canal segments (i.e., large diameter canal, ampulla, small diameter canal); and the canal lumen diameters. Three species were used, Raja eglanteria (Clear-Nosed skate); Rhinobatos lentiginosus (Spotted Guitarfish), and Rhinobatos productus (Shovel-Nosed Guitarfish). The dimensional relationships were generally similar in all three species with only minor variations noted.

Both the horizontal and anterior canals were oval-shaped, having major/minor axes of 14 mm/8 mm, and 12 mm/7 mm, respectively. The posterior canal was nearly circular-shaped having axes of 15 mm/13 mm. Anatomically all three canals were divided into three segments; thick-walled, small diameter segment (SDS); ampulla (AS); and thin-walled, large diameter segment (LDS). The length percentage values of these three segments to the circumference were approximately:

	HOR	ANT	POST
SDS	65	59	55
AS	7	9	8
LDS	28	32	37

All three canals appeared to be largely separated from either the saccular or utricular chambers such that these chambers were not a direct segment of any canal. The posterior canal appeared to be complete and independent with a possible connection near the endolymphatic duct. The LDS of the horizontal canal consisted of two portions: a short LDS communicating with the anterior canal LDS. Hence the LDS of both the horizontal and anterior canals formed a common duct along the majority of its length.

Particular attention was directed to a comparison of the lumen diameters of the small diameter thick-walled canal segments. In cross-section, the horizontal SDS was approximately triangular in shape, while that of the vertical SDS's were circular to oval-shaped. The lumen dimensional ratios were: HOR-ANT 1.5; HOR-POST 1.5; and ANT-POST 1.0. Hence, the lumen diameter of the horizontal canal SDS was 33% less than that of the vertical canals SDS's.

This anatomical information in this study defines the necessary boundary conditions to determine accurate hydrodynamic models of these receptors.

49.12 LINEAR PREDICTION OF SEMICIRCULAR CANAL AFFERENT RESPONSES FROM SWIMMING MOVEMENTS IN THE GUITARFISH. D.P. O'Leary and R.F. Dunn. Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15213.

Initiation of swimming movements is controlled by muscular contractions which result in relatively brief rotational acceleration pulses at the guitarfish's head. We investigated the afferent response profiles predicted from these brief acceleration pulses when the latter were considered as stimuli for the semicircular canals.

Signal processing techniques derived from linear systems theory provided the basis for predicted neural responses, in accord with the apparent linearity of semicircular canal afferents. Linear system transfer function parameters were first determined from single units in afferent nerves innervating each of the three canals, via cross-spectral analysis of experimental spike train responses resulting from pseudo-random ("white noise") rotational acceleration stimuli. The transfer functions were then Laplace transformed into time-domain impulse response functions, which were convolved with swimming motion acceleration trajectories to produce predicted afferent responses.

High speed cinematography was used to record swimming trajectories in a sea water tank. Film segments were digitized frame-by-frame to determine time series of sequential fish positions, which were twice differentiated to obtain acceleration trajectories.

Results showed that parameters determining the earliest epochs of the afferent linear system impulse responses dominated the profile of the predicted responses during the first 1 to 3 seconds following initiation of swimming movements. Moreover, these "dominant" parameters corresponded to an initial early time constant as opposed to the later "cupular" time constant often described as a system integrator. Consistent difference were found among predicted responses from vertical and horizontal canals, corresponding to differences in swimming movement dynamics in the respective planes stimulating these canals.

These results are consistent with a parametric control model in which afferent nerves with specific response parameters project information to the brain from specific receptor regions that are maximally stimulated by swimming movements that match the response parameters.

50.1 STUDIES ON PRIMARY CELL CULTURES OF DISSOCIATED HUMAN FETAL BRAIN. J.W. Walsh*, G. Goranflo* and J. Oeltgen* (SPON: E.T. Iwamoto). Div. of Neurosurgery, Univ. of Ky. Med. Ctr., Lexington, KY 40536.

Tissue from the brain of human fetuses of 11 to 21 weeks gestation was established in primary cell culture to provide a substrate for specific morphological and virological investigations. The fragments of tissue obtained from each specimen were mechanically disaggregated by repeated aspiration through large bore capillary pipettes and then seeded into tissue culture flasks or onto collagen-coated glass coverslips. Approximately 1000 flask and 200 coverslip cultures have been studied. Tissues of each gestational age were cultured separately so that the relative survival and maturation of their constituent cells could be investigated. All cultures were maintained in RPMI salt solution, 10% fetal calf serum, 600 mg% glucose and antibiotics. At days 3, 5, 9 and 12, the overlying nutrient medium was removed and the unattached cells that it contained were separated by centrifugation, resuspended in fresh nutrient medium, and inoculated back into the same culture flasks or dishes. After 12 days, the nutrient medium was changed to one containing 3% fetal calf serum. The cultures were then maintained and studied for periods of up to six months.

Each culture was examined with phase contrast microscopy throughout its period of cultivation and serial photomicrographs were taken. Cultures were also stained with hematoxylin and eosin, and phosphotungstic acid hematoxylin and by the Bodian's and Holtzer methods. Acetylcholinesterase, glial fibrillary acidic acid, galactocerebroside and tetanus-toxin like neuronal cell surface marker were localized in specific cell types and electron microscope and time lapse cinematography studies were done.

At first, a monolayer of immature astrocytes was formed. After successive reintroduction of unattached cells, neuroblasts and immature oligodendroglia were seen. Numerous long neurites grew from small tissue clumps. Myelin formation was not seen. When gestational age was considered, tissue obtained from 14 week fetuses contained numerous bipolar neuroblasts that retained their configuration through their period in culture. After 16 weeks gestation, maturation into multipolar neurons took place over a 3 to 4 week period. If the tissue were of gestational age of more than 18 weeks, neuroblasts and oligodendroglial cells could not successfully be maintained. The results suggest that there is a critical period in human neuronal development at about 18 weeks gestation and confirm that before this stage their maturation and growth can be studied by cell culture techniques.

50.2 HOMOTYPIC EXTRACELLULAR MATRICES ENHANCE THE PROLIFERATION OF HUMAN NEUROBLASTOMA CELLS. Angelika Michler-Stuke* and Jane E. Bottenstein. Department of Pediatrics, University of California, Los Angeles, CA 90024.

The extracellular matrix produced by cells in vitro corresponds in part to the intercellular material on which cells in the organism proliferate, aggregate, migrate, and/or differentiate. Some of the components of in vivo and in vitro extracellular matrices have been identified. These may include different types of collagen, elastin, glycosaminoglycans, proteoglycans, hyaluronate-proteoglycan aggregates, and several glycoproteins (e.g., fibronectin and laminin). Although in vitro studies have described the biochemical composition of mouse and rat neuroblastoma extracellular matrices, no functional role for these neuronal matrices has been reported.

We have investigated the relationship between LA-N-1 human neuroblastoma-derived extracellular matrices and the proliferation of autologous LA-N-1 cells in serum-free defined media. Cell-free extracellular matrices were prepared from high density cultures by treatment with 0.02% EGTA. These homologous extracellular matrices increased the incorporation of tritiated thymidine into TCA-precipitable material three-fold in cultures of moderate density and nine-fold in low density cultures. Enzymatic treatments of the matrices indicated that trypsin> neuraminidase>hyaluronidase diminished their growth enhancing effect. DNase, RNase and collagenase treatment had no effect. The sialoglycoprotein fibronectin alone or in combination with a polylysine coated substratum could not mimic the effect of the extracellular matrices. The specificity of extracellular matrices derived from other donors, including different cell types, will be discussed as well as the influence of neuronal-glial matrices. The significance of these results may lie in their relevance to normal neuroblast proliferation.

50.3 CHICK EMBRYO SPINAL CORD CELLS CULTURED IN DEFINED MEDIUM AND ALTERATIONS IN HIGH AFFINITY GABA UPTAKE. C.R. Walker, C.A. Glass* and R.C. Strohman*. Dept. Zoology, U.C.Berkeley, Berkeley, CA 94720

We have successfully cultured chick embryo spinal cord cells in a completely defined medium. Seven day old chick embryo spinal cords were dissociated with 0.1% trypsin and plated on polylysine coated 35mm dishes(1ml of 0.01mg/ml polylysine, Sigma II, in H_2O overnight, 3x rinse before use). The medium is MEM with Eagles salts with added amino acids to conform to the DM-153 medium of H. Katsuda & F. Takaoka(1976) in Methods of Cell Biology ed. O.M. Prescott, v. 14, pp. 145-158. 10μM HEPES, 0.5μg/ml insulin, and 0.1μM dexamethasone were also added.

The neuronal cells exhibit extensive neurite development and survive at least two weeks. Non-neuronal cells do not survive and cultures appear to be completely neuronal. The cells can be refed with a serum containing medium after several days and few non-neuronal cells are seen after a week. This procedure appears to be a very effective way to obtain pure neurons for biochemical studies without toxic drugs.

Chick spinal cord cells have a high affinity uptake mechanism for GABA and this mechanism was investigated in the defined medium. Autoradiography revealed that a majority of the neurons are GABAnergic and may suggest that these neurons survive preferentially in this medium. A kinetic analysis of ^{3}H-GABA uptake was done using spinal cord cells plated in the defined medium at 0.2 spinal cords per dish. One half of the cultures were refed with a medium containing 10% horse serum and 1.5% embryo extract after 24 hrs. The high affinity uptake at 4 days was the same for both groups, Km=3μM. The Vmax or uptake capacity of the two groups was different, defined medium, Vmax= 2.6pmo/dish and serum medium, Vmax=8.0pmol/dish. This difference probably represents the more extensive neurite development that is seen with neurons in serum.

In a separate experiment, cells were refed serum at day 5 then analysed at day 8 for GABA uptake. This experiment showed that the older neurons in defined medium had a lower affinity, Km=12μM than the neurons in serum, Km=2.5μM. Others have reported that the affinity for GABA uptake decreases with the age of neurons in culture. This decrease maybe due to changes in membrane structure and culturing in defined medium may speed up this process. It is known that cells cultured in defined media have different lipid composition of membranes than cells cultured with serum. These changes we have found in the kinetic properties of GABA uptake may represent an example of regulation of a cell property by membrane lipids.

50.4 COMPONENTS OF THE PERIPHERAL NERVOUS SYSTEM DEFINED BY MONOCLONAL ANTIBODIES. Carson J. Cornbrooks, Richard P. Bunge, and David I. Gottlieb. Dept. Anat. & Neurobiol., Wash. Univ. Sch. of Med., St. Louis, MO 63110.

The interaction between three cell types (Schwann cells, neurons and fibroblasts) is essential for the development and maintenance of the PNS. In an attempt to define cell surface or secreted molecules which play a role in these processes, monoclonal antibodies were made against components of the PNS. Balb/c mice were immunized with preparations of Schwann cells and neurons grown in culture for 5 weeks and one month later received a second immunization of sciatic nerve obtained from a 6 day postnatal rat. Four days after the second injection, the mouse spleen cells were fused with SP2/0 myeloma cells and hybridomas were obtained by standard techniques (Galfré et al., Nature 266:550-552, 1977). The binding of hybridoma-secreted antibodies was initially screened using ^{125}I-RaM FAB'2 secondary (2°) antibody and cells cultured from rat dorsal root ganglion (DRG). These DRG preparations were housed in plastic, multiwell dishes which provide reproducible cultures of neurons with proliferating Schwann cells in defined medium (Bottenstein and Sato, PNAS 76:514-517, 1979) or fully differentiated (myelinating) Schwann cells in serum-embryo extract containing media. Wells containing hybridomas which demonstrated high binding to PNS cells and poor binding to lung preparations were cloned and ascites tumors were produced. An antibody designated B3 demonstrated saturable binding to cultures containing neurons and Schwann cells and considerably lower binding to preparations of sciatic nerve fibroblasts, and DRG neurons after 8 and 23 days in culture. Visualization of B3 binding with 2° antibody conjugated to fluorescein or HRP revealed a ring of staining surrounding myelin sheaths in 10λg, frozen sections of adult sciatic nerve. Myelin sheaths and axons were not stained. Immunohistochemical staining with HRP conjugated 2° antibody of cultures containing both neurons and Schwann cells without fibroblasts revealed staining over the surface of axon-related Schwann cells. At the electron microscopic level a flocculant precipitate of the reaction product was observed associated with the Schwann cell basal lamina surrounding Schwann cells related to both myelinated and unmyelinated axons. We believe this monoclonal antibody is directed against an antigenic component of the basal lamina which is secreted by the differentiating Schwann cell. Further studies will be directed to determine the role of this antigen during the neuron-Schwann cell interaction. (Supported by NIH Grant GM28002.)

50.5 MAINTAINED MITOTIC ACTIVITY IN MORPHOLOGICALLY DIFFERENTIATED RAT PHEOCHROMOCYTOMA CELLS TREATED WITH NERVE GROWTH FACTOR. M.J. Ignatius*, C.E. Chandler* and E.M. Shooter, Dept. of Neurobiology, Stanford Univ. School of Medicine Stanford, CA 94305.

Cultures of rat pheochromocytoma (PC12) cells continue to synthesize DNA for up to 14 days in the presence of nerve growth factor (NGF), (Gunning et al., in press). In cultures treated with NGF for eight days, both process-bearing and non-process-bearing PC12 cells have labelled nuclei following a brief incubation with ^{3}H-thymidine. The present study, in addition to further characterizing the continued DNA synthesis in NGF treated PC12 cells, looks at whether the presence of ^{3}H-thymidine uptake actually reflects cellular division in morphologically differentiated neurons.

PC12 cells (courtesy of D. Schubert) were grown on polylysine coated plastic cover slips in DMEM with 10% horse serum. Some cultures were given 50 ng/ml β-NGF every other day while control cultures lacked NGF. DNA synthesis in individual cells was determined by adding ^{3}H-thymidine (1μCi/ml) for 2 hrs, followed by fixing and processing for autoradiography. In all instances nuclear labelling was reduced by 95% with 10 μM cytosine arabinoside, a DNA polymerase inhibitor. In 8 day old control cultures (no NGF) 30% of the cells had labelled nuclei, after 2 hr ^{3}H-thymidine pulse. In cultures treated with NGF for 8 days, 7% of the cells were still synthesizing DNA. The fraction of process bearing and non-process bearing cells which had labelled nuclei were identical; thus these labelled cells (7%) were not a subpopulation of NGF non-responsive cells. Even after 14 days in culture with NGF, 7% of the cells with neurites were still synthesizing DNA during a two hr pulse. With continuous ^{3}H-thymidine labelling in the presence of NGF from 8 to 13 days in culture, 65% of the process bearing cells were labelled, indicating again that labelled cells were not a minority population of abnormal or rapidly dividing cells. Thus both morphologically differentiated and undifferentiated PC12 cells respond to NGF by slowing down but not stopping their synthesis of DNA.

The DNA synthesis observed was accompanied by normal cellular division and did not result in polyploid or cells with or multinucleate. This conclusion is supported by two findings. Fewer than 2% of the cells were multinucleate and the amount of DNA per nuclei remained constant, as determined by flow micro fluorimetry. Preliminary time lapse cinematography has shown a number of morphologically differentiated cells dividing in culture.

50.6 EVIDENCE FOR VASOPRESSIN-LIKE NEURONS IN PRIMARY CULTURES OF DISSOCIATED FETAL MOUSE HYPOTHALAMUS. D.T. Theodosis *, P. Legendre*, I. Cooke and J.D. Vincent. INSERM, Rue Camille Saint-Saëns, 33077 - BORDEAUX-CEDEX (France)

Cells cultured from fetal mouse hypothalamus have been studied by light and electronmicroscopy to correlate their morphology and immunoreactivity with electrophysiology. Following techniques described by Faivre-Bauman et al. (Brain Res., 185 : 289, 1980), hypothalami were dissected from 14 day fetal mice, mechanically dissociated, plated on 35 mm Lux dishes and grown in Ham's F 12 supplemented with 10 % fetal calf serum and 1 % glucose at 37°C, 5 % CO_2. No antibiotics were present after the first week. After 21 days, the cultures are composed of a continuous basal layer of glial and mesenchymal cells over which neurons (identified by morphology and electrophysiology) are growing in discontinuous patches. Phase contrast, intracellular injection of horseradish peroxidase or lucifer yellow demonstrates neurons whose extent and complexity of processes increase with age. Three types predominate: (a) the largest, pericarya 10-20 μm, have 2 or 3 stout dendrite-like processes bearing numerous spines, and a long thin axon-like process, occassionally branching, often with dilatations; (b) neurons with a stellate arborization of thin, spine-bearing processes and a single long axon-like process; (c) neurons from which a single process emerges and bifurcates close to the soma. In EM, many features typical of neurosecretory neurons are found including dense-cored secretory granules (100-200 nm) which occur in small numbers in perikarya and more frequently in processes and dilatations. Synapses, identified by the presence of pre- and post-synaptic densities ans synaptic vesicles, are seen to impinge onto these elements. Immunocytochemical staining (using immunofluorescence and the unlabeled antibody enzyme method with PAP) shows that a number of neurons of type (a) react positively to vasopressin antisera. The immunoprecipitate is localized mainly in processes and dilatations and less abundantly in perikarya. It is at no time evident within the basal layer. All neurons displayed action potentials and complex synaptic-like responses. Plateau depolarizations of 1/2-5 min duration were recorded from type (a) neurons (see Legendre, et al., this vol.).

51.1 CLONIDINE DECREASES SEROTONIN SYNTHESIS AND METABOLISM IN RAT BRAIN CORTEX, John F. Reinhard, Jr. and Robert H. Roth. Depts. of Pharmacology & Psychiatry, Yale University School of Medicine New Haven, CT 06510

Considerable electrophysiological evidence suggests that serotoninergic neurons are modulated by a facilitory noradrenergic input. Pharmacologic studies have shown that the alpha noradrenergic agonist clonidine affects brain serotonin metabolism. Unfortunately, there is little agreement as to the direction or the mechanism of these effects. Thus, the present studies were undertaken to resolve the nature of clonidine's serotoninergic interactions.

Tissue indoles and catechols were measured using liquid chromatography with electrochemical detection. MHPG was measured by gas chromatography-mass spectrometry.

Time-course studies revealed a maximal decrease of both 5-HIAA and MHPG at 3 hours; the decrease was evident at 2 hours, persisted until 4 hours, and was no longer present at 6 hours.

Dose-response studies, conducted at 3 hours, demonstrated changes in MHPG with as little as 30 ug/kg (i.p.), while significant changes in 5-HIAA were not observed below 300 ug/kg.

Administration of clonidine prior to decarboxylase inhibition with Ro4-4602, antagonized the Ro4-4602-induced accumulation of both DOPA and 5-HTP by 33%.

The possibility that clonidine acts by decreasing noradrenaline release was tested by administering L-amphetamine along with clonidine. Amphetamine completely antagonized the clonidine-induced decrease in 5-HIAA, at a dose which when given alone did not alter either 5-HIAA or MHPG.

The present studies reveal that clonidine decreases cortical serotonin synthesis and metabolism. The correlation between the changes in 5-HIAA with those of MHPG, and the antagonism of the clonidine-induced decrease in 5-HIAA by L-amphetamine, suggest that clonidine decreases serotonin metabolism by reducing the release of noradrenaline molecules into brain synapses. This effect may be due to clonidine's interaction with autoreceptors of noradrenergic cell bodies or nerve terminals. (These studies were supported by NIH grant MH-14092; J.F.R. was supported by NRSA #1 F32 MH08358-01.)

51.2 CHOLINERGIC DENERVATION AND BLOCKADE INCREASE α ADRENERGIC RECEPTOR BINDING IN THE RAT BRAIN. A. Leslie Morrow*, Charles C. Wurtz*, Rebekah Loy and Ian Creese, Dept. Neurosciences, Univ. Calif. San Diego, La Jolla, CA 92093.

Many studies have suggested an intricate relationship between adrenergic and cholinergic activity. Recently, cholinergic activity has been implicated in the regulation of non-cholinergic receptor systems. The present studies were undertaken to determine if alterations in muscarinic activity through surgical denervation of the septo-hippocampal pathway or by pharmacological blockade using the muscarinic antagonist atropine directly affect α adrenergic binding in the CNS.

Electrolytic or aspiration lesions of the cholinergic septo-hippocampal projection were performed on adult female albino rats. After 9-30 days the binding of [^{3}H]WB4101 to hippocampal homogenates was assayed in parallel for lesioned and sham-operated animals at three concentrations: 1 nM, .5 nM and .2 nM. For each pair (n=16) an increase in binding was observed. Scatchard plots of the data indicated there was no change in affinity but that cholinergic denervation produced about a 39% ($p<.005$, 1-tailed Student's t-test) increase in the number of binding sites for the α_1 adrenergic ligand. No alterations in muscarinic, α_2 or β adrenergic binding were detected.

Atropine sulfate (2 mg/kg) or physiological saline (.2 cc) was administered s.c. to female albino rats every 12 hrs for 21 days. Adrenergic binding using [^{3}H]prazosin (PRAZ), Kd=.12 ± .01 nM, and muscarinic binding using [^{3}H]QNB, Kd=.05±.01 nM were measured in the thalamus and limbic cortex (including hippocampus, dentate gyrus, subiculum, entorhinal cortex and cingulate gyrus). Assays and analyses of saline and atropine treated tissue were performed in pairs and differences are expressed as percent increase over control.

Chronic atropine treatment resulted in an up-regulation of PRAZ binding in the limbic cortex (X=15.1±4.5%, $p<.05$) and in the thalamus (X=11.9±3.5, $p<.025$). This increase was present in animals sacrificed 6 hrs, but not 48 hrs, following the last injection. In addition there was a simultaneous increase in [^{3}H]QNB binding in the limbic cortex (X=35.9±4.9, $p<.001$) which had diminished but was still significant after 48 hrs (X=16.3 ±2.2, $p<.05$). Affinities were unchanged for both ligands.

Considered together these results strongly suggest cholinergic regulation of α_1 adrenergic receptors in the CNS. It is possible that the PRAZ up-regulation following atropine treatment was due to the antagonist action of atropine at the receptor (Ki=750 nM for [^{3}H]PRAZ binding). We are presently investigating this possibility.

51.3 STIMULATION OF DOPAMINE RECEPTORS INHIBITS VIP SENSITIVE ADENYLATE CYCLASE ACTIVITY IN MALE RAT ANTERIOR PITUITARY. P. Onali*, J. P. Schwartz and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Vasoactive intestinal peptide (VIP) stimulates adenylate cyclase (a.c.) activity of pituitary gland (Borghi et al., FEBS Lett. 108:403, 1979) and selectively increases prolactin release in vitro (Enjalbert A. et al., Neuroendocrinology 31:200, 1980). Since dopamine (DA) inhibits prolactin release by acting on D-2 receptors, we used the activation of a.c. by VIP as a model to investigate the possible linkage of DA receptors with a.c. in male rats anterior pituitary. DA failed to affect the basal activity of pituitary a.c. at concentrations as high as 10^{-4}M, but inhibited the stimulation of a.c. elicited by different concentrations of VIP (10^{-8} to 5×10^{-7}M). This inhibition occurred without an apparent lag phase, was dose-dependent and reached a maximum (50-60% reduction of the VIP stimulation) at 10^{-5}M. The IC_{50} of DA, was approx. 4×10^{-7}M. DA receptor agonists such as apomorphine, A-6,7-DTN and bromocryptine mimicked the effect of DA. Classical neuroleptic drugs and (-)sulpiride, a selective DA D-2 receptor blocker, antagonized the inhibitory effect of DA stereospecifically. Phentolamine (10^{-8} to 10^{-5}M) did not block DA inhibition. The VIP sensitive a.c. was not affected by l-phenylephrine and l-isoproterenol, whereas it was significantly inhibited by noradrenaline (NA) at 10^{-5}M. The effect of NA was antagonized by 1 μM (-)sulpiride but not by 1 μM phentolamine. Dopamine failed to affect the activation of a.c. by prostaglandin E_1, a hormone which does not stimulate prolactin release. Muscimol, a GABA agonist which inhibits prolactin release in vitro, did not change the magnitude of a.c. stimulation by VIP. The results show that stimulation of D-2 receptors exerts an inhibitory effect on the activation of a.c. by VIP and indicate that these DA receptors are linked in an inhibitory manner to a.c. in anterior pituitary.

51.4 THE EFFECTS OF TRH ON THE IN VIVO RELEASE OF NE FROM THE MEDIAL PREOPTIC/ANTERIOR HYPOTHALAMUS OF THE RAT. S.K. Salzman*, M.S. Sellers*, and A.L. Beckman. Research Dept., Alfred I. duPont Inst., P.O.Box 269, Wilmington, DE 19899.

It is now widely accepted that thyrotropin releasing hormone (TRH) is a neurotransmitter or neuromodulator in the CNS. This tripeptide has been implicated as a mediator of arousal. One important question that must be addressed is what portion of TRH action is mediated by other neurotransmitter systems? We are investigating the possibility that the effects of TRH are mediated by an ability to augment the release of norepinephrine (NE) in the medial preoptic/anterior hypothalamus (POAH), as has been indirectly demonstrated in other brain regions.

Ten male Sprague-Dawley rats have been implanted with push-pull cannulae in the medial POAH. After postoperative recovery and habituation to the testing chamber, rats were perfused with an artificial CSF at a rate of 20.6 μl/min with a Harvard syringe pump. After a 30 min. washout period, 3 serial 20 min. samples were collected under baseline conditions where-upon an artificial CSF containing TRH (1.0, 3.0, 10.0 or 100.0 μg/ml) was remotely switched into the push flow, and 3 additional 20 min. samples collected. NE, and its major metabolite, free MHPG, were detected in all samples by liquid chromatography with electrochemical detection using DHBA as the internal standard.

Addition of TRH to the inflow resulted in behavioral and motor activation at all dose levels. At the higher dose levels (10.0 and 100.0 μg/ml), TRH produced a series of behaviors reminiscient of the opiate abstinence syndrome. The release of NE and MHPG correlated with arousal state (NE and MHPG in pmol/20 min ± SEM): waking with movement - 1.83 ± 0.33 (N=12), 3.59 ± 0.45 (N=6); waking, no movement - 0.72 ± 0.14 (N=11), 0.84 ± 0.13 (N=3); behavioral sleep - 0.70 ± 0.20 (N=6), 0.36 ± 0.10 (N=4).
In the pre-TRH baseline samples, NE was released at a rate of 0.89 ± 0.12 pmol/20 min (N=23) and MHPG at 0.70 ± 0.09 pmol/20 min (N=11). TRH augmented the release of one or both compounds; NE and MHPG in pmol/20 min: TRH (1.0 μg/ml) - 2.22 ± 0.32 (N=4), 0.44 ± 0.06 (N=4); TRH (3.0 μg/ml) - 2.62 ± 1.51 (N=3), 3.17 ± 1.81 (N=2); TRH (10.0 μg/ml) - 2.54 ± 1.13 (N=3), MHPG not determined; TRH (100.0 μg/ml) - 0.29 ± 0.19 (N=3), 3.00 ± 0.62 (N=4).

These results indicate that pharmacological doses of TRH can augment NE release in the medial POAH, and suggest that this may in part be responsible for the arousing effects of TRH.
(Supported by the A.I. duPont Inst. and NSF Grant BNS 78-19002).

51.5 PRESYNAPTIC INTERACTIONS OF CHOLINERGIC SYSTEM WITH AMINERGIC AND PEPTIDERGIC SYSTEMS CONCERNING RELEASE OF PEPTIDE HORMONES. Y. Yukitake*, and N. Hagino, (SPON: V. Williams) Department of Anatomy, Univ. of Texas Health Sci. Ctr., San Antonio, TX 78284.

The presynaptic receptors and uptake of blood borne materials were investigated electronmicroscopically in the posterior pituitary gland of the rat since peptidergic, aminergic and cholinergic axon terminals in the posterior pituitary have no synaptic connections. There are three types of vesicles in axon terminals in the posterior pituitary: Type 1 vesicles are 120-150 nm in diaeter and contain dense droplets; Type 2 vesicles are 40-50 nm in diameter and appear as clear vesicles; Type 3 vesicles are 50-70 nm in diameter and contain small dense granules. Cholinergic axon terminals contain only type 2 vesicles, however, peptidergic axon terminals contain type 1 vesicles together with type 2 vesicles and aminergic axon terminals contain both type 2 and 3 vesicles. In addition, coated pits are found on the membrane surface of the three kinds of axon terminals. Horseradish peroxidase (16% HRP) was infused intravenously under urethane anesthesia. Fifteen minutes later the animals were perfused with fixative and the brains were removed and processed for visualizing the HRP in the posterior pituitary by electronmicroscopy. Tetramethylbenzidine was used as a substrate for the HRP. Coated pits and vesicles associated with all three types of axon terminals were found to contain the HRP. Intravenous infusion of acetylcholine (Ach, Carbachol 120 μg/ml/hr in 2.5% dextrose in 0.5% saline, 286 mosmoles/kg volume) under urethane anesthesia increased the diameter and quantity of type 2 vesicles in all three types of axon terminals, and further, Ach tended to suppress the release of type 1 vesicles from peptidergic axon terminals caused by urethane anesthesia. It suggests that peptidergic axon terminals may accept Ach through coated pits and the release of peptide hormones may be suppressed at the level of axon terminals. Furthermore, cytochemical reaction of dopamine dependent adenylate cyclase (DD-AC) as an indication of dopamine receptors was investigated in the posterior pituitary. All three kinds of axon terminals demonstrated positive reaction for DD-AC; DD-AC was found within axon terminals and sometimes in between type 1 vesicles. This suggests that dopamine receptors are present in all three kinds of axon terminals and may be involved in the uptake of the dopamine. It is concluded that the uptake of neurotransmitters by the axon terminals of the posterior pituitary may be involved in the regulation of peptide hormone release. 51.6 INTERACTIONS OF ESTROGEN WITH CHOLINERGIC AND DOPAMINERGIC SYSTEMS IN THE REGULATION OF PROLACTIN SECRETION. N. Hagino, D. Liu*, A.T. Modak and W.B. Stavinoha, Departments of Anatomy and Pharmacology, Univ. of Texas Health Sci. Ctr., San Antonio, TX 78284.

Acetylcholine (Ach) in blood is associated with rat estrous cycles, and further, ovarian estrogen is one of the factors controlling Ach in blood and CNS. Estrogen elevates serum levels of prolactin (PRL), therefore if ovarian estrogen interacts with Ach in blood and CNS to regulate PRL secretion, intravenous or intracerebroventricular application of Ach could alter blood levels of PRL. In 6 intact female rats under urethane anesthesia intravenous infusion of 2.5% dextrose in 0.5% saline maintained 125.7 ± 38.0 ng/ml of serum PRL. Following this Ach (Carbachol 120 μg/ml/hr in 2.5% in 0.5% saline) was infused and this resulted in an increase of serum PRL at 15 min (738.0 ng/ml); however, serum PRL was reduced at 60 min (345.6 ng/ml) and 120 min (175.0 ng/ml) during Ach infusion. Intracerebroventricular infusion of Ach (7.5 μg/μl/hr) using Alzet minipump increased serum PRL (139.1 vs 28.9 ng/ml) in 6 unanesthetized freely moving rats.

These results suggest the hypothesis that Ach may act directly on the tuberoinfundibular dopaminergic neurons (TIDA) to suppress their activity and in turn facilitate PRL secretion.

In order to elucidate the problem, Ach (120 μg/ml/hr) was infused intravenously under urethane anesthesia in 10 ovariectomized rats (ovex) and 11 estradiol benzoate (5 μg/rat for 3 days) primed ovex rats and serum PRL was assayed by RIA. Ovex rats exhibited Ach concentration in plasma (0.32 nmol/ml) and in cellular compartments (cc 0.37 nmol/ml), and serum PRL (65.5 ng/ml) persistently. Infusion of Ach for 2 hrs following infusion of vehicle in ovex rats increased serum PRL during the infusion period, and no reduction of serum PRL was observed. Intact rats infused with Ach under similar conditions showed a reduction in serum PRL. Injections of estrogen in ovex rats increased Ach in plasma (1.04 nmol/ml) and cc (0.93 nmol/ml). Ach infusion in estrogen primed ovex rats suppressed serum levels of PRL.

The results illustrate the possible involvement of acetylcholine as a neurohormone in the regulation of prolactin secretion and since the dopaminergic system is involved in the regulation of prolactin secretion, an interaction of estrogen with cholinergic and dopaminergic systems is indicated. (Supported by NIH Grant NICHD-10071).

52.1 ABERRANT NEURITE AND MEGANEURITE DEVELOPMENT IN FELINE SPHINGOMYELIN LIPIDOSIS AS REVEALED BY THE GOLGI METHOD. Steven U. Walkley, Henry J. Baker* and Dominick P. Purpura. Dept. Neuroscience, Rose F. Kennedy Center for Research in Mental Retardation and Human Development, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Golgi studies of human and feline gangliosidoses have revealed that certain types of neurons in these disorders develop conspicuous enlargements interposed between somata and axon hillocks (meganeurites) and additionally sprout secondary neurites from these same areas. Ultrastructurally, both meganeurites and secondary neurites have been shown to be the site of synapse formation, these contacts being associated with afferents of unknown origin. Golgi-demonstrable morphological changes which were qualitatively similar but quantitatively less severe also have been described in feline mannosidosis. It has been proposed that the insidious development of these abnormal structures and their associated synaptic input are primary contributors to the neurobehavioral deterioration evident in these disorders.

A 7-month old Balinese cat with a history of progressive neurobehavioral deterioration was killed humanely and tissues taken for biochemical and morphological assessment. Light microscopic, ultrastructural, and biochemical findings, including the demonstration of a 20-fold elevation of sphingomyelin in liver, were consistent with a diagnosis of sphingomyelin lipidosis or Niemann-Pick disease. Golgi studies were performed on a wide variety of CNS regions and successful impregnations revealed an array of morphological changes which appeared to be specific for given types of neurons. Neocortical pyramidal neurons demonstrated axon hillock-associated neurite growth and occasional meganeurite development. Other pyramidal neurons were normal looking or demonstrated dendritic spine decrement. Significant somatic enlargement was not a conspicuous feature. Occasional neocortical intrinsic neurons also were observed that possessed meganeurites but not secondary neurites. Meganeurite development was found to be of greater prominence in the amygdala and claustrum, and secondary neurite growth also was observed on many neurons of these areas. In the caudate, medium spiny cells generally lacked meganeurite and neurite growth, although axon hillock enlargement sometimes was observed. Rarely, medium spiny cells were found which displayed prominent meganeurite development. In the cerebellum, basket, stellate and Purkinje cells were found which had focal dendritic enlargements but no meganeurite or neurite growth.

Thus sphingomyelin storage disease in the cat represents another lysosomal disorder in which aberrant neurite and meganeurite growth occurs at axon hillock regions on select types of neurons. (Supported by NS-07512 and NS-10967).

52.2 PERTURBED MICROTUBULAR ARRAYS WITHIN CORTICAL NEURONS IN MENTAL RETARDATION. N. Bodick*, J. K. Stevens, and D. P. Purpura. Albert Einstein College of Medicine, Rose F. Kennedy Center for Research in Mental Retardation, Bronx, NY 10461, and Playfair Neuroscience Unit, University of Toronto, Toronto, Ontario, Canada.

Golgi impregnated biopsy tissue from the frontal cortex of developmentally retarded infants and children reveals an alteration in the dendritic structure of pyramidal cells. In contrast to the normal spine-studded cylinder, these processes are varicose: pronounced swellings occur along the length of the dendrite.

The microtubular array within these varicose dendrites has been reconstructed in 3-space, using a computer-graphic representation generated from serial electron micrographs. A new tracing strategy, microalignment (Stevens, Brain Res. Reviews, v. 203,No. 3, p. 265, 1980), facilitates data collection from small structures, over a large field.

Microtubules, within the constricted regions of the varicose dendrite occur in close parallel array. Within the varicosities, the relatively few microtubules frequently spiral. Notably, these expanded regions correspond to discontinuities in the microtubular array. Although synapses persist on these dendrites, the occurrence of spines is reduced.

The microtubular structure of the varicose dendrite is contrasted to that of the normal cortical dendrite in the mouse. In the normal dendrite, segmented tubules occur in parallel array. The tubules occupy the process in a space-filling fashion i.e., the shape of the array mimics the shape of the cell. It is suggested that, in the varicose dendrite the perturbed microtubular array underlies the perturbed cell shape. Quantitative description will be given.

52.3 TRIMETHYLTIN (TMT) INDUCED HIPPOCAMPAL LESIONS IN MICE. L. W. Chang, T. Tiemeyer*, G. R. Wenger* and D. E. McMillan*. Department of Pathology and Department of Pharmacology, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Alkyltin compounds are used extensively in plastic industries and in agriculture. Among alkyltin compounds, trimethyltin (TMT) is found to be extremely neurotoxic and has a selective toxic impact on the hippocampal formation. Mice were found to be very sensitive to TMT neurotoxicity and may serve as an animal model for the study of this potent neurotoxiciant. BALB/c and C57BL/6 mice, in groups of 6,were given a single intraperitoneal injection of trimethyltin (TMT) chloride at a dosage of 3.0 mg/kg body weight. Control animals were injected with equal volumes of saline solution. Whole-body tremor was observed in all TMT-treated animals within 24 hours. All animals were sacrificed at 48 hours post-injection. Animals were anesthetized with an intraperitoneal injection of Nembutal, chest opened surgically, and perfused intracardially with saline solution followed by 2.5% buffered glutaraldehyde. Brains were removed surgically and sliced before fixation. Half of the brains (right hemisphere) were fixed in Bouin's solution followed by 10% buffered formalin for light microscopy study. The other half of the brains (left hemisphere) were fixed in 2.5% buffered glutaraldehyde followed by 1% buffered osmium tetroxide for electron microscopy investigation. Extensive neuronal necrosis which appeared as cells with eosinophilic cytoplasm and pyknotic nuclei were observed in the granule cells of the fascia dentata in the hippocampal formation. Vacuolar changes in the fascia dentata as a result of neuronal loss were also evident in some animals. Necrotic changes in the pyramidal cells of the hippocampal formation were only minimal under these toxic conditions. With electron microscopy, it was revealed that significant accumulation of lysosomes and extensive degenerative changes occurred in the neuronal cytoplasm of the granule cells in the fascia dentata. Some pyramidal cells were also affected but most of these cells were spared. The present study demonstrated not only a sensitive model for the investigation of TMT neurotoxicity but also a system for chemical induction of a specific lesion in the granule cell layer of the hippocampus and should allow future behavioral studies to elucidate the toxic impacts of TMT as well as the function of the granule cells in the hippocampal formation. (Partially supported by an Institutional Research Grant from the University of Arkansas for Medical Sciences.)

52.4 MEMBRANE AND CYTOPLASMIC FACTORS IN NITROSOUREA SENSITIVITY OF HUMAN GLIOMA CELL LINES IN VITRO. B. H. Smith, M. Vaughan*, P. L. Kornblith*, M. A. Greenwood*, A. Robinson*, N. Shitara*, and P. E. McKeever*, SPON: (J. Kebabian). Surgical Neurology Branch, NINCDS, NIH, Bethesda, MD 20205.

Nitrosourea-sensitive and resistant glioma cell populations have been defined utilizing a microtiter chemotherapeutic agent assay (Kornblith, Smith, and Leonard, 1981). The basis of this clinically significant difference in sensitivity is not known. The mechanism by which nitrosoureas act to kill tumor cells has been thought to be alkylation and DNA-strand crosslinking. In an effort to determine whether non-nuclear factors may be involved in the sensitivity or resistance of human glioma-derived cell lines to nitrosoureas, we have used a combination of microcinematographic and scanning and transmission electron microscopic and electrophoretic methods to study the interaction of 1,3-bis(2 chloroethyl)-1-nitrosourea (BCNU) with neoplastic glial cell lines LM (sensitive) and NN (resistant) derived and maintained in our laboratory.

Marked bleb formation and cell retraction were observed to occur in a dose-dependent relationship (at 15μg/ml BCNU) within minutes of BCNU addition in sensitive cells (90%) but not resistant cells. The surface changes reflect major cytoskeletal rearrangement at a time too early to be accounted for by known interstrand DNA crosslink mechanisms and suggest that cytoplasmic and/or membrane events may be significant in the cytotoxic action of nitrosoureas. Sensitive glioma cells show more rapid uptake and slower release of ^{14}C-BCNU and its metabolites as well. Seven and one half percent SDS-polyacrylamide gel electrophoretic studies of ^{14}C-BCNU binding are now being utilized to study cytoplasmic binding in resistant and sensitive cells. Such studies may be useful in determining and modifying abnormal glial growth control mechanisms.

52.5 AMYLOID PLAQUES IN EXPLANTS OF SCRAPIE MOUSE BRAIN. G.S. Merz* P.A. Merz* and H.M. Wisniewski (Spon: G.Y. Wen) Dept. of Pathological Neurobiol., Inst. for Basic Res. in Mental Retard., Staten Island, N.Y. 10314

To unravel the origin of amyloid plaques of the type associated with dementia and aging we examined similar plaques in IM mice infected with scrapie strain 87V. The plaques are a prominent pathological feature especially in the needletrack left by intracerebral inoculation. Our first step has been to explant the needletrack into tissue culture and follow the fate of the plaques in vitro. Needletrack with adjacent cortical and subcortical tissue was aseptically removed from the brain, embedded in 3% agarose in culture medium and cut into 200 μ slices roughly perpendicular to the needletrack. Slices were mounted in a Maximov slide assembly on collagen coated coverslips. Extensive neuronal autolysis and tissue necrosis was evident for the first few days in vitro. Later, there was extensive outgrowth of fibroblasts, macrophages and other, unidentified cell types. Numerous cell types also populated the tissue slice. Addition of congo red to the culture medium revealed (within 24 hr.) amyloid plaques by their characteristic green-red-birefringence in polarized light. By electron microscopy the overall appearance of the plaques was that of a loose deposit of amyloid with no discernable core structure. The fibers were typically unbranched, straight and 10 nm in diameter. They were arranged in clusters and interspersed among cellular processes. Ultrastructural features suggested the cells associated with the plaque were predominately macrophages and microglia. Occasionally small numbers of amyloid-like fibers were seen in the cytoplasm of microglia. None were seen in macrophages. These features are essentially the same as those seen in vivo even though the plaques were cultured for over a month before fixation. Two observations suggest the in vitro deposition of amyloid. Two cultures devoid of birefringence for 7 days after addition of congo red subsequently developed areas of red/green birefringence. Second, a few cultures showed an increase in the mass of birefringence. Furthermore, in no case were plaques lost from a culture even in cases when they were followed for up to 80 days in vitro. Taken as a whole these observations suggest in vitro amyloid plaques and their associated cells represent a useful approximation of in vivo circumstance and should provide a useful approach to the origins and evolution of CNS amyloid.

52.6 NEURAL DIFFERENTIATION AND REGULATION OF MEASLES VIRUS REPLICATION. Carol A. Miller* and Michael C. Graves.* University of Southern California School of Medicine, Department of Pathology and University of California, Los Angeles, Department of Neurology. Los Angeles, CA 90033

The state of development and differentiation of the CNS has been shown to affect replication of many neutropic viruses. Subacute sclerosing panencephalitis, a persistent virus infection of the CNS in children, has been directly correlated with measles virus infection prior to age two. To examine the role of neural differentiation in measles virus replication, N_2A cells, a clonal murine neuroblastoma line, and TE671 cells, a human medulloblastoma culture, were incubated for 3 days with medium containing 2.5 ug/ml papavarine, an inhibitor of cyclic AMP phosphodiesterase, infected with measles virus, and refed with the agent. Neural-specific differentiation was assessed by quantifying neurite formation, and either acetylcholine esterase or choline acetyltransferase activity. Intracellular cyclic AMP levels were determined by radioimmunoassay. Papavarine-treated cells manifested a marked reduction ($>10^5$ pfu/ml) in release of infectious virus compared to control cultures. Treated cells manifested elevated levels of cyclic AMP, over a 15-20% increased numbers of neurites, and in TE671 cells, a ten-fold elevation of neural specific enzyme activity. Removal of papavarine two to seven days post-infection resulted in release of infectious virus, reaching maximal control levels within 48 hours. Changes in viral replication are neural specific, and did not occur in companion treated monkey kidney cells (CV-1, or Vero). Using immunofluorescent staining, markedly decreased amounts specifically of the viral Matrix (M) protein were seen in treated cultures. The role of cyclic AMP in mediating regulation or modification of viral proteins will be discussed. These results suggest that host cell factors, possibly including cyclic AMP may be significant both in converting an acute infection in the CNS into a persistent one, as well as the reactivation of a latent infection.

52.7 OPIATE RECEPTORS ON CULTURED OAT-CELL CARCINOMA CELLS REGULATE ADENYLATE CYCLASE. C.B. Pert, S. Gentleman*, U.K. Schumacher*, D. Carney*, A. Gazdar* and J. Minna*. National Institute of Mental Health and National Cancer Institute, Bethesda, MD 20205

About 25% of all lung cancers are of the small cell (SCCL) type, a rapidly growing lung tumor which metastasises early and widely, often to the brain. Recent studies of established lines which retain a constant genetic composition have revealed the presence of high dopa-decarboxylase levels and neurosecretory-like vesicles. Like other APUD cells, small cells or oat cells, as they are often called, manufacture hormones and neuropeptides. For example, the tetradecapeptide bombesin appears to be a highly selective marker for oat-cell carcinoma since it was present in 17 out of 17 oat-cell lines examined but was not present in 8 non-oat-cell lung tumors of various types (Moody et al., in preparation). In membranes derived from at least one cell line (NCI-H69), the β-receptor agonist, isoproterenol (5 μM) caused a two-fold stimulation of adenylate cyclase activity, an effect completely reversible by 10 μM propranolol. A significant reversal of the isoproterenol-induced stimulation of adenylate cyclase was produced by the opiate receptor ligands morphine (1 μM), D-Ala^2-D-Leu^5-enkephalin (50 nM), β-endorphin (0.5 μM), ethylketocyclazocine (10 nM) and etorphine (10 nM). These opiate effects could be reversed by opiate antagonists. [^{125}I]D-Ala^2-D-Leu^5-enkephalin bound specifically to oat-cell membranes. The binding could be displaced by the following opiate receptor ligands, in order from the most to the least potent: etorphine, leu-enkephalin, met-enkephalin, D-Ala^2-D-Leu^5-enkephalin, ethylketocyclazocine, β-endorphin and morphine. While specific [^{3}H]dihydromorphine binding on oat-cell membranes was undetectable, selective ion effects on specific [^{3}H]D-Ala^2-D-Leu^5-enkephalin were clearly measurable. Oat cells appear to have the "primitive" opiate receptor, which, "fixed" in the adenylate-cyclase-coupled "δ" conformation, is unable to assume the μ state. Therapeutic strategies to exploit the presence of high-affinity opiate peptide binding sites on oat cells might include the use of [^{131}I]-labeled opiate peptides or the use of opiate peptides coupled to other cell poisons for precise target delivery.

53.1 DIFFERENTIAL ACTIVATION OF LIMBIC AND CORTICAL DOPAMINERGIC SYSTEMS TO STRESS AND ANTICIPATION OF STRESS. J.P. Herman*, D. Guillonneau‡ R. Dantzer‡ P. Mormède‡ H.Simon *and M. Le Moal. Lab. Neurobiol. des comportements, Univ. Bordeaux, Bordeaux France.

Dopaminergic (DA) terminals of the mediofrontal and cingulate cortices and of the nucleus accumbens (AC) has been described to be activated by severe stress, such as electrical foot-shocks or immobilization. In the present study we extended these investigations to other terminal areas of the mesolimbic and mesocortical systems using two sort of stress : electrical shocks and the placing of the animal in a new environment. Also in view of the participation of some of these structures in cognitive functions, we tested whether the anticipation of a stress would affect their DA activity. Dopaminergic activity was followed in the mediofrontal cortices, olfactory tubercle, AC, striatum, septum and amygdaloid complex of the rat by measuring their DOPAC content. Activation of the pituitary-adrenal axis was evaluated by measuring plasma corticosterone levels. Placing the rats in a new environment for 20 min augmented the DOPAC level of the AC accumbens by 34 %, while no change could be detected in the other structures tested. Plasma corticosterone level went up to 447 ng/ml. On the other hand a 20 min electrical foot-shock session (650 shocks, 1.5 mA, 180 msec) activated the dopaminergic terminals of the mediofrontal and sulcal cortices, nucleus accumbens and amygdaloid complex (DOPAC levels 168, 148, 150 and 175 % resp. compared to controls) in rats previously habituated to the shock-chamber, while plasma corticosterone level augmented by 270 % (control : 159 pg/ml) The same changes were observed in the rats shocked on two consecutive days and sacrified after ten second shock session. On the other hand, in rats placed without shock in the chamber in which they were shocked on the previous day only the mediofrontal cortex reacted by significant elevation of its DOPAC content. This elevation was less than that seen in the rats shocked twice + 35 vs 65 % ; the increase in plasma corticosterone level was diminished (+ 149 vs. + 265 %).

53.2 EFFECTS OF 6-OHDA LESIONS TO THE FRONTAL CORTEX, NUCLEUS ACCUMBENS OR CORPUS STRIATUM ON AMPHETAMINE-INDUCED BEHAVIOR AND ACQUISITION OF THE CONDITIONED AVOIDANCE RESPONSE. H. Simon*, M. Le Moal and G.F. Koob. Lab. Neurobiologie des comportements, Univ. Bordeaux, Bordeaux France and A.V. Davis ctr. Behavioral Neurobiology, Salk Inst., San Diego, Calif. 92138.

Male, Sprague-Dawley rats were subjected to 6-hydroxydopamine (6-OHDA) lesions of three terminal areas of the midbrain dopamine (DA) system : frontal cortex (F.C.), N=8, Region of the Nucleus Accumbens (N.Acc) N=10, and the Corpus Striatum (C.S.), N=10,in order to determine the specific DA terminal region responsible for deficits in acquisition of the conditioned avoidance response (CAR) observed following treatment with DA receptor blockers. Lesions were made by infusing 8 µg (base) of 6-OHDA dissolved in 2 µl of vehicle (0.1 mg/ml ascorbic acid in saline) through a 30 gauge needle over a 8 minute period. Sham operated rats, N=10, received vehicle alone. Rats were allowed 10 days to recover from surgery and then were tested in photocell cages for motor activation induced by d-Amphetamine (AMPH), 1.0 and 4.0 mg/kg, S.C., Photocell beam breaks were counted every 10 min. and frequency observations of stereotyped behavior (sniffing, head down, rearing, locomotion, grooming, licking) were made every 20 min. As previously reported (Kelly, Seviour and Iverson, BRAIN RES. 94,1975), lesions to the N. Acc differentially blocked the locomotion induced by AMPH, but not the more intense stereotyped behavior. In contrast, C.S. lesions blocked the more intense stereotyped behavior, but not the locomotor activity. F.C. lesions had no effect on locomotion or stereotyped behavior. Subsequently (days 18-24 post-lesion), the rats were trained in a one-way CAR in a shuttle box as described by Beninger et al.,(JPET 213, 1980). The rats with N. Acc. lesions showed a significant, but weak impairment of acquisition of the CAR. The F.C. and C.S. rats showed no impairment relative to the shams. A fifth group of rats subjected to a combined 6-OHDA lesion to both the region of the N. Acc. and C.S. were transiently aphagic and adipsic, but regained feeding within 10 days post-lesion following daily intubations and access to a sweetened diet. These rats showed no response to either dose of AMPH and were more severely impaired in the acquisition of the CAR. These results suggest that a severe deficit in the CAR requires the destruction of the whole midbrain DA system, and that both the mesolimbic and nigrostriatal DA systems act in concert to produce response initiation to important environmental events.

53.3 MONOAMINE CHANGES FOLLOWING CONDITIONED EMOTIONAL RESPONSE. P.K. Burns*, M.P. Sands*, D.R. Cherek, J.E. Smith and J.D. Lane (SPON: J.L. Steinberg). Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Conditioned emotional response (CER) is thought to be an animal model for anxiety. CER has frequently been used to evaluate behavioral-drug effects, with anxiolytics clearly attenuating the emotional response. To evaluate the neurochemical changes associated with this paradigm, groups of three littermate Fisher F-344 rats were food deprived and shaped to lever press in a standard operant chamber. Lever pressing was maintained by a variable interval (VI) 1 min schedule of food presentation. Following stabilization of responding, one hour classical conditioning sessions were initiated. Classical conditioning consisted of presenting conditioned stimulus (tone) of varying lengths (2 min-10 min) and unconditioned stimulus (foot shock, 1mA, 500 msec) approximately 8 times during each session. UCS was presented at the end of CS. One rat of each group received this classical conditioning for 5 sessions. To isolate the conditioning component from the shock history and animal activity, the other two littermates received yoked CS (tone) or USC (shock) only. On test day, the CS was presented to the triads for 15 minutes while lever pressing was maintained by the food presentation schedule, after which the animals were totally frozen and stored at -70°C until analysis. The pre-tone and post-tone responding on the VI1 schedule were compared. The CER animal responded very little (<<1 res/min) after tone presentation, while both controls continued at pre-stimulus rates (circa 15 res/min). Brains were dissected into discrete cortical and sub-cortical areas and the content and utilization of biogenic amines and amino acid neurotransmitters determined. There were very few changes in content of neurotransmitters or their metabolites, suggesting that small functional pools were being utilized. Comparison of shock history (shock only versus tone only) revealed predominantly decreases in turnover of DA, NE and 5-HT in multiple areas. Comparisons of the conditioning/emotional component (CER versus shock only) revealed a general increase in turnover of DA and NE in multiple areas and mixed changes in turnover of DA and 5-HT in limbic versus motor areas. These data are consistent with CER being a model for studying emotional behavior in the presence of an aversive stimulus, and suggest roles for biogenic monoamines in modulating the behavior. (supported by USPHS Grant MH-31835).

53.4 STRIATAL DOPAMINE RELEASE IN FREELY MOVING RATS DURING COLD STRESS. Richard W. Keller, Jr., Michael J. Zigmond, and Edward M. Stricker, Department of Biological Science, University of Pittsburgh, Pittsburgh, PA 15260

Animals sustaining dopamine (DA)-depleting brain lesions show impaired behavioral responses to homeostatic challenges. Nonetheless, most previous attempts to measure increases in striatal DA turnover during such stressors have failed, possibly because the changes are too transient to be detected by conventional biochemical means. We have employed voltammetric electrodes implanted in striatum to monitor extracellular DA concentration during cold stress. Carbon paste-epoxy electrodes (150 um) were prepared according to the method of Conti et al. (Life Sci. 23: 2705, 1978) except that dodecyl sodium sulfate was added to the carbon paste mixture. As a result of this treatment, and the choice of oxidizing voltage (+0.5V), the electrodes were observed in vitro to be 4 times more sensitive to DA than to two other potentially interfering compounds, dihydroxyphenylacetic acid and ascorbic acid. Electrodes were stereotaxically implanted in 200-300 gm male, Sprague-Dawley rats. Four carbon paste-epoxy electrodes were placed bilaterally in striatum. A Ag/AgCl reference electrode and an auxiliary electrode were placed in contact with cortex. Animals were allowed at least 48 hr to recover and then tested for up to 3 months. During testing electrical connection was made via a cable and commutator. Chronoamperometric measurements were made on each electrode every 4 min by applying a +0.5V pulse of 500 msec duration and averaging the current during the last 30 msec. This average current was proportional to DA concentration in vitro and was used for calibration and measurement. The ability of electrodes to monitor endogenous DA release was further suggested by their responsiveness to amphetamine (5 mg/kg, i.p.), a drug which releases DA but is not itself detected by our electrode. Following a 1-hr period of stabilization, animals were placed in a 3-cm ice water bath. In 15 of 20 cases, cold stress produced an increase in current which was maximal by 1-4 min (the initial measurement). This signal had usually decayed significantly by the second or third measurement (4-8 min later) but did not return to baseline during the 45-min cold exposure. We observed a briefer increase in signal when animals were removed from the ice bath, and still smaller increases when rats were transfered from one cage to another. All environmentally-induced increases in current were completely blocked by the administration of α-methyl-p-tyrosine (125 mg/kg, i.p.) 4 hr before testing. These results suggest that DA is released in striatum soon after exposure to external stimulation. (Supported by NIMH grant 29670.)

53.5 SHORT- AND LONG-TERM EFFECTS OF UNCONTROLLABLE STRESS ON EXPLORATORY PATTERNS. V. Bruto* and H. Anisman. Department of Psychology, Carleton University, Ottawa, Ontario, Canada.

Unlike the behavior of animals that had been exposed to escapable shock, animals that had received yoked inescapable shock exhibit severe deficits of later escape behavior. We similarly observed that only the latter treatment disrupted the pattern of exploration in a free-running 8-arm radial maze. Specifically, naive mice or mice that had received 60 escapable shocks (150 μA) exhibited a systematic pattern of exploration in which they tended to visit those arms that had least recently been explored (spontaneous alternation). Moreover, a prominent response sequence consisted of successive visits to immediately adjacent arms. Exploratory patterns did not appear to be related to, or influenced by, motor activity. In contrast, in mice that had received inescapable shock, the pattern of exploration was altered, and appeared to progress in a haphazard fashion. Although the altered exploratory pattern was transient, being absent 24 hours after inescapable stress, it could be re-induced if mice were re-exposed to just 15 shocks prior to test. Among naive mice the 15 shock treatment was without effect. The inescapable shock treatment was found to provoke a transient reduction of NE in several brain regions, and like the behavioral deficits could be re-induced by limited stress re-exposure. Finally, pharmacological manipulations that depleted DA and/or NE successfully mimicked the effects of inescapable shock. It is suggested that in addition to deficits of response initiation and maintenance, uncontrollable stress provokes a short-term alteration in the way in which animals attend to or respond to environmental stimuli. These behavioral changes might be subserved by the effects of stress on catecholamine activity, and long-term behavioral deficits might be due to conditioning or sensitization of the mechanisms governing catecholamine activity.

53.6 HABITUATION OF AGGRESSION IN MICE: EFFECT OF BLOCKING SEROTONIN TRANSMISSION. J.T. Winslow* and K.A. Miczek (SPON: P.B. Dews). Dept. Psychology, Tufts Univ. Medford, MA 02155.

The decline of aggression during consecutive episodes of fighting appears to be a habituation phenomenon. Previous experiments showed that the frequency of biting and threats by male mice on conspecific intruders declined in the course of ten 5-minute confrontations distributed over 2 h. Aggression returned to about 50% of original levels when a new intruder was introduced, indicating dishabituation, and fully recovered within about 1 h. We reported earlier that d-amphetamine selectively blocked the decline of aggression suggesting an activating role for catecholamines on aggression, (Neurosci. Abstr.,1980, 112, 42.5). Serotonin systems may mediate inhibition of behavior by inhibiting catecholamine activation. The objective of our experiments was to describe the effect of interfering with serotonin transmission on the decrement of aggression in repeated confrontations between mice. We investigated the effect of blocking serotonin transmission with methysergide, p-chloroamphetamine, and lisuride on agonistic and non-agonistic behavior in mice. Aggressive behavior was generated in a male mouse, housed with a female, by introducing an unfamiliar group-housed male mouse into the home cage.

Methysergide (1,3 10mg/kg, IP), a serotonin receptor blocker, produced a dose dependent reduction of all behaviors measured and did not selectively affect aggressive behavior. Parachloroamphetamine (10mg/kg, IP), a serotonin synthesis inhibitor, increased attack, threat, and locomotion only 24 hrs. after injection when its neurochemical effects were producing a non-specific increase of endogenous levels of 5HT and CA; all behaviors returned to baseline levels 1 and 2 wks later, when PCA is selectively blocking serotonin synthesis. Lisuride (0.03, 0.3, 1.0 mg/kg, IP), like LSD, blocks indices of central and peripheral serotonin activity, but may also have properties of a dopamine agonist; this drug dose-dependently reduced both agonistic and non-agonistic behavior. Residents became hyperreactive: frequently assuming defensive postures and squealing at the approach of the intruder. A significant increase in the number of aggressive intruders was observed during treatment of the resident mice.

The data indicate that aggression in mice is not modulated by a dual system of catecholamine activation and serotonin inhibition. Although catecholamine does appear to be involved in the activation of aggression, blocking serotonin transmission did not result in release from inhibition. Suppression of behavior was observed, possibly as a consequence of peripheral effects of serotonin blockade.

54.1 POSTNATAL BEHAVIORAL EFFECTS OF ETHANOL CONTINUOUSLY ADMINISTERED TO MICE IN UTERO. D. M. Gilliam and A. C. Collins* (SPON: W. Proctor). Inst. for Behavioral Genetics, Univ. of Colorado, Boulder, CO 80309.

There have been few previous reports of behavioral and developmental measures taken on animals that were continuously exposed to ethanol in utero. The method used in the present study was devised to permit continuous chronic exposure of gestating mice to specific ethanol concentrations.

In the first experiment, gestating C3H mice received continuous infusions of 16.25±.82 g/kg/day ethanol via a surgically implanted jugular cannula for 48±6 hr starting at day 15±.5 of gestation. Fetal whole body ethanol concentrations (FBEC) and amniotic fluid ethanol concentrations were highly correlated with the mothers' blood ethanol concentrations. Fetal brain ethanol concentrations were 76% of FBEC.

In the second experiment, gestating C3H mice received continuous iv infusion of either ethanol (12.6±.7 g/kg/day) or saline during the final 8 days of gestation. Offspring were assessed neonatally for developmental and behavioral measures as described by Wahlsten (Brain Res., 72:251, 1974) or for open-field activity and ethanol preference as adults. Offspring of mice that received saline during gestation did not differ on any measure from offspring of mice that served as operated or unoperated controls. Offspring of ethanol-treated mothers showed hyperexcitability, muscular weakness, and evidence of delayed parturition. Prenatal ethanol treatment did not alter ethanol preference, but offspring of ethanol-treated mothers showed significantly higher open-field activity scores than did offspring of saline-treated mice.

54.2 EFFECTS OF CHRONIC ALCOHOL CONSUMPTION ON RAT MATERNAL BEHAVIOR. Freya A. Weizenbaum and William Hartigan, Jr.*. Dept. Psychology, Vir. Polytech. Inst. and S.U., Blacksburg, VA 24061.

Chronic alcohol treatment during pregnancy and continuing through lactation adversly affects rat pup growth and survivorship. Since pup development is dependent upon the integrity of maternal behaviors, it was hypothesized that the pup impairments would be associated with decrements in the maternal behavior of Alcohol-dams. Therefore, the purpose of the present study was to investigate the effects of chronic alcohol consumption on rat maternal behaviors. Alcohol treatment was initiated 40 days prior to pregnancy and continued till day 14 postpartum, when the experiment was terminated. On day 1 postpartum, litters were culled to 6 pups and the litters were cross-fostered either across treatment conditions, or within a treatment condition across dams. The offspring of Alcohol-dams that were paired with Alcohol-dams postpartally, showed a significant retardation in body weight and a higher mortality rate than Water-pups paired with Water-dams. As predicted, there were significant decrements in Alcohol-dam maternal behavior, measured in 15-minute tests on day 3 or 4, and on day 7 or 8 post-partum. Alcohol-dams showed significant increases in latency to contact and in latency to retrive Alcohol-pups. Also the number of Alcohol-pups retrived and the time in contact with the Alcohol-pups was significantly reduced. Furthermore retrival behavior, in the day 3 - 4 maternal test, was positively related to subsequent pup mortality. The poor performance of the Alcohol-dam in the maternal test was not due solely to alcohol consumption. Alcohol-dams that consumed equivalent amounts of alcohol, but which were paired with Water-pups postpartally showed a level of maternal behavior that was similar to that of Water-dams paired with Water-pups. Moreover, pup prenatal alcohol exposure was not a sufficient condition for impairing maternal-young interaction. Maternal behavior pup growth and pup surviorship in the Alcohol-pup/Water-dam group was similar to that of the Water-pup/Water-dam group. Thus the results of this experiment indicate that the post-partum deficits induced by alcohol are significantly influenced by both the mother and the pups, and that their contributions are synergistic rather than additive.

54.3 EFFECTS OF EARLY POSTNATAL ETHANOL CONSUMPTION IN THE RAT. T. Sonderegger, H. Calmes*, D. Colbern*, S. Corbitt*, and E. Zimmermann. Dept. Psychol., U.Nebr.-Lincoln, Lincoln, NE. 68588; Dept. Anat. and BRI, Sch. Med., UCLA, Los Angeles, CA. 90024

Separation of the effects of malnutrition from those of ethanol present a serious methodological problem in animal studies of the fetal alcohol syndrome. This problem has been studied in the rat during the gestation period using low doses of ethanol but not in the postnatal period while the brain is still developing.Thirteen litters of Charles Rivers CD albino rats were adjusted to sizes of 8 pups on Day 1 after birth. Pups were randomly assigned to one of three groups: ethanol (E); Sustagen (S), or handled (H). From Days 2-9, E pups were fed doses of 20% ethanol, with doses increasing from 0.8 to 1.2 mg/g, twice daily. The ethanol was in a 20% Sustagen (Mead Johnson) solution; S animals received equal volumes of isocaloric Sustagen; H animals were handled. (A study on another group of rat pups similarly treated showed high levels of blood alcohol (75% of original feeding level) 4 hours after the feeding.) Of the original 101 pups, 99 survived. Same sex body weights did not differ among postnatal treatment groups during treatment nor at subsequent weighings on Days 21,49, 147, or Day 180, showing that malnutrition, as indicated by body weight deficits, was not present. Activity measures, obtained beginning on Day 49, did not differentiate among postnatal treatment groups although females were more active than male counterparts. Between Days 116-147, some animals from each group were tested for the pituitary-adrenal stimulating effects of ethanol. Plasma samples obtained 30 min. after an injection of ethanol (2 mg/kg/ip) were assayed fluorometrically. Steroid levels were elevated and within the expected ranges for the sex of an animal similarly treated with ethanol but same sex postnatal treatment group levels did not differ. On Day 180, females from each group were anesthetized and implanted with chronic electrodes aimed at the medial forebrain bundle. Animals from the E,S,and H groups learned to bar-press for rewarding electrical brain stimulation. Current thresholds and bar-ressing rates were comparable, suggesting unimpaired neural substrates of reinforcement. In this study, low doses of ethanol did not cause behavioral, neuroendocrine, or growth impairment when malnutrition effects (body weight deficits) were controlled.

54.4 THE EFFECTS OF ADRENOCORTICOTROPIN AND ADRENALECTOMY ON VOLUNTARY ETHANOL INTAKE IN MICE. M. J. Kassam* and J. N. Pasley* (SPON: R. E. Stull). Dept. of Physiology and Biophysics, Univ. Ar. Med. Sci., Little Rock, AR 72205.

Recently, it has been suggested that adrenal glucocorticoids play a permissive role in the development of both tolerance to and dependence on ethanol (Sze, Drug and Alcohol Dependence 2:318, 1977; Wood, Psychopharmacol 52:67, 1977; Tabakoff and Yanai, Psychopharmacol 64:123, 1979). This study was designed to examine the effect of adrenocorticotropin (ACTH) treatment on voluntary ethanol ingestion in intact and adrenalectomized C57/BL6 mice, a high ethanol preferring strain. All mice were adult males, singly caged and maintained at 25° C on a 12:12 LD cycle with Purina Laboratory Chow *ad libitum*. Animals were divided into eight groups of eight mice each. Four groups remained adrenally intact and received either 4 units ACTH or gelatin vehicle injections. Within a given injection protocol, mice were further divided to be tested for selection of 5% or 10% ethanol. The treatments for the four groups of adrenalectomized mice were arranged in the same manner. The adrenalectomized mice were allowed a one week recovery period before testing and were maintained on daily i.m. injections of 50 µg cortisol acetate (Upjohn). Drinking bottles fitted with ball bearings were presented in a three bottle-two choice paradigm; one calibrated drinking bottle contained tap water, another contained ethanol in tap water; and the third bottle was empty. Individual ethanol and water consumption were measured daily between 0900 and 1100 hrs with bottle position also being changed daily. Daily subcutaneous injections of either 4 units ACTH (Cortigel-40, Savage) or the gelatin vehicle also occurred between 0900 and 1100 hrs. At the end of the 21 day injection period, all animals were killed by cervical dislocation. Thymus and adrenal glands were weighed to the nearest 0.0001 gram. Trunk blood was collected for later determination of corticosterone levels in serum by RIA. Adrenalectomized mice, whether or not treated with ACTH,demonstrated a decrease in ethanol selection during the injection period, as opposed to intact mice, in which case an increase in ethanol selection was observed, independent of ACTH treatment ($p<0.05$). Food intake did not differ with treatment. Adrenal and thymus weights reflected the various treatments to which the animals were exposed. The results argue against a direct role of ACTH in ethanol drinking but support the notion of adrenal gland involvement in ethanol preference in mice.

54.5 P3 AMPLITUDE DIFFERENTIATES SUBJECTS WITH AND WITHOUT A FAMILY HISTORY OF ALCOHOLISM. R. Elmasian, H. Neville, D. Woods*, M. Schuckit*, and F. Bloom*. Salk Institute, San Diego, CA 92138.

Genetic background has long been suspected as a factor in alcoholism (Goodwin, D.W., Arch Gen Psychiatry, 36: 57-61, 1979). Only recently, however, has the correlation between family background and the development of alcoholism been supported by physiological findings (e.g. Schuckit, M.A. and Rayses, V., Science, 203: 54-55, 1979). We studied event related potentials (ERP's) to further test the hypothesis that ethanol might have different effects on neural processes associated with cognitive functioning in subjects with and without a family history of alcoholism (Schuckit et al, in preparation). Family history positive subjects (FHP - those with alcoholic parents or siblings) were matched on height-weight ratio and personal drinking history with family history negative (FHN) subjects. None of the subjects were themselves alcoholic so that the effects of past alcohol abuse would not be confused with possible risk factors. Before receiving ethanol, the P3 response generated when subjects detected a rare 75 msec tone burst in a background of 300 msec tone bursts was similar in amplitude (about 13 microvolts; recorded vertex to mastoid) and latency (about 360 msec) for the two groups. After .56 g/kg ethanol P3 latency increased to 490 msec in both groups. Although P3 amplitude was essentially unchanged in the FHN group, it was reduced to less than 60% of baseline amplitude in the FHP group. The different effects of ethanol on P3 in the two groups can be observed in individual subjects and have been replicated in another experiment (Neville and Synder, in preparation). The P3 differentiation of FHP subjects from FHN subjects is theoretically important since it is the first direct physiological evidence that ethanol differentially affects cognitive and related neural functions in those at high risk for developing alcoholism (FHP subjects) and those at low risk (FHN subjects). This research is supported by PHS AA 07273, NIAAA 03504, and the Medical Research Service (Special Biology of Alcoholism Grant) of the Veterans Administration.

54.6 AN INVESTIGATION OF THE INTERACTION BETWEEN THE REINFORCING PROPERTIES OF FOOD AND ETHANOL USING THE CONDITIONED PLACE PREFERENCE PARADIGM. R.B. Stewart* and L.A. Grupp, Dept. Pharmacology, Univ. of Toronto, Toronto, Canada M5S 1A8.

Ethanol can maintain self-administration behaviour (e.g., Smith & Davis, Physiol. Psychol. 4: 91, 1974) and therefore has positive reinforcing properties and also produces a conditioned taste aversion (e.g., Lester et al., Quart. J. Stud. Alc. 31: 578, 1970) and therefore has aversive properties. Thus, different environmental factors and contingencies may interact in very different ways with ethanol to determine how its administration affects behaviour. In order to assess one such possible interaction, we used the conditioned place preference paradigm and compared the behavioural effects of ethanol alone to those when it was combined with the availability of food.

Rats were maintained at 85% of their free feeding weights. In the Ethanol only condition every second day was an ethanol trial and three groups of rats were given intraperitoneal (i.p.) injections of 250, 500 or 1000 mg/kg ethanol and placed in a distinctive box for 30 min - half of each group in the white box and half in the black box. Intervening days were saline trials and the animals received i.p. saline injections and put in the opposite coloured box. In the Ethanol and Food condition a second set of three groups were treated identically to the Ethanol only groups with the addition that food was available in both boxes during the ethanol and saline trials. After four ethanol and four saline trials a test trial without injections or food was given where the animals shuttled freely for 15 min between a black and a white compartment. Relative preference was assessed by comparing the time spent in the two compartments.

In the Ethanol only condition the 250 and 500 mg/kg groups spent equal time in both compartments (t_7=1.6, N.S.; t_7=0.32, N.S.) while the 1000 mg/kg group showed a significant aversion to the side paired with ethanol (t_7=6.5, $p<.01$). In the Ethanol and Food condition the 250 mg/kg group again showed no preference or aversion for either compartment (t_7=1.05, N.S.), but, in contrast to the Ethanol only condition, the 500 mg/kg group showed a significant preference for the side paired with ethanol and food (t_7 =2.95, $p<.05$), and the 1000 mg/kg group spent equal time in both compartments (t_7=0.24, N.S.).

These findings indicate that ethanol does interact with other reinforcing stimuli in its environment in a way that cannot be predicted from its effects when presented alone. Thus the observed interaction with food at the 500 and 1000 mg/kg doses appeared to be one that could not be predicted by simply adding the individual effects of food, ethanol and saline.

54.7 LOW LEVEL HYPERBARIC ETHANOL ANTAGONISM: TIME COURSE. R.D. Malcolm*, D.A. Finn* and R.L. Alkana. Insitute for Toxicology, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

Our recent studies have demonstrated that exposure to environments of 4-12 atmospheres absolute (ATA) of helium-oxygen (He-Ox) beginning immediately after ethanol injection causes a pressure and dose-related antagonism of ethanol narcosis in mice. The present investigation examined the effect on hyperbaric ethanol antagonism of pressurizing at different time points after ethanol administration. Drug-naive, male C57 mice were injected i.p. with 3.6 g/kg ethanol (20% w/v). Following loss of their righting reflex, they were placed in hyperbaric chambers. Time course mice were kept in a chamber atmosphere of 1 ATA air for 0, 5, 10 or 20 minutes before pressurization to 12 ATA He-Ox. Other groups of mice were kept at 1 ATA air throughout testing (controls) or switched to 1 ATA He-Ox at times paralleling pressurization of the time course mice. Upon wake-up, the chamber was decompressed and whole brains were removed and prepared for subsequent gas chromatographic determination of brain ethanol concentration (BEC). Immediate post-ethanol exposure to 12 ATA He-Ox significantly reduced sleep-time and increased wake-up BECs. Delaying the onset of hyperbaric exposure did not reduce the antagonistic effect. Similar significant reductions in sleep-time and increases in wake-up BECs were seen in mice pressurized 5-20 minutes after ethanol administration. The 1 ATA He-Ox mice did not display a reduced sleep-time or increase in wake-up BECs. The similar antagonistic efficacy of immediate and delayed pressurization indicates that there is not a critical time period during which hyperbaric pressure must be applied in order to induce antagonism and suggests that hyperbaric induced alteration of ethanol distribution to the brain does not represent an important factor in mediating the antagonism. These findings are in accordance with membrane expansion/fluidization theories of anesthesia. (Supported by NIAAA Research Grant AA03972).

54.7 ACUTE EFFECTS OF ETHANOL ON LIMBIC AFTERDISCHARGES. Henry Lesse. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, Calif. 90024.

Acute effects of ethanol on the initiation and maintenance of electrically induced limbic afterdischarges (AD) were studied in cats performing a bar pressing task. Current thresholds for evoking AD and AD durations in the amygdala, hippocampus and septal region were determined following alternating saline and ethanol administrations. Three doses (0.4, 0.8 & 1.6 Gm/kg; I.V.) were tested at 96 hr. intervals.

Ethanol-induced changes in limbic afterdischarges were found following low doses which produced neither observable changes in arousal state nor altered task performance. Elevations of hippocampal AD threshold followed the high dose and a biphasic effect was evident in some subjects after the low dose. By contrast, increases in amygdalar and septal AD threshold were induced by all test doses. This effect proved dose-related and greater in the amygdala than in the hippocampus (90% vs 12% following the high dose). In addition, ethanol induced dose-related reductions in AD duration which were greater in the amygdala and septal region than in the hippocampus. These effects were found when limbic AD were localized and also when fully developed motor convulsions were evoked. Restrictions in AD propagation to distant sites occurred during both early and late stages of seizure development. Time-course experiments at post-infusion intervals of 10 min. to 24 hrs. indicate that single doses of ethanol result in protracted changes in AD threshold and duration with biphasic effects beginning 8 - 16 hrs. after drug administration. These results suggest that ethanol has potent but differential acute effects in modifying the excitability of closely related limbic structures.

54.9 PROMOTION OF STEREOTYPY BY ALCOHOL. L. D. Devenport, V. J. Merriman*, and F. A. Holloway. Dept. Psychiat. & Behav. Sci., Univ. Okla. Health Sci. Ctr., Oklahoma City, OK 73190.

Even at moderate doses, ethanol seems to have as one of its principal actions the narrowing of behavioral variability (Devenport et al., Alcoholism: Clin. and Exp. Res., in press). This is apart from any stimulant or depressant property it may possess. In order to exhibit this action more plainly and to assess its boundaries, the behavior of rats in an 8-arm radial maze (after Olton & Samuelson, J. Exp. Psychol.: Anim. Behav. Process. 2:97, 1976) was observed across alcohol doses of 0, .75, 1.5 and 2.0 g/kg (injected i.p. as a 10% w/v solution). The experiment was conducted with a view toward assessing 1) topographic variability, 2) spatial variability, and 3) sequential variability.

The four groups of male rats were food-deprived and placed individually in the central compartment of the radial maze with access available to all arms. Subjects were permitted 10 min to run from arm to arm or until they obtained 8 rewards, (90 mg Noyes pellets). This experiment was conducted with reward replacement. That is to say, rewards were replaced as the animal returned to the central compartment. In principle, a subject could obtain its allotted pellets by returning 7 times to the same arm. Three 10 min (or 8 pellet) trials were afforded in daily sessions. Throughout each trial, the number of separate arms visited (spatial variability), the order of visitation (sequential variability), and the number of alternative non-goal directed behaviors emitted (e.g., rearing, sniffing, etc; topographic variability) were recorded.

Except at the lowest dose, alcohol exerted a dose-related attenuation of all forms of behavioral variability: Fewer arms were visited, the sequence of visitation was more stereotyped, and the number of behavioral topographies was fewer.

Phase 2 of the experiment imposed a win-shift rule (pellets were not replaced) in an effort to bring stereotypy into conflict with formal task requirements. Not surprisingly, alcohol groups performed inefficiently, returning to previously visited arms. We conclude that alcohol broadly attenuates behavioral diversity. Performance on any particular task is likely to depend upon whether that task rewards stereotypy or variability.

54.10 PRINCIPAL COMPONENT ANALYSIS OF THE EFFECTS OF ALCOHOL ON VISUAL EVOKED RESPONSES IN THE GENICULO-STRIATE SYSTEM. T.J. Willey, K.R. Erickson*, D.M. Riley*, A.F. Lawrence and J.M. Fuster. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, Calif. 90024.

Flash evoked potentials were recorded with implanted electrodes from the lateral geniculate nucleus and striate cortex of two monkeys performing a delayed matching-to-sample task. The flash served on every trial as an alerting signal preceding the cue (sample). Electrical and behavioral records were taken before and after intravenous injection of control saline or ethyl alcohol (0.25, 0.5, 1.0, or 2.0 g/kg) with a remotely controlled Sage pump. A PDP-12 computer was used to process the data. Potential records following each flash were digitized and stored on disk for each of the 200 trials of an experiment. A principal component analysis was done on data from each electrode site and animal. Templates of evoked response were obtained by grouping data under all experimental conditions and by using potential measures in successive time points after flash as variables. The first five eigenvectors were computed and plotted. Correlations with sub-averages from the original data (in successive groups of ten events) were also computed and plotted for control, low dose (0.25 and 0.5 g/kg), and high dose (1.0 and 2.0 g/kg). An analysis of variance was performed comparing pre- and post-drug correlation coefficients. Control and low-dose categories showed little or no shift in correlation coefficients. Significant deviations from pre-drug correlation were seen at high drug levels in each site and monkey. One of the first two eigenvectors showed shifts in lateral geniculate nucleus, indicating action of alcohol in that nucleus or at a previous stage of the visual pathway. By contrast, the first three eigenvectors showed correlation shifts in striate cortex. This difference from geniculate data may have at least two possible explanations: a) separate populations of cortical neurons differing in onset of response to and recovery from alcohol, or b) alcohol effects on subcortical structures (e.g., brain-stem reticular formation) that, in addition to the lateral geniculate body, provide input to the striate cortex. (Supported by grant NIAAA 03513).

54.11 EFFECTS OF NALOXONE ON ETHANOL TOLERANCE AND INDUCED TASTE AVERSION IN MICE. D. Miceli, M. Ptito, P. Marfaing-Jallat and J. LeMagnen (SPON: P. Pépin). Lab. de Neuropsychologie Expérimentale, Univ. du Québec, C.P. 500, Trois-Rivières, Québec, G9A 5H7, Canada.

It has been suggested that alcohol and opiates share a common mechanism of action in the CNS. Some evidence in favor of or against the latter hypothesis has been based on the ability of naloxone, a specific opiate receptor antagonist, to counteract various ethanol-induced behavioral alterations. The aim of the present study was to examine 1) naloxone interaction with regard to initial and acquired tolerance to ethanol in mice using the rotarod test 2) the effect of pairing ethanol and naloxone on subsequent spontaneous ethanol consumption. The study was performed on 44 male C57BL mice aged 6-7 wks assigned to 4 groups (N=11). Each received starting at 10 a.m. and over 10 consecutive days (Days 1-10), paired IP injections of either ethanol (3 g/kg: E), saline (S) or naloxone (10 mg/kg: N); groups SS, SN, ES, EN followed 20 min later by rotarod tests. Nervous tolerance was measured by the number of falls at 2 and 3 min intervals. At 10 a.m. on the day following the last day of behavioral tests, mice were offered a two-bottle choice between ethanol (5% V/V) and water over the next 10 days (Days 11-20). Throughout Days 1-10, SS and SN animals showed virtually perfect scores indicating no effect of naloxone per se. An effect of alcohol was observed in groups ES and EN accompanied by significant development of tolerance. However, the number of falls recorded during Days 1-4 were significantly higher in EN compared to ES mice (respectively $\bar{X}\pm$S.E. 14.3±0.8, 14.2±1.1 and 9.8±1.8, 10.0±1.8 for Days 1-2 and 3-4; 2 min values). Such differences were no longer apparent thereafter, attaining respectively 6.2±2.0 and 5.7±2.0 on Days 9-10. During the ethanol-water choice period, no differences were observed between groups SS, SN and ES; (respectively 78±4, 77±3 and 71±2 % ethanol/total fluid intake: Days 11-12; 92±1, 95±2 and 93±4 %: Days 19-20) but significantly smaller quantities of ethanol were drunk by the group EN (respectively 34±10 and 43±13 %. Rotarod tests conducted on Days 22-23 after 3 g/kg ethanol showed a maintenance of tolerance enhancement in groups ES (5.1±1.7) and EN (5.6±1.9) compared to SS (12.3±1.4) and SN (12.9±0.9). The results demonstrated that naloxone produced 1) an initial reduction in nervous tolerance towards ethanol, which attenuated with increasing tolerance acquisition and 2) a strong and persistent aversion to ethanol flavor following IP pairings with the drug. Naloxone's initial potentiation of ethanol-induced behavioral deficits is consistent with its effect on ethanol-induced taste aversion and its non-specific and hypernociceptive action on aversive or stressful stimuli.

55.1 MECHANISMS OF BEHAVIORAL RECOVERY FROM LESIONS IN COCKROACHES: A TEST OF SUFFICIENCY. Noga Vardi and Jeffrey M. Camhi. Sect. Neurobiology & Behavior, Cornell Univ., Ithaca, NY 14850

Cockroaches turn away from wind gusts such as those produced by a predator's strike. The wind is detected by means of filiform hairs located on the cerci — two posterior appendages. If one ablates the left cercus, on most trials performed the next day, the cockroaches respond to wind from the left by turning incorrectly toward the left. After 30 days, however, the cockroaches make significantly more correct turns toward the right (Vardi and Camhi, Neurosci. Abst., 1979). In correlation with this behavioral recovery, we found physiological recovery among a group of individually identified cells, the giant interneurons (GI's), which are known to mediate in part the directional escape behavior. These GI's receive most of their input from the ipsilateral cercus. Thus, ablation of the left cercus renders most of the left GI's silent, whereas the right GI's remain responsive. However, after a 30-day period of behavioral recovery, the left GI's give somewhat enhanced responses to wind, specifically, they regain about 1/4 of their normal number of action potentials, which show normal directional selectivity.

We asked whether this partial GI enhancement was sufficient to account for behavioral recovery, or whether it was necessary to postulate further neuronal changes in the thoracic ganglia, where the GI's evoke responses in the leg motor neurons. We attacked this question by producing a situation in which the left GI's gave the same number of action potentials as after 30 days of recovery from left cercal ablation, but without having any recovery period. Specifically, we ablated only part of the left cercus such that the number of action potentials in GI's 1, 2, and 3, which are thought to be important in setting the initial direction of turning, would be comparable to the number observed in these GI's after behavioral recovery from full left cercal ablation. The turning responses of the partially ablated cockroaches were tested the next day. The mean angle of turn, in response to wind from 140 to 180° left (180° = head-on wind), was 22° to the right and the percentage of correct turns (i.e., toward the right) was 71%. This behavior is remarkably similar to that of the behaviorally recovered animals whose mean angle of turn is 23° right and whose percentage of correct turns is 73%. Thus we conclude that the number of action potentials in the left GI's 1, 2, and 3, or other parameters correlated with it in these or other ascending neurons, is sufficient to account for the behavioral correction which occurred during the 30-day recovery period. No change in the readout of the ascending information by thoracic motor centers need be postulated to account for behavioral recovery.

(This work was supported by NSF grant BNS 79-09663.)

55.2 ADJUSTMENT OF ESCAPE TURNING BEHAVIOR FOLLOWING UNILATERAL CERCAL ROTATION IN THE COCKROACH. Christopher M. Comer and Jeffrey M. Camhi. Sect. Neurobiology and Behavior, Cornell University, Ithaca, NY 14850

Cockroaches (Periplaneta americana) turn away from small puffs of wind, such as those generated during the strike of a natural predator. These turning responses are believed to be mediated by giant interneurons (GIs) in the abdominal nerve cord. The wind receptors are filiform hairs oriented along the cerci — a pair of abdominal appendages.

The behavioral plasticity exhibited by this system (Vardi & Camhi, Neurosci. Abs. 1980; Volman, Camhi & Vardi, Neurosci. Abs. 1980) indicates that a cockroach can compensate for a gross imbalance of activity in the two cercal sensory nerves. Within 30 days, nymphal cockroaches correct turning mistakes induced by either ablating or merely covering up one cercus. Behavioral recovery in both instances is corelated with changes in GI wind responsiveness.

We were interested in determining if cockroaches could also adjust to changes in the pattern of activity in the cercal sensory nerves. To investigate this question, we filmed the wind-mediated escape responses of animals which had one cercus misaligned. Each cercus normally extends caudally from the abdomen at an angle of about 60° from the long axis of the body. In a group of nymphs, we rotated the right cercus medially and glued it in a position nearly parallel to the body axis. This causes directionally specific mistakes: most winds from the right elicit appropriate turns to the left, however, frontal winds within 30° right of midline elicit inappropriate turns to the right. Two and 3 weeks later the animals behaved similarly. At 4 weeks, though, these insects made a significantly greater percentage of left (correct) turns in response to right frontal winds (χ^2 test, $p < .02$) than they had initially. Our analysis suggests that this 'correction' corresponds to a directional shifting of escape behavior such that the angular extent of the frontal region from which winds elicit wrong turns becomes smaller.

Preliminary electrophysiological studies indicate that unilateral cercal displacement causes a rotation of the directional wind-receptive fields of some GI's which parallels the deviation of the cercus. Studies of the GI's in 'corrected' animals are now in progress.

(This work was supported by NSF grant #BNS 79-09663.)

55.3 DIRECTIONALITY OF ACOUSTIC ORIENTATION IN FLYING CRICKETS. G.S. Pollack and N. Plourde*. Dept. of Biology, McGill University, Montreal, Que. H3A 1B1

Tethered flying crickets attempt to steer towards a loudspeaker broadcasting conspecific calling song. A component of steering behavior is lateral flexion of the abdomen. We measured the effects of sound location and intensity on the amplitude of steering behavior, as indicated by the extent of abdominal flexion.

Teleogryllus oceanicus females performing stationary flight were stimulated with an electronically synthesized calling song model with a carrier frequency of 5 kHz. The song was played sequentially from two loudspeakers located in the cricket's horizontal plane, at equal angles to the left and right of the midline. The song was first played from the left for 12 seconds, and then was switched to the right for an additional 12 seconds. Amplitude of the steering attempt was taken as the angular difference in abdominal position (measured with a capacitative position transducer) just before and 12 seconds after the song was switched from the left to the right.

For all speaker locations, steering amplitude showed a characteristic intensity function. Abdominal flexions were small at threshold intensity (50-60 dB SPL), increased to a plateau which was maintained over an intensity range of 70-90 dB, and then decreased at higher intensities. This function is the result of binaural processing; when crickets were unilaterally deafened abdominal flexion increased monotonically with intensity.

The plateau level of abdominal flexion varied systematically with the azimuth of the sound source. Flexions were small when the speakers were located close to the midline and increased regularly to a maximum when the speakers were at 90° to the midline. This relationship held for posterior as well as anterior speaker locations. The minimum deviation of the speakers from the midline needed to elicit steering behavior was 2.5-5°.

Thus, flight phonotaxis behavior is graded; its amplitude varies both with sound intensity and sound location. These findings suggest that the amplitude of steering behavior is determined by the apparent difference in sound intensity at the two ears.

55.4 MODULATION OF A SENSORY-MOTOR SYNAPSE BY NEUROACTIVE PEPTIDES IN APLYSIA CALIFORNICA. Jeff Goldberg* and Ken Lukowiak* (SPON: G. Mpitsos). Dept. of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta T2N 1N4.

The gill withdrawal reflex of Aplysia californica has proven to be an excellent model system for investigating the neurophysiological mechanisms underlying behavioral state. Gill reflex behavior is mediated by the peripheral nervous system and modulated by the central nervous system according to the animal's biological needs. The three behavioral states that have been described are the facilitated, normal and suppressed states. These classifications are based upon the comparison of gill reflex amplitude to the amplitude of centrally mediated, spontaneous gill movements (SGMs). Our present concern centers around the suppressed state, which is characterized by: 1) reflex amplitudes less than 35% of SGM amplitudes; 2) increased rate of habituation in comparison to preparations displaying the normal state. Although suppressed behavior is associated with food satiation or sexual activity, it can also be induced upon superfusion of methionine enkephalin, arginine vasopressin or arginine vasotocin over the abdominal ganglion. Concomitant to the behavioral effects, these bioactive peptides bring about a reduction in the number of action potentials evoked in central gill motor neurons upon tactile stimulation of the siphon. To determine the site of action of these peptides, we obtained simultaneous intracellular recordings from a siphon mechanoreceptor (LE) and one of its follower motor neurons (L_7, L_9, LB_{S1}). Single presynaptic action potentials evoked short latency EPSPs in the postsynaptic motor neuron. In preparations displaying the normal behavioral state, superfusion of arginine vasotocin over the abdominal ganglion reduced the evoked EPSP amplitude by 50%. In addition, the rate of decrement of EPSP amplitude upon repeated excitation of the LE neuron (one action potential per 30 seconds) was increased during arginine vasotocin superfusion.

In behaviorally suppressed preparations, superfusion of the enkephalin antagonist naloxone over the abdominal ganglion increased the evoked - EPSP amplitude by more than 100%. Since conductance changes were not observed in the postsynaptic motor neurons upon application of the drugs, a presynaptic site of action is postulated. The presynaptic gate may be located at the LE terminal for the modulation of transmitter release. Alternatively, there is evidence that the number of functional synapses between the sensory and motor neuron is modulated through a gating of neuronal transmission at the branch points of LE neurites.

55.5 MULTIMODAL SENSORY INTERNEURONS IN THE BRAIN OF THE FLATWORM, ALLOEOPLANA CALIFORNICA. Michael H. Solon and Harold Koopowitz. Developmental and Cell Biology, Univ. of California at Irvine, Irvine, CA 92717.

Arousal is of considerable interest in the study of complex behavior. In polyclad flatworms, vibration is an effective arousal stimulus. While investigating the neural basis of this phenomenon, we found cells in the brain of Alloeoplana which are excited by water-borne vibration and by light offset. Lucifer Yellow fills of these cells showed them to fall into two categories. One group consists of single somata which send neurites across the midline, the other of pairs of dye-coupled somata located symmetrically across the midline. Both types are multipolar, and send processes to the lateral and posterior nerves leading into the ventral submuscular plexus.

These are not primary sensory cells. Excitatory input is compound, and was reversibly blocked by 200 mM Mg^{++} or 4 mM Cd^{++}. Cells habituated to repetitive stimuli of either modality, and we found clear instances of dishabituation of one modality through stimulation via the other.

Under normal conditions, activity in these cells, regardless of the frequency or duration, did not evoke obvious muscular activity. Intracellular injection of tetraethylammonium (TEA) increased spike duration forty-fold, and each such spike was followed by a contraction of the anterior margin of the animal. These contractions were blocked by 200 mM Mg^{++} or 4 mM Cd^{++}. Those cations did not, however, abolish the plateau of the TEA spike, but rather prolonged it. Tetrodotoxin (TTX) abolished both the spike and the plateau, and no activity was seen in its presence. This suggests that the plateau is not due to an inward calcium current. There may, however, be an inward calcium current which activates a calcium-sensitive potassium current, since repolarization of TEA spikes is further prolonged by high Mg^{++} or Cd^{++}.

These cells do not elicit motor activity in the absence of TEA. Further, they do not appear to send processes into those areas that contracted after the cells had been filled with TEA, suggesting that they are not motor cells. It seems more likely that they are interneurons which receive multimodal input, and affect motor pathways through weak synaptic connections. This is what one might expect in a modulatory pathway such as might mediate arousal.

55.6 PHYSIOLOGICAL AND MORPHOLOGICAL CHARACTERISTICS OF VIBRATION SENSITIVE NEURONS IN THE BRAIN OF THE POLYCLAD FLATWORM, NOTOPLANA ACTICOLA. C. Larry Keenan* and Harold Koopowitz, Dept. of Developmental and Cell Biology, Univ. of California, Irvine, CA 92717.

Intracellular recordings of vibration evoked activity in ventrally and dorsally located brain cells of the marine flatworm, Notoplana acticola, reveal both similarities and differences between these two classes of cells. Ventrally located cells send major processes contralaterally across the midline of the bilaterally symmetrical brain. These cells have never been observed dye-coupled to other cells. Dorsally located neurons are of two general morphological types. One group has cells that are rarely dye-coupled to other cells and never with bilateral symmetry. The processes of these cells project contralaterally across the brain midline. The other type is normally strongly dye-coupled to a mirror image counterpart across the brain midline. These cells send major processes ipsilaterally. The physiological parameters that were compared include latencies, amplitudes and rise times of synaptic potentials, and the decrement of response to repeated vibration stimuli. High Mg^{++} and high Cd^{++} concentrations, or low Ca^{++} concentrations result in abolishment of the vibration responses. Under the same conditions, however, the cells could be driven to spike by injecting depolarizing current. Tetrodotoxin (TTX), tetraethylammonium (TEA), low Na^{+}, and low Ca^{++} all had separate effects on the various components of the vibration responses. The morphologies of the cells were analyzed after they had been iontophoretically filled with either the fluorescent dye Lucifer Yellow CH or horseradish peroxidase (HRP). The morphology and electrophysiology of these vibration-responding cells suggest they function as sensory interneurons. Furthermore, although these brain cells are found in a group of animals at the base of the phylogenetic tree, they nevertheless exhibit morphological and physiological complexities similar to those found in the neurons of both higher invertebrates and vertebrates.

WITHDRAWN

56.2 INTERACTION OF SYNTHETIC PYRETHROID INSECTICIDES WITH KAINIC ACID AND THEIR EFFECT ON KAINIC ACID BINDING TO MOUSE FOREBRAIN MEMBRANES. Christina G. Staatz*, John J. Lech* and Alan S. Bloom (Spon: L.F. Tseng). Dept. of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226.

Permethrin (NRDC 143 3-phenoxybenzyl [1R,1S]-cis,trans-3-[2,2-dichlorovinyl]-2,2-dimethylcyclopropane carboxylate), a synthetic derivative of the pyrethin-based insecticides, produces neurotoxic symptoms in mice consisting of hyperactivity and tremor. At high doses this can progress into a state of sustained clonic seizures. This syndrome has been demonstrated to be predominantly central in origin (Staatz, C.G., Bloom, A.S. and Lech, J.J., Fed. Proc. 39:624, 1980) as a 200 fold increase in potency occurs following central (icv) as opposed to peripheral (iv) injection. On gross observation the toxic syndrome produced by permethrin is similar to that seen following either cerebral or peripheral injection of kainic acid, a dicarboxylic acid containing pyrrolidine which is a rigid analog of glutamate and a potent neuro-excitant. Kainic acid is able to potentiate the convulsive action of permethrin; mice injected with a subconvulsive dose of kainic acid, i.p. and subsequently injected with a subconvulsive dose of permethrin, i.v., show a 50% incidence of convulsions. Also, following pretreatment with kainic acid (icv 60 ng/mouse), 3 days prior to permethrin injection, the ED50 for permethrin-induced convulsions was reduced more than 4-fold. In light of these observations the effect of pyrethroids was investigated on the in vitro binding of [^{3}H] kainic acid (^{3}HKA) to membranes prepared from mouse brain. In these studies decamethrin [(S)-α-cyano-3-phenoxybenzyl-(1R,3R)-cis-3-(2,2-dibromovinyl)-2,2-dimethyl-cyclopropane carboxylate)], a representative member of the cyano-class of pyrethroid insecticides, was used because of its greater potency. The specific binding of ^{3}HKA to mouse forebrain membranes was measured at 4°C and was found to be saturable with a dissociation constant (K_D) of 16 nm and an apparent maximal density of binding sites (Bmax) of 120 fmol/mg protein. Decamethrin in doses ranging from 1 nm to 20 μm caused a dose-dependent decrease in the amount of ^{3}HKA specific binding, the maximal effect being a 40% reduction when compared to vehicle. These results suggest a possible interaction of this pyrethroid with a kainic acid binding site. (Supported by USPHS grants ES-01080 and ES-01985).

56.3 EFFECTS OF PERMETHRIN, A SYNTHETIC PYRETHROID INSECTICIDE ON OPERANT BEHAVIOR AND FEEDING. Alan S. Bloom and Christina G. Staatz*. Dept. of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226.

The synthetic pyrethroids are a group of potent insecticides that exhibit a very favorable insect:mammal toxicity ratio and a desirable rate of biodegradability. They are believed to kill insects by an action on the nervous system. High doses (~500 mg/kg, IP) of permethrin (NRDC 143, 3-phenoxybenzyl [1R, 1S]-cis, trans,3-[2,2-dichlorovinyl]-2,2-dimethylcyclopropane carboxylate) produced a syndrome in rodents that consists of increased responsiveness to external stimuli, hyperexcitability, and tremors and convulsions that may result in death. To investigate the toxicity of doses of permethrin below the threshold for this syndrome, operant conditioning techniques were used. Male Sprague-Dawley rats, maintained on a 23 hour food deprivation schedule, were trained to respond on a VI-20 second schedule for food reinforcement. After stable response rates were achieved, each animal was tested 20 minutes after the IP injection of 15, 30 and 60 mg/kg of technical grade (40% cis-60% trans) permethrin or its emulphor-ethanol vehicle. Treatment order followed a latin square design. These doses of permethrin lowered response rates by 12%, 25% and 60%, respectively. The effects of the 30 and 60 mg/kg doses were statistically significant. The vehicle itself was without effect. In spite of the significant effects on operant behavior, by gross observation these animals did not appear to be affected by the drug.

In order to determine if the decrease in operant response rate was due to drug induced anorexia, the effects of permethrin on food intake were also studied. Food intake was measured for both 1.5 and 24 hour periods after treatment with permethrin using the same design as in the operant studies. Significant decreases in food intake were observed only after the 60 mg/kg dose (44% in the 1.5 hour study and 16% in the 24 hour study). These data indicate that subconvulsive doses of permethrin can have significant effects on learned behavior and that these effects may be due in part to drug induced anorexia.

56.4 EFFECT OF REPEATED ADMINISTRATION OF DESMETHYLIMIPRAMINE ON THE NIGHT-TIME RISE IN MELATONIN OF RAT PINEAL GLAND. W.E. HEYDORN, D. BRUNSWICK* AND A. FRAZER. Depts. of Psychiat. and Pharmacol., Univ. of Penn. and Vet. Admin. Hospital, Phila., Pa. 19104.

It has been shown that repeated administration of antidepressants to rats diminishes responses elicited by catecholamine-induced activation of β-adrenergic receptors. In most studies, the response measured was the production of adenosine 3',5'-monophosphate (cyclic AMP). In view of such observations, we examined whether repeated treatment of rats with desmethylimipramine (DMI) would diminish an adrenergic response mediated via cyclic AMP. Male rats, kept in a 12 hour light/dark cycle (lights out at 1900 hours), were injected for seven days with either saline or DMI (10mg/kg, twice daily). In one experiment, twenty-four hours after the final injection of saline or DMI, the rats were killed and the specific binding of ^{3}H-dihydroalprenolol (^{3}H-DHA) to pineal gland homogenates was measured. In another experiment, rats were decapitated at the following times (always 24 hours after the final saline or DMI injection): 1000, 1600, 1930, 2200, 2400, 0200, 0400 or 0600 hours. The pineal glands were removed and frozen for subsequent analysis of melatonin by radioimmunoassay. In animals killed in the middle of the light cycle, repeated administration of DMI lowered the binding of ^{3}H-DHA significantly, from a control value of 711±49 fmoles/mg protein (n=7) to a value of 480±50 fmoles/mg protein (n=6) in DMI-treated rats ($p<0.01$). Similar results were obtained if animals were killed in the middle of the dark cycle. The content of melatonin in the pineal gland rose markedly (over twenty-fold) during the night. Treatment of rats with DMI decreased significantly the content of melatonin in the pineal gland ($F=8.88$; $p<0.01$). However, the magnitude of the inhibitory effect of DMI treatment on the night-time rise of pineal gland melatonin was rather small (about 20%) and significant decreases in melatonin content of the pineal gland in DMI-treated rats were not seen at all time points. Our results indicate that melatonin formation may not be compromised as markedly as cyclic AMP production by the DMI-induced development of β-adrenergic receptor subsensitivity. 56.5 BEHAVIOR AND ELECTROPHYSIOLOGY OF CATS MAINTAINED CHRONICALLY ON A NEUROLEPTIC. R. B. Glassman, H. N. Glassman* and B. M. Baltrus*
Dept. of Psychology, Lake Forest College, Lake Forest, IL 60045.

To survey the brain for changes that might be relevant to tardive dyskinesia cats, having chronically implanted arrays of 30 gross electrodes, were observed during 1-3 periods of 1 to 11.5 months on chlorpromazine (25-50mg/day, orally) and during .5 to 3 months following withdrawal. A preliminary report was presented in 1977 (Abstract #1405). Histologically verified electrode placements were in frontal cortical areas, basal ganglia, amygdala, thalamus, substantia nigra, and other points. While behavioral results were positive, electrophysiological observations gave only weak clues to possible underlying factors:

Behavior. Six of 9 cats showed increased incidence of licking during maintenance and all showed a further increase on withdrawal. In a typical case, the average number of licks during a 5-min. observation period was 11 before drug, 8 during early maintenance, and 89 after 3.5 months maintenance. During the first week of withdrawal there were 230 licks per 5-min. period, decreasing to 63 licks by the 10th week. In varying degrees, withdrawal also caused increased paw or body shakes and "fly-chasing movements" of the skin of the back.

Potentials evoked by forelimb stimulation. Cortical potentials meeting our criterion of .16 mV were observed in 8 cats before drug. Potentials at some points increased in amplitude during drug in all cats (up to threefold) and decreased to baseline or below on withdrawal.

Potentials evoked in striatum by substantia nigra stimulation. There was a widespread progressive decrease in amplitude during drug and withdrawal in 2 of 4 cats. In one cat, amplitude increased on drug and decreased below baseline on withdrawal. In the 4th cat a variable record showed no net change. Occasional testing with stimulation of other points also usually showed EPs decreasing with time but in one cat stimulation of some points was associated with increased cortical EPs during drug, which returned to baseline on withdrawal.

Cortical spindling evoked by stimulation of caudate and other subcortical points. Spindles increased in duration and amplitude, in 3 of 4 cats, during early drug maintenance. A decrease in amplitude by the end of the experiment was not clearly related to treatment conditions.

Spontaneous EEG. Slowing during early drug maintenance appeared greater at more rostral points, greatest in cortex.

Terminal acute behavioral probes. Behaviors elicited by high doses of apomorphine, haloperidol, physostigmine or atropine included licking; PCPA and 5-HTP did not elicit licking.

Supported by the Illinois Department of Mental Health and Developmental Disabilities.

56.6 CHRONIC LITHIUM ADMINISTRATION: PARTIAL REDUCTION OF HALOPERIDOL-INDUCED BEHAVIORAL SUPERSENSITIVITY WITHOUT AN INFLUENCE ON DOPAMINE RECEPTOR ELEVATION. D.A. Staunton, P.J. Magistretti, S.N. Deyo*, W.J. Shoemaker, and F.E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037.

Spontaneous locomotor activity and dopamine receptor responsivity were assessed after 4 weeks of dietary treatment with the anti-manic drug, Li. Prolonged dietary Li administration was not accompanied by overt toxicities and led to growth rates approximately 60% of those observed in animals fed the control diet. Moreover, the diet consistently yielded serum and brain Li values in the prophylactic range for manic-depressive disease (0.8-1.2 mEq/L). Four weeks of Li administration led to diminished spontaneous locomotor activity compared to subjects on the control diet, with or without pair-feeding. The depression of locomotor activity following an injection of apomorphine was less severe in subjects that ingested Li compared to those with free access to the control diet. As previously reported (Pert et al, Science 201: 171), chronic Li administration partially attenuated apomorphine-evoked stereotyped behaviors in animals rendered supersensitive to the drug by daily injections of haloperidol (HAL) for three weeks.

In a series of parallel experiments, the influence of chronic dietary Li adminstration was evaluated on dopamine receptor supersensitivity in the rat corpus striatum. In contrast to previous data (Pert et al., ibid) the attenuation of HAL-induced behavioral supersensitivity following long-term dietary Li administration was not accompanied by prevention of increased ^{3}H-spiroperidol binding sites in the corpus striatum. For example, in the subjects used for behavioral analysis, Scatchard analysis revealed that three weeks of treatment with HAL resulted in a 27% elevation of neostriatal ^{3}H-spiroperidol binding sites in animals fed the control diet versus a 29% elevation in those given Li. Similar results were obtained when the withdrawal period from chronic HAL was varied (range 1-14 d). In these experiments, HAL-pretreatment did not affect the affinity of ^{3}H-spiroperidol for its binding site and long-term Li exposure affected neither the K_D or the B_{max} values. In addition, neostriatal dopamine-sensitive adenylate cyclase was not affected by either long-term dietary Li or chronic neuroleptic treatment. As a group, these results are incompatible with the hypothesis that the anti-manic action of Li is related to its ability to prevent dopamine receptor supersensitivity. An influence of the drug at other receptor sites or a non-receptor-mediated action of the drug can not be excluded. Supported by NIMH 08080, 29466, and NIAAA 07273. PJM supported by Swiss NSF.

56.7 INFLUENCE OF AGE ON THE EFFECT OF CHRONIC FLUPHENAZINE ON RECEPTOR BINDING IN RAT BRAIN. H. Shelat, C. H. Misra, R. C. Smith. Department of Biological Psychiatry, Texas Research Institute of Mental Sciences, Houston, Texas 77030.

Some of the side-effects of chronic administration of neuroleptic to man, such as tardive dyskinesia, have increased prevalence in the geriatric patient treated with neuroleptics. Recently, we have shown (Misra et al, 1980) that aging rat brain has a reduced number of dopaminergic of adrenergic receptors. The present work has been done to keep in mind, that changes in receptor function after chronic administration of neuroleptics in the aging brain may provide clues to some of the underlying pathophysiology of tardive dyskinesia and other side-effects of neuroleptics. The effects of age on alterations in brain dopaminergic (spiperone), β-adrenergic (DHA), α-adrenergic (WB-4101) and cholinergic (QNB) binding induced by chronic administration of fluphenazine was studied in the rat. Compared to age-matched saline controls, older-age (25 month) fluphenazine rats showed: (a) a similar increase in specific spiperone binding (at .1 nM) but a slightly smaller increase in the B_{max} of spiperone binding in the striatum than younger fluphenazine-treated rats; and, (b) a substantially greater increase in the B_{max} of DHA binding and slightly greater increase in B_{max} of WB-4101 binding in the cerebral cortex than younger fluphenazine-treated rats. There was no significant interaction of age with the effect of chronic fluphenazine on QNB binding in rat striatum.

56.8 THE ACUTE AND CHRONIC EFFECTS OF LITHIUM ON THRESHOLD OF INTRACRANIAL REINFORCEMENT. G. P. Cassens, V. W. Slayton* and D. Manigold* Dept. of Psychiatry, Harvard Med.Sch. Boston,MA 02115

Although it is generally recognized that chronic administration of lithium is required for its clinically therapeutic effects in the treatment of mania and bipolar depressions, relatively few investigators, heretofore, have systematically explored the effects of chronic administration of lithium on intracranial self-stimulation (ICSS) behavior. Moreover, previous studies have measured lithium's effects on rates of response for intracranial reinforcement (ICR), but these procedures do not discriminate between drug-induced alterations in motor response and changes in threshold of reward. In these studies, we found that acute administration of lithium (0.5,1.0 and 2.0 mEq/kg) produced significant dose-related increases in threshold of intracranial reinforcement, using a rate-independent measure previously described (Cassens,G.P. and Mills,A.W.,Psychopharmacologia, 30:283,1973). After chronic injection of lithium (1.0 mEq /kg given once daily for 23 days), significant increases in threshold were observed during the first 1-5 days of lithium administration; however, by Day 7 these threshold elevations were not significantly different from pre-drug thresholds despite continued treatment with lithium.

It has previously been proposed that withdrawal from chronic administration of amphetamine may serve as an animal model of drug-induced or naturally occurring bipolar depressions. Amphetamine withdrawal in the rat responding for ICSS is characterized by significant increases in threshold of ICR, i.e. decreased sensitivity to intracranial reward(Leith, N. and Barrett,R. Psychopharmacology , 46:19,1976; Cassens,G. in press). In order to explore the prophylactic effects of lithium on the"depression" induced by amphetamine withdrawal, on Days 13-17, lithium and saline pretreated animals received chronic escalating doses of d-amphetamine (1-12 mg/kg)according to the method of Leith and Barrett (1976). While lithium, at the dose used in this study (1 mEq/kg) tended to attenuate the threshold-decreasing effects of 1 mg/kg of d-amphetamine, lithium did not block or attenuate the increases in threshold of ICR observed during amphetamine withdrawal. These results will be discussed in relation to lithium's clinical effects in the treatment of mania and bipolar depressions.

This research was supported in part by Grant No.MH15413 from the National Institute of Mental Health, and by grants to the first author from the Milton Fund and the Charles A. King Trust Award for Medical and Surgical Research.

56.9 TOLERANCE DEVELOPMENT DURING DIFFERENTIAL PAVLOVIAN CONDITIONING WITH MORPHINE. Richard W. Lambert*, and Michael Gabriel (SPON: E.B. Gardner). Dept. Psych., Univ. Texas, Austin, TX 78712.

It has been suggested (eg. Siegel, J. Comp. Physiol. Psych., 89:498,1975) that the tolerance that develops to many drugs including morphine is due, in part, to associative processes. Specifically, it is held that stimuli reliably paired with drug administration acquire the capacity to elicit a conditioned response (CR) that is in opposition to the physiological effects of the drug. When the drug is administered in the presence of stimuli with such capacity, the CR that they elicit competes with the effects of the drug, producing an attenuated response (ie. tolerance).

The present study attempted to assess the development of the postulated conditioned response during trials, and its moment by moment within-trial time course, by recording continususly the physiological response measures of heart rate and peripheral ear temperature during differential Pavlovian conditioning. The conditional stimula (CSs) were pure tones (1kHz and 8kHz), and the unconditional stimulus (UCS) was a 10 mg/kg dose of morphine sulfate solution injected through a chronic indwelling jugular cannula. The rabbits alternately received one or two conditioning trials per day, the trials spaced not less than 10 hours apart. On each conditioning trial the tone CS was presented for a total duration of 11 min. Three min. after CS onset the rabbit was injected with morphine, on CS+ trials, or saline, on CS- trials. Following 24 conditioning trials (12 with each CS), each subject received a test trial in which the CS+ was paired with saline, and another in which the CS- was paired with morphine. Interspersed between the last few conditioning trials the subjects received two additional test trials in which morphine or saline were administered in the absence of any CS.

Tolerance was manifested in the form of a progressive reduction over trials in the magnitude of the hyperthermic and bradycardic responses to the morphine UCS. However, no significant heart rate or temperature responses occurred to the CSs in anticipation of the morphine UCS during conditioning. Nevertheless evidence for a role of conditioning in tolerance development was obtained form the test trial data: the morphine UCS produced its original (large) hyperthermic effect in tolerant subjects, on test trials in which the drug was not preceded by the CS+. These results suggest that the conditioned response contributing to tolerance development in the present study was not manifested by the thermal and cardiovascular measures during CS presentations. Rather, the response in these measures was withheld until the time of UCS delivery.

56.10 BRAIN OPIATE LEVELS AND MORPHINE TOLERANCE TO THE NOCICEPTIVE TAIL FLICK TEST. C. Advokat and L. Isaac. Pharmacol. Dept., Univ. Ill. Coll. Med., Chicago, IL 60680

Previous work demonstrated that the acquisition of tolerance following morphine pellet implantation was facilitated by experience with the tail flick assessment (TF) procedure, and that, as long as the pellet remained intact, tolerance was retained for at least seven days. The purpose of the present work was to determine the relationship between brain opiate levels and the acquisition of tolerance and to determine whether retention of tolerance is influenced by "extinction" trials or electroconvulsive shock (ECS).

For each study, male, albino rats (200-225 gm) were implanted with a pellet containing 75 mg of morphine.

To assess the acquisition of tolerance one group of animals received TF tests at 3, 6, 12, 24 and 48 hours post-implant while a second group of rats was not tested until the 48 hour interval. At each time point, several animals from each group were killed and their brains removed, cleared of blood and frozen. Morphine concentration in whole brain was determined by the radioimmunoassay method. Brain opiate levels did not differ between tested and non-tested animals at 48 hrs although tested animals were more tolerant to the TF procedure than non-tested animals at this time.

To examine the retention of tolerance, animals received a TF test at 3, 6, 12, 24 and 48 hours after the morphine implant. Following these tests, pellets were either removed or left intact. Half of the animals in each of these two groups were left undisturbed for one week, the other half received additional TF tests during this period. By the end of the week there was no difference in TF latency among the four groups. However, following a morphine injection (5.0 mg/kg s.c.) animals with intact pellets were more tolerant than animals without pellets and those animals who received extra TF tests were less tolerant than those who did not.

To determine the effect of ECS on retention, another group of animals was tested at 3, 6, 12, 24 and 48 hours post-implant. Immediately thereafter one half received ECS (35 mA, A.C., 0.5 sec duration via ear clips) while the other half was not shocked. In contrast to the results of the preceding experiment these two groups differed in TF latency one week later. Rats who had ECS were less tolerant than controls. However, in response to a morphine injection the groups did not differ in TF latency.

These experiments demonstrate that acquisition and retention of tolerance can be significantly influenced by the environmental context in which they are assessed. More importantly, present work indicates that environmental factors are more critical than opiate levels in the acquisition of tolerance.

57.1 THE ROLE OF ENDOGENOUS OPIOID SYSTEMS IN ECS-INDUCED POSTICTAL ELECTROGENESIS AND BEHAVIORAL DEPRESSION IN RATS. F.C. Tortella, A. Cowan and J.W. Holaday, Dept. of Pharmacology, Temple Univ. School of Medicine, Philadelphia, PA 19140 and Dept. of Medical Neurosci., Walter Reed Army Institute, Washington, DC 20012

Electroconvulsive shock (ECS) produces postictal opiate-like EEG and behavioral effects in rats which are antagonized by naloxone (NX) (Tortella et al, Soc. Neurosci. Abstr. 6: 318, 1980). Subsequent experiments have demonstrated a selective, naloxone-sensitive action of ECS in attenuating RX 336-M-induced wet-dog shakes and excessive grooming in rats (Tortella et al, Fed. Proc. 40: 287, 1981). In the present study, we assessed the involvement of pituitary endorphins in ECS-induced postictal electrogenesis (EEG-voltage output) and depression in rats.

Sham-hypophysectomized (SHAM) and hypophysectomized (HYPOX) male albino Sprague-Dawley rats (200-250 g; Zivic-Miller) were prepared with cerebrocortical EEG and temporalis muscle EMG electrodes. The animals were divided into 4 groups and injected s.c. with either NX (3 mg/kg) or saline (S) 10 min prior to transauricular ECS (0.2 sec, 60 Hz, 50 mA). In SHAM-S rats, ECS increased electrogenesis 65 ± 18% (s.e.) above control. Duration of the associated postictal depression was 3840 ± 530 sec. NX antagonized the postictal increase in EEG voltage output and behavioral depression. Hypophysectomy (HYPOX-S group) partially attenuated the ECS-induced electrogenesis and decreased the duration of postictal depression. Note, however, that hypophysectomized rats were unresponsive to NX (HYPOX-NX group). These data are summarized in Table I.

Table I. Effects of Hypophysectomy on ECS-induced Voltage Output and Duration of Postictal Depression.

Group	N	Voltage Output (% above controls ± s.e.)	Postictal Depression (mean, sec ± s.e.)
SHAM-S	6	65 ± 18*	3840 ± 530
SHAM-NX	6	9 ± 11^{+}	1117 ± 755^{+}

These results confirm our earlier reports of opiate-like EEG and behavioral effects of ECS in rats and support the hypothesis of an ECS-induced activation of endogenous opioid systems. On the basis of all our data, it would appear that pituitary endorphins are released during ECS and are involved in the mediation of postictal events.

57.2 Effects of Naloxone on Brain Stimulation Reward Threshold in the VNB and MFB. M.J. Lewis, Dept. of Psychology, Howard University Washington, D.C. 20059

The effects of the opioid antagonist naloxone on brain stimulation reward (BSR) threshold were investigated at two brain sites in albino rats. Male albino rats were surgically implanted with platinum bipolar electrodes in either the hypothalamic medial forebrain bundle (MFB) or the mesencephalic ventral noradrenergic bunble (VNB). All were trained to leverpress (L-P) for BSR under a concurrent fixed-ratio/continuous schedule of reinforcement. This schedule was used to determine BSR threshold independent of response rate using a method similar to Huston and Mills (Comm. Behav. Biology 5, 331-340, 1971). After stable performance was established, all rats received a series of 3 intraperitoneal injections of saline, 5 minutes prior to BSR session. They then received injections of naloxone HCl (Endo Lab., Garden City, N.Y.) similarly administered. Threshold was significantly ($p < .05$) increased by 1.0 and 5.0 mg/kg, ip of naloxone in animals with VNB sites, but not MFB sites. The 0.5 mg/kg approached statistically significant ($p < .10$) increase in animals with VNB implants. No effect was seen in MFB animals at this dose. These data are in agreement with those previously reported (Lewis, Soc. Neurosci. Abstr. 6, 367, 1980) showing a selective decrease of BSR response rate by naloxone in animals with implants in the VNB, but not in animals with MFB implants. They are also consistent with our previous data (Lewis, Margules, Costa, and Jacobowitz, Brain Res., 107, 156-167, 1976) indicating the importance of the mesencephalic VNB in opioid effects. (Supported by NIDA grant DA-02176 and NIH grant RPE-1397).

57.3 THE EFFECTS OF ACTH, MORPHINE AND NALOXONE ON LOCOMOTOR ACTIVITY IN THE RAT. R.S. Blair* and Z.H. Galina* (SPON: Z. Brown). Dept. of Psychology, Concordia University, Montréal, Québec.

We have previously reported that ACTH and naltrexone affect the locomotor activity of rats. Our results revealed that low doses of either ACTH or naltrexone enhanced motor activity while high doses of these drugs depressed activity. When we examined the effects of naltrexone on ACTH-induced activity, naltrexone was observed to reverse the depressive effects of ACTH. In the present investigation, we examined the interactions of ACTH, naloxone and morphine in three separate experiments.

In Experiment I, male wistar rats were given a subcutaneous (s.c.) injection of morphine (0,1 or 4 mg/kg) in combination with a s.c. injection of $ACTH_{1-39}$ (0,50 or 200μg/kg). Fifteen minutes after the injections, animals were placed in an open field and activity counts were recorded for 30,60 and 90 minutes. An analysis of variance of the activity counts revealed significant main effects of Morphine, ACTH and Time. All interactions with time were significant. Briefly, ACTH was found to attenuate the excitatory effects of morphine and to potentiate the depressive effects of this opiate.

Experiment II followed the same procedure as Experiment I except that naloxone (0,0.5 or 2 mg/kg) was injected instead of ACTH. An analysis of variance revealed that naloxone produced an overall decrease in activity counts and appeared to attenuate morphine's excitatory effect.

Experiment III followed the same procedure as Experiment I except ACTH and naloxone were injected. An analysis of variance revealed a significant main effect of Naloxone and a significant interaction of ACTH X Time. Naloxone produced an overall decrease in activity counts and did not affect the behavioural effects of ACTH.

The results of the present investigation are in agreement with previous studies showing that ACTH has mixed agonist-antagonist properties. Since naloxone alone produced an overall decrease in activity, it is difficult to determine the extent to which the behavioural effects of ACTH are mediated by naloxone-sensitive, opiate receptors.

57.4 ENHANCED LOCOMOTOR RESPONSE TO β-ENDORPHIN INFUSED[1] INTO THE VENTRAL TEGMENTUM OF MORPHINE PRE-TREATED RATS. J.M. Schwartz*, C. Ksir[2], G.F. Koob, and F.E. Bloom. A.V. Davis Ctr. for Behavioral Neurobiology, The Salk Institute, P.O. 85800, San Diego, California 92138.

The biphasic effect of a high dose of morphine (M) on locomotor activity (catalepsy followed by excitation) is modified selectively by chronic M treatment: tolerance develops to the depressant action while the excitatory effect is enhanced, and the latency to its appearance is decreased (Babbini and Davis, Br. J. Pharm. 1972). This enhancement of excitatory effect after chronic M treatment is extremely persistent, remaining intact eight months after cessation of chronic M administration (Babbini et al., Neuropharm. 1975). A possible locus for this effect has been demonstrated insofar as repeated local application of M to the dopamine-rich A10-ventral tegmental area (VTA) resulted in progressive increases in locomotor activity of rats (Joyce and Iversen, Neurosci. Lett. 1979). Furthermore, intraventricular β-endorphin (β-E) produced an initial excitatory locomotor response in rats pretreated with M, whereas M-naive controls showed a biphasic response of initial depression followed by excitation (Browne and Segal, Neuropharm. 1980).

The present experiment demonstrates that both M-pretreated and M-naive rats respond to β-E stereotaxically infused into the A10-VTA region with only an excitatory locomotor response, and also that the M-pretreated rats show an enhanced locomotor response compared to lactose-pretreated controls. Physical dependence and tolerance to M were induced by s.c. implantation of three 75 mg pellets of morphine sulfate for 6 days. This resulted in a transient hyporesponsiveness to both β-E and M locomotor activating effects at 24 hours following pellet removal (probably secondary to acute abstinence syndrome), followed by a protracted hyperresponsiveness at 72 hours and thereafter. Subsequent to recovery from the abstinence syndrome, both central infusion of β-E into the VTA and peripheral M administration in moderate doses independently caused a sustained increase in locomotor activation as compared to lactose-pretreated controls. This effect is maintained for at least two weeks. These results demonstrate that opiate receptors localized within or near the VTA mediate some of the stimulatory effects of opioid peptides and suggest that tolerance and sensitization can occur at the receptor level.

57.5 RADIATION-INDUCED HYPERACTIVITY IN THE C57BL/6J MOUSE: EVIDENCE FOR THE RELEASE OF ENDOGENOUS OPIATES. G.A. Mickley, K.E. Stevens*, M.H. Girone*, W.C. Kass*, G.A. White* and G.L. Gibbs* Dept. of Behavioral Sciences and Leadership, USAF Academy, CO 80840 and Penrose Cancer Hospital, Colorado Springs, CO 80903.

Systemic injections of morphine produce a locomotor hyperactivity in the C57BL/6J mouse (McClain, Catravas and Teitelbaum, Soc. Neurosci. Abstr., 3:279, 1977). This hyperactive response is characterized by a sterotypic "stalking" motion and an elevated "straub" tail. Since various stresses have been shown to produce release of endogenous opiates (Katz, Roth, Schmaltz & Sible, Behav. and Neural Biol. 28:366-371, 1980) the present study used hyperactivity of the C57BL/6J mouse as a measure of endogenous opiate release after exposure to the stress of ionizing radiation. In most species irradiation produces hypokinesia and a generalized malaise (Mickley and Teitelbaum, Aviat. Space and Environ. Med. 49:868-873, 1978). However, in this study we predicted that radiation exposure would produce locomotor hyperactivity in the C57BL/6J mouse due to endogenous opiate release.

Baseline measures of locomotor activity were recorded for 2, .5 hour periods before exposure to either 1500 or 2500 Rads (R) of ^{60}Cobalt radiation. After irradiation, mice (1500R: N=6; 2500 R: N=9) were placed back in the activity monitors and locomotion was again recorded for .5 hour. Other mice (1500R: N=6; 2500R: N=9) underwent the same procedure but were sham irradiated. Exposure to ionizing radiation produced a statistically-significant dose-dependant increase in locomotor activity as compared to an average pre-irradiation baseline (Wilcoxon Ranks Test $p < .05$). Irradiated subjects were significantly more active than the sham-irradiated mice (Mann-Whitney U, $p < .05$) and many exposed animals exhibited locomotor "stalking" and elevated "straub" tails.

In a second experiment, the radiogenic hyperactivity was challenged with the opiate antagonist naloxone (2 mg/kg, i.p.). Drug injections were given immediately after irradiation (1500R: N=6; 2500R: N=6) or sham exposure (1500R: N=6; 2500R: N=6). Naloxone attenuated the hyperactivity of irradiated mice to such an extent that the amount of locomotion was indistinguishable from baseline (Wilcoxon Ranks Test, $p > .05$). Irradiated mice injected with naloxone, were actually somewhat less active than sham-exposed subjects which received the drug. None of the naloxone-treated irradiated mice exhibited "straub" tails or "stalking".

Since irradiated C57BL/6J mice exhibit behaviors similar to those observed after injections of morphine, and since these behaviors can be reversed by naloxone, the present studies suggest that some radiogenic changes in behavior may be mediated by release of endogenous opiates.

These studies were supported by the USAF School of Aerospace Medicine.

57.6 PLASMA BETA-ENDORPHIN IN RATS IS INCREASED BY PSYCHOLOGICAL STRESS. J.L. Meyerhoff, B.N. Bunnell and E.H. Mougey*. Dept. Med. Neurosciences, Div. Neuropsychiatry, Walter Reed Army Inst. of Research, Washington, D.C. 20012.

Exposure to physical stressors such as bone fracture (Guillemin, et al, Science 197:1367-1369, 1977) or inescapable electric footshock (Rossier, et al. Nature 270:618-620, 1977) has been reported to cause two- to threefold elevations in plasma beta-endorphin levels in rats. We wished to determine whether significant elevations might also occur following psychological stress such as exposure to stimuli previously paired with inescapable electric footshock. Male Sprague-Dawley rats were adapted to handling for one week and assigned to three groups: Experimental, Shock Control, or No-shock Control. On four consecutive days, all rats were placed in Foringer operant chambers for 15 min sessions. Experimental and Shock Control groups were given footshock during the sessions on a variable time 30 sec schedule. Shock duration was 5 sec and intensity was 0.15 watts. No-shock Controls were placed in the chambers, but no shock was administered. On the fifth day, all rats were placed in the chambers for either 5 or 15 min; Experimental and No-shock Controls did not receive shock, while the Shock Controls were given shock as before.

	Days 1-4	Day 5
Exp	Shock	No Shock
SC	Shock	Shock
N-SC	No Shock	No Shock

(Exp = Experimental, SC = Shock Control, N-SC = No-shock Control)

All rats were then immediately sacrificed by decapitation. Trunk blood was collected in cold, heparinized tubes, and centrifuged for 10 min at 4°C. The plasma was transferred to tubes containing traysylol and stored at -35°C. The samples were extracted to concentrate the immunoreactive fraction and then assayed for beta-endorphin immunoreactivity using antibody produced in rabbits in our laboratory (the antibody is completely cross-reactive with beta-lipotrophic hormone).

The results are given as pg/ml ± S.E.M. beta-endorphin immunoreactivity.

	5 min	15 min
Exp	748.0 ± 102 (N=8)	1049.7 ± 117 (N=7)
SC	1150.8 ± 230 (N=8)	1415.4 ± 70 (N=7)
N-SC	492.5 ± 63 (N=8)	478.6 ± 60 (N=7)

Beta-endorphin immunoreactivity was significantly increased in both Experimental and the Shock Control groups at 5 and 15 minutes. The values for the No-shock Controls remained low at both 5 and 15 minutes. These data indicate that release of beta-endorphin can be elicited by psychological stress.

57.7 OPIOID AND NONOPIOID MECHANISMS OF LONG-TERM ANALGESIA. S. F. Maier*, R. C. Drugan*, J. W. Grau*, R. Hyson* and A. J. J. MacLennan*. University of Colorado, Boulder, CO 80302 USA; J. Madden IV* and J. D. Barchas. Stanford University, Stanford, CA 94305

Rats exposed to an extended series of inescapable shocks (80 5 sec shocks at an average interval of one min) display the well documented short-term stress-induced analgesia which dissipates relatively quickly. However, a pronounced analgesic reaction can be reinstated 24 hrs following the inescapable shock session by a brief reexposure to mild shock, which itself is insuffucient to induce an antinociceptive reaction. This long-term analgesic reaction following inescapable stress is completely reversed by opiate antagonists, completely cross tolerant with morphine, and requires the integrity of the pituitary adrenal axis for its expression. However, a wealth of evidence has recently been reported indicating that stressors produce both opiate sensitive and non-opiate analgesic reactions. Here we report experiments assessing factors which lead to the opioid nature of the long-term analgesia. Evidence regarding the differential environmental factors necessary for the expression of both forms of analgesia will be presented. We report that it is either the number of inescapable shocks or the duration of inescapable shock exposure which determines whether the resulting analgesia is reversible by opiate antagonists and reinstatable 24 hr later by shock reexposure. Both brief and extended exposures produce analgesia, but only the analgesic reaction developing after extended duration is reversible by naltrexone and reinstatable later. Furthermore, these analgesias occur sequentially in the stressed subject as exposure to shock continues. We further report that stress parameters which produce naltrexone-reversible analgesia also produce morphine super-sensitivity and that morphine produces an analgesic reaction reinstatable by stress. Additional characteristics of this reinstatable analgesia will be presented.

57.8 EFFECTS OF LESIONS OF THE BRAIN'S BETA-ENDORPHIN SYSTEM ON STRESS-INDUCED ANALGESIA IN RATS. J. E. Kelsey and Walter A. Hoerman IV*. Dept. Psychology, Bates College, Lewiston, ME 04240.

Although endorphins and enkephalins have been implicated in mediating some forms of analgesia, the role of the brain's Beta-endorphin system in mediating analgesia remains unclear. Presumably, if this system is involved, lesions of this system should reduce the release of Beta-endorphin and reduce analgesia produced in many situations. To examine this hypothesis, the effects of lesions of the arcuate nucleus of the hypothalamus, which contains the cell bodies of the brain's Beta-endorphin system, were examined on analgesia produced by exposure to stress. stress. In contrast to our expectations, we found that exposure to inescapable foot shocks produced significantly more analgesia, as indicated by elevated tail flick latencies, in the rats with lesions of the arcuate nucleus than in sham-operated controls when the rats were tested more than two weeks following surgery. However, when the rats were tested 3-7 days following surgery, the stress tended to produce less analgesia in the rats with arcuate nucleus lesions than in the controls.

There were no differences between any of the groups in pre-stress sensitivity to pain, and the lesions appeared to extensively damage the cell bodies presumed to contain Beta-endorphin. Furthermore, the effects of these lesions did not appear to be due to damage to nearby non-endorphin systems. Therefore, we suggest that our data implicate the brain's Beta-endorphin system in the mediation of stress-induced analgesia and suggest that our results reflect the effects of time-dependent compensatory changes, such as deenervation supersensitivity, occurring within the damaged Beta-endorphin system. To further examine this hypothesis, the magnitude of morphine-induced analgesia is currently being examined on rats with arcuate nucleus lesions.

57.9 ROLE OF NEUROPEPTIDES IN NOCICEPTIVE PROCESSES. M. M. Wallace, R. J. Bodnar, D. Badillo-Martinez*, G. Nilaver and E. A. Zimmerman. Dept. of Psychology, Queens College, CUNY, and Dept. of Neurology, Columbia University CPS, New York, NY.

The anatomical distribution and behavioral effects of the neuropeptides, B-endorphin (BE), met-enkephalin (ME), arginine-vasopressin (VP), substance P (SP) and neurotensin (NT) are suggestive of their respective roles in pain inhibition. To assess further the role of each in nociception, anti-sera raised specifically against each of these peptides plus oxytocin (OXY) were administered intracerebroventricularly (5 ul: 1 ul/15 sec) to rats in determining alterations in nociceptive thresholds, activity and temperature. One hundred and eight animals were tested for tail-flick latencies and subdivided as to anti-sera concentration (100, 50 and 10% dilution) and anti-sera group (two anti-sera plus vehicle). Following each injection, rats were tested over three levels of radiant heat at 15, 30, 60 and 90 min post-injection in an incompletely counterbalanced design. Significant concentration-dependent, intensity-dependent and time-dependent effects were observed. Anti-sera to BE and ME elicited short-lived hyperalgesic responses with intense radiant heat. Anti-sera to SP, VP, NT and OXY elicited biphasic effects with hyperalgesia at intense radiant heat levels and analgesia at moderate radiant heat levels. These effects appeared to be specific to the anti-sera since injections of normal rabbit serum and preimmune serum were without effect across thermal intensities and across time course. Twelve animals tested on the flinch-jump test received microinjections at the high concentration of each anti-sera and vehicle across the same time course in an incomplete counterbalanced design. Yet, no significant differences were found employing flinch-jump thresholds. Since some of these peptides alter thermoregulation and activity, we assessed undiluted anti-sera effects on core body temperature 15, 30, 60 and 90 min after injection. While anti-sera to AVP induced significant hypothermia 60 and 90 min later, anti-sera to ANT and AOT induced hyperthermia across the time course. All other anti-sera were without effect. Finally, activity levels were determined in 15 min blocks for up to 90 min following undiluted anti-sera or vehicle injection. No differences in activity patterns were observed across injections. Given the differential time courses both across anti-sera for a particular behavior and within an anti-sera across behaviors, it is concluded that these observed effects are specific to a particular anti-sera's modulation of that behavior, rather than an epiphenomenological result. (Supported by NIH Grants 14449, 5805RR07064 and AM20337.)

58.1 LESIONS OF NUCLEUS MEDIANUS BUT NOT ORGANUM VASCULOSUM PRODUCE ADIPSIA AND THIRST DEFICITS IN RATS. Thomas W. Gardiner*, Michael L. Mangiapane, and John B. Simpson. (SPON:J.H. Jacoby) Dept. Psychology, U. Washington, Seattle, WA, 98195.

Lesions of various size were made in male Long Evans rats in the area forming the rostral wall of the third cerebral ventricle, from the anterior commissure to the organum vasculosum laminae terminalis (OVLT). Larger lesions produced animals which became adipsic and exhibited inappropriate diuresis, as has been described previously (Johnson and Buggy, AJP 234(3):R122, 1978). However, with discrete lesions , adipsia was observed in some animals that nonetheless conserved fluids normally during dehydration(urine output comparable to water deprived controls), suggesting that the two dysfunctions are neurologically separable. More discrete lesions generally produced animals which showed a very transient adipsia (1-2 days) but in some cases, adipsia was prolonged (up to 7 days). Further, these lesions also reduced the drinking response of several rats to hyperosmotic thirst challenges (2ml of 2M NaCl).

Selective ablation of the ventral portion of nucleus medianus(VNM), with minor subcommissural periventricular damage caudal to VNM, resulted in prolonged adipsia and refractoriness to NaCl drinking in several animals. However, complete ablation of VNM did not result in adipsia or NaCl deficits in some animals including two rats with additional ablation of OVLT and some periventricular tissue. Extensive damage limited to periventricular tissue, or the tissue lying rostral to VNM (dorsal to OVLT) did not result in adipsia or NaCl drinking deficits in any animals unless substantial damage to VNM was also present. Selective ablation of all of OVLT likewise did not produce adipsia or decreased response to hypertonic NaCl. The inconsistencies here suggest that fiber projections terminating in or passing through this region may play an important role in producing behavioral deficits following these lesions. Disruption of drinking could occur following damage to fibers at several locations, despite inconsistent damage to nuclear groups per se.

In summary, selective VNM ablation was observed to result in adipsia and chronic drinking deficits to NaCl in several rats, but was not always sufficient to produce behavioral abnormalities. Destruction of surrounding tissue, including OVLT did not produce these deficits unless VNM was also damaged. Supported by HL 21800.

58.2 SELECTIVE REDUCTION BY IMMOBILIZATION STRESS OF OPIATE-RELATED HYPERPHAGIAS. S. Sangiah[1], M. T. Lowy*, and G. K. W. Yim, Dept. of Pharmacol. & Toxicol., Sch. of Pharmacy & Pharmacal Sci., Purdue Univ., West Lafayette, IN 47907, and Dept. Physiological Sci., Oklahoma State Univ., Stillwater, OK 74074.

Our previous studies with naloxone (Life Sci. 26: 2113, 1980) and dexamethasone (Life Sci. 27: 2553, 1980) have identified nocturnal feeding and the hyperphagias induced by 2-deoxy-D-glucose (2-DG), food deprivation (FD) and tail pinch (TP) as opiate dependent, whereas insulin-induced feeding operates through an opiate-independent mechanism. Since stress can cause subsequent reduction of endorphin release, and block other opiate-related phenomena, the aim of the present study was to determine if acute 1 hr immobilization (IMM) stress might selectively block the opiate-dependent hyperphagias. As anticipated, the stimulation of 4 hr daytime intake of rat chow by 2-DG (400 mg/kg) was decreased following IMM (5.8 $\pm$ 0.4 vs. 3.8 $\pm$ 0.5 g, $p < 0.05$), whereas the hyperphagia following 10 U/kg insulin was not decreased (3.6 $\pm$ 0.3 vs. 3.2 $\pm$ 0.6 g). In addition, 4 hr nocturnal feeding was markedly reduced by IMM (7.4 $\pm$ 0.8 vs. 2.8 $\pm$ 0.4 g, $p < 0.01$) as was FD-induced hyperphagia (10.8 $\pm$ 1.1 vs. 6.8 $\pm$ 0.5 g, $p < 0.01$). However, TP-induced eating of a palatable substance (3 min) was not reduced by prior IMM (3.1 $\pm$ 0.2 vs. 3.6 $\pm$ 0.3 g). Since the TP induced eating is more nonspecific and also dependent on a dopaminergic component, the present results are still consistent with the premise that IMM disrupts an endogenous opiate system, which is important for the full expression of the 2-DG, FD and nocturanal-induced hyperphagias. In contrast, insulin hyperphagia appears to operate through an opiate-independent mechanism. (Supported in part by Pharmacology/Toxicology Training Grant GM-70904, and American Cancer Society Grant CH-194).

58.3 EFFECTS OF BILATERAL SUBSTANTIA NIGRA DAMAGE ON SCHEDULE INDUCED, SCHEDULE DEPENDENT, AND INGESTIVE BEHAVIORS. D. L. Armstrong*, M. J. Wayner, F. C. Barone, T. Orsland*, B. Falk* and J. Sgromo* (SPON: C. S. Weiss). Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210.

Substantia nigra (SN) damage has been reported to produce changes in motor and ingestive behaviors of rats. Since schedule induced and schedule dependent behaviors have provided a sensitive measure of the severity and duration of lesion induced behavioral effects (Loullis and Wayner, Physiol. Behav. 22: 575-582, 1979; Wayner et al., Physiol. Behav. 18: 503-511, 1977; Physiol. Behav. 20: 427-434, 1978; and Physiol. Behav. 21: 1015-1025, 1978), these behaviors were utilized as a model to study in more detail the effects of various types of damage to the SN. Male rats were reduced to 80% of ad lib feeding body weight and were trained to press a lever for food on a FI-1 min schedule. When schedule dependent lever pressing and schedule induced licking and drinking stabilized during 30 min daily test sessions, the animals were divided into 3 groups, anesthesized with Equi-Thesin, and prepared for surgery. One group consisted of those animals receiving bilateral electrolytic lesions in the SN (LESION group, 1 mA anodal current for 15 sec). Another group consisted of those animals receiving bilateral microiontophoretic ejections of kainic acid in the SN (KA group, 12 µA cathodal current for 5 min through a glass electrode filled with 100 mM kainic acid, pH 7.4 using NaOH). The last group were sham operated controls (CONTROL group). Animals were also examined weekly on a series of behavioral tests frequently used to assess deficits in sensorimotor coordination. When the behavioral data had been collected the animals were perfused intracardially and the brains were removed, sliced into 40 µm sections, and stained with cresyl violet in order to verify histologically the extent of tissue damage. Following surgery, in the LESION group, lever pressing, licking, and water consumption were initially eliminated, then partially recovered, and continued at reduced levels for the remainder of the study. Powdered wet-mash supplements and stomach intubation were required to sustain these animals. In the KA group more transient decreases occurred in lever pressing, licking, and drinking which gradually recovered to pre-surgery baseline levels of responding. The CONTROL group was not affected. Results indicate that SN ascending fibers are critical to the maintenance of schedule induced licking and drinking. Substantia nigra neurons are also important since kainic acid applied in this area disrupts responding under these conditions. (Supported by NIH Grant NINCDS USPHS No. 13543.)

58.4 THE EFFECT OF DOPAMINE-DEPLETING BRAIN LESIONS ON SUCKLING AND WEANING IN RATS. John P. Bruno*, Abigail M. Snyder*, Edward M. Stricker, and Michael J. Zigmond (Spon: D. Kupfer). Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

Large striatal dopamine (DA) depletions, produced by intracerebral injections of the neurotoxin 6-hydroxydopamine (6-HDA), lead to aphagia and adipsia in adult rats, thus suggesting a role for cerebral DA in the control of eating and drinking. We now report the effect of DA-depleting brain lesions on ingestive behavior in neonatal rats. To selectively destroy central DA neurons, rat pups were injected at 3 days of age with desmethylimipramine (25 mg/kg, sc) followed 30 min later with 6-HDA (200 ug/10 ul, ivt). Suckling behavior appeared to be unaffected by 6-HDA although striatal DA was depleted by 99%, which would have produced prolonged aphagia and adipsia in adults. Lesioned pups grew well and were only 20% lighter than controls (39g vs 49g) 2 wk after 6-HDA. Developmental landmarks such as the appearance of fur (at 10-12 days of age) and eye-opening (at 14-15 days) were not affected. By 27 days of age, late in the normal weaning period, these rats weighed 50% less than controls (51g vs 104g), a difference that was maintained through adulthood, yet most rats (17 of 21) survived weaning at this time; during the first 3 days lesioned rats ate chow and drank water and gained 2 g/day, although they consumed much less than controls, which gained 8 g/day. Lesioned rats weaned at 18 days of age, early in the normal weaning period, had much more difficulty. These rats consumed little and lost 3 g/day during their first 3 days on a diet of chow and water, whereas control rats ate and drank and gained 3 g/day. When provided with mixed cereal and milk, the lesioned rats simply maintained their body weight at first and did not begin to grow for 3-7 days. In either case, associated with their low food and fluid intakes were body temperatures which ranged from 31-34 °C. Such marked hypothermia was not observed in lesioned rats weaned at 27 days of age or in control rats weaned at 18 days of age. These results indicate that destruction of central dopaminergic neurons in neonatal rats has little effect on growth until weaning but has a marked effect thereafter, especially when the animals are prematurely weaned. Supported by NIMH Fellowship MH08488 and USPHS Grants NSMH-16359 and MH-29670.

58.5 FUNCTIONAL ROLES OF THE LATERAL HYPOTHALAMUS AND PREFRONTAL CORTEX DURING BAR-PRESS FEEDING BEHAVIOR IN MONKEY. T. Ono, H. Nishino*, M. Fukuda*, K. Sasaki*, and K. Muramoto*, Dept. of Physiol. Fac. of Med., Toyama Med. and Pharmaceu. Univ., Toyama 930-01, Japan.

Unit activity in the lateral hypothalamus (feeding center, LHA) and the prefrontal cortex (FC) was recorded during monkey bar-press feeding behavior which comprised three stages; i) discrimination of food, ii) drive to obtain, iii) real ingestion reward. Their functional roles were deduced from the unitary responses to feeding events. Results were: In the LHA; 1) Of 199 neurons recorded, 69 responded in one or more stages of the feeding task. 2) Firing responses were divided into 3 patterns. Type I responded only in the discrimination stage. Type II responded only in the ingestion stage. Type III responded throughout all 3 stages. 3) Neurons which may be concerned with discrimination of food or non-food were Type I and Type III neurons. Food specific responses were more frequently observed in Type III(80%) than in Type I(15%). 4) Thirteen Type III neurons which seemed to recieve inputs from multiple sources, responded throughout the bar-press stage even in high FR schedule trials. These responses continued more than 10 seconds and seemed to be related with internal and external "drive" to obtain food. 5) Type II responses (mostly inhibition) appeared after food was put into the mouth. This response disappeared when either an aversive food was given, or the monkey became satiated, or glucose or morphine was injected intravenously. In the FC; 1) Of 167 neurons recorded, 77 responded in one or more stages of the feeding task. 2) Neurons in area 8 responded transiently at the sight of food, while neurons in area 10 responded throughout the bar-press stage. 3) In the ingestion stage 40 neurons responded while the monkey ate food. 4) Some neurons responded upon the approach of some significant material(food) toward the monkey. These responses stopped as soon as the monkey took the object in its hand. 5) Six neurons in area 10 responded to the movement of experimenter to manipulate food, or to push the start button, or to the rustle of a bag which contained food. These neurons, however, never responded to the sight of food presented in front of the subject.
The results suggest that the LHA is related to food discrimination, to the drive to obtain it, and to reward perception through situation specific neurons; the FC is related to the drive to obtain food, to reward anticipation, and to reward recognition, also through situation specific neurons.

58.6 LONG-TERM STABILITY OF ELECTRICALLY INDUCED BEHAVIOR IN GROUND SQUIRREL SUGGESTS NEURAL SPECIFICITY. J.D. Hallonquist. Dept. of Psychiatry, Mount Sinai Hospital, Toronto, Ont., Canada M5G 1X5.

Electrical stimulation of the lateral hypothalamus (LH) in animals can produce behaviors such as carrying of objects, eating and drinking. Such induced behaviors in rats have raised basic questions important for understanding neural substrates of motivation. First, does the stimulation activate the same neural systems involved in normal initiation of the behavior? Second, is the type of induced behavior determined by the specific neural system activated, or by the stimulation of a single functional mechanism which interacts with internal and external cues as well as past experience? The present findings relate to the second (specificity) question.

Sixty-five golden-mantled ground squirrels (Citellus lateralis) with stimulating electrodes bilaterally placed in the LH were screened for electrically induced behavior in the presence of food pellets. During the single 15 min. screening period, 98/130 sites supported 1 of 2 topographically distinct behaviors -- either induced eating (69 sites) or induced holding (29 sites) of the food pellets; no site supported both behaviors. Only 2 squirrels showed neither behavior at both sites. Of particular interest were 9 squirrels which showed different behaviors at bilateral sites, although directed at the same pellets.

Subsequent experiments produced no switching of the induced behavior observed during screening at a particular site. Forced ingestion of pellets via suprathreshold current levels with a consequent rise in threshold for induced eating did not precipitate emergence of induced holding. Furthermore, over a period of 1 year, unilateral sites (8 eating, 4 holding) were tested monthly in 12 squirrels, while bilateral sites (8 eating, 2 holding) were tested alternately approximately every 10 days in 5 squirrels. Despite pronounced circannual cycles of home cage food intake, body weight, body temperature and reproductive state in the squirrels, the behavior induced with threshold current levels at a particular site did not change, even in 2 squirrels which displayed different behaviors towards the pellets at bilateral sites.

The rapid initial appearance and long-term stability of the induced behaviors, coupled with their specificity to the electrode site and not the individual squirrel, suggest that different neural systems subserve the 2 induced behaviors, and argue against plasticity of motivational systems at the level of the LH in these feral animals (Supported by Canadian NRC grants to N. Mrosovsky, Depts. of Psychology & Zoology, U. of Toronto, and the author while at the Dept. of Psychology, U. of Toronto).

58.7 TRAIN LENGTH OF REWARDING STIMULATION AFFECTS FOOD INTAKE DURING FOOD/REWARDING BRAIN STIMULATION COMPETITION. R.A. Frank, R.L. Preshaw* and R.M. Stutz*. Dept. of Psychology, University of Cincinnati, Cincinnati, O. 45221.

It has been demonstrated that increasing the intensity of rewarding electrical stimulation of the brain (RESB) increases the ability of the stimulation to compete with drinking in water-deprived rats (Morgan & Morgenson, Psychon. Sci., 6: 337, 1966). However, it is unclear whether increasing the current intensity of RESB reduces water intake due to an increased field of stimulation (activating fibers that specifically inhibit water intake) or whether increases in intensity produce more effective stimulation of critical fibers (thereby increasing the incentive value of the stimulation).

The relative merits of these two hypotheses were assessed by studying the effects of manipulations of train length of RESB on the ability of RESB to reduce food intake. This manipulation was chosen because changes in train length do not influence the size of the stimulating field about the electrode tip. In addition, it has been demonstrated that changes in train length can modify the incentive value of RESB.

Rats were implanted with medial forebrain bundle electrodes (n=12) and trained to press a lever for RESB. They were then tested for baseline food intake on four consecutive days. Food was available only during 45 min test sessions. Three days of ad lib feeding followed these sessions. Subsequently, subjects were given limited access (45 min/day) to food and a lever that produced RESB on a fixed ratio (FR) 4 schedule for four consecutive weeks. A different train length of RESB was used during each week (250, 500, 750 and 1000 msec). Six subjects received an ascending order and six were exposed to a descending order of train length.

Train length was found to have a significant effect on food intake ($p < .05$), as did days of deprivation ($p < .01$), the week of the study ($p < .05$) and the train length X days of deprivation interaction ($p < .05$). We interpret the significant effect of train length and train length X days of deprivation interaction as evidence that RESB can reduce food intake by virtue of its incentive value rather than by replacing food or inhibiting food intake (see Spies, J. Comp. Physiol. Psychol., 60: 153, 1965).

However, it should be noted that the effect was small and that deprivation, experiential and subject-specific factors appear to play an important role in determining the ability of RESB to compete with food and water intake.

58.8 ORGANIZED BEHAVIOR PATTERNS AND SELF-STIMULATION INDUCED BY INTRAHYPOTHALAMIC ELECTRICAL STIMULATION IN 3-DAY-OLD RATS. Timothy H. Moran*, Mark F. Lew*, and Elliott M. Blass, Johns Hopkins University, Baltimore, MD 21218

When 3-day-old rats are stimulated (40-60uAx500m sec) through electrodes terminating in the medial forebrain bundle, a progressive organized pattern of behavioral recruitment is obtained. The rats first mouth and make slight licking movements. If a paw is contacted by the mouth, it is licked. Then licking becomes vigorous and is no longer directed towards the body or the cage substrate. If passage of current is continued, licking becomes extensive and is integrated with exaggerated gaping behaviors. This pattern intensifies and becomes incorporated into whole-body rolling from side to side. This pattern continues past current termination and often gives way to a stretch response that is remarkably similar to that induced by milk letdown. Occasionally, a lordosis response, similar to that seen in palpated, sexually receptive adult females, is also obtained. These behaviors are reliably induced and invariably occur in the sequence just described (N=15).

Only rat pups exhibiting this sequence push a paddle that produces self-stimulation. Rate of lever pressing is approximately double that of yoked control rats (X298.5vs137). Furthermore, in a more difficult 2-lever discrimination task, the rewarded paddle is also pressed with approximately twice the frequency of the nonrewarded one.

These data show that (a) complex motor patterns are organized centrally in 3-day-old rat pups; (b) these patterns can be fractionated into their component parts; and (c) that a central reward system exists in Day 3 rats that, when activated, can support changes in performance instrumental to self-stimulation.

58.9 OROSENSORY FACTORS IN DIETARY SELECTION AFTER FOOD DEPRIVATION AND SUPPLEMENTATION. M. G. Miller, J. F. TEATES*, and H. E. LIPPA*. Food & Drug Administration, Washington, DC, 20204.

To investigate the role of sensory factors in the adjustment of protein/carbohydrate selection to metabolic requirements,"recovered", partially trigeminally deafferented rats (400-450g) and a surgical control group were subjected to metabolic challenges and their food selection patterns were studied. Animals had access to two isocaloric diets, consisting of crude soy or starch, both with equal amounts of fat, vitamins and minerals. Deafferentation impaired somatosensory input from the lower anterior portion of the oral cavity. The metabolic challenges consisted either of depletion by food deprivation (4 days) or of daily supplementation by isocaloric-isovolemic intragastric protein or carbohydrate loads (10 days).

Food-deprived control rats selectively increased their protein intake on the day of refeeding by 30%, apparently compensating for the negative nitrogen balance during food deprivation. Carbohydrate intake was raised insignificantly. A gavage of protein prior to refeeding suppressed the disproportionate increase of protein. Deafferented rats showed no compensatory change in protein intake, and their total food intake stayed at predeprivation levels.

Daily supplemental protein or carbohydrate loads were compensated for calorically by reducing oral intake in the control and deafferentation groups. In contrast, only control animals compensated for the qualitative (protein or carbohydrate) composition of the intubation. This was most conspicuous after protein gavage. The selection pattern in both intubation control groups gradually returned to the preintubation baseline, resulting in highly aberrant intakes (oral + intragastric) of protein or carbohydrate, respectively. Deafferented rats never compensated selectively for the qualitative aspects of the intubation. Reduction of intake from both diet fractions was proportionate throughout the intubation period. The variability of the selection parameters was increased after food deprivation as well as during supplementation.

Control mechanisms for protein intake appear to be sensitive to the acute metabolic state. However, oral somatosensation has to be intact to allow behavioral adjustment.

58.10 ABOLITION OF GLUCOPRIVIC FEEDING BY FOURTH VENTRICULAR INJECTION OF ALLOXAN. Joan M. Murnane and Sue Ritter, Coll. of Vet. Med., Wash. State Univ., Pullman, WA 99164.

Alloxan is a toxic agent which, when injected peripherally, destroys glucose-sensitive pancreatic β cells. Recent studies have shown that alloxan may also be toxic to glucose-sensitive cells within the brain. We have shown that injection of alloxan directly into the lateral brain ventricles permanently impairs the centrally-mediated feeding response to glucoprivation. This deficit appears to be a specific effect of the drug on gluco-receptors since it can be blocked by co-administration of D-glucose. Thus, alloxan appears to be a useful tool with which to localize and characterize brain glucoreceptor cells.

In order to refine the localization of brain glucoreceptors we have compared the effect of lateral (LV) and fourth ventricular (IV V) infusion of alloxan on glucoprivic feeding. Adult male Sprague-Dawley rats were given either alloxan (40 ug in 5 ul saline), glucose plus alloxan (40 ug alloxan in 5 ul of 3M D-glucose) or saline (5 ul) through LV or IV V cannulae. Feeding and blood glucose responses were measured for 6 hr following injection of 2DG (150 and 350 mg/kg, s.c.) or insulin (2 U/kg, s.c.). Blood glucose responses to 2DG and insulin were not altered by alloxan. Although alloxan at both injection sites impaired glucoprivic feeding, IV V injections were most effective. After LV alloxan, rats ate 37% of control in response to 150 mg/kg 2DG ($p < .01$) and 64% of control in response to insulin ($p < .001$), but did not differ significantly from control in response to the higher dose of 2DG. In comparison, in rats that received alloxan in the IV V, feeding was reduced to 29% of control after 150 mg/kg 2DG ($p < .001$), 46% of control after 350 mg/kg 2DG ($p < .001$) and 37% of control after insulin ($p < .001$). As reported previously, animals injected simultaneously with glucose and alloxan did not differ from control on any test. We also found that alloxan itself elicits feeding when injected in low doses into the IV V. This result suggests that alloxan interacts with a cellular component normally involved in detection of glucoprivation. Alloxan does not impair glucoprivic feeding by damaging catecholamine (CA) neurons or by decreasing CA release since neither regional CA concentrations nor the increase in CA turnover normally observed after insulin or 2DG were altered in alloxan treated rats. Our findings (1) support other work suggesting that glucoreceptor cells controlling glucoprivic feeding reside in the hindbrain, (2) suggest that these cells are probably not CA neurons, and (3) suggest that the adrenal response to glucoprivation may be controlled by a population of cells separate from those controlling glucoprivic feeding.

58.11 FRAGMENTED BEHAVIORAL SEQUENCES DURING FEEDING BEHAVIOR FOLLOWING FIMBRIA-FORNIX TRANSECTIONS IN THE RAT. A. B. Dodek* and B. Osborne. Dept. of Psychology, Middlebury College, Middlebury, VT 05753.

Damage to the hippocampus has been shown to alter feeding and drinking behavior, but the role of the hippocampus has been obscured by inconsistencies -- both increased and normal feeding and drinking behavior have been reported. Some of the differences may be a result of differences in time of measurement or conditions of measurement, as well as the particular behavior measured. In an attempt to gain a more complete description of the effects of hippocampal damage on feeding and drinking behavior and to address the inconsistencies in the literature, detailed analysis of feeding and drinking following fimbria-fornix transection were examined. The behavior of 8 rats with complete fimbria-fornix transection and 10 operated controls was continuously monitored and recorded during the AM and PM and ad lib conditions and also following restricted food access. The rats were housed in large individually enclosed observation cages and the following behaviors recorded: food consumption, water consumption, intermeal intervals, meal duration, total eating time, sleep time, general activity, frequencies of rearing, grooming, carrying shavings, sleeping, drinking, eating, and hoarding. It was found that fornix-transected rats were generally more active and exhibited increased frequencies of rearing, eating, and drinking. In addition, the meals and intermeal intervals of fornix-transected animals were of shorter duration. Food and water consumption were unaffected by fornix-transection as were the frequencies of grooming, sleeping, and carrying shavings. Furthermore, fornix-transected rats hoarded less food pellets under restricted food conditions. These results and those from previous studies may be explained by a basic deficit in the organization of behavior. Although behavior remains adaptable and the components of the behavior and diurnal patterns were not altered, the frequency and sequencing of behavior appears disrupted by hippocampal damage. Moreover, these data are comparable to those from feeding studies following recovery from lateral hypothalamic damage (Rowland, N., J. Comp. Physiol. Psychol., 91:1039, 1977) suggesting a functional similarity.

58.12 DISSECTION OF CORTICAL VS DIENCEPHALIC CONTRIBUTIONS TO MOTOR ACTIVITY, ORIENTING, AND EATING USING A DISCONNECTION PARADIGM. I. Q. Whishaw and B. Kolb. Department of Psychology, University of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4.

It is well known that lateral hypothalamic (LH) lesions produce aphagia-adipsia, sensorimotor neglect, and catalepsy-akinesia. The rats show a sequence of recovery from each deficit which parallels in some ways the development of movement (see Teitelbaum and Epstein, 1962 and subsequent work). Decortication produces similar types of behavioral changes, but the nature of the abnormalities and the sequence and degree of recovery are partly different (Whishaw, Schallert and Kolb, 1981). In sum, investigations of hypothalamic and cortical function suggest there are at least two systems which partly share control over feeding, sensorimotor and motor activity, and one has a cortical and one has a hypothalamic origin. We are pursuing a line of research intended to dissect the relative contributions of each of these structures. In the present study we report the results obtained using a disconnection paradigm. Unilateral hypothalamic lesions were paired with unilateral-contralateral decortication (control groups consisted of single or combined ipsilateral lesions).

Following unilateral cortex removal, rats displayed profound and chronic contralateral neglect. If the rats also received a contralateral hypothalamic lesion they showed bilateral sensorimotor neglect but recovered orienting contralateral to the LH lesion, in the classic rostrocaudal sequence. Thus, the integrity of the neocortex is necessary for detecting contralateral sensory events. Following unilateral hypothalamic lesions the rats showed a mild turning bias ipsilateral to the lesion; contralateral decortication markedly potentiated this bias. Thus the influence of the intact hypothalamus is released by ipsilateral cortical removal. Rats which received both lesions together showed a syndrome of aphagia-adipsia, sensorimotor neglect, and akinesia-catalepsy. They recovered sensory abilities contralateral to the intact cortex and recovered from a turning bias contralateral to the intact hypothalamus. Recovery from both disabilities occurred in the predictable rostro-caudal sequence. Aphagia and adipsia appeared to be a consequence of these mutually antagonistic disabilities. Thus, the results show that the cortex and the hypothalamus have both facilitory and antagonistic influences in their control of various behaviors.

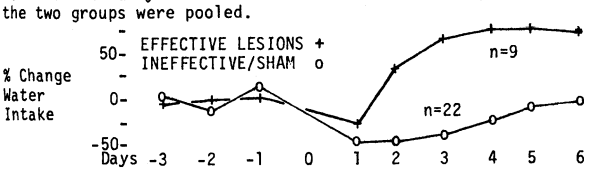
58.13 CONTROL OF DRINKING BY A HEMODYNAMIC PONTINE PATHWAY. D. G. Ward and J. H. Kelm* (SPON: M. J. Cronin). Dept. Physiology, Univ. Virginia Sch. of Med., Charlottesville, VA 22908.

There is increasing evidence for a role of vascular volume sensed by atrial receptors in the control of drinking (Zimmerman M. B., et al., Science 211:489, 1981). However the central neural pathways responsible are undefined. We have shown previously that neurons in the anteroventral locus coeruleus and in the locus subcoeruleus respond to changes in atrial filling (Ward, D. G., et al., Brain Res. 181:75, 1980); and that electrical stimulation of the same region inhibits ACTH release by the pituitary (Ward, D. G., et al., Endocrinol. 99:1220, 1976). To define the role of this ascending pathway in the control of drinking, daily water consumption was measured before and after placement of bilateral lesions in the dorsal-rostral pons of 31 cats. Thiopental was used for anesthesia, sterile surgery was performed and 60ml lactated Ringer's was administered intraperitoneally to facilitate recovery. As shown in the Figure, anesthesia alone (SHAM) was associated with decreased water intake. In contrast, lesions that bilaterally included the anteroventral locus coeruleus and the adjacent dorsal subcoeruleus (EFFECTIVE LESIONS) were associated with a marked increase in water intake that was statistically different from the sham animals ($P<0.01$; ANOVA). Lesions that were bilaterally limited to the dorsal or posterior extent of the locus coeruleus, to the dorsal periventricular gray or to the lateral periaqueductal gray (INEFFECTIVE LESIONS) were associated with a pattern of water intake that was not statistically different from the sham animals ($P>0.5$). Thus the two groups were pooled.



The site of highest density of overlap of all the lesions associated with hyperdipsia corresponds precisely to the pontine region shown previously to both inhibit ACTH and contain neurons with input from cardiovascular receptors sensing changes in vascular volume. Accordingly, the present data suggest strongly that the anteroventral locus coeruleus and dorsal subcoeruleus tonically inhibit drinking and is responsible for the control of drinking in response to changes in vascular volume.

58.14 LONGER-TERM ADAPTIVE CHANGES IN AMPHIBIAN NERVOUS SYSTEM. (2) CHANGES IN FEEDING BEHAVIOR DURING OSMOTIC ADAPTATION. Jim W. Dole*, Betty B. Rose*, Ken H. Tachiki*, Roger A. Baldwin* and Claude F. Baxter (SPON: W. Riege). Dept. of Biology, Calif. State University, Northridge, CA 91330, and Neurochemistry Labs, VA Medical Center, Sepulveda, CA 91343.

Feeding behavior of toads is a behavioral paradigm involving a fixed sequence of motor patterns: 1) orienting the body and head toward the prey; 2) extending the tongue and retracting the prey into the mouth; and 3) swallowing the prey. This stimulus-response chain has been extensively studied.

Feeding behavior was assessed in normal, fresh water-adapted (FWA) toads and in toads adapting or adapted to a hyperosmotic (400 mOs) external medium. Toads were placed, one at a time, in an aquarium in the presence of live mealworms. The actions of the toad were observed until six mealworms had been consumed or 15 min had elapsed. Feeding behavior was altered in the hyperosmotically-adapting or -adapted (HOA) toads. We recognize four behavioral states: State A: FWA toads feed rapidly and strike accurately with the tongue. Time elapsed between placement of a toad in the tank and its first attempt to feed (lag time) is short (30±23 sec). Strike accuracy ranged from 67 to 100% ($\bar{X}$ = 89%). State B: Most, but not all, HOA toads showed total disinterest in the mealworms. Instead, they exhibited restlessness and apparent "escape" behavior when placed in the feeding tank. State C: After a variable time period in state B, toads usually showed renewed interest in feeding. In this state, however, lag time was long (173±184 sec) and strike accuracy averaged only 23%; in a 15-min time period, toads often made up to 30-50 tongue flicks, many off-target by a cm or more without successfully capturing a mealworm. State D: Some toads returned to a behavioral state comparable (in strike accuracy and lag time) to that exhibited by FWA toads. The time required to reach a given state was highly variable. Our results show that the HOA toads typically pass through a series of behavioral states returning to a behavior exhibited by FWA toads.

At least two external cues are known to stimulate feeding behavior: visual cues in initiating prey capture are well established and, also, we have found that odors of prey play a role. Toads show evidence of learning the odor of a novel prey after a single experience. Thereafter, the feeding response can often be induced by odor alone. These results suggest that several parts of the brain are involved in the control of feeding behavior.

58.15 LONGER-TERM ADAPTIVE CHANGES IN AMPHIBIAN NERVOUS SYSTEM. (1) PUTATIVE NEUROTRANSMITTER AMINO ACID CHANGES DURING HYPEROSMOTIC ADAPTATION. Claude F. Baxter, Roger A. Baldwin*, Ken H. Tachiki*, Jim W. Dole* and Betty B. Rose*. Neurochemistry Labs, VA Medical Center, Sepulveda, CA 91343, and Dept. of Biology, Calif. State University at Northridge, CA 91330.

This is the first of three interrelated abstracts.

It has been observed that when the toad Bufo boreas is adapting to an altered osmotic environment, this adaptation is accompanied by significant changes in the levels of many amino acids in tissues of its nervous system. Specifically, when plasma osmolality is elevated (with NaCl) to 400 mOs or above, the levels of all putative neurotransmitter amino acids (PNTAA), excepting taurine, are elevated in brain tissues within 3 to 5 hrs. Levels of glutamate, aspartate, γ-aminobutyric acid and glycine (expressed as μmol/g tissue wet wt.) are elevated within 24 hrs by from 100% to 200%. Similar elevations of PNTAA are observed after 24 hrs, when the non-ionic osmolyte mannitol is used to elevate plasma osmolality. However, in this latter case, the PNTAA elevations are in part offset by a decreased water content of the brain tissues. Whereas NaCl hyperosmolality resulted in an 8% decrease in cerebral water content, an equivalent hyperosmolality induced with mannitol resulted in a 22% decrease in cerebral water content. Using NaCl as the osmolyte, the peak PNTAA concentrations in brain tissues are reached within 48 to 72 hrs. These levels are maintained for from 72 to 96 hrs and then decline, returning to more normal levels within another 72 to 96 hrs. With mannitol as the osmolyte, the early time sequence of amino acid changes are slower than those described with NaCl but, in both cases, the rates of PNTAA changes are compatible with some inductive mechanisms. All evidence to date indicates that these inductive mechanisms, whether inside or outside of the nervous system, are unrelated to corticosteroids or antidiuretic hormone. A comparison of changes in brain PNTAA induced by lactamide, mannitol and NaCl suggests that the extent of elevation in PNTAA is correlated to the octanol/water partition coefficient (i.e., membrane permeability) of each osmolyte. Thus, the restrictive compartmentation of an osmolyte between blood plasma and brain tissues and/or interstitial fluid and the intracellular compartments, rather than the actual plasma osmolality, may initiate the inductive mechanisms. Other experimental data suggest that elevated PNTAA levels in brain tissues may, in part, be the result of an altered transport of these amino acids across the blood-brain barrier. (Supported by the Medical Research Service of the Veterans Administration.)

58.16 LONGER-TERM ADAPTIVE CHANGES IN AMPHIBIAN NERVOUS SYSTEM. (3) NEUROCHEMICAL CORRELATES OF PUTATIVE NEUROTRANSMITTER AMINO ACID CHANGES AND FEEDING BEHAVIOR. Ken H. Tachiki*, Jim W. Dole*, Betty B. Rose*, Roger A. Baldwin* and Claude F. Baxter (SPON: E. Geller). Neurochemistry Labs, VA Medical Center, Sepulveda, CA 91343, and Dept. of Biology, Calif. State University at Northridge, CA 91330.

The adaptation of toads (Bufo boreas) to a hyperosmotic environment results both in alterations of levels of putative neurotransmitter amino acids (PNTAA) in the brain, and in changes of feeding behavior in response to the presentation of a prey which the toads had learned to identify as food. The brains from toads sacrificed before treatment (fresh water controls) and following initiation of hyperosmotic adaptation were dissected into three areas: cerebral hemispheres, optic lobes and olfactory bulbs. Each sample was analyzed for free amino acids employing an automated amino acid analyzer. Patterns of temporal changes in PNTAA levels of the cerebral hemispheres were compared with changes in patterns of feeding behavior. Results indicated a correlation of the PNTAA glycine, glutamate and γ-aminobutyric acid (GABA) with behavior. Marked changes in levels of aspartate occurred during time periods when little or no behavioral changes were observed.

Distinct states of feeding behavior were observed during 12 days of observation. These states were evaluated independent of adaptation time. State A represents the apparently normal feeding behavior seen in toads prior to hyperosmotic adaptation. In state B, feeding behavior is extremely low or absent. State C represents an intermediate state in which there is attempted feeding behavior but little catching of prey. We have designated apparently normal feeding behavior in hyperosmotically-adapted toads as state D. Plasma osmolality of toads in states B, C and D were essentially identical. A comparison of the PNTAA levels in the cerebral hemispheres of toads of state A vs. state B and state B vs. state D indicated a correlation between feeding behavior and levels of aspartate, glutamate and GABA. If both methods of analysis (i.e., pattern analysis and content analysis) are applied, only the PNTAA glutamate and GABA show a consistent correlation with feeding behavior in the cerebral hemisphere. Results of similar analyses of PNTAA in the optic lobes and the olfactory bulbs of these toads will be presented. (Supported by the Medical Research Service of the Veterans Administration.)

59.1 INFEROTEMPORAL NEURON DISCHARGE IN VISUAL MEMORY. Joaquin M. Fuster and John P. Jervey*. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, Calif. 90024.

This research is an attempt to elucidate the involvement of the neurons of the inferotemporal cortex (area TE, Bonin and Bailey, 1947) in higher visual functions. To that end, single-unit activity was explored with microelectrodes in the inferotemporal cortex of nine monkeys performing a task (delayed matching-to-sample) that required the perception and temporary retention of colors or patterns presented in a translucent plastic disk. The activity of some 500 task-related units was recorded extracellularly and statistically analyzed.

A large majority of the inferotemporal units investigated showed an excitatory reaction on appearance of the stimulus. About thirty percent showed different reactions depending on which color appeared in the disk. Many units exhibited activated firing in the period (16 - 20 sec.) during which the animal had to retain the stimulus to meet task demands. Differential (i.e., color-dependent) firing during the retention period was seen in about one-tenth of the cells. Cells activated during that period, whether differentially or not, were found particularly common in the cortex of the lower bank of the superior temporal sulcus. By contrast, inhibition and lack of differentiation in the retention period were the rule among units in a region outside of inferotemporal cortex (i.e., upper bank of that sulcus). The use of color/pattern combinations revealed that some inferotemporal units responded differently to a color depending on whether or not that color had to be attended to in order to meet the requirements of the task. Other units, however, appeared attuned to physical properties of the stimulus regardless of context.

The results of this study indicate that inferotemporal neurons participate in encoding and temporary retention of visual information. The latter function seems to be primarily represented in the cortex of the ventral bank of the superior temporal sulcus.

59.2 VISUOTOPIC ORGANIZATION ON THE PRELUNATE GYRUS IN THE RHESUS MONKEY. W. M. Maguire* & J. S. Baizer. Division of Neurobiology, Physiology Dept., SUNY/AB Med. Sch., Buffalo New York 14226.

We have studied the visuotopic organization of the dorsal two thirds of the prelunate gyrus and surrounding cortex, a region comprising the most dorsal and medial parts of V4, as anatomically defined by Zeki. Cells and cell clusters were studied in the awake monkey trained to maintain fixation on a small spot of light.

We have found two topographic representations of the lower contralateral visual quadrant, including the central 30^{o} of the visual field. Together, they occupy the middle third of the gyrus and extend into the anterior bank of lunate sulcus and the posterior bank of superior temporal sulcus. They are contiguous, joined by a representation of the vertical meridian and the periphery. Their peripheral representations lie near the lip of the posterior bank of the superior temporal sulcus, a few millimeters above where the Sylvian fissure joins it.

Receptive fields cluster around the vertical meridian and become increasingly central as one moves diagonally across the gyrus in a generally ventral direction moving into the anterior bank of lunate sulcus. The more ventral area increases considerably in size as one moves into areas of central representation. The area ventrally covers the gyrus completely, occupying parts of superior temporal sulcus and anterior lunate as well. Its horizontal meridian is down in superior temporal sulcus. The foveal boundary is as yet undetermined.

The more dorsal area contains a representation of part of the upper contralateral field as well as the lower. The horizontal meridian runs in a generally posterior direction across the gyrus, beginning a few millimeters above the level of the Sylvian fissure and extending into the anterior bank of the lunate sulcus. A complete representation of the central 10^{o} of the upper visual field lies dorsal to the meridian.

Dorsal to these two areas, cortex remains visually responsive, though more dorsally it becomes increasingly difficult to drive. We are as yet unable to characterize the apparently haphazard organization here.

The topography of the gyrus is made difficult to see by large receptive fields and considerable field scatter. We have found it can be clearly revealed by careful plotting of multiunit receptive field centers and the use of many closely spaced tracks in a single animal.

59.3 PATTERNS OF 2-DEOXYGLUCOSE LABELING IN EXTRASTRIATE VISUAL CORTEX OF UNSTIMULATED AND UNIDIRECTIONALLY STIMULATED MACAQUE MONKEYS. A.Burkhalter*, D.C.Van Essen and J.H.R. Maunsell. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Physiological recordings in the posterior bank of the superior temporal sulcus (STS) of the macaque monkey have shown a high incidence of direction selective neurons in the middle temporal area (MT) and an area medial to it (Van Essen et.al.,J.Comp. Neurol.:198,1981).

We have used the 2-deoxyglucose (2DG) labeling technique to examine the spatial organization of cells in the STS having similar direction preferences. Animals were anaestethized with N_2O and paralyzed prior to 2DG injection. The pattern of labeling in the right hemisphere of an animal exposed to left-to-right stimulation in the left hemifield was compared to that in the unstimulated hemisphere and in both hemispheres of a control animal given no visual stimulation.

In both hemispheres of the control animal the labeling pattern was remarkably non-uniform throughout extrastriate cortex. Labeling was usually densest in layer IV, but isolated patches in other layers as well as radially oriented columns of high density were common. The distribution of columnar or patchy labeling was not entirely random, in that the labeling was consistently more dense along the V1/V2 border and along the margin of MT. Labeling within MT showed occasional patches and columns. There was no obvious asymmetry in the labeling of the two sides, but the detailed patterns were not identical.

In the experimental animal there was a significant asymmetry in the labeling within the STS. This was especially pronounced in the dorsal part of MT, where the visual periphery is represented and where the stimulation was probably most effective. In this region there were distinct columns on the stimulated side and more uniform labeling, albeit with some patchiness on the unstimulated side. Columns on the stimulated side were 0.2 - 0.4mm wide, spaced about 1mm apart and aligned with columns on neighboring sections over a dorso-ventral extent of about 1mm. In the STS lateral to MT, where direction selectivity is not a prominent feature, distinct columns of about the same size and spacing were observed on the stimulated side, while the patches on the unstimulated side as well as in the control animal were less sharply defined.

These results suggest that stimulation altered the pattern of 2DG uptake in the STS and that the representation of stimulus direction in MT is at least to some degree organized in columnar fashion.

59.4 STRUCTURE AND DISTRIBUTION OF FUNCTIONAL COLUMNS IN MONKEY VISUAL CORTEX. M.L.J. Crawford, J. Miears* and L. Black*. U. of Texas, Houston, Texas 77025.

By scanning microdensitometry, we have mapped the distributions of 2-Deoxyglucose patterns induced in the visual cortex of monkeys stimulated by luminance-matched grating patterns. Serial assembly of density patterns illustrates a mosaic of columns throughout striate cortex which differs in spacing from foveal to more peripheral visual field representations.

Scanning the striate columns across the cortical layers shows a density profile difference between columns induced by black and white and color stimulation. Binocular black and white stimulus induced columns have two density peaks, one in layer 6 and another in layer 4, with relatively less activity in superficial layers. Luminance matched red and green stimulation produces high densities in lower layer 4 and layer 5 with a high density in what appears to be layer 3. The two patterns appear similar in structure, but the color pattern is shifted in phase toward more superficial layers.

Pre-striate patterns are mapped and shown to be stimulus dependent but do not seem to change in V2 between color and luminance stimulation. Distributed throughout the posterior bank of lunate and extending downward to occupy both banks of the inferior occipital sulcus, these high density patterns appear as spots or triangles with the base deep in layer 5 and 6 and virtually no pattern in the superficial layers. Serial profiles show these columns to wax and wane in density as they course in approximately parallel rows.

59.5 DYNAMICS OF FIRING PATTERNS IN THE VISUAL CORTEX. J. Patera*, Center for Applied Mathematics, University of Montreal, Montreal, Quebec, Canada and Gordon L. Shaw, Physics Department, University of California, Irvine, CA 92717.

Mountcastle has presented a columnar organizing principle for the functioning of the neocortex in which there are basic irreducible processing units: minicolumns of neurons. The minicolumns are coupled together into columns or networks presumably resulting in sophisticated spatial-temporal firing capability, that is, sophisticated processing. Consider the primary visual cortex where Hubel-Wiesel analyses established the orientation specificity (as well as other attributes such as left-right dominance) to light bar stimuli of the minicolumns. It was suggested (G. Shaw, P. Rinaldi, K. Roney, to be published) that sequences of rotating light bar stimuli be used along with one or several closely spaced recording microelectrodes to study the possible dynamics or flow of firing activity among the minicolumns in the column (the Hubel-Wiesel hypercolumn). An investigation of these effects requires variation of a number of parameters associated with the stimulus. We present a framework for developing and describing in a simple pictorial manner the various relevant sequences of time dependent stimuli. The measured firing responses can then be placed on the same plot and the "effective connectivity" between neurons in different minicolumns can be deduced. These plots are also used to design and interpret psychophysics experiments analogous to the electrophysiology one noted above.

59.6 NUMBER OF NEURONS IN LAYER IV OF A CORTICAL "MODULE." Bennett Solnick*, Thomas L. Davis, and Peter Sterling. Dept. of Anatomy, Univ. of Penna. Sch. of Med., Phila., Penna. 19104.

A cortical column might be formed, according to Mountcastle, by replication of a smaller, precisely-wired neural circuit which he termed a "module." In cat area 17 the smallest modular unit may be that which analyzes with one eye (half of the ocular dominance hypercolumn) a small region of visual field for stimulus orientation over 10 degrees (one-eighteenth of the orientation hypercolumn; Hubel and Wiesel, '74). The tangential dimensions of such a module are 500 X 48 μm and the volume occupied in this module by layer IVab (250 μm thick) is $6 \times 10^6 \mu m^3$. We have estimated the total number of neurons in this volume and also the upper limit of the number of cells belonging to several specific cell types.

Three series of one-micron thick autoradiograms were prepared from tissue in which exogenous ^{3}H-GABA had been accumulated by certain neuronal types. The total number of neurons was estimated by counting neuronal nucleoli and dividing by the average number of sections in which a nucleolus appeared. We estimated the number of type II stellates (large, dense somatic distribution of round and flat vesicle endings) by counting all large neurons (17-22 μm) that showed, in an electron micrograph of an adjacent thin section, a high density of round and flat vesicle endings. The number of neurons accumulating exogenous GABA at 3-10 times background were also counted; these are known to comprise several subgroups (Hamos, Davis, and Sterling, this Volume).

For that part of a module occupied by layer IVab, the total number of neurons was about 350. Of these, no more than 12 (3.5%) could be class II. The actual number is probably smaller since there were indications within this group of heterogeneity. About 28 cells (8%) accumulated GABA. Since there are at least four subgroups of these cells, the maximum number belonging to a single type is probably about 1-2%.

That the receptive fields of individual neurons scatter means that the patch of visual field "seen" by the module is larger than the individual receptive fields. If every point in this patch is to be seen by at least one member of each cell type, then several members of each type must be present in the module. The present findings suggest, therefore, that the number of each cell type present within a module may be close to the minimum needed to give complete coverage. At this level of organization there may be very little "redundancy". (Supported by NEI grant EY00828 and NINCDS NS05881).

59.7 SEVERAL GROUPS OF NEURONS IN LAYER IVAB OF CAT AREA 17 ACCUMULATE ^{3}H-GAMMA-AMINOBUTYRIC ACID (GABA). James E. Hamos, Thomas L. Davis and Peter Sterling. Dept. Anat., Univ. Pa., Phila., Pa. 19104.

In earlier experiments, we found that approximately 10% of the neurons in layers II-VI in cortical area 17 accumulate ^{3}H-GABA. The neurons in layer IV were stellate and sparsely contacted by synaptic terminals. In this study, we have examined GABA-accumulating neurons in layer IVab in greater detail and found evidence of considerable morphological heterogeneity.

We injected into the visual cortex .02-1μl of ^{3}H-GABA (2.5×10^{-4}M) or a mixture of ^{3}H-GABA (2.5×10^{-3}M) and 'cold' β-alanine (1.5×10^{-5}M) and perfused with aldehydes one to two hours later. Blocks near the injection sites in area 17 were processed for electron microscopy and series of consecutive thin sections were prepared as electron microscope autoradiograms. By partially reconstructing the cell bodies of GABA-accumulating neurons, we were able to group them according to differences in level of GABA accumulation, soma shape and size, distribution of terminals on the soma, and ratio of flat vesicle to round vesicle terminals.

Certain neurons, as reported previously, were heavily labeled (>10X background) and had a sparse distribution of somatic synaptic terminals (<20 terminals/100μm^2). This group could be further subdivided into medium-sized spherical cells (11-15μm in diameter) and large fusiform cells (20-25μm X 7-12μm). Another group of neurons was distinctly but more moderately labeled (2.5-6X background) and had a dense distribution of somatic synaptic terminals (>20 terminals/100μm^2). These neurons could be subdivided into small spherical cells (10-12μm) and larger spherical ones (15-18μm).

GABA is important in generating certain properties of the receptive fields of simple and complex cells (Sillito, 1975). Should the GABA-accumulating neurons prove to be GABAergic, it will be of interest to determine which of these morphologically different cell groups might be responsible for the various physiological effects. (Supported by NEI grants EY00828 and EY05397).

59.8 CHANDELIER CELLS IN RAT VISUAL CORTEX. Alan Peters, Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

Golgi impregnated chandelier cells in rat visual cortex have been examined by both light and electron microscopy, using the combined Golgi/EM technique of gold toning. All of the impregnated chandelier cells encountered have been in layer II/III. Many are present throughout area 17, but their numbers increase at the area 17/18a border, and to a somewhat lesser extent at the area 17/18 border. Most of the chandelier cells are bitufted neurons with groups of dendrites extending from the upper and lower poles of the cell body, although some have a more multipolar configuration. The cell bodies are characterized by a pale nucleus surrounded by perikaryal cytoplasm rich in cisternae of rough endoplasmic reticulum and ribosomes. Both the cell body and the sparsely spinous dendrites receive axon terminals forming asymmetric and symmetric synapses. The most characteristic feature of these neurons is the axon, which arises from either the lower pole of the cell body, or from the base of one of the dendrites in the lower tuft. It forms branches which spread laterally and terminate in vertical strings of boutons. The boutons in each string form symmetric synapses with the axon initial segments of layer II/III pyramidal cells, the uppermost bouton in each string being 8-14 μm distant from the pyramidal cell axon hillock. The boutons of the chandelier cell axon are irregular in shape and packed with pleomorphic synaptic vesicles, so that they are readily identified in thin sections. Some layer II/III pyramidal cells seem to receive boutons from more than one chandelier cell, and still others appear to receive no chandelier cell synapses. Evidence is presented to show that the axonal boutons of chandelier cells give a positive reaction with antibody to glutamic acid decarboxylase (GAD), the enzyme which synthesizes GABA. Hence chandelier cells are GABA-ergic neurons and are probably inhibitory in function. Other GAD-positive axon terminals synapse with the more proximal portions of the pyramidal cell axon initial segments, as well as with their axon hillocks, cell bodies and dendrites. These latter terminals are probably derived from the smooth or sparsely spinous multipolar stellate cells, so that at least two different types of non-pyramidal cells inhibit the layer II/III pyramidal cell of rat visual cortex.

Supported by NIH grant NS 07016.

59.9 COMPARISON OF THE RESPONSE PROPERTIES OF THREE TYPES OF MONOSYNAPTIC S CELL IN CAT STRIATE CORTEX. Michael J. Mustari, Jean Bullier* and Geoffrey H. Henry*. Dept. of Physiology, Australian National University, Canberra, A.C.T.

The receptive field properties of three types of S cell receiving a monosynaptic input from the LGN were quantitatively studied in the striate cortex of the anaesthetised and paralysed cat. The nature of the afferent input to these units was identified from their response latency to electrical stimulation delivered at different sites in the optic tract and optic radiations. From these latency measurements we determined whether the cell under study received a direct input from the LGN and whether this input originated from brisk transient (BT) or brisk sustained (BS) cells (Bullier, J. and Henry, G.H., J. Neurophysiol. 42:1251, 1979).

Two types of monosynaptic S cell were located in lamina 4, one type received a fast conducting input from the fast stream (BT) while the other type received its input from the slow (BS) stream. The third group comprised monosynaptic S cells located in lamina 6. When response properties of the 3 types of S cell were compared no significant differences were observed in direction selectivity, ocular dominance, binocular interaction, the strength of side band inhibition, spontaneous activity, or in the persistence of the response to flashing stimuli.

Class differences were found in the size of the receptive fields. S cells in lamina 4a, belonging to the fast stream in general, had larger receptive fields than their counterparts in lamina 4b driven by the slow stream. If 1° is taken as a cut off value, 80% of S cells in the fast stream were found to have receptive field measurements (in both the dimensions parallel and perpendicular to the optimal orientation) greater than the cut off while in 80% of S cells in the slow stream each of these two dimensions was less than the cut off value of 1°. Both of these S cell types exhibited strong end zone inhibition. By contrast the monosynaptic S cells of lamina 6 had weak or no end zone inhibition and had receptive field lengths (parallel to optimal orientation) in the range of 2-6°. In the dimension perpendicular to the line of optimal orientation there was no observed distinction between lamina 4 and lamina 6 S cells. In their velocity preference most (80%) fast input S cells of lamina 4 responded to stimuli moving faster than 10°/sec while slow input S cells ceased to respond when stimulus velocity exceeded this level.

The presence of quantitative differences in receptive fields that are essentially similar to one another suggest that fast and slow input S cells of lamina 4 perform complementary functional roles in the striate cortex.

59.10 CORRELATION BETWEEN VELOCITY CHARACTERISTICS AND RESPONSIVENESS TO STATIONARY STIMULI IN VISUAL CORTICAL NEURONS OF THE CAT. J. Duysens, G.A. Orban and O. Verbeke*. Lab. Neuro- en Psychofysiologie, KULeuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

In the visual cortex one finds cells which respond exclusively to slow stimulus movement (velocity low pass type, VLP) and others which prefer very fast movement (velocity high pass type, VHP; Orban et al., J. Neurophysiol., in press). To understand the mechanisms underlying the differences between these two velocity types the responses to stationary presented stimuli were compared with the responses to moving stimuli in 66 cells from areas 17, 18 and 19 in paralyzed and N_2O anesthetized cats. A narrow bar of light was projected either over different parts of the receptive field for a fixed period of 1 second or else at a fixed location but with different durations ranging from 20 to 5000 msec.

VLP cells were found to require much longer minimal durations of stationary stimulation (> 80 msec) than VHP cells which fired even for stimuli as short as 20 msec provided high contrast and optimal slit width were used. The minimal duration of stimulation could be used to accurately predict the upper cut-off velocity of VLP cells indicating that the inability of these cells to respond at high velocities is mainly linked to their high demand for temporal summation. VLP cells were also found to respond tonically and with long latency (median = 254 msec) to flashed bars of light whereas VHP cells discharge phasically and with short latency (median = 58 msec). Some cells exhibited a velocity response profile intermediate between the VHP and VLP type. These cells, which responded well to slow or fast movement but little to medium velocities, showed both phasic and tonic response components when presented with stationary stimuli. No strict correlation was found between the different velocity types and the presence or absence of spatial overlap of ON and OFF zones.

It is concluded that VLP and VHP cells constitute distinguishable populations not only on the basis of their velocity characteristics but also with respect to their response properties in the presence of stationary stimuli.

59.11 RESPONSE PROPERTIES OF CELLS IN THE VISUAL CORTEX OF THE RAT. R.A. Burne, J.G. Parnavelas, and C.-S. Lin, Dept. of Cell Biology, The Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235

This study was undertaken with the general aim of correlating structural and functional properties of single neurons in the visual cortex, area 17, of Long Evans pigmented rats. Extracellular spike responses to visual stimuli presented manually or by a computer-controlled system were recorded in animals anesthetized with 1% halothane. Post-stimulus time histograms and raster analyses were used to quantify response characteristics following presentation of visual stimuli. The morphological structure of functionally identified cells was determined with intracellular injection of horseradish peroxidase (HRP). Beveled glass micropipettes (20-70 Megohms) containing 4-8% HRP in 0.2 M KCl with 0.1 M Tris buffer at pH 7.6 were used in this study.

Visually responsive cells comprised 90% (296/327) of the cells recorded in area 17. Five percent of these cells responded only to stationary stimuli with either on-center (9/15; 60%), off-center (2/15; 14%) or on-off (4/15; 26%) properties. The remaining neurons (95%) responded to both stationary and moving stimuli or only to movement. They were classified as complex, simple, hypercomplex or non-oriented. Complex cells comprised the majority (122/281; 44%) of the movement sensitive cells and were distinguished from simple cells (77/281; 27%) by 1) the presence of spatial overlap of excitatory peaks evoked by a stimulus moving through the field in opposite directions, 2) the absence of inhibitory sidebands and 3) the lack of spatial summation in the receptive field. Hypercomplex cells (35/281; 13%) differed from other cell types by demonstrating a reduction (> 60%) in response frequency as the preferred stimulus was elongated beyond the excitatory region. Non-oriented cells (45/281; 16%) responded to moving stimuli over a wide range of orientations.

Of the cells successfully filled with HRP, complex cells (15) were pyramidal in morphology and located in layers II through VI. Simple cells (4) were both pyramidal and non-pyramidal in appearance and were located in layers II & III and IV. Finally, hypercomplex cells (3) were pyramidal in appearance and their perikarya were situated in layers II & III and V.

Our results suggest that neurons of the rat visual cortex have well defined receptive fields and have properties similar to those reported for animals with more developed visual systems.

59.12 VESTIBULAR SYSTEM MODIFICATION OF SOME NEURONAL CHARACTERISTICS IN THE VISUAL CORTEX OF THE CAT. R. H. Lahue, Jr.*, S. Reinis, D. S. Weiss*, K. E. Money and J. P. Landolt, (SPON: R. G. Marteniuk) Univ. of Waterloo, Waterloo, & DCIEM, Toronto, Canada

The intertrial firing rate and orientation specificity of cells in the visual cortex of the cat as well as the size, shape and retinal position of their receptive fields have been shown to be affected by head and body tilt. To further analyze this phenomenon, some of these characteristics have been investigated following the administration of two nystaganogenic agents, deuterium oxide and mannitol, and following galvanic stimulation of the vestibular system. While these manipulations did not affect receptive field position, they did lead to alterations in receptive field size and shape and intertrial spontaneous firing rate. Changes in area were often biphasic with a brief initial decrease followed by an extensive and extended increase. Changes in receptive field area and spontaneous firing rate were not always parallel. Neither receptive field characteristics nor spontaneous firing rate were affected in labyrinthectomized animals subjected to the same manipulations. Furthermore, the spontaneous firing rate of non-visual cortical cells was unaffected. These experiments demonstrate that the vestibular system participates in the control of activity of visual cortical cells and that functional modification of cell characteristics as a result of head tilt is not artifactual.

Supported by DCIEM Research Contract 3279017/8SU79-00225.

59.13 EFFECT OF LABYRINTHECTOMY ON VISUAL CORTICAL CELL CHARACTERISTICS IN THE CAT. S. Reinis, R. H. Lahue Jr.*, D. S. Weiss*, J. P. Landolt and K. E. Money. U. of Waterloo, Waterloo, and DCIEM, Toronto, Ont., Canada.

Receptive field size, shape and retinal position, as well as optimal stimulus parameters and intertrial firing rates of complex cells in cortical area 18 were examined in terms of their responses to head tilting of 10^{o}, 20^{o} and 30^{o} in both intact and labyrinthectomized cats. In intact animals, receptive field size changed in all cells in a more or less regular fashion as a function of head tilt. Receptive field position and intertrial firing rate also varied though less regularly. In labyrinthectomized animals changes in receptive field area were usually within the probable limits of experimental variability. However, the variability in receptive field position and intertrial spontaneous firing rates in labyrinthectomized animals equalled that observed in intact animals. These results indicate that several characteristics of visual cortical cells are altered by head tilt, but vestibular input is not the only factor controlling these changes.

Supported by DCIEM Research Contract 3279017/8SU79-00225.

59.14 EFFECTS OF CONVERGENT SQUINT IN CATS ON TEMPORAL PROPERTIES OF STRIATE NEURONS, Michael S. Shansky,* Yuzo M. Chino* and Wayne L. Jankowski,* Fredrich A. Banser,* Illinois College of Optometry, Chicago, IL.

Kittens were reared with a surgically-induced convergent squint in one eye (via section of the lateral rectus during the third post-natal week), the temporal response properties of cortical cells were measured and comparisons made between the squinting eye, non-squinting eye and normally reared cats. The best responses to varying drift rates of sinusoidal gratings of an optiimum spatial frequency were shifted to lower temporal frequencies in the strabismic cats for both the operated and non-operated eyes compared to normal cats. Likewise the temporal high frequency cutoffs were significantly lower among all the cell groups in the squinting animals. In addition, a dramatic increase in both latency of response to chiasm stimulation and visual stimulation was found for the squinting and non-squinting eyes in the experimental animals, such that the latency values were, in many cases, more than twice those found in normal cats. Spontaneous activity was also significantly higher in the strabismic cats, but no differences were found in the peak responses to a moving slit of light. These results suggest that animals reared with abnormal interocular alignments will suffer major neurophysiological deficits with regard to processing temporal information.

(Supported by Grants EY-01444 and EY-03588)

59.15 A CONVERGENT SQUINT IN KITTENS ALTERS SPATIAL RESPONSE PROPERTIES OF STRIATE CORTEX UNITS, Yuzo M. Chino,* Michael S. Shansky,* Frederick A. Banser,* and Wayne Jankowski,* Illinois College of Optometry, Chicago, IL.

Spatial properties of striate neurons were investigated in cats reared with a unilateral, surgically-induced convergent squint. Extracellular recordings were made when the animals were one year old. Contrast sensitivity functions in the operated cats, extrapolated from responses to drifting sinusoidal gratings, revealed shifts to lower spatial frequencies of both the peaks and high-frequency cut-offs.

Receptive field dimensions were significantly larger in the squinting animals, the orientation tuning (half-width at half-height) was far less sharp in normally-reared cats.

Some properties (e.g. direction selectivity) appeared to be unaltered in the strabismic animals, but overall we conclude that there is a significant modification of receptive field properties in the cortices of cats sustaining convergent squint during development.

(Supported by Grants EY-01444 and EY-03588)

59.16 TEMPORAL INTEGRATION IN THE VISUAL SYSTEMS OF THE CAT AND HUMAN. D. Brenner, E. Kaplan* and R. Shapley* Rockefeller University, New York, NY 10021.

We investigated the temporal integration of visual signals in the nervous system by measuring the phase of the neural response as a function of temporal frequency. Stimuli were sine wave gratings undergoing contrast reversal with a sinusoidal time course at temporal frequencies from 0.5Hz to 80Hz. The spatial frequency range was 0 to 3c/deg and 0.05 to 0.4 peak contrast. Average luminance was in the range 20-60 cd/m^2. Neural responses were averaged and Fourier analyzed to yield response amplitude and phase at the modulation frequency and its harmonics. For 47 cells of the cat lateral geniculate nucleus, and for 32 geniculate cell/s-potential pairs, the phase was proportional to temporal frequency from about 3Hz to about 30Hz. The slope of the line was approximately 40 msec. for the geniculate cells and their retinal inputs represented by s-potentials. Spatial frequency and contrast had rather little effect on the slope of the phase line in the geniculate or retina. The slopes were similar for X and Y, and "on" and "off" cells.

The linear phase vs. temporal frequency dependence is consistent with a constant time delay, or latency, but it is also consistent with a more plausible model, namely a cascade of neural low-pass filters. The slope of 40 msec. would be the sum of the time constants of the filters in the cascade.

Visually evoked cortical responses (to the same kind of stimuli) in cat and in man were subjected to the same analysis. The cat evoked potentials were measured with electrodes placed within area 17 of the cat's cortex. The human evoked responses had been measured previously by neuromagnetic recording from the occipital cortex. Both sets of evoked response data yielded similar linear phase vs. temporal frequency graphs, with slopes of approximately 80-120 msec. In terms of the filter cascade model, there is an additional stage of temporal filtering between the geniculate input and the units which generate the cortical evoked response. This stage of cortical temporal filtering has an approximate total integration time of 60 msec. The similarity between results in cat and in man suggests a similarity in cortical mechanisms of temporal integration.

This work was supported by NEI grants EY1472 and EY188.

59.17 CRANIAL, SUBDURAL AND INTRACORTICAL RESPONSES TO VISUAL STIMULI IN THE AWAKE RHESUS MONKEY. G. Dagnelie*, E.H. van der Marel* and H. Spekreijse* (SPON: M.H. von Meijenfeldt). The Netherlands Ophthalmic Research Institute, 1005 EK Amsterdam, Netherlands.

The search for the origin of the visually evoked potential (VEP) can be advanced by the use of invasive recording techniques. Since the rhesus monkey's visual cortex presents a structure analogous to that of man we have compared VEPs recorded at the scalp of monkey to those recorded simultaneously with cranial, subdural and intracortical electrodes.

Four rhesus monkeys were trained to fixate at a TV screen on which checkerboard and bar patterns as well as homogeneous fields could be presented. After establishing the VEP distribution with scalp electrodes a chronic preparation was obtained by placing five stainless steel screws in the skull bone and three electrode bundles (each containing seven recording sites at 5 mm intervals) in the cerebrospinal fluid over the temporo-occipital cortex. When the relationship between scalp and subdural VEP had been determined two electrode bundles containing seven recording sites at 0.3 and 0.5 mm intervals were inserted perpendicularly 2.5 cm from the midline into area 17. For those components of the VEP that originate close to these bundles it was expected that a change of polarity would be observed from superficial to deep cortical layers. A connector on the frontal part of the skull permitted a free choice of derivations during the experiment.

The following conclusions were reached:

- VEPs from bone electrodes bear a strong resemblance to VEPs recorded with scalp electrodes
- VEPs from subdural electrodes show a stronger dependence on electrode location than bone or scalp derivations
- The subdural VEP to luminance stimuli is less localized and represented more occipitally than those to pattern stimuli
- In subdural VEPs the different cortical origin of the response components can be established more easily than in scalp or bone recordings
- In the intracortically recorded VEP a change of polarity of response components is only observed under a limited number of stimulus conditions

59.18 Neural Circuitry of the Neocortex examined in the in vitro brain slice preparation. N. Chiaia, C. Shaw and T. J. Teyler. Neurobiology Program, N.E. Ohio College of Medicine, Rootstown OH 44272 and Psychology Dept., Dalhousie Univ., Halifax, Nova Scotia B3H 4J1.

The in vitro brain slice technique has been applied to the study of the neocortex. Cortical blocks were removed from adult rats deeply anesthesized with halothane, sectioned coronally at 400-700 u, and placed in a brain slice chamber. Cortical slices typically showed normal histology and spontaneous and evoked neural activity for 8 hours or longer. Single unit and evoked potential recordings were made from different layers of the cortex using micropipettes. Evoked potentials to afferent simulation of differing intensity and frequency and from different cortical layers were analyzed.

Evoked potentials from all but the most superficial layers of the cortex showed a characteristic 6 component response to simulation of underlying white matter. This evoked potential closely resembled cortical responses recorded in vivo by other investigators following afferent stimulation. The response amplitude of all components increased as stimulus intensity was raised. Radial movement of the recording electrode showed the components 1, 2, and 3 had their largest amplitude in the deepest cortical layers. Component 4 reached its greatest amplitude and shortest latency in layer 4, and components 5 and 6 reached their greatest amplitudes in the more superficial layers. The frequency following for various components was measured showing greater decline in amplitude for components 4 through 6 than for 1 through 3.

These results, together with those from in vivo investigations suggest that the first 3 components represent afferent fiber input. Component 4 represents the initial postsynaptic response which is localized in layer 4. Components 5 and 6 represent later additional cortical activity. Further support for the intercortical orgin of component 4 was provided by lateral intercortical stimulation within layer 4 giving an evoked potential composed mostly of component 4. With lateral movement of the recording electrode in layer 4 the evoked potential disappeared in under 1mm, suggesting a fairly restricted afferent input to the recording site. These results suggest that the cortical brain slice may be an appropriate model system in which to study cortical neural circuitry.

59.19 QUALITY OF COLOR VISION OF DECORTICATE GROUND SQUIRRELS. E. Kicliter. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, P.R. 00936.

Ground squirrels maintain color vision after removal of their visual cortex, but the quality of the persisting color vision has not been studied. Two adult ground squirrels (Spermophilus tridecemlineatus) were trained to perform both brightness and color discrimination tasks in a darkened two-choice visual discrimination apparatus. The color task was based on pseudoisochromasy (Kicliter and Loop, Vision Res. 16: 951-956, 1976). After initial acquisition of these discriminations, the size of the stimuli was varied and the minimal target size for color and brightness discrimination was determined. I then determined the spectral sensitivity of the animals using an increment threshold method at a background luminance of 6.1 cd/m^2. The posterior neocortex, including the cortical target of the dorsal lateral geniculate, was then removed in two stages and the three functions were again determined for each animal. The results showed no difference in target size required for color discrimination. Some performance decrement for brightness discrimination occurred with larger target sizes. The postoperative spectral sensitivity curves, like the preoperative curves, were bimodal. Postoperatively there was some sensitivity loss extending across the spectrum. That these changes were minor indicates that neither the discrimination of the color of small targets nor photopic spectral sensitivity requires the integrity of the geniculocortical system. (Supported by NIH grant NS-07464).

59.20 EFFECTS OF TELENCEPHALIC VISUAL SYSTEM LESIONS ON REVERSAL AND DIMENSIONAL SHIFT IN TURTLES (CHRYSEMYS PICTA). J. Cranney and A. S. Powers, Dept. of Psychology, Bryn Mawr College, Bryn Mawr, PA 19010.

There are two regions of the telencephalon of reptiles that receive visual projections from the thalamus: the core nucleus of the dorsal ventricular ridge (CN) and the dorsal cortex. The present research was undertaken to examine whether lesions of these structures produce different effects on visual tasks. Previous research had led us to expect that turtles with CN lesions would have sensory deficits while turtles with cortical lesions would have deficits that were not sensory, but rather associational.

We studied the performance of 16 turtles (Chrysemys picta) that were given lesions of the CN or dorsal cortex or sham lesions. In a standard two-key situation, all turtles were given a series of ten visual discrimination problems in sequence. On each problem, two dimensions were present, pattern (horizontal vs. vertical stripes) and color (red vs. green), one relevant and one irrelevant. The turtles were run on each problem until they reached a criterion of 85% correct initial choices. The correct choice on each problem was as follows:

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
H+	R+	V+	G+	V+	H+	G+	R+	H+	R+

Two of these problems, (6) and (8), are reversals of the previously learned discriminations. The rest all involve shifts of dimension, from pattern to color or vice versa.

For the most part, our hypotheses were confirmed. Animals with CN lesions had a deficit on problems (1) and (3), no deficit on problem (2), and no obvious deficit on any of the other problems. We interpret these findings to mean that CN lesions produce a sensory deficit that recovers with practice. Recovery may be due to the turtle's learning to compensate for the deficit or to the gradual takeover of function by other structures or to both these factors. The deficit appeared to be specific, in that it was not found on color problems. Cortically-lesioned animals had no deficit on problem (1), although they showed a deficit on problem (3), a dimensional shift to pattern, which was a reversal of the first pattern problem, and on problem (6), which was a pattern reversal. Thus it appears that lesions of the cortex damage some associative mechanism that makes it possible for a turtle to change its responses from one situation to another. In spite of the visual projection to the dorsal cortex, lesion of this area does not seem to produce a sensory loss on problems of moderate difficulty.

60.1 SYNAPTIC SPECIFICITY OF REGENERATING RETINAL TERMINALS IN THE GOLDFISH OPTIC TECTUM. M.J. Airhart* & R.M. Kriebel* (SPON: M. Moffroid). Dept. of Anatomy & Neurobiology, The University of Vermont, Col. Med., Burlington, VT 05405.

Regenerating axons of the goldfish retinotectal pathway have been used extensively as a model system for studies on fiber specificity. These studies have measured axonal specificity on the basis of the retinotopic distribution of regenerating fibers using electrophysiological recording techniques and light microscopic autoradiography. Neither of these two assays allows determination if specificity exists at the synaptic level. The quantitative aspects of synapse formation and the synaptology of regenerating retinal terminals has never been used as a measure of specificity. Therefore, the purpose of this study was to answer the following question: to what extent do regenerating retinal terminals reestablish their original morphology, synapse density, and synaptology? An electron microscopic study of the normal retinotectal pathway and its synaptic neuropil, the stratum opticum(SO) and stratum fibrosum et gresium superficiale(SFGS), was done to provide baseline information for studies involving retinal synaptic specificity. A population of retinal terminals was identified in the SO and SFGS using a combined short term and long term electron microscopic degeneration study. The retinal terminal was found to exhibit a combination of morphological features that allowed direct identification of control and regenerated retinal synapses. Retinal synapse density, spherical vesicle associated synapse density (S) and total synapse density were determined from a standardized sample area ($621\mu^2$). The results showed little variability in synaptic parameters between control animals. Retinal terminal synaptology was examined both qualitatively and quantitatively. Retinal terminals did not synapse on cell soma or proximal dendrites, but rather on relatively small postsynaptic profiles. The size of the postsynaptic profiles fell within two area distributions: 87% size range $0.01\text{-}0.4\mu^2$ and 13% size range $0.41\text{-}1.10\mu^2$. This control data was used to evaluate the three experimental parameters used in defining synaptic specificity. Qualitative and quantitative changes in the retinal synapse population as well as the synapse densities of two related parameters, total synapse and S synapse densities, were examined in the SFGS during optic nerve regeneration. As early as 16 days postcrush, regenerating retinal terminals were observed in the SFGS. By postcrush day 63, retinal synapse density, S synapse density, and total synapse density were all equal or within 87% of control values. Further, the data strongly suggested that retinal synapses form a normal synaptology. (Supported by PHS 5429-16-19).

60.2 EFFECT OF DELAYED AFFERENT ARRIVAL ON SYNAPSE LOCALIZATION ON THE AMPHIBIAN MAUTHNER CELL. S.M. Leber and P.G. Model. Dept. Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

The spatial patterning of inputs upon a neuron can be very precise. We have disrupted normal afferent-target cell temporal relationships in the development of an identified vertebrate central neuron to see whether temporal coordination is required for the correct localization of afferent terminals. The Mauthner cell (M-cell) of the axolotl (Ambystoma mexicanum) receives synapses from the ipsilateral vestibular nerve (nVIII) only on the ventral surface and branches of its lateral dendrite. The nVIII terminals (club endings) are distinctive at the EM level.

The ear and vestibular ganglion are of ectodermal placodal origin. The earliest axons from the ganglion enter the medulla at Harrison stages (s) 34+/35-, at about the same time that the M-cell begins to differentiate. To delay axonal ingrowth, prospective ear/ganglion placodes from younger (s23) embryos were unilaterally grafted in place of ears and ganglia from older (s33/34) animals. LM examination of embryos over successive days following surgery showed that a significant delay in the ingrowth had occurred. During this delay, the M-cell's lateral dendrite continued to grow and the experimental axons thus reached a larger and more differentiated target than did the control axons.

LM examination of 21 mm feeding larvae revealed that the grafts had developed into anatomically normal ears and nVIII ganglia. The vestibular nerves entered the medullae at the correct location. The M-cells on the operated side were normal, but the branches of the proximal lateral dendrite exhibited increased variability. EM examination of these cells showed that club synapses had indeed formed despite the late arrival of the axons, and comparison with control M-cells revealed a similar distribution of the club endings on the ventral surface and branches of the proximal lateral dendrite. Fewer club synapses, however, were seen on the operated side.

Thus disruption of the coordination of afferent and target cell differentiation does not prevent correct synapse localization. The data conflict with models which attempt to account for such spatial patterning solely on the basis of spatio-temporal relationships during development.

60.3 ESTABLISHMENT OF CORTICAL TOPOGRAPHY IN HAMSTER PYRAMIDAL TRACT NEURONS DURING DEVELOPMENT. K. Kalil and T. Reh. Department of Anatomy and Neurosciences Training Program, University of Wisconsin, Madison, WI 53706.

Pyramidal tract neurons in the adult hamster are topographically organized in the sensorimotor cortex. Injections of HRP into the dorsal column and trigeminal nuclei, and the cervical, thoracic, and lumbar spinal cord show that retrogradely labeled neurons occupy a continuous band in the deep part of layer V. The origin of the pyramidal tract extends in the A-P direction from the level of the posterior commissure to the very frontal pole and mediolaterally from the midline to the rhinal sulcus to encompass MI, SI, and SII. Within this region the lumbar area is confined to a narrow posteromedial strip of cortex. The representation of the cervical cord lies primarily rostral and lateral to the lumbar area, but some overlap occurs between caudal cervical and rostral lumbar cortex. The trigeminal region lies primarily lateral to cortical areas projecting to the spinal cord.

Experiments were undertaken to determine whether this topography is already present early in development or whether it emerges from an initially overlapping projection. Infant hamsters from 5-21 days of age were injected with lectin conjugated HRP (Sigma) into localized regions of the spinal cord and medulla, sacrificed 24-48 hours later, and the brains processed according to the TMB method of Mesulam. The use of lectin conjugated HRP resulted in very sensitive cortical labeling.

We found that cortical neurons occupying a continuous band in layer V had already established their adult topography as early in development as the pyramidal tract axons had grown out to their targets and could be retrogradely labeled. In contrast to a previous report in the rat (Bates and Killackey, 1980, Neurosci.) we found no change in the extent of the cortical distribution of pyramidal tract neurons during development. Since cortical representations did not overlap significantly, it is unlikely that topography was established by the elimination of axon collaterals. Further, cortical cell migration is ending and neuronal differentiation still proceeding at the earliest ages examined in the present experiments. Thus the establishement of cortical topography is an early developmental event which occurs prior to or during target innervation, and may therefore be independent of synaptogenesis.

60.4 MOTOR INNERVATION OF THE CHICK HINDLIMB AFTER DORSAL-VENTRAL LIMB ROTATIONS. B. Ferguson* (SPON: C. F. Stevens) Biology Department, Yale University, New Haven, CT. 06511.

Specific motoneuron (MN) nuclei in characteristic positions in the rostro-caudal and medio-lateral (ML) planes of the spinal cord innervate particular muscles selectively in the developing chick hindlimb (Landmesser, L. (1978) J. Physiol. 284:371;391). The position of MNs in the spinal cord is related to the embryonic origin but not to the function of the muscle (Landmesser, L. (1978) and Ferguson, B. (1978) Soc. for Neurosci. Abstr. 4:111). All MNs innervating muscles derived from the dorsal (D) muscle mass (MM) are situated laterally, ventral (V) MM situated medially in the spinal cord. In view of the strict correlation between MN position and muscle origin, DV limb bud rotations were done at stages 16-17 (Hamburger and Hamilton), prior to MN outgrowth. Horseradish peroxidase (HRP) backfills of 10 stage 34-37 embryos showed that MN innervation remained specific for both muscles of the thigh and shank regardless of altered limb orientation (Ferguson, B. 1978). Since this result could be due to selective MN outgrowth or random MN outgrowth with death of incorrect connections, motor nuclei innervating D or V shank muscles were localized prior to MN cell death in 9 st. 29-30 embryos. In every case the position of stained MNs in the cord was normal. Thus MN axons can detect and respond to a DV limb rotation to retain specific synaptic connections. Motor innervation of the limb thus cannot occur by a passive mechanism.

Normally, axons destined for D or V shank collect within each spinal nerve before spinal nerves converge. Reconstructions of st. 29 embryos with DV rotated limbs show that HRP stained MNs collect more distally, after the spinal nerves converge to form the sciatic plexus. As in controls, axons destined for V shank collect medially, D shank laterally. Unlike controls, just after or as axons collect, they shift position in the ML plane, to maintain normal orientation in the rotated limb. This delay in grouping of axons in DV rotated limbs could result from conflicting positional cues as axons pass from unaltered to DV rotated tissue. The shift in axon position within the nerve trunk indicates that growing axons actively orient by reference to their environment. The nerve patterns in these embryos suggest strong mechanical effects on nerve branching and spinal nerve convergence. MNs innervating a muscle were always appropriate, but not all cord segments normally innervating a muscle did so in embryos with DV rotated limbs due to some spinal roots not entering normally into the plexus; instead, branching to the tail, body wall, or ending in a neuroma. The nerve branching pattern was abnormal and differed in each embryo due to slight shifts of the limb in anterior-posterior and/or proximal-distal axes.

These experiments show that MNs respond actively to positional cues during outgrowth and can compensate for a DV limb rotation by altering both their position in a nerve trunk and path through the limb. Also, mechanical factors affect the paths of MNs in the limb. (Supported by NIH Grant NS10566 to L. Landmesser.

60.5 ONTOGENETIC CHANGES IN THE TARGETS OF LAYER Va BARREL FIELD NEURONS. H. P. Killackey and G. O. Ivy. Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

We have previously demonstrated (Ivy and Killackey, J.C.N. 195, 1981) that during the first postnatal week, the callosal projection neurons of rat parietal cortex are distributed in continuous bands. In particular, cells in lamina Va of the barrel field area can be densely labeled by contralateral injections of horseradish peroxidase (HRP). However, during the second postnatal week, these cells gradually cease to be labeled after contralateral HRP injections, even though neurons in adjacent "callosal" regions are heavily labeled from the same injections. In the present study, we decided to investigate the fate of these layer Va barrel field neurons which formerly projected across the corpus callosum.

First, in order to determine if these cells die, we used the fluorescent dyes fast blue and true blue as neuronal fate markers. We injected either fast or true blue into one hemisphere of six postnatal day (PND) 6 rats and allowed them to survive until PND 20 to 25, well past the time at which most barrel field callosal neurons "disappear." We find that these former callosal projection neurons do not die, rather they remain labeled in the continuous neonatal pattern. Next, we sought to determine if these neurons project elsewhere. We accomplished this by temporal double labeling. We injected fast blue into the contralateral cortex of four rats at PND 7. Later, at PND 20 to 25, we injected nuclear yellow into the ipsilateral motor cortex and allowed a 4 to 16 hr survival time. This motor region is a known projection area of the barrel field (Akers and Killackey, J.C.N. 181, 1978) and we have confirmed in four rats with HRP that many of the neurons of origin of this projection are located in lamina Va. We find that many neurons in layer Va of the barrel field are double labeled. This suggests that many of the initial callosal projection neurons send axons to the ipsilateral motor cortex. Finally, we sought to determine if these dual projections are present simultaneously in the neonatal rat. In three PND 7 rats, we injected fast blue into the contralateral cortex and nuclear yellow into the ipsilateral motor cortex and allowed a survival time of 4 to 16 hr. Following this procedure, double labeled cells are present in layer Va of the barrel field.

We interpret our results as suggesting that the specific adult patterns of connectivity are achieved through mechanisms which include a selective elimination of collateral processes.

60.6 CORTICOSPINAL AND CORTICOTECTAL NEURONS: MECHANISMS OF ONTOGENETIC CHANGES IN DISTRIBUTION. G. O. Ivy and H. P. Killackey. Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

During the first few postnatal days (PNDs) in the rat, both the corticospinal (CS) and corticotectal (CT) projection neurons have a continuous distribution in lamina Vb throughout most areas of the neocortex. However, after two weeks, each of these types of projection neuron achieves a more discrete distribution. This phenomenon parallels that which we have previously demonstrated for the callosal projection neurons (Ivy and Killackey, J.C.N. 195, 1981). We decided to investigate these distributional changes of CS and CT neurons in more detail utilizing the retrograde transport of fluorescent dyes.

First, we confirmed the adult pattern of CS and CT neurons in single animals using two different dyes (fast blue and nuclear yellow). We find that there are three populations of cells with different areal distributions: one projecting only to the spinal cord (CS), a second only to the tectum (CT) and a third to both places (CST). Next, we sought to determine the neonatal distribution of these projection neurons with double labeling techniques. In the neonate, we do not find areally distinct populations of projection neurons, rather we find all three types (CS, CT and CST) intermixed and widely distributed. Further, there are more double labeled (CST) neurons in the neonate than in the adult. Finally, we sought to determine if the adult distribution is achieved by a process of selective cell death or by a loss of collaterals. We accomplished this by temporal double labeling. We injected fast blue into the spinal cord of three PND 2 rats and later, at PND 15, we injected nuclear yellow into the tecta of these same rats and allowed them to survive for 8 to 24 hr. We find that many of the CS neurons which were retrogradely labeled with fast blue at PND 2 are still present at PND 15 to 25 and are distributed in a pattern similar to that of the neonate. Further, there are double labeled neurons in regions where they would not normally be found in the adult.

We interpret the present findings as indicating that the ontogenetic changes in the distributions of at least CS neurons are not due to selective cell death but, it seems, to a selective loss of collateral processes. The present results support and extend our findings on intracortical projection neurons (Killackey and Ivy, this vol.). Together, these findings suggest that selective process elimination may play an integral role in sculpting neocortical connectivity.

60.7 DISTRIBUTION OF THALAMIC TERMINALS WITHIN NEOCORTICAL FIELDS OF THE REELER MOUSE. V.S. Caviness,Jr. and D.O. Frost E.K. Shriver Center, Waltham, MA 02154 and Yale University, New Haven, Conn 06510

The reeler mutation in mice causes inversion in the relative positions of the principal neocortical neuronal classes. The radial pattern of distribution of thalamocortical axons within the majority of neocortical fields of the mutant is studied by anterograde degeneration (Fink and Heimer) after large dorsal thalamic lesions. In the agranular fields at the lateral margin of the hemisphere terminals are diffusely distributed. In all other fields terminals are concentrated in either two or three tiers. An outer tier, overlaping the polymorphic cell zone, and a middle tier, overlaping the granule and the upper portion of the medium pyramidal cell zones, are present in all fields. Only these two tiers are found in fields where the medium pyramidal cells are distributed uniformly, (e.g.,fields 17,3,1,4 and 6). A third or inner tier is located at the lowest margin of the cortex and is present in fields where medium and small pyramidal cells are concentrated in a "lamina" at this level. (e.g.,fields 18a,41,40 and 3i).

The tiered distribution of thalamocortical terminals presumably reflects the distribution of receptive surfaces for these terminals. The basal dendrites of medium pyramidal cells, normally concentrated in neocortical layers III and IV,are, a principal synaptic target for thalamocortical axons.Observations from Golgi impregnations indicate that this dendritic class is dispersed widely in the lower half of the mutant neocortex in a fashion that does not match the tiered distribution of the axon terminals. Further, at all levels this dendritic class is abnormally intermixed with apical dendritic arbors of medium and small pyramidal cells, classes of dendrites normally not in receipt of large numbers of thalamic axon terminals. Thus terminals of the reeler thalamocortical projection may be concentrated in tiers at the cost of accepting an abnormal mix of dendritic classes as their synaptic partners.

60.8 ANTEROGRADE AND TRANSNEURONAL TRANSPORT OF FLUORESCENT DYES IN THE RAT VISUAL SYSTEM. James N. Davis and Patterson McKinnon*. Neurology Research Laboratory, Duke Univ. Med. Ctr., Durham, NC 27710.

The retrograde transport of fluorescent dyes has proved useful in analyzing neuroanatomical projections. In order to evaluate anterograde transport, we injected 10 µl of 10% either Bisbenzimide (BSBZ), BSBZ and polyornithine, DAPI, Evans blue, or Propidium Iodide into the posterior chamber of the right eye of male 180-200 gram Sprague-Dawley rats. Three days later the brains and eyes were rapidly removed and frozen on dry ice. 16 µ frozen sections were dried on glass slides, cleared with xylene, mounted with Entellan and viewed with a Leitz Dialux microscope equipped for incident fluoroscopy.

Although all dyes could be detected in retinal ganglion cells, only BSBZ and DAPI could be detected in the brain. Of these two dyes BSBZ was present in the contralateral projection from the injected eye, while DAPI was only detected in the ipsilateral optic nerve, chiasm and contralateral optic tract in one animal. BSBZ was detected in cell nuclei in the ipsilateral optic nerve, optic chiasm, contralateral optic tract, contralateral dorsal and ventral optic tract nuclei, the contralateral lateral geniculate nucleus and the stratum griseum superficiale of the contralateral superior coliculus. Cells detected in the nerve, chiasm and tract were glial as judged by the light microscopic appearance and the known lack of neurons in these pathways. The large size and topography of the cells labeled in contralateral terminal areas suggested that these nuclei might be neuronal. Only one third of the animals injected with any dose (3 to 10 µl) of BSBZ demonstrated good labeling regardless of time of survival (12 hours to 7 days). Dose-dependent retinal necrosis and inflammation were present in all animals injected with polyornithine and BSBZ and in over half of the animals with BSBZ alone. Anterograde transport of BSBZ was not able to label the ipsilateral visual projections representing 5-10% of the total retinal projection. Furthermore no labeling was detected of the suprachrasmatic nucleus, another sparse projection. Thus anterograde transport under these conditions was not a sensitive technique for analyzing neuronal connectivity. However the presence of apparent transneuronal transport offers the intriguing potential of identifying target cells for a pathway using flourescent dyes.

61.1 MOTOR INNERVATION OF THE CUTANEOUS TRUNCI MUSCLE. E. Theriault+ and J. Diamond. Dept. of Neuroscience, McMaster Univ., Hamilton, Ont. L8N 3Z5.

The cutaneous trunci muscle (CTM) of the rat is an extensive sheet of skeletal muscle that moves only the skin; it originates on the lateral aspect of the humerus (bilaterally) and inserts into the skin of the back and flanks. The muscle fibres run in a rostro-caudal direction and AChE staining shows end-plates in dorso-ventral rows at right angles to the longitudinal axis of the muscle. The reflex activation of CTM demonstrates local sign (see accompanying Abstract by Nixon et al.). While the sensory nerves that evoke this reflex are segmental, all the motoneurons of the CTM are in a circumscribed region of the spinal cord rostral to the sensory inputs that drive them. The motor axons emerge from the brachial plexus in 3-4 major nerves. Electrophysiological and histochemical (glycogen depletion) studies indicate that each of these nerves innervates a rostro-caudal (longitudinal) column of muscle; however the reflex activation of CTM involves dorso-ventral (transverse) segments of the muscle. This is an intriguing situation, and we are examining how the morphology of the CTM and the pattern of its innervation are designed to allow the segmental expression of the local sign character of its reflex activation. Retrograde horseradish peroxidase (HRP) labelling shows that the motoneuron pool is located in the ventral horns of C6, C7 and C8, and consists (on each side) of approximately 350 somata in a semi-lunar arrangement at the most anterior edge of the gray matter. However there is no obvious organization of the pool that corresponds with the major motor nerves. In preliminary experiments the injection of HRP directly into the muscle mass gave results suggesting that the motoneuron pool may have an intrinsic organization that corresponds to the "dermatomal" (dorso-ventral) pattern of the reflex response. In the salamander (Macintyre and Diamond, 1981, Proc. R. Soc. Lond. 211: 471) and in the rat (Jackson and Diamond, in preparation), the sprouting of intact sensory nerves is often confined to "domains" whose borders are similar to those of the sensory dermatomes. We are studying whether sprouting of remaining CTM motor axons (which is detectable by one week after partial denervation of CTM) is similarly constrained territorially, whether electrical activity in the intact motor nerve influences the rate of sprouting (as it does high-threshold sensory nerves (Nixon et al., Soc. for Neurosci. Abstr. #59.2, 1980)), whether ventral rhizotomies (of C6, 7 or 8) will reveal a possible segmental innervation of CTM, and if there is any selectivity of reinnervation of CTM by regenerating axons.

61.2 LOCAL SIGN IN A CUTANEOUS SKELETAL MUSCLE REFLEX IN THE RAT. B. Nixon, P. Jackson, E. Theriault+ and J. Diamond. Dept. of Neurosci., McMaster Univ., Hamilton, Ont. L8N 3Z5.

"Local sign" in a reflex describes the orienting of an evoked movement to the region where a sensory stimulus is applied. We are studying a mammalian reflex in which local sign can be described quantitatively, the activation in the rat of the cutaneous trunci muscle (CTM), a thin sheet of skeletal muscle that lies just below, and is inserted into, the back and flank skin. A forceps pinch of dorsal skin results in a localized contraction of both the underlying CTM, and that in the corresponding region of skin on the contralateral side; as the forceps pinch is moved rostrally or caudally so do the two foci of the reflex responses move. Low-threshold, (touch and pressure), stimulation is ineffective. The afferent input reaches the spinal cord through the segmental (T4-L3) dorsal cutaneous nerves (DCNs). All of the motor output to CTM however originates from a relatively localized region of the spinal cord at the C6-8 level, rostral to all the DCNs that drive the reflex (see accompanying Abstract by Theriault and Diamond). When we electrically excite a DCN and record from that DCN and the CTM motor nerves we find that two groups of afferent fibres (in the Group III (Aδ) and C categories) can evoke the reflex. In a 250 g rat excitation of a single DCN at threshold for activation of Group III fibres results in a brief EMG with a rostro-caudal spread of 3-4 cm; the location where the EMG has the shortest latency (12-15 msec) is always 1-1.5 cm rostral to the centre of the receptive field of the stimulated nerve. Supra-threshold stimulation causes a more generalized CTM response over several cm; with a large enough stimulus a second brief EMG of longer latency (40-50 msec) is elicited, clearly associated with the appearance of a C fibre potential in the excited DCN. With a just-threshold stimulus this second reflex response is localized in much the same way as the early one. The local sign of the reflex can thus be measured physiologically, and in terms of shortest latency of the responses at "threshold" excitation of two groups of sensory afferents, and is clearly related to a skin region that includes the "sensory dermatome" of the segmental afferent input. We are currently investigating the effects on the development of the local sign character of this polysynaptic reflex of (1) neonatal capsaicin treatment (to reduce or eliminate particularly the C fibres), and (2) changes in the locations and sizes of sensory or motor fields in neonates produced by e.g. nerve sprouting after partial denervation, and by selected nerve redirections and regeneration.

61.3 MOTOR UNITS DIVERSIFY IN SIZE AS SYNAPSE ELIMINATION PROCEEDS IN THE NEONATAL RABBIT SOLEUS MUSCLE. Herman Gordon and David C. Van Essen, Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

During the first two weeks of post-natal development, motor units of the rabbit soleus muscle shrink 4- to 5-fold in average size as redundant synapses are eliminated. We have examined the distribution of motor unit sizes throughout this period in order to address several models of how synapse elimination might occur. Motor unit sizes were estimated by stimulating single motor axons in ventral root filaments and measuring the resultant muscle tensions in an in vitro preparation. In muscles aged 0-5 days postnatal the width of the distribution of motor unit sizes (twice the standard deviation) was .96 times the mean, whereas the width of a similar distribution for muscles aged 12-18 days postnatal was 1.86 times the mean. A few of the older motor units were even comparable in absolute size to the largest units from younger muscles, suggesting that they had escaped extensive loss of synapses. Also, we observed a significant number of extremely small motor units <1/10 of the mean in size.

These results indicate that (1) a uniform down-scaling of motor unit sizes does not occur and (2) small motor units are not at a competitive advantage over large units during synapse elimination. With regard to the latter conclusion it will be important in the future to determine whether the distribution of motor unit sizes in the adult rabbit soleus muscle is as uniform as that reported for the rat, as this could imply a secondary stage of motor unit reorganization.

Interestingly, models in which synapses are lost at random with respect to size of motor units are consistent with an increase in variability. On the other hand, the diversification could also reflect differing abilities of the motor neurons, independent of their sizes, to compete for targets. One possibility involves a recent claim by Miyata and Yoshioka (J. Physiol., 309:631-646, 1980) that only motor neurons from the more rostral of the two spinal roots innervating the rat soleus muscle undergo synapse elimination. Such a situation would indeed result in a diversification of motor unit sizes. However, when we looked in the rabbit soleus we found marked synapse elimination and diversification of motor unit sizes in innervation from both spinal roots, although a slight bias may exist for elimination of synapses from rostral motor neurons.

61.5 DEVELOPMENT OF THE INTERLIMB LOCOMOTOR PROGRAM IN BULLFROG TADPOLES. Donald J. Stehouwer and Paul B. Farel. Dept. Physiol., Sch. Med., Univ. N. Carolina, Chapel Hill, N.C. 27514

Throughout most of larval development, tadpoles use only axial muscles to swim, holding their hindlimbs in an extended position against the tail. By Stage XVII, the hindlimbs participate in swimming either by alternate or by simultaneous thrusts. The present study uses the isolated CNS to examine the development of the neuronal activity underlying this behavioral change and compares this development to the endogenous patterned bursting of primary motoneurons present throughout larval life and known to underlie swimming (Stehouwer and Farel, Brain Res., 1980; 1981).

Primary motoneurons, which are born embryonically, persist only through larval stages, innervate axial musculature and are physiologically and anatomically well-developed, even in young larvae. In contrast, motoneurons innervating the hindlimbs form the lumbar lateral motor column (LMC) and are not born until larval stages. Primary and LMC motoneurons of the larva send their axons to the periphery in different fascicles of the ventral root. These fascicles can be dissected apart and studied separately in electrophysiological experiments.

Prior to Stage XI, axons of LMC motoneurons show a tonic burst discharge coinciding with episodes of patterned burst activity in axons of primary motoneurons. The tonic burst in LMC axons appears to underlie the hindlimb extension maintained during swimming at these stages of development. However, by Stage XIV, patterned burst activity develops in LMC motoneurons and bears a 1:1 frequency relationship with activity in primary motoneurons. In contrast to primary motoneurons, which always burst alternately on the two sides, ventral root axons of LMC motoneurons show both alternating burst activity (the bursts being phase-shifted 180° with respect to bursts in ipsilateral primary motoneurons) and bilaterally synchronous bursts. These two modes of activity can be seen in the same animal and probably underlie the two different behavioral uses of the hindlimbs during swimming.

Because the activity of motoneurons innervating flexors and extensors is combined, the bursts of activity recorded from LMC motoneuron axons in the ventral roots are less discrete than bursts recorded from primary motoneuron axons. More discrete bursting can be recorded from peripheral nerve branches. Bursts recorded from different branches showed varying phase relationships.

These results relate the development of hindlimb use during swimming to changes in motor program activity recorded in vitro and provide a preparation for investigating the cellular events underlying development of motor rhythmicity.

61.6 CHARACTERISTICS OF A CORTICOSPINAL TRACT WITH AN ABBERANT TRAJECTORY. B.S. Bregman and M.E. Goldberger. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA. 19129.

Tactile placing (TP) is spared following neonatal spinal hemisection (L1, dorsal columns spared) but is abolished by adult lesion (Bregman and Goldberger, 1980). The anatomical basis of spared TP is the presence in neonatal operates (NO) only, of corticospinal input from the hemisphere contralateral to the lesion. This was determined by HRP injections into the spinal enlargement in adult animals caudal to the neonatal or adult hemisection, which revealed labeled cells in the contralateral sensorimotor cortex in NOs. (Bregman & Goldgerger, 1981). The spared CST cells are morphologically indistinguishable from normal, and are found in areas 4,3,1,2 and 5 in lamina V. In a representative NO, 746 cells were labeled. 83.4% were located in area 4, motor cortex, with substantially fewer in area 3, (8.4%); area 1-2, (3.7%); and area 5, (4.2%). Most cells are small to medium diameter but the range is 16-72μm. The distribution is unimodal with a mean diameter of 30.9 (± 1.7)μm. This distribution is different from that of published reports of cells of origin of the normal CST (Groos et al. 1978) where there was a larger mean cell diameter (41.9μm) and a bimodal distribution of cells. The unimodal distribution of spared CS neurons suggests that most of the large cells have: 1) died; 2) failed to reach the lumbar enlargement; or 3) failed to reach the adult size. Removal of NO's sensorimotor cortex in adulthood abolishes the spared TP and, when degeneration methods are used, reveals the aberrant CST pathway. In the cervical and thoracic segments the CST occupies a normal position in the dorsolateral funiculus. As the compact bundle of fibers approaches the lesion (L1) it disperses moving through the dorsal horn, medially. Most fibers then occupy the spared dorsal funiculus. Caudal to the lesion fibers remain in the dorsal funiculus, but as the lateral funiculus begins to reappear, degenerating fibers are found there too. They are not confined to the normal dorsolateral position but are dispersed in the lateral funiculus. Results indicate no regeneration of cut axons through the lesion site. Since rubro-, lateral vestibulo- and many reticulo-spinal neurons are unlabeled it appears that the plasticity of the late-developing corticospinal tract is not shared by other descending pathways which are more developed on the day of birth. The absence of brainstem-spinal tracts in the lateral funiculus may permit greater dispersal of the growing corticospinal axons. In spite of its aberrant course, the spared CST mediates sparing of some motor functions.

61.7 PLASTICITY OF INFERIOR OLIVARY AFFERENTS FOLLOWING NEONATAL HEMICEREBELLECTOMY IN RATS. R.S. Swenson* and A.J. Castro. Depts. of Anatomy, National College of Chiropractic, Lombard, IL 60148 & Loyola Univ. Stritch School of Medicine, Maywood, IL 60153

Following neonatal hemicerebellectomy, the pontine gray and the inferior olivary complex (IOC) contralateral to the lesion show a considerable loss of cells. Ipsilateral cortical projections to the reduced pontine gray develop an anomalous crossed projection to the opposite side (Leong and Lund, Brain Res. 62: 218-221). The current study examined whether pathways normally terminating in the missing IOC will similarly remodel to the spared olive after neonatal hemicerebellectomy. Since previous work from this laboratory (Anat. Rec. 199:251A) has shown the rostral mesencephalon and caudal diencephalon to provide the heaviest input to the IOC of the rat, certain nuclei in this region, namely the subparafascicular nucleus and the nucleus of Darkschewitsch, were selected for the current study.

Tritiated leucine (50 uCi/ul) was stereotaxically injected into the subparafascicular and Darkschewitsch nuclei of 23 normal and 14 neonatally hemicerebellectomized rats under pentobarbital anesthesia (40mg/kg). Dense labeling was observed in the ipsilateral descending MLF in both groups. In the normal animal, these fibers distributed primarily ipsilaterally to all olivary subdivisions except the dorsal accessory olive, with a light contralateral distribution. In the neonatally hemicerebellectomized animals, many labeled fibers decussated to the spared side, 300-500u caudal to the rostral pole of the olive. This anomalous decussation terminated in the same olivary subdivisions that normally receive input from the subparafascicular and Darkschewitsch nuclei.

Although the abnormally increased crossed projection may result in a decrease in the normal inputs to the spared IOC, the observed remodeling indicates that the spared IOC receives a substantially more bilateral input from the subparafascicular and and Darkschewitsch nuclei.

61.8 THE POSTNATAL DEVELOPMENT OF CORTICOPONTINE SYSTEMS ARISING FROM SENSORIMOTOR AND VISUAL CORTICES IN THE RAT. C.E. Adams*, G.A. Mihailoff and D.J. Woodward (SPON: R. Galosy). Depts. of Cell Biology and Physiology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

The impetus for this report evolved from a series of ongoing studies in this laboratory concerning the anatomy and physiology of cortico-ponto-cerebellar interactions. The postnatal development of the corticopontine system was studied in Long-Evans hooded rats beginning at postnatal day 1 (birth=day 0) and extending through postnatal day 20. Axonal trajectory and terminal field distribution of corticopontine fibers were visualized through routine autoradiographic procedures following injection of 0.10 μl ^{3}H-Leucine (65-75 μCi/μl; sp. act. 139 Ci/mmole) into sensorimotor (SM) or visual (VIS) cortices and allowing 24-48 hours survival. The developmental patterns in the sensorimotor and visual projections were quite similar and thus the following account represents the general features of this development except where specific variations are noted. Between day 1 and day 3, labeled axons were clearly present within the cerebral peduncle coursing longitudinally through the pontine nuclei ipsilateral to the injection site. Silver grain accumulation suggestive of sparse terminal labeling was also apparent over pontine gray neuropil during this period, being located rostrally after VIS injections and more caudally following SM injections. The period between day 3 and day 10 was characterized by an apparent increase in the density of terminal labeling. In the case of both SM and VIS projections the terminal labeling occupied the general regions of pontine gray where labeling has been observed in the adult although the pattern was clearly more diffuse than that seen in the adult. Between days 10 and 16 there appeared to be a distinct focusing or constriction of terminal projection zones for both SM and VIS systems. The five longitudinally oriented columnar zones which have been shown to receive somatotopically organized SM input in the adult were clearly delineated by postnatal day 16. In addition, the relatively sparse contralateral SM projections observed in the adult were in place by day 13. Thus, by postnatal 16, both SM and VIS corticopontine projection systems had attained their adult configuration. These findings correlate well with a previous Golgi study of postnatal neuronal maturation in the pontine nuclei which demonstrated an emergence and proliferation of dendritic spines between days 10 and 12. Ultrastructural studies in adult rats have shown that corticopontine axons synapse primarily on spines and distal portions of the dendritic tree. 61.9 THE DEVELOPMENT OF SEROTONINERGIC PATHWAYS WITHIN THE SPINAL CORD. STUDIES USING THE NORTH AMERICAN OPOSSUM AS AN EXPERIMENTAL MODEL. T. Cabana*, F. DiTirro, R. Ho and G.F. Martin, (SPON: E. Keith Michal). Dept. of Anatomy, School of Medicine, The Ohio State University, Columbus, Ohio 43210.

Brainstem neurites, some of which transport monoamines, were reported to grow into the opossum's spinal cord very early in development (Martin et al. 1978). In the brainstem, 5HT neurons were identified by the Falk-Hillarp technique within raphe and adjacent areas of the reticular formation as early as 5 days after birth (17 days after conception) (Humbertson and Martin, 1978). In opossums of the same age, injections of horseradish peroxidase into the thoracic cord produced labeling of neurons in comparable areas of the brainstem: the presumptive nuclei pallidus, obscurus and magnus raphae and the adjacent reticular formation.

A series of pouch young opossums was processed by the peroxidase-antiperoxidase technique of Sternberger (1970) for the presence of serotonin (5HT). 5HT-containing varicosities were present within the spinal cord as early as the sixth (6) postnatal day. They were located within dorsolateral areas of the marginal zone where they were most numerous, as well as within ventral, lateral and dorsal regions. Furthermore, there was evidence for growth of 5HT axons into the intermediate (mantle) zone. At cervical and rostral thoracic levels they occur within lateral regions of the dorsal horn, around the central canal and within the ventral horn; at more caudal levels they were restricted mainly to lateral areas of the dorsal horn. Of particular interest is the existence of 5HT-containing cell bodies ventral to the central canal. By postnatal day 13 the distribution of 5HT neurites is comparable at all levels of the cord. They continue to grow into the intermediate zone and by day 22 are numerous within the lateral parts of the dorsal horn (presumptive laminae IV-VII), the intermediolateral cell column, the presumptive lamina X and the ventral horn where they approximate presumed motoneurons by at least day 31. 5HT elements were not found within laminae I and II until after postnatal day 51.

Thus, serotoninergic bulbospinal neurites innervate the presumptive laminae IV-VII of the dorsal horn, as well as autonomic and somatic motoneurons relatively early in development, but laminae I and II considerably later. In developing opossums, unlike the adult, 5HT cell bodies were identified ventral to the central canal. Supported by BNS-80-08675. We thank Dr. Robert Elde for the 5HT antibodies.

61.10 EFFECTS OF NEURAL BLOCKADE ON BEHAVIORAL DEVELOPMENT IN XENOPUS EMBRYOS. Lanny J. Haverkamp and Ronald W. Oppenheim. Neurobiol. Progr., Univ. N. Carolina, Chapel Hill, NC 27514 and Neuroembryol. Lab., Dorthea Dix Hosp., Raleigh, NC 27611.

The dictum that neural function during embryogenesis is without effect on later behavior, and by implication without effect on the development of early neural networks, is largely based upon the experiments of Harrison, Matthews and Detwiler, and Carmichael done in the first third of the century. Since the conclusions drawn from these works are not entirely warranted by the reported data and since a repetition of the studies (Fromme,1941) reached an opposite conclusion, we have conducted a quantitative and more thorough study using the same basic procedures.

Embryos were immersed in solutions of either chloretone ($3x10^{-4}$by wt.) or xylocaine ($1.5x10^{-4}$) prior to the onset of embryonic motility (st.17). These animals were removed from the drug solution at st.35 (about 24 hr. later) by which time normal animals are hatching and will readily swim. Stage-matched normal animals from the same spawning were compared to experimental as well as to control animals immobilized by the drugs for 1/2 hr. at st.35. Spontaneous activity and responses to tactile stimulation were recorded on videotape 1 and 2 hr. after removal from the drug solutions and at st.40 and 44 (about 24 and 48 hr. after removal). In a third experiment, animals injected with 2ug -BTX at st.23 (resulting in 20-28 hr. immobility) were compared to vehicle-injected control animals at st.41 and 44. Spontaneous behavior and response to repeated substrate vibration were recorded for all groups at 10 days of age (st.48). The videotape records were replayed at reduced speed and the animals' movements traced onto a computer graphics tablet. Various parameters of activity were then derived through computer analysis.

The spontaneous and induced activity of the experimental animals was clearly subnormal for the first 2 hr. after removal from the drug, a result attributable to residual drug effect. At st.40 (about 24 hr. after release from the drug) levels of activity and responsiveness of experimental animals were comparable to those of normal embryos. At st.44 and 48, experimental and normal animals were qualitatively and quantitatively indistinguishable.

These experiments confirm the early studies and reconcile them with the disparate findings of Fromme. They also indicate that the long-term effects of functional deprivation in early postnatal systems are without parallel during the earliest stages of neural development. Further experiments involving longer-term immobilization and more precise characterization of behavior during the first 24 hr. after drug release are in progress. Neuroanatomical effects of this functional blockade are also under investigation.

61.11 HABITUATION OF MOTOR ACTIVITY: GENETIC AND DEVELOPMENTAL ASPECTS. Donna G. Atwater*, Janice E. Gellis*, Walter C. Low, Michael M. Myers*, David Whitehorn, and Edith D. Hendley. (SPON: R. Rotundo) Dept. of Physiology and Biophysics, Univ. of Vermont, Burlington, Vermont 05405.

The spontaneously hypertensive rat (SHR) has been shown to exhibit higher levels of motor activity in comparison to their parent strain, the Wistar Kyoto (WKY). In addition to genetic differences, evidence suggests that the level of motor activity in the SHR decreases with age. We now report that genetic and developmental factors also influence the habituation of motor activity in the SHR, WKY, and their progeny, the F2 generation.

The F2 generation was bred using SHR males and WKY females. Seven pairs of SHR/WKY rats were randomly mated to produce an F1 strain. Mean systolic blood pressure (BP) of the SHR males was 190±3 mmHg, BP for the WKY females was 110±1 mmHg, BP for the F1 males was 139±2 mmHq, and the BP for the F1 females was 130±1 mmHg. F1 animals were then randomly bred to produce the F2 generation, with BPs of 151±5 mmHg.

Measurements of motor activity were made with an automated activity cage (30cm X 30cm X 25cm) consisting of four light sources and photodetectors, coupled with a digital counter to monitor the movement of the animals. Each animal was placed in the activity cage for four 15 minute trials during a single day, with the time between each trial ranging from 60 to 75 minutes. The activity of each trial was expressed as a percentage of the total activity of the first trial.

Adult male SHRs (32 weeks) were found not to habituate with repeated trials, whereas adult male WKYs (32 weeks) exhibited a continual decrease in total activity over four trials. Young male SHR, WKY and F2 rats (12 weeks) also exhibited a decrease in total activity over four trials. However, rate of habituation for the F2 rats was significantly greater than that for the SHRs ($p<0.001$, 2 way ANOVA): and the rate of habituation for the WKYs was significantly greater than that of the F2 rats ($p<0.001$, 2 way ANOVA). No difference was observed in the rate of habituation between the adult WKY males (32 weeks) and the young WKY males (12 weeks).

These results suggest that there is a genetic influence in the rate of habituation of motor activity in the comparison of adult SHR and adult WKY males, and in the comparison of young F2, SHR and WKY rats. Furthermore, the inability of adult SHRs to habituate compared with young SHRs is suggestive of developmental alterations in responsiveness of SHRs to their environment.

This work was supported by PHS grant 5429-19-18, HL 24110, and grants from the American Heart Association and its Vermont affiliate.

61.12 MORPHOLOGY AND PHYSIOLOGY OF THE CLAW CLOSER NEURONS IN SNAPPING SHRIMP. John A. Wilson and DeForest Mellon Jr. Department of Biology, University of Virginia, Charlottesville, VA 22901.

Adult Alpheid shrimp possess the unique ability to transform a pincer claw into a snapper claw following the loss of the snapper or section of the nerve trunks to the claw. Changes in both the diameters of the cell bodies and several properties of the muscle have been well documented to occur during transformation (Mellon, in prep. for review); however, the electrical and morphological properties of the neurites and axons have not been studied. We have therefore examined the anatomical and biophysical properties of snapper and pincer closer neurons.

Double barreled microelectrodes were used to impale the axons of the neurons to the claw closer muscle 100-500 uM distal to where the nerve leaves the ganglion. Input resistance was determined by recording the change in voltage in one barrel of the electrode in response to a measured current pulse passed from the other barrel. Our comparison of input resistances for the four snapper closer neurons shows them to have equal input resistances to those of their contralateral homologues, the pincer closer neurons. This finding allowed us to predict that the axonal and dendritic morphology should also be similar for both the snapper and pincer neurons. We therefore intracellularly stained the eight neurons with cobaltous ions, Timm's intensified the ganglia, and examined the resultant preparations. The diameter of the neurites and length of the major branches for pairs of contralaterally homologous neurons are the same.

Furthermore, we have measured the length constant and found that our recording site should be less than 1λ away from the terminations of all the branches even though they change diameter. We therefore found no biophysical or anatomical differences between the axons and neurites of the snapper and pincer closer neurons which can explain their different roles in behavior.

We interpret our findings to support Ritzman's (J comp. physiol. 1974) contention that the neural circuitry for the snapping behavior is present in both the snapper and pincer. As we, like Ritzman, have observed pincers to "snap", the only necessary neural change may be a supplementation of the sensory input. Claw transformation may be therefore primarily a process of growth and specialization of the claw and the closer muscle with the only major change in the closer neurons being the increase in the diameters of their cell bodies. Supported by USPHS Research Grant NS 15006 (to DeF. Mellon).

61.13 MATCHING OF MOTOR AXON AND MUSCLE FIBER PROPERTIES DURING AN ALTERATION IN CRAYFISH MUSCLE FIBER GROWTH. Gregory Lnenicka* and DeForest Mellon, Jr. Dept. of Biology, Univ. of Virginia, Charlottesville, VA, 22901

During growth of the most lateral muscle fibers of the crayfish superficial flexors, the input resistance decreases as predicted by cable theory. Meanwhile, the amplitude of the EJP produced by axon 6 in the most lateral muscle fibers remains constant. Factors contributing to the stability of the EJP amplitude during growth are an increase in the quantal content of release at synaptic sites, and an increase in the current produced by a quantum of transmitter (Lnenicka and Mellon Neurosci. Abstr. 6 497) We wish to determine if these factors can be regulated by the rate of muscle fiber growth.

By surgically reducing muscle fiber tension, we have produced a decrease in muscle fiber growth. This procedure was performed unilaterally on single abdominal segments in small animals (carapace length 1.4 cm.). After two months of growth (carapace length 3.0 cm.), the most lateral muscle fibers on the operated side had increased their radius by 2.3x while on the control side the radius increased by 4.4x. If the muscle fiber electrical constants are not different on the two sides, cable theory predicts the input resistance to be 2.7x greater on the operated side. However, this predicted difference in the input resistance was not reflected in the EJP amplitude. Preliminary results show no significant difference in EJP amplitude between the two sides.

Experiments are in progress to determine how the normal EJP amplitude is maintained during abnormally slow muscle fiber growth. Possible explanations currently being explored include the following: a change in the muscle fiber electrical constants, resulting in an abnormally low input resistance for the experimental muscle fibers; the quantal content of release and/or the current produced by a quantum of transmitter increases at a less than normal rate. (Supported by a grant from the Muscular Dystrophy Association.)

62.1 β-ADRENERGIC RECEPTORS IN RAT BRAIN MICROVESSELS: CHANGES DURING AGING. M. Trabucchi, H. Kobayashi+, P.F. Spano+ Depts. Pharmacol. and Pharmacognosy, Univ. of Padua and Milan , Italy.

Recent observations suggest a possible neurogenic control of cerebral microcirculation mediated by a number of receptors for neurotransmitters located on brain microvessels. This system may be relevant in the control of vascular function during aging. We characterized the β-adrenergic receptors located on brain microvessels using (^{125}I)-iodohydroxybenzylpindolol (IHYP) as a radioligand. The brain microvessels have been prepared using albumine flotation and glass beads filtration technique from gray matter of rat cortices. The preparation, predominantly composed of capillaries and free from neural and glial elements, was subjected to radioreceptor assay. The binding is linear with protein concentration up to at least 80 μg per tube. It was saturated at 200 pM of IHYP concentration. The K_D value calculated by Scatchard analysis was 69 ± 8 pM. The maximum bound was 108 ± 6 fmol/mg protein. The binding reached the equilibrium within 30 min and was dissociated by addition of (-)-propranolol. The inhibitory effects of isomers of propranolol and isoproterenol on this binding showed that (-)-isomers were two orders of magnitude more potent than the (+)-isomers.

The binding was inhibited by isoproterenol, epinephrine and norepinephrine with Ki values of 2×10^{-7}M, 2.5×10^{-6}M and 1.2×10^{-5}M, respectively. A modified Scatchard analysis of the inhibitory effects of practolol, metoprolol and zinterol on IHYP binding shows that the proportion of β_2-receptors was about 80% of total β-adrenergic receptor population. The scatchard analysis of the IHYP binding to microvessels prepared from cortices of aged (24 months) and mature (3 months) rats shows that the density of receptor sites is reduced by aging (B_{max}: 84 ± 4 fmol/mg prot and 106 ± 5 fmol/mg prot respectively) without changes in the affinity constant (K_D: 75 ± 9 pM and 71 ± 7 pM, respectively). This result suggests that the changes in brain circulation observed during aging may be at least partially due to a reduction of β-adrenergic control of cerebral microvessels. Moreover these functional alterations are in the same line with the changes observed during aging at neuronal level.

62.2 AGED DEGENERATING PATHWAYS ARE REFRACTORY TO AXONAL PENETRATION. Michel Paré* and R. Levine. Dept. of Biology, McGill University, Montréal, Québec, Canada H3A 1B1

We have examined the effect of aging of degenerating pathways in the brain of the goldfish on their suitability as conduits for regenerating axons. Our experiments were performed as follows. We removed the right eye of 25 goldfish. These animals were then allowed to recover from surgery for times varying from 2 to 12 weeks, after which the right tectal lobe was removed. In some animals the eye and the tectal lobe were removed at the same time. In all cases animals were allowed to survive for varying lengths of time following tectal lobe removal and then sacrificed 24 hrs. after intraocular injection of 30 μCi ^{3}H-proline. The brains of these animals were then processed for autoradiography to allow us to visualize the trajectories of optic fibers which were growing through the brain following the removal of their target structure (the tectum).

We found that if the eye and the tectal lobe were removed at the same time, optic fibers from the remaining eye grew to the remaining tectal lobe through, among other pathways (Lo and Levine, 1981, Br. Res. 210: 61), the transverse commissure and the denervated optic tract of the opposite side. The penetration of the degenerating optic tract by large numbers of fascicles was seen in animals which had survived as long as 4 weeks after enucleation before undergoing tectal lobe removal. On the other hand, in animals which survived for 8 or 12 weeks after enucleation, the majority of the regenerating optic fibers appeared to grow preferentially through the transverse commissure. While these animals did show some invasion of the optic tract it was always far more sparse than the earliest post enucleation animals and often did not fill the entire tract cross section.

On the basis of these observations we conclude that the character of degenerating pathways may change over time in such a fashion as to make those pathways relatively refractory to invasion by regenerating axons.

62.3 THE EFFECT OF AGE ON BRAIN CAPILLARIES. P. Hicks, C. Rolsten*, D. Brizzee* and T. Samorajski. Texas Research Institute of Mental Sciences, Houston, Texas 77030.

The effect of age on brain capillaries has been described in human, primate and rat cortex (Hunziker et al, J. Gerontol., 1979; Burns et al, J. Gerontol., 1979; Knox and Oliviera, Acta Neurpathol., 1980). However, there are no reports of the effect of age on capillaries from non-cortical brain regions. Therefore, we have measured several capillary components from the rat frontal cortex (FC) and hippocampal CA 1 region (HC) to determine if regional differences occur in capillary morphology with aging.

Male Fischer 344 rats 3-, 9- and 24-months old were prepared for electron microscopy following intracardiac perfusion. Capillary measurements were made with a planimeter from photomicrographs enlarged to 30,000X. Corrections were made for differences in photographic enlargement.

There is an age-related increase (30%) in the cross-sectional areas of the basement membrane of both the FC and HC. There are no age-related differences in the cross-sectional areas of the capillary endothelial cells in either brain region. However, the cross-sectional area of the capillary lumen increases (39%) with age in the FC and decreases (11%) with age in the HC. The pericyte cross-sectional area is greater in the HC than in the FC.

These results indicate that age-related changes occur in both the FC and the HC capillaries, but the changes may differ between brain regions.

Age	N		Basement Membrane	Endothelial Cell	Lumen	Pericyte
3	4	FC	0.69	1.96	11.5	0.50
		HC	0.71	2.00	14.3	0.84
9	3	FC	0.72	2.03	13.6*	0.53
		HC	0.72	1.91	14.5	0.56*
24	5	FC	0.90**	2.08	16.0**	0.53
		HC	0.90**	2.13	12.9*	0.76

Capillary cross-sectional areas are given in μ^2. N= the total number of rats used at each age. A minimum of 10 capillary profiles were measured from each rat. *p<.05 and **p<.01 when compared to the 3- or 9-month old rats.

62.4 MORPHOMETRY OF AGING NEURONAL NUCLEI. MB. T. Buschmann, J. S. Geoffroy* and A. LaVelle. Dept. Anat. & Gen. Nursing, Coll. Med. & Coll. Nursing, Univ. Illinois Med. Ctr., Chicago, IL 60612.

Changes in the diameters, areas and perimeters of nuclei and changes in the nuclear envelope (NE) form factor which indicates the spherical or nonspherical character of the nucleus, and in nuclear envelope invagination (NEI) length and number of neocortical neurons were studied in selected ages from the lifespan of the golden hamster. The ages ranged from newborn to 700 days.

The animals were anesthetized, perfusion fixed and epoxy embeded via standard EM procedures. Thick sections (1 μm) were stained with toluidine blue. The slides were coded by an uninvolved individual so that the data were collected blindly. Camera lucida drawings were made of all layer V pyramidal nuclei in one section from each slide that exhibited apical dendrites and ample cytoplasm. The measurements of the area and the perimeter of each profile were obtained by computer-assisted image analysis (Bio-Quant, R&M Biometrics, Nashville, TN). From these measurements a form factor was calculated ($A4\pi/p^2$). Diameters and numbers of NEI were measured and counted and the boundary density (NE length per unit nuclear area) was calculated from the direct measurements of areas and perimeters (B/A = perimeter area) and were also determined by classical point counting stereology ($B_A = \frac{\pi}{2} \times \frac{Ii}{P_T \times 2d}$).

The data indicate that nuclear diameter, area, and perimeter increased with age and peaked at 15 days. After 15 days, the diameter and area decreased significantly although the perimeter remained constant due to the associated increase in nuclear envelope invaginations. Also because of these invaginations, the boundary density increased with age and peaked at 500 days. Correlative to this, the form factor calculation indicated that the spherical configuration of the nucleus at 5 days changed to a nonspherical form with age.

The increases in diameter, area, and perimeter are indicative of the rapid growth phase that occurs until 15 days. The subsequent constancy of nuclear perimeter and the decrease in nuclear diameter and area during maturation and aging, correlates with the associated increase in the nuclear boundary density which is due to the increase in the length and number of peripheral NEI which in turn is reflected in the form factor. Therefore, these results are verified by both the indirect stereology and the direct image analysis.

In conclusion, nuclear envelope invaginations, which begin to appear during the stages of rapid perikaryal growth, peak in number and dimensions at maturity and persist during subsequent aging. This is indicative of a relatively high level of continued synthetic activity.

62.5 SPIKE PROPAGATION IN DENDRITES OF YOUNG AND OLD HIPPOCAMPAL GRANULE CELLS. C.A. Barnes and B.L. McNaughton. Inst. of Neurophysiology, University of Oslo, Norway.

Both anatomical and neurophysiological experiments have shown a profound deafferentation of hippocampal granule cells in senescent rats. This loss (about 30%) of excitatory input to the granule cells could potentially be disruptive to information processing in this system unless it was compensated for in some way. Two forms of such compensatory change have, in fact been found: 1) a lowering of the discharge threshold and a decrease in the latency of the orthodromically elicited action potential in old granule cells; 2) stronger synaptic responses in the old animals (Barnes & McNaughton, J. Physiol. 309, 473-485, 1981).

One possible mechanism for the decrease in the threshold of the granule cells is that the area of electrical excitability could expand to include more of the proximal dendritic tree during senescence. Such an expansion would explain both the age differences in threshold and action potential latency. The experiment reported here was designed to test this hypothesis using current source density analysis to compare young and old rat fascia dentata.

Hippocampal slices taken from 13 young (8 mo) and 13 old (29 mo) rats were prepared using standard techniques. A fixed stimulating electrode was placed in the mossy fibres to antidromically activate the granule cells, and a movable recording pipette was placed 50 μm from the bottom of the cell body layer. Constant intensity stimuli were delivered and the corresponding field potential responses were recorded at 10 μm intervals along a line parallel to the dendritic axis. Current source densitites were computed by taking the second derivatives of potential versus spatial position.

There were no detectable differences between age groups in either the distance travelled by the peak inward current in the proximal dendritic tree, or in the current propagation velocity. The hypothesis of a shift in the action potential trigger zone predicted that the antidromic spike should have propagated further up the dendritic tree in old granule cells, on the assumption that the inward current was of a classical Hodgkin-Huxley type. It remains possible that there exists some slowly activated voltage-sensitive inward current which is responsible for spike initiation following synaptic (orthodromic) activation. This possibility is currently under investigation.

62.6 UPTAKE AND STIMULATED RELEASE OF [^{3}H]-DOPAMINE FROM STRIATAL SLICES OF YOUNG, MATURE AND SENESCENT RATS. John R. Whitaker*, Jeffrey M. Thompson and J.A. Joseph. Laboratories of Behavioral Sciences and Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore, MD 21224.

In previous experiments it was determined that aged rats, unilaterally lesioned in the substantia nigra, exhibit decreased rotational behavior following amphetamine administration (Joseph et al., J. Gerontology, 33, 643-649, 1978; Joseph et al., Neurobiol. Aging, 1, 119-125, 1980). These experiments and others suggested that these deficits may be the result of decreases in DA turnover, loss of DA receptors or reduced numbers of striatal neurons during senescence. The present experiments were carried out to determine whether age-related changes in presynaptic events occur in the striatum and might account for these rotational behavior deficits. Thus, we determined [^{3}H]-DA uptake and release following KCl or amphetamine administration in striatal slices from young (7 mos), mature (12 mos) and senescent (24 mos) Wistar rats.

Striatal slices were incubated in [^{3}H]-DA. Some slices were collected by vacuum filtration after increasing incubation times to determine [^{3}H]-DA uptake. Other slices were washed and placed in a multi-channel perfusion system and washed for 30 min. Timed perfusate samples were then collected before and during addition of KCl (80 mM) or amphetamine (10^{-6} - 10^{-2}M). The amount of [^{3}H]-DA released in each sample was determined.

No significant age-related differences in release were detected when the slices were stimulated by 80 mM KCl (Peak release as a percent of total radioactivty: 24.1%, 7 mo; 23.2%, 12 mo; 21.9%, 24 mo; $t(12) < 1$; $p > 0.05$). While there was a dose-dependent stimulation of release by amphetamine ($F(7,21) = 11.96$, $p < 0.001$; 3 (age) by 4 (dose) analysis of variance), no age-related differences in amphetamine stimulation were seen ($F(2,21) < 1$; $p > 0.05$). Uptake was maximum in all age groups by 15 min and no significant differences were seen as a function of age and time ($F(6,45) = 1.66$; $p > 0.05$).

These results indicate that the age-related motor-behavioral deficits measured by the rotational model are not produced by changes in striatal DA uptake and release, but may be more closely associated with other synaptic alterations, such as loss of striatal DA receptors which occur during senescence.

62.7 DECREASED SPROUTING AND DEGENERATION OF NERVE TERMINALS OF ACTIVE MUSCLES IN AGED RATS. J.L. Rosenheimer and D.O. Smith. Dept. of Physiology, University of Wisconsin, Madison, WI 53706.

The architecture of the end-plate region in the phrenic nerve-diaphragm muscle was examined in aged (28 mos) and control (10 mos) rats, upon cholinesterase staining of the end-plate and silver-gold impregnation of the axon and its terminal arborization. The average number of nerve terminals per end plate was 18 and 13 in the aged and the control animals, respectively; this difference is significant statistically. The number of motor axon collaterals, from which terminal branches emanate, projecting into the end plates, was not significantly different for the two age groups. Thus the increased number of terminal endings in the older animals is due to more frequent branching within the end-plate region. In 1.7% and 1.6% of the muscle fibers in the control and the aged rats, respectively, there was a second end plate; more than two end plates were never observed. There was no significant difference in the size of the end-plate region of the two age groups.

In 23% and 43% of the end plates of aged and control rats, respectively, there were signs of terminal degeneration. There were indications of sprouting in 10% and 41% of the end plates of the aged and the control animals, respectively. Among the aged rats, there were no cases in which both sprouting and degeneration were seen in the same end plate; both phenomena were observed in 11% of the young animals. Thus, degeneration and new growth appear to be independent processes which occur less frequently in aged rats.

Synaptic sites in animals of both age groups were examined in electron micrographs. The nerve terminals of the aged rats contained 1.38 times as many synaptic vesicles as those of the control rats; the average diameters of the synaptic vesicles in the control and the aged rats were 50 and 49 nm, respectively.

It is concluded that in nerve terminals of aged rats, there is a decreased rate of membrane degeneration and growth. In this preparation, the rate of degeneration declines more rapidly; therefore, the imbalance between these two processes results in greater numbers of nerve terminals and synaptic vesicles, although they may not all be functional.

62.8 NEUROGENESIS IN THE DENTATE GYRUS OF THE 8 AND 11 MONTH OLD RAT. M.S. Kaplan* and D.H. Bell* (SPON: E. Reyes). Department of Anatomy, University of New Mexico School of Medicine, Albuquerque, NM 87131

Only a few investigators have attempted to study cell proliferation in the adult brain with radioautography after H^3-thymidine injection. The infrequent occurrence of labeled cells in the adult precludes any reasonable chance of observing labeled neurons with EM radioautography. To date we have identified apparent labeled neurons, with the light microscope, in the dentate gyrus granular layer of rats injected with H^3-thymidine at 8 and 11 months after birth. In the next few months these labeled granular neurons will be quantified then re-embedded and thin sectioned for subsequent electron microscopic identification.

Male rats, 8 and 11 months after birth, were given single intraventricular injections of H^3-thymidine (5uCi/injection), and after a 19 or 27 day survival the animals were perfused with a mixture of aldehydes. One micrometer plastic sections of dentate gyrus were cut, dipped in Kodak NTB-3 emulsion, and exposed at 4°C. In the resulting radioautographs, a cell was considered labeled if it had 4-5 grains over the nucleus, a value considerably above background. Although labeled cells in these mid-aged rats have not yet been re-embedded or examined in the electron micorscope (April 1981), they appear as typical labeled granular neurons previously described in the 3 month old rat (Science, 197: 1092-1094, 1977).

The population dynamics of granular neurons in animals aged 3, 8 and 11 months after birth are now being evaluated. Our preliminary data indicates that the labeling index of dentate gyrus granular neurons does not change much between these ages. If it is assumed that the S phase for the precursors of granular neurons is approximately 8 hours, then for every successive 8-hour period sample another equal percentage of labeled cells would be observed. Assuming steady additions of granule cells from 3 to 11 months these newly formed cells could result in considerable growth or turnover and implies a considerable plasticity in the hippocampus.

WITHDRAWN

62.10 MAPPING OF NEOSTRIATAL TRANSMITTER SYSTEMS AS A FUNCTION OF AGING. R. Strong*, T. Samorajski, and Z. Gottesfeld. (Spon: J. Schoolar). Texas Res. Inst. of Ment. Sci. and The Univ. of Tex. Med. Sch., Houston, Texas 77030

Functional imbalance of striatal cholinergic and dopaminergic neurotransmitter systems has been reported for age-related neurodegenerative disorders. Thus choline acetyltransferase (ChAT) and glutamic acid decarboxylase (GAD) have been found to be lowered in Huntington's disease, while dopamine (DA) is decreased in Parkinson's disease.

The functional association of dopaminergic and cholinergic neostriatal neuronal elements has been demonstrated pharmacologically, anatomically and electrophysiologically, in experimental animals. In addition, these neurotransmitter systems are reported to have a heterogeneous distribution within the striatum, suggesting differential functional organization for this region.

Since age related deficits of both pre- and post-synaptic dopaminergic and cholinergic neurochemical markers have been report ed for whole neostriatum of rats (Strong, et al., 1980, Finch, et al., 1980, Timiras, et al., 1980) it was of interest to compare the distribution of these neurotransmitter systems within the striatum and their alteration with age.

A total of 18 male Sprague-Dawley rats[1] age 6, 16, and 26 months were used in this study. Animals were decapitated, their brain was removed and frozen in dry ice, then cut coronally (300 μm thick) in a cryostat at -8°C. Tissue punches were removed from the central and lateral portions of 11 consecutive striatal sections and assayed for ChAT (Fonnum, 1976) and GAD (Fonnum, et al., 1970). For catecholamines, punches were removed adjacent to the central sites taken for ChAT and GAD and then assayed according to Coyle and Henry (1973). ChAT activity and DA levels manifested a heterogeneous pattern and, in general, were 50% higher rostrally than caudally and ChAT was higher laterally than medially. GAD and norepinephrine (NE) were more homogeneously distributed. Significant age-related changes in ChAT and DA were also manifested in a heterogeneous manner. There were extensive deficits (30-50%) of DA and ChAT in the rostral and caudal parts of the striatum but no significant changes in the other regions. There were no age-related changes in GAD while NE showed a lesser decrease compared to DA or ChAT.

The present data, especially the age related changes, is consistent with previous reports of, and further reiterates, the close synaptic association between the cholinergic and dopaminergic systems in the neostriatum.

62.11 INTRASTRIATAL INJECTIONS OF DOPAMINE-ACTIVE AGENTS AND AGE-RELATED ALTERATIONS IN BEHAVIOR IN THE RODENT. J. A. Joseph, J. R. Whitaker* and J. F. Cubells, Jr. Lab. of Behavioral Sciences, Gerontology Res. Ctr., National Inst. on Aging, NIH, Baltimore, MD 21224.

Age-related differences in sniffing, grooming and rotational behavior following intrastriatal injections of amphetamine (AMP) or dopamine (DA) were examined in young (N=7) and old (N=7) male and female (N=4 and 3 respectively) Wistar rats, unilaterally lesioned in the left substantia nigra with 6-hydroxydopamine. After recovery from surgery (1 week) all animals were injected (i.p.) with AMP (2 mg/kg) and rotations counted for 10 minutes. All animals had to exhibit at least 25 rotations or they were not used. One week after screening, several successive doses of AMP dissolved in .5 ul D_2O (pH adjusted to 5.5 to 6.0 using $NaHCO_3$ and 1 M HCl) were administered on alternate days (1 dose/day) through cannulae chronically implanted into the right (intact) striata. After this regimen DA, dissolved in .5 ul N_2 bubbled D_2O and pH adjusted to 5.5-6.0, was administered in a regimen similar to that for AMP. Vehicle injections were comprised of pH adjusted D_2O of same volume. Prior (1 1/2 hrs) to the DA injections, the animals were pretreated with 50 mg/kg of nialamide administered i.p. The number of rotations, sniffs, and grooms were assessed by observation. Rotations were recorded as a ratio of left over right turns (L/R). Results for the L/R index are illustrated in the table and show that old animals exhibited lowered L/R indices to both AMP and DA as the drug doses were increased [analysis of variance, AMP, age x dose, $F(4,48)=2.95$ $p<.05$; DA, age x dose, $F(3,33)=3.61$ $p<.05$]. These results indicate that neither the application of an indirect (AMP) nor a direct (DA) dopamine agonist will increase rotation in these senescent animals despite the use of a wide range of doses. It is suggested that the loss of striatal DA receptors previously found in the senescent animal by several laboratories contributes to decrements seen in this behavior. Neither AMP nor DA produced increases in sniffing or grooming behavior as a function of drug dose. Thus, age differences in these behaviors could not be determined.

62.12 INFLUENCE OF AGE AND ENDOGENEOUS NOREPINEPHRINE ON OXIDATIVE METABOLIC RESPONSES TO ELECTRICAL STIMULATION OF RAT CEREBRAL CORTEX IN SITU. A.L. Sylvia, S.I. Harik, J.C. LaManna and M. Rosenthal. Dept. Physiology, Duke Univ. Med. Ctr., Durham, N.C. 27710 & Dept. Neurology, Univ. Miami Sch. Med., Miami, FL 33101

In this study, we test two hypothesis: (1) that there are age-related differences in the ability of the cerebral oxidative metabolic system to respond to stimulus-provoked increases in energy demand; and (2) that such differences may be related to changes in the cerebral concentration of norepinephrine (NE) with age. The latter hypothesis evolved from the observation that the rate of re-reduction of Cyt. a,a_3 following oxidation by stimulation was slowed in cerebral hemispheres of mature rats depleted of NE by ipsilateral 6-hydroxydopamine lesion of the nucleus locus ceruleus (LC) (Br. Res. 204, 87, 1981). Cyt. a,a_3 redox responses to stimulation were monitored by reflection spectrophotometry in young mature (6 mo.) and aged rats (28 mo.) two weeks after unilateral LC lesion or sham operation. In control (C), sham operated (S) and lesioned (LC) hemispheres of young mature and aged animals, cortical stimulation invariably produced transient oxidations of Cyt. a,a_3. While the rates of the oxidation and re-reduction responses were consistently rapid and similar in control and sham operated hemispheres of young mature animals, they were significantly and uniformly slower in (C),(S), and (LC) hemispheres of aged rats. In young mature animals, the stimulus evoked Cyt. a,a_3 cortical responses recorded in LC lesioned hemispheres were also significantly slower than those recorded in (C) and (S) contralateral hemispheres. The temporal kinetics of the responses resembled those observed in all hemispheres of aged rats. There were no significant age-related differences in cortical NE concentrations in either control or sham operated hemispheres. However, the cortical NE content in LC lesioned hemispheres was decreased by approximately 90% compared to (C) and (S) contralateral hemispheres in both age groups studied. These data demonstrate that cerebral oxidative metabolic capabilities do vary with age. The observation that stimulus evoked cortical responses in NE-depleted hemispheres of young mature rats closely resemble those normally obtained in aged animals, suggest the involvement of noradrenergic mechanisms responsible for the age-related changes in metabolic responsivity to direct cortical stimulation. However, the finding that NE-depletion did not additionally alter the Cyt. a,a_3 metabolic responses normally obtained in old rats, implies that these metabolic changes are independent of NE concentration.

62.13 CHANGES IN NEUROTRANSMITTER SYNTHETIC ENZYMES AS A FUNCTION OF GENOTYPE AND AGE IN MICE. S.B. Waller*, D.K. Ingram*, M.A. Reynolds* and E.D. London. Laboratories of Neurosciences and Behavioral Sciences, National Institute on Aging, Gerontology Research Center, Baltimore City Hospitals, Baltimore, Maryland 21224.

Effects of genotype and age on neurotransmitter synthetic enzymes (choline acetyltransferase, CAT; glutamic acid decarboxylase, GAD; and tyrosine hydroxylase, TH) were studied in C57BL/6J and A/J mice that were 4, 18 or 24 months (mo) of age. Enzyme activities were assayed radiometrically in the frontoparietal cortex, striatum, hippocampus and cerebellum. All differences noted were significant at $p < 0.05$.

Genotype. TH activity was higher in the C57BL/6J strain compared to the A/J strain in all brain regions of all age groups except the striatum at 4 mo, hippocampus at 18 mo and cortex at 24 mo where there were no strain-related differences.

CAT activity was higher in the C57BL/6J mice except at 24 mo, when cerebellar activity was greater in the A/J strain.

GAD activity of A/J mice was higher than in C57BL/6J mice in the cortex and striatum at 4 mo and the cortex at 18 mo. In contrast, GAD activity was lower in the cerebellum and striatum of 24 mo old A/J mice than in C57BL/6J mice.

Age. Striatal TH of both strains was not affected by age. TH activity increased in A/J mice between 4 and 18 mo in the cortex, cerebellum and hippocampus and between 4 and 24 mo in the cortex and cerebellum. TH in C57BL/6J mice increased between 4 and 18 mo in the cortex and cerebellum and between 4 and 24 mo in the cerebellum, but declined in the cortex between 18 and 24 mo.

GAD activity declined between 4 and 24 mo in the A/J striatum and C57BL/6J cortex, and increased between 18 and 24 mo in the AJ hippocampus and between 4 and 24 mo and 18 and 24 mo in both striatum and hippocampus of C57BL/6J mice.

Between 4 and 18 mo and 4 and 24 mo, CAT activity increased in the cortex of both strains, the A/J cerebellum, and the C57BL/6J hippocampus. Between 18 and 24 mo, CAT activity was elevated in the A/J cerebellum and the hippocampus of both strains. Striatal CAT increased in C57BL/6J mice between 4 and 24 mo.

In conclusion, age-associated alterations in activities of neurotransmitter synthetic enzymes vary with the genetic strain under investigation. Increases in enzyme activity may represent age-related changes in affinities for substrates or cofactors. These findings underscore the importance of parallel studies using several inbred strains or hybrid strains in aging research.

62.14 NEURON NUMBER DOES NOT DECLINE IN CORTICAL BARRELS OF AGING MICE. C.A. Curcio* (SPONS: P.D. Coleman) Dept. of Anatomy, Univ. of Rochester Sch. of Med. and Dent., Rochester, N.Y. 14642

Decline in neuron density is an important feature of the aging human cortex. To determine if there is absolute loss of cortical neurons with age one needs to know both cell density and tissue volume. The barrel is a morphological and functional unit of rodent somatosensory cortex whose discrete nature makes it a suitable system in which to address this question in an experimental animal. Cells have been counted in one identified barrel, C3, in male C57Bl/6 mice aged 4, 12, 22, 26, 30, and 33 months.

Neuron density in C3 was determined from a computer model of the barrel (Curcio and Sloan, J. Neurosci. Meth., in press) based on 3-dimensional reconstruction of 3 1-micron sections cut in a plane tangential to the pial surface. Barrel volume was determined from the cross-sectional area, also measured from tangential sections, and the height of layer IV, measured from frontal sections through the opposite hemisphere. Data were collected blind with respect to age and were evaluated with ANOVA statistical methods.

The number of neurons in C3 did not decline with age ($F = 1.12$, $p > 0.25$). The mean number for all 25 barrels studied was 1698 (s.d. 201). Barrel volume also showed no age-related trends.

Supported by N.I.H. training grant GM07136 to C.A.C. and N.I.H. grant AG1121 to P.D. Coleman. Animals obtained from N.I.A. colony.

62.15 STRIATAL AND CEREBRAL CORTICAL CALMODULIN IN AGED C57BL/6J MICE. J.A. SEVERSON AND C.E. FINCH. DEPT. OF PSYCHIATRY AND DEPT. OF PHYSIOLOGY AND BIOPHYSICS, USC SCHOOL OF MEDICINE, LOS ANGELES, CA 90033.

The nigro-striatal dopaminergic (DA) pathway exhibits age-related declines in several neurochemical parameters, including losses in DA receptor binding sites and DA-sensitive adenylate cyclase. The multifunctional calcium-binding protein, calmodulin (CaM), is of interest with age due to its putative role in coupling the DA receptor to striatal adenylate cyclase and because CaM varies directly with DA receptor number and DA-sensitive adenylate cyclase activity in young rodents.

Striata and cerebral cortices from male C57BL/6J mice, 3, 9 and 28 mo., were analyzed for CaM by phosphodiesterase activation assay. Striatal CaM levels increased 50% between 3 and 28 mo., but cortical CaM was unchanged. Striatal CaM levels increased with age in soluble and particulate fractions. However, in both regions, the percent of CaM in the soluble and particulate fractions was constant with age. In all ages, on a percent basis, striatal CaM in the particulate fraction was increased equally by the presence of Ca^{2+} during homogenization and was decreased equally by EGTA.

The data indicate that striatal CaM and DA receptor binding sites are regulated similarly with age. Possibly, mechanisms that maintain striatal DA receptors at a level found in young mice deteriorate more rapidlywith age. The ubiquity and multifunctionality of CaM complicates the interpretation of these data. However, the interaction of CaM with the DA receptor-adenylate cyclase complex suggests that CaM may increase to facilitate DA receptor coupling with adenylate cyclase as compensation for fewer DA receptors during aging.

62.16 REGIONAL DISTRIBUTION OF BRAIN PHOSPHATASE ACTIVITY IN AGING RAT. J.L. Fuchs, D.A. Deane*, M.L. Hendrix*, and G.S. Lynch. Dept. of Psychobiology, Univ. of Calif., Irvine, Calif. 92717

A growing body of evidence points to an important association of phosphatases with glial and vascular elements in the brain. In light of studies showing age-related changes in both astrocytes and blood vessels, it becomes of interest to investigate possible effects of aging on the distribution of brain phosphatase activity. Accordingly, we have used histochemical techniques to identify 5'-nucleotidase, alkaline phosphatase, ATPase, and acid phosphatase throughout the brain of young adult (3-4 mo), middle-aged (12-14 mo), and old (24-31 mo) rats. The most marked changes were found in 5'-nucleotidase and alkaline phosphatase.

5'-Nucleotidase activity in rat brain increased substantially during the period from young adulthood to middle age, with little change thereafter. The greatest increases were seen in regions of forebrain, diencephalon and midbrain. Radioassay of brain homogenates revealed 63% more 5'-nucleotidase activity per mg protein in the forebrain of middle-aged and old rats than in the young adults. 5'-Nucleotidase activity in most of the 7 other body organs assayed showed a slight decline with age. Thus the increase is not generally characteristic of aging body tissues, and probably represents aging processes particular to brain.

In brain sections stained for alkaline phosphatase activity, young adult rats appear to have a considerably finer network of blood vessels; the older groups show fewer, but in some instances, thicker vessels. The differences probably reflect changes in enzyme activity of vascular endothelium, and were not seen in unstained sections from brains perfused with India ink. The alkaline phosphatase data suggest functional changes in brain vasculature, a findin, which would be compatable with reports of structural aging in blood vessels.

These experiments indicate that aging has a selective effect on phosphatases which have been linked to brain elements showing structural changes during aging. Research is now in progress to test whether changes in these enzyme activities can be used to predict the severity of structural alterations in the aging brain.

Supported by NIA Grant (AG00538).

62.17 AGING REDUCES ACETYLCHOLINE AND CARBOHYDRATE METABOLISM *IN VITRO*
G.E. Gibson and C.Peterson* (SPON: F.Plum)
Cornell University Medical College, Burke Rehabilitation Center White Plains, New York 10605

In vivo, the synthesis of whole brain acetylcholine (ACh) declines by 45 and 65% in 10 and 30 month old mice compared to 3 month old mice, respectively. We now report that this decrease is associated with an age-related reduction in oxidative metabolism and an impaired release of ACh.

Age-related changes in carbohydrate metabolism were assessed with brain slices from two strains of mice (C57Bl and Balb/c). $^{14}CO_2$ production was measured from labelled substrates: [U-^{14}C]-glucose (an indicator of overall glucose oxidation), [3,4-^{14}C]-glucose and [1-^{14}C]pyruvate (indices of flux through pyruvate dehydrogenase with low or high concentrations of pyruvate, respectively). When incubation were in low K^+ buffer, $^{14}CO_2$ production from [U-^{14}C]glucose decreases (% decline in C57Bl-Balb/c strains, respectively) by 19-23% (10 month) and 35-42% (30 month) compared to 3 month old mice of their corresponding strains. High K^+ (31 mM) stimulated $^{14}CO_2$ production 2-3 times more in the aged brain (10 and 30 month old mice) than in the young brain (3 month old mice). Thus in high K^+ incubations glucose oxidation declined from the 3 month control value by only 8-6% (10 month) and 13-17% (30 month) in the C57Bl and Balb/c strains, respectively. An age-related decrease in $^{14}CO_2$ production from [1-^{14}C]pyruvate and [3,4-^{14}C]glucose paralleled the reduction with [U-^{14}C]glucose, which suggests that aging alters flux through pyruvate dehydrogenase.

Aging decreased the synthesis of ACh from [U-^{14}C]glucose in vitro. In low K^+ buffer, synthesis declined 28 and 39% in 30 month old mice compared to 3 month old mice in C57Bl and Balb/c strains, respectively. However, in high K^+ buffer, ACh synthesis decreased only 9 and 25% in the two strains. Since these in vitro changes in ACh synthesis and carbohydrate oxidation were small compared to the decline in ACh synthesis in vivo, we examined the release of [^{14}C]ACh from aged brain slices that had been preincubated with [U-^{14}C]glucose. Aging had no effect on the non-Ca^{2+}-dependent-release nor on the low K^+-Ca^{2+}-dependent-release. The high K^+-stimulated-Ca^{2+}-dependent-release decreased 37 and 79% (Balb/c) and 48 and 79% (C57Bl) in 10 and 30 month old mice compared to their 3 month old controls, respectively. This decrease paralleled the decline in the in vivo synthesis of ACh with aging. The data presented implies that decreases in oxidative metabolism, ACh synthesis and in the release of ACh contribute to a reduction in cholinergic function in the senescent brain.

62.18 SENESCENT CHANGES IN BALANCE, COORDINATION, AND CEREBELLAR MICROANATOMY.
S. Zornetzer[a], F. Bloom, R. Mervis[b], and J. Rogers. Salk Institute, La Jolla, CA 92037 and [b]Dept. Pathology and Neuropathology, College of Medicine, Ohio State University, Columbus, OH 43210.

Recent studies have shown pathologic electrophysiological changes in rat cerebellum with age (1-3). The present experiments investigate their behavioral and anatomical correlates. On a task requiring balancing and walking on progressively narrower planks in order to obtain food, 25 month-old male Sprague-Dawley rats (N=11) are significantly impaired even on a plank three times the size of that successfully negotiated by 6 month-old cohorts (N=13). For example, on a 38 mm wide plank, 25 month-old subjects fall an average of 1.17 ± 0.35 times in 10 trials. Rats 6 months-old average 0.15 ± 0.07 falls per 10 trials on a 13 mm wide plank, and never fall on 25 or 38 mm planks. Likewise, the 25 month-old subjects are significantly worse in balancing on and matching speed with a rotating rod even when the rod diameter is two-fold greater than that used by the younger animals. On 51 and 102 mm diameter rods, old rats fall at running speeds of 1.7 ± 0.5 and 3.2 ± 0.8 cm/sec, respectively, while young rats fall at 5.9 ± 0.3 and 10.2 ± 1.0 cm/sec. On both tests of coordinated locomotor activity, 25 month-old subjects clearly divide into two subpopulations, one moderately impaired compared to 6 month-old rats and the other grossly impaired. This dichotomy is of particular interest in current research where subjects of the behavioral experiments described above are compared on three parameters of cerebellar microanatomy: dendritic atrophy of Purkinje cells in Golgi sections, axodendritic synaptology of Purkinje cells in electron microscopic sections, and Purkinje and granule cell counts in light microscopic sections. Data from these anatomical and behavioral assays complement the age-related pathology already revealed by our electrophysiological studies of senescent cerebellum (1,2); the correlation and cross-validation of such changes could provide sequelae of neural aging based on a multidisciplinary series of measurements.

62.19 A QUANTITATIVE GOLGI STUDY OF DENDRITIC SPINE TYPES IN AGING RATS.
James R. Connor and Marian C. Diamond. Dept. of Physiology-Anatomy, University of California, Berkeley, CA 94720

Dendritic spines are small, thorn-like appendages that characteristically extend from pyramidal cells in all areas of the cerebral cortex. The density of dendritic spines is influenced by a wide variety of phenomena. Although variations in the morphologic appearance of dendritic spines has been qualitatively reported, few quantitative accounts of these structurally different spines exist.

We have previously distinguished two categories of dendritic spines and reported a difference in density of spine types as a function of age. The first category includes all spines with a thin stalk and a terminal expansion resembling a lollipop (type L). The second category of spines includes those with no terminal expansion, thus having a nubbin configuration (type N). The functional meaning of these spine types is unknown, but they probably represent differences in the electrophysiological input to the neuron.

In this particular study, retired breeder, Sprague-Dawley male rats from GIBCO laboratories were placed at 14 months into either isolation (1 rat to a 30X 20X 28 cm cage) or remained in standard colony (3 rats in a cage of the same size). All other variables were identical. After 6 months the rats were sacrificed and the brains placed in a Golgi-Cox solution. Segments for counting spine densities came from apical, oblique, and basal branches of layers II, III, Va, and Vb pyramidal neurons of the occipital cortex.

Our results show that the density of type N spines is consistently greater on neurons from isolated rats regardless of cortical layer or dendritic segment counted. This difference was most prominent in layer II on neurons whose apical shaft diameter was between 1.1 - 2.0 um.

The type L spine density was, in general, not affected by either of the two housing conditions with one exception. In layer Vb, the type L spine density was consistently greater on segments counted from isolated rats.

It is interesting to note that in conditions such as aging, isolation, and deafferentation, spines without a terminal expansion (type N) selectively increase in density.

62.20 EFFECTS OF AGING, ENVIRONMENT AND/OR CASTRATION ON LAYER III AND LAYER V DENDRITES IN FELINE AUDITORY CORTEX.
Anne S. Kaplan and Arnold B. Scheibel. Brain Research Institute and Departments of Anatomy and Psychiatry, UCLA, Los Angeles, CA. 90024.

Dendritic branching parameters were measured in Golgi-stained auditory cortex (mid-ectosylvian g.) from three groups of cats: OLD = 12-17 years old, castrated pets; YNG1 = 1½-2 years, intact cage-raised; YNG2 = 1½-2 years, castrated pets. Five Layer III (LIII) pyramids from each of four cats in each group were chosen with strict, unbiased criteria. Five Layer V (LV) pyramids were also chosen from the same cats in groups OLD and YNG2. The basilar dendrite system of each of these cells was drawn (in 2-D) at 600X, with a camera lucida system. Several measures were then applied to the drawings, including: concentric ring analysis (D. Sholl, J. Anat. 1953); total dendritic length (as sum of intersections of all rings); number, average length, and total length of each branching order; and number, average length, and total length of terminal (EBR) and bifurcating (XBR) branches.

In both layers, the total dendritic length was greater in YNG2 than in the other groups (LIII: YNG2 = 2950μ, OLD = 2267μ, YNG1 = 2155μ; LV: YNG2 = 3112μ, OLD = 2194μ). In LIII, this difference is largely accounted for by (A) higher average length of EBR in YNG2 (104μ vs. 92 & 91μ); and (B) shorter and fewer XBR in YNG1 (14μ, 48 XBR) as compared to OLD (18μ, 57 XBR) and YNG2 (18μ, 63 XBR). In LV, the difference between YNG2 and OLD is not due to longer EBR (130 vs. 123μ) so much as to the greater numbers of EBR (14 vs. 9) and XBR (25 vs. 18) in YNG2.

There were no differences between groups in either layer in the number of primary branches, which averaged 4.2 in LIII and 5.7 in LV. For most other measures, the pattern in LIII was YNG2 > OLD ≥ YNG1; for LV it was YNG2 > OLD.

Since the hormonal and environmental status of YNG2 and OLD was similar, the differences between these groups may indeed be age-related, or, at least, related to the diseases of aging. In LIII, this aging process seems to be one of dendritic dying-back, i.e., shortening of more distal processes. In LV, there may in addition be loss of whole branches, but net loss of entire dendrites does not appear to occur in aging cat auditory cortex.

The fact that YNG1 differed greatly from YNG2, and slightly or not at all from OLD, suggests either that castration and/or environmental stimulation may counteract aging effects in older cats, or, that the absence of these factors may cause young brains to appear old. A shift in the balance between growth and retraction (Buell & Coleman, Science 1979) may be involved. Further, the effects of these factors may be limited to cortex, as the caudate nuclei of these same OLD cats show senescent losses when compared to cats similar to YNG1 (McAllister, et al., this meeting).

63.1 CENTRAL CONTROL OF AVIAN VOCALIZATION: NEURONAL RECORDINGS FROM SINGING BIRDS. James McCasland and Masakazu Konishi, Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

Discrete telencephalic nuclei HVc and RA have been implicated by lesion studies in the control of vocalization of songbirds (Nottebohm, F., in Prog. in Psychobiol. and Physiol. Psych. Vol. 9, 1980). We confirm the role of HVc in vocalization by presenting neuronal recordings taken from HVc of singing birds. However, we do not find clear support for the concept of hemispheric dominance of song control, also developed by Nottebohm et al., who showed strikingly asymmetric effects following unilateral lesions of HVc or RA, or unilateral section of the hypoglossal nerve innervating the avian vocal organ, the syrinx. It was concluded from their studies that left-side song control nuclei played a dominant role in song production.

Recordings of multiple-unit activity were obtained from three species of birds, using chronically implanted coaxial electrodes. Comparisons with preoperative songs ensured that no deficits had resulted from implantation procedures. Lesions were used to verify electrode locations.

Recordings from within the HVc boundary show greatly increased neuronal activity clearly corresponding to the timing of song elements, whereas control recordings from outside the HVc boundary show no such changes in activity. Thus HVc either generates or relays temporal cues for song. Recordings from the same electrode locations show activity associated with calls, which unlike songs in these species do not require learning from other birds.

The simplest neural correlate of hemispheric lateralization would be the presence of activity during vocalization in the dominant side, and absence of activity in the other side. Multi-unit recordings from right and left HVc of the same bird show a striking correspondence in onset time and duration of increased neuronal activity for any given vocalization. Since electrode locations vary widely, many cells must participate in vocal control simultaneously in both hemispheres, so that any simple use-disuse mechanism of dominance at the HVc level must be ruled out.

Since the effects of lesioning HVc can only be assessed by measuring the motor output of the syrinx, such lesions cannot distinguish between lateralization at the HVc level and that at more peripheral levels. The intrinsic syringeal musculature in lateralized species is more massive on the left side than on the right. Thus the mechanisms underlying this peripheral asymmetry may be a profitable focal point for future investigations of dominance in the vocal control system. (Supported by a grant from Pew Memorial Trust)

63.2 RELATION OF SYNAPTIC AND MECHANICAL COUPLING BETWEEN MOTOR UNITS AND MUSCLE SPINDLE AFFERENTS. J. Munson, J. Fleshman, G. Sypert, and J. Zengel. Dept. of Neuroscience, Univ. of Fla. Coll. of Med., Gainesville, Fla. 32610.

Two group Ia afferents from the same muscle may produce EPSPs of very different amplitude in the same homonymous motoneuron (Mendell & Weiner, J. Physiol. 255). Following the suggestion of Binder & Stuart (J. Neurophysiol. 43) we tested whether the afferent-to-motoneuron synaptic coupling strength is related to the motor unit-to-afferent mechanical coupling strength. In barbiturate-anesthetized cats, micropipette electrodes were used to (1) record EPSPs generated by single MG group Ia or group II spindle afferents in MG motoneurons, and (2) stimulate MG motor units by passing brief current pulses. Tetanic contractions of single motor units were produced by 330 ms, 40 Hz trains repeated 1/s. Afferent discharge during the final 200 ms of the tetanus was compared with the 200 ms preceding the next tetanus; 30-120 repetitions of the tetanus were analysed for each case.

Motor unit contraction decreased Ia discharge rate in 84% of 118 cases, while increasing the rate in 10% (for group II: 62% and 22% of 37 cases). Overall, a rank correlation of .37 ($p < .0002$) was found between 40 Hz tetanic tension and the motor unit's ability to alter Ia discharge rate. In pooled data, no correlation was found between the amplitude of the EPSP produced by an afferent in a motoneuron and the ability of the corresponding motor unit to alter the discharge rate of that afferent.

To search for more subtle effects, we studied the interactions of single motor units with pairs of Ia spindle afferents. Overall there was no relation between the relative sizes of EPSPs produced by two afferents and the relative effectiveness of the motor unit in altering their discharge rates. However, for fast-twitch motor units we found a weak positive rank correlation between the ratio of the amplitudes of EPSPs generated by two afferents in a motoneuron and the ratio of the suppression of the respective afferents by the motor unit ($r=.23$, $p < .04$). A very weak tendency may exist for spindle afferents to project strongly to fast twitch motor units with which they are more strongly coupled mechanically. For slow twitch motor units, we found a weak negative rank correlation between the ratio of the amplitudes of the EPSPs generated by two afferents in a motoneuron and the ratio of the suppression of the respective afferents by the motor unit ($r=-.41$, $p < .05$). A very weak tendency may exist for spindle afferents to project more weakly to slow twitch motor units with which they are coupled more strongly mechanically.

We conclude that the cat's MG muscle is not strongly characterized by "reflex localization" (Cohen, J. Neurophysiol. 16). Supported by NS 15913 and Medical Research Service of the VA.

63.3 GROUP III MUSCLE AFFERENTS WHICH EXCITE GAMMA MOTONEURONES IN THE CAT. P. H. Ellaway*, P. R. Murphy* and Anita Tripathi*. (SPON: P. L. Gildenberg). Dept. of Physiology, University College London, London WC1E 6BT, England.

Some mechanoreceptors in muscle supplied by the small (Gp III) myelinated axons have low thresholds to stimuli such as applied pressure, taps and contraction. We find that activity in these receptors excites discharges in gamma motoneurones to muscle spindles of the same or adjacent muscles.

Experiments were performed on decerebrated cats usually with a spinal cord section at T8-10. The left hind limb and tail were denervated extensively except for the muscle (triceps surae or flexor digitorum/hallucis longus) under study. Functionally single, tonically firing, gamma motoneurones were isolated by dissection of a cut fascicle of the peripheral nerve to the same group of muscles. Gamma motoneurones were identified by their axonal conduction velocities (range 15-45 m/sec).

Gamma motoneurones could be excited, inhibited or not affected by electrical stimulation of another muscle nerve at a strength sufficient to excite Gp III (5-30 m/sec) axons. The most powerful and striking effect was a short duration (5-20 msec) excitation which could take the form of one or two driven spikes. Central delays as short as 2 msec indicate close coupling and do not exclude the possibility of a monosynaptic connection.

The type of receptor which might elicit the reflex excitation was investigated by comparing sensory responses of Gp III afferents and reflex responses of gamma motoneurones to different stimuli. At the peak, or during relaxation, of an isometric muscle twitch elicited by electrical stimulation of the muscle nerve some gamma motoneurones showed a short duration driven response similar to that caused by electrical stimulation of Gp III axons. On recording the afferent discharges from triceps surae, 15 out of 38 receptors with Gp III axons discharged one or more spikes at fairly constant latency during or after the peak of a twitch contraction. Among these contraction sensitive units 8 out of 10 tested had low thresholds to firm pressure, taps and squeezing applied to the muscle. These stimuli also excited gamma motoneurones.

The majority of the 23 Gp III units not responding to contraction had high thresholds to mechanical stimuli. Our evidence indicates that it is the lower threshold Gp III mechanoreceptors, sensitive to non-noxious stimuli, which can provide a potent excitation of gamma motoneurones via a spinal segmental pathway.

63.4 LONG-TERM POST-STIMULUS REDUCTION IN AXON EXCITABILITY WHEN TESTED WITH SUBMAXIMAL ELECTRICAL STIMULI IN VIVO OR IN VITRO. F.A. Potts* and R.R. Young. Lab. of Clinical Neurophysiology, Mass. General Hospital, Boston, MA 02114.

The duration of the relative refractory period of large myelinated axons in mammalian mixed nerves varies with factors such as temperature and axon diameter but, when tested with supramaximal stimuli, rarely exceeds 5 msec under ordinary conditions. However, when the second ("test") stimulus is submaximal, activating 50% of the alpha motor axons or less, decreased excitability of individual large motor or sensory axons persists for 150-200 msec after the first stimulus and is maximal at about 50 msec. We have demonstrated this in normal rat and human nerve-muscle preparations in situ and in excised nerves in vitro in a special chamber at 37°C. With paired stimuli activating 1, 25 or 50% of the alpha motor axons, the compound muscle action potential following the second stimulus is about 40% as large as that following the first stimulus at inter-stimulus intervals of 50 msec. There are also 2 "superexcitable" phases, at 10-15 msec and 250 to 600 msec, when the second stimulus produces a larger response than the first.

Mechanisms underlying the unexpectedly prolonged period of subnormal axon excitability, which may include afterhyperpolarization-longlasting increases in potassium conductance, remain to be definitively elucidated. However, such long-term changes significantly affect the ratio of the number of axons stimulated by the second to the number stimulated by the first of two equal stimuli when their strength is at or below firing threshold for many large axons in a mixed nerve. Two "equal submaximal stimuli", separated even by 50 msec, are not equally effective stimuli. Experiments using paired submaximal stimuli, such as the ordinary H-reflex recovery curves, should be interpreted in light of these fluctuations in excitability which occur far beyond the usually accepted limits of the relative refractory period.

The shape of the "recovery curve" for large axons in a mixed nerve bears a remarkable resemblance to the shape and timing of what are proported to be "H-reflex excitability curves".

63.5 SENSORY PROPERTIES OF THE INFERIOR OLIVE OF THE CAT. R.S. Gellman*, A.R. Gibson and J.C. Houk. Neuroscience Prog. and Physiology Dept., Northwestern Univ. Med. Ctr., Chicago, IL 60611.

Recent anatomical studies have documented an ordered and precise organization of the projection of the inferior olive (IO) upon the cerebellar cortex. The results reported here demonstrate a corresponding degree of organization of the sensory properties of the IO. We have recorded from 270 units in 11 cats anaesthetized with pentobarbital. The locations of recording sites were confirmed histologically. Cells in the IO had extracellular action potentials displaying secondary spikes, low spontaneous activity (1-2/sec), and did not follow stimuli above about 8 Hz.

The dorsal accessory nucleus (DAO) (N=101) shows a clear somatotopy, which agrees well with the known anatomy (Berkley and Hand, J. Comp. Neur. 180, 253). Penetrations stepping from medial to lateral successively yield units that respond to stimulation of the contralateral (5% bilateral) face, forelimb, hindlimb and tail. Most units have small receptive fields confined to one area of the body, though units on the borders between regions occasionally showed mixed properites. An approximately equal number of cells responded to superficial stimuli (tap, touch, air puffs) as to deep stimuli (squeeze, limb movement). All but 2 cells in the DAO had purely excitatory responses. Mean latencies to electric shocks were short (chin=13 ms; forelimb=15 ms; hindlimb=24 ms).

In the medial accessory nucleus (MAO) (N=139) 30% of cells responded to inputs from more than one body area, frequently bilateral. Receptive fields (N=90) were excitatory (56%), inhibitory (27%), or contained excitatory and inhibitory subareas (17%). Cells with similar properties tend to cluster in small areas that are consistent between cats. A third of the cells could not be driven by sensory stimuli, and many were driven only by hard squeeze. Latencies were long (up to 300 ms) and variable. Medial parts of the MAO had units driven by clicks (latency 45 ms) or light flashes (latency 45 ms) or both.

In the principal nucleus we recorded few cells (N=30). Only ½ of these were driven by sensory stimuli, and most of these received input from more than one body area. Latencies were intermediate (mean forelimb=25 msec).

Although the DAO and MAO differ dramatically in their response properties, both are highly organized and consistent in detail from cat to cat. The character of DAO receptive fields suggests a possible role in the detection of mechanical contact with the external environment. The mixed properties of MAO units suggest a more complex function.

63.6 MECHANISM OF POSTURAL CONTROL IN CRAYFISH LIMBS. Jack D. Marrelli* (SPON: J. Larimer) Dept. of Zoology, The Univ. of TX., Austin, TX. 78712.

The myochordotonal organ of the crayfish spans the merus-carpus joint of the cheliped (claw). Its sensory neurons are in series with a small receptor muscle. The discharge of these neurons is influenced by the tension generated in this muscle by merus-carpus joint movements.

We examined mychordotonal organ action on the joint flexor muscle for postural control by first producing sinusoidal disturbances of the resting joint. We then compared the flexor responses in the intact case with the flexor responses when the sensory neurons were severed. Joint motion was imposed over an arc of 35 degrees at a frequency of 0.2 Hz. Joint velocity ranged from -10 degrees/sec to +10 degrees/sec. The averaged flexor activity (n=100) was compared to the velocity of the joint during the imposed perturbation and was found to be closely proportional in both phase and amplitude to the velocity of the joint movement.

When the sensory neurons were cut there was no flexor discharge at joint velocities below 2 degrees/sec. Above 2 degrees/sec, the flexor discharge as a function of joint velocity could be described by a linear regression line with slope 2 (PPS/degrees/sec. When the sensory neurons were intact the relation between flexor discharge and velocity was almost identical at velocities above 2 degrees/sec. At velocities below 2 degrees/sec, however, the flexor discharge was greatly enhanced by myochordotonal action. In this region a regression line describing the flexor discharge as a function of the joint velocity had a slope of 10 (PPS/degrees/sec).

These data demonstrate that the myochordotonal organ contributes an intense but very limited excitatory influence upon the flexor muscle when the flexor is stretched from rest by joint extension. We suggest that these myochordotonal organ properties have two major advantages for postural control. First, if the objective of a postural support system is to remain in a predetermined position in spite of fluctuating external forces, then mychordotonal organ high sensitivity and rapid response to the earliest sign of imposed movement is desirable. Secondly, because high sensitivity reflexes proportional to velocity would tend to promote instability, some mechanism would be required to limit the velocity sensitivity. The mychordotonal organ provides an upper limit of response of 2 degrees/sec.

63.7 AN AUTORADIOGRAPHIC ANALYSIS OF THE CINGULO-PONTINE PROJECTION IN THE RAT. K. Sripanidkulchai and J. M. Wyss. Department of Anatomy, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

The manner in which the limbic cortical areas are able to influence those areas of the brain whose function is better understood, has been a matter of interest for many years. One route by which they might influence the motor output of the organism is via the projections of the cingulate cortex to the ventral pontine gray matter. In 1969 Domesick (Brain Research 12:296-320) presented evidence based on degeneration techniques, which clearly demonstrated both the existence of this pathway, and its topographical organization. The present study used the autoradiographic technique to further investigate this topography. In each of thirty-five rats, a single, iontophoretic injection (apx 10-30 nl) of a mixture of ^{3}H proline, ^{3}H leucine and ^{3}H lysine (20-60 mCi per ml) was made via a 10 µm tip glass pipet into one or more of the divisions of the mesial cortex. The results corroborate the basic finding of Domesick, in that anterior areas of the cingulate project most heavily to the rostromedial ventral pontine gray whereas the more posterior retrosplenial cortex projects predominantly to the lateral portion of the rostral levels of the pontine gray. Within this basic framework, the present data allow us to give a more complete analysis of these projections. Orthogradely transported label from retrosplenial injections remains predominantly confined to the lateral half of the rostral pontine gray and is organized according to the anterior-posterior (medial to lateral in the pons) and dorsoventral (dorso ventral in the pons) position of the cells of origin. Very light labeling of more medial portions of the pons probably reflects the presence of fibers passing on into the dorsal brainstem. Injections in the anterior portion of the cingulate cortex (area infraradiata) demonstrate the rather more complex organization of these efferents and the bilaterality of this projection. Finally we have been able to demonstrate in the present data that these cingulo-pontine projections do not overlap the projections from either the somatosensory or motor cortex. Rather they are positioned around these projection areas on the medial, ventral and lateral borders.

This work was supported by grants NS 05683 and NS 16592 from the National Institutes of Health and by a predoctoral grant to K.S. from the government of Thailand.

63.8 MOTOR CORTEX STIMULATED VIBRISSAE MOVEMENT. MAPS OF INCREASED (14C)2 DEOXYGLUCOSE UPTAKE IN SOMATOSENSORY CORTEX, CORTICOSPINAL TRACT & SUBCORTICAL STRUCTURES OF THE RAT, F.R. Sharp, K. Evans* and G.K. Bigley*. Dept. of Neurosciences, UCSD Sch. Med., San Diego, CA 92103.

Electrical stimulation of motor cortex 'vibrissae area' produced contralateral movements restricted to the vibrissae in 9 awake rats. (14C) 2-deoxyglucose (2DG) was injected and cortex stimulated with a bipolar electrode at 5 trains/sec for 45 minutes. Autoradiographs of stimulated animals were compared to sham-operated controls and structure boundaries identified from Nissl stains.

Stimulation increased 2DG uptake in a 2.0mm diameter region about the stimulating electrode in motor cortex. Posterior to this region a columnar increase of 2DG uptake occurred in the barrel field of SmI cortex (Durham, et al. JCN,178:629-644). Subcortical regions which increased 2DG uptake ipsilateral to cortical stimulation included: ventroanterolateral (VL) and ventromedial n. thalamus; reticular n. thalamus-ventral; caudate and putamen-mid, dorsolateral region; globus pallidus-two dorsal segments; substantia nigra; subthalamic nucleus; zona incerta; entopeduncular nucleus; deep mesencephalic nucleus (n. cuneiformis); pontine nuclei-medial; and the medial corticospinal tract. A few animals had increased 2DG uptake in ipsilateral centrolateral (CL) and parafasicular n. of thalamus. Contralateral increases of 2DG uptake occurred in: lateral nucleus of cerebellum; a small region in posterior cerebellar hemisphere; a restricted portion of the midcerebellar hemisphere in granular and molecular layers; and an anterior paravermal region.

Structures related to motor and sensory vibrissae function appear to be activated mono-and polysynaptically. The motor nucleus for vibrissae movement-the facial nucleus, did not seem to increase 2DG uptake. However, the medial corticospinal tract in the pons did increase 2DG uptake ipsilateral to cortex stimulation. The results will be related to known anatomical connections.

63.9 CONVERGENCE OF SPINAL AND CEREBELLAR INPUT IN THE THALAMIC VENTRAL TIER OF A PROSIMIAN, GALAGO. J.C. Pearson*, H.M. Murray and C.H. Phelps. Depts. of Anatomy, Wright State Univ. Sch. of Med., Dayton, OH 45435, and Univ. of New Mexico, Sch. of Med., Albequerque, NM 87131.

A previous report in Galago acknowledged the ventral intermediate nucleus (Vim) as being separate from the ventral posterior lateral nucleus (VPL) based on criteria that (1) spinal input to Vim is widely separated from that to VPL, and (2) cell bodies in the Vim are scattered in organization as compared to the clustered arrangement of those in VPL. In order to more precisely define the extent of the area acknowledged as Vim, and to further examine the suggestion that Vim should be considered as a separate entity from VPL, the thalamic termination of cerebellar fibers were examined in this prosimian with particular emphasis on the possible convergence of cerebellar and spinal input in the ventral tier. In the present study the Fink and Heimer method was employed to examine the termination of cerebellothalamic fibers in six adult lesser bushbabies after lesions were placed stereotaxically in the caudal parts of the lateral cerebellar nucleus. Sections containing cerebellothalamic degeneration were compared with slides from fourteen Galagos which had received spinal hemisections at cervical, thoracic and lumbar cord levels. Results indicate a direct overlap of cerebellar and spinal input in the area of Galago ventral tier previously identified as Vim. This area is located medial and slightly dorsal to the rostral extension of VPL. In this area of convergence cells are scattered in appearance and slightly larger than neurons in VPL. Spinal degeneration is sparse in Vim compared to the moderate termination of cerebellothalamic fibers. Cerebellar terminals are also located more dorsally and rostrally in the region identified as the caudal portion of the ventral lateral complex (VL_C). Based on this evidence, the Vim in Galago may correspond to the VPL_O as recently described in monkey. However, the hodological and cytoarchitectural differences between Vim and VPL outlined above, and the relatively substantial nature of the Vim area in Galago ventral tier appear to support the designation of this area as the ventral intermediate nucleus in this prosimian.

63.10 "RECALCULATION" OF VISUALLY-CUED MOTOR OUPUT DURING REACTION TIME DELAYS EVOKED BY IMPOSED JOINT DISPLACEMENTS. M.J. Eastman* and W.G. Tatton, Playfair Neuroscience Unit, University of Toronto, Toronto, Ontario.

Three macaques were trained to make fast flexion or extension movements of the wrist (mean velocities of approximately 400°/sec) in response to randomly-distributed arrays of yellow and red light emitting diodes (LEDS) positioned so as to encompass their full visual fields. The visually-cued movements were initiated from a neutral wrist zone of 5° in width, signalled by a coextensive array of green LEDS, to mechanical stops placed at 45° of flexion and extension. The monkeys were required to maintain the neutral position for a random interval of 4.5 to 6.0 seconds prior to delivery of the flex (yellow) or extend (red) cue. A torque motor assembly coaxial with the wrist joint, unexpectedly imposed step loads of random duration, onset and magnitude independent of or at a series of randomly-ordered delays (0,20,40,60,80,100,120 msecs) following the onset of the visual cues. EMG was recorded from flexor carpi ulnaris and extensor digitorum communis together with wrist position and velocity. EMG reaction times (RTs) for unperturbed movements were distributed from 120 to 260 msec. Most movements showed EMG RTs of 140 to 160 msec and highly reproducible trajectories as measured by crossing time distributions for 12, 24 and 36° positions from the neutral zone. Step loads that displaced the wrist in a direction opposite to the cued movement delayed the minimum and modal EMG RTs by 70 to 80 msec as measured from the onset of the step loads. Despite the delay in EMG output the distributions for crossing times were shifted by less than 30 msec. The trajectory compensation for the imposed displacements was achieved by increased initial movement velocities resulting from appropriate increases in the magnitude of agonist EMG output despite variation in the timing and size of the imposed displacements. The input/output relations for the reflex responses in the stretched muscles (i.e. EMG output for a given displacement velocity) showed alterations of "gain" (maximum 300%) beginning between 60 and 80 msec after the visual cue. The "gain" increase was initiated 75 to 80 msec prior to the onset of the visually-cued agonist EMG activity. The "gain" increases were not accompanied by increases or decreases in the background EMG activity which was constant for both the agonist and antagonist muscles during the reaction time interval. The findings will be considered in the context of the CNS mechanisms underlying the interactions between programmed motor output and somatosensory input during the RT preparation for a visually-cued movement. (Supported by MRC grant 5218)

64.1 COMBINED INTRACELLULAR RECORDING AND LIGHT AND EM ANALYSIS OF NEURONS OF THE RAT GLOBUS PALLIDUS. W.M. Falls and M.R. Park, Dept. of Anatomy, Michigan State Univ., East Lansing, MI 48824.

Globus pallidus (GP) neurons in rats were impaled with intracellular microelectrodes containing 4% HRP in 0.1 M tris buffer (pH 7.6) and a low concentration of KCl (0.5M). The response to caudate-putamen stimulation is a monosynaptic IPSP of latency 5.1 to 9.8 msec (n=22). Comparison with extracellular controls shows no initial transmembrane depolarization. Dividing latency into straight-line distance between recording and stimulating sites and allowing 0.7 msec for synaptic delay yields conduction velocities of 0.4 to 0.8 m/sec. All recovered neurons were of a single morphological type and were distributed throughout GP. The dendritic fields remain completely within GP, spanning up to 600 µm mediolaterally, stretching for at least 800 µm rostrocaudally, and often extending over 1mm dorsoventrally. Medium to large somata (10x20 to 15x30µm) give rise to 3-5 short (20µm) proximal dendrites (2.5-4µm in diameter) and sparsely branching distal dendrites which may run for more than 800µm without appreciable change in diameter (1-2µm). Dendrites emit a few widely scattered spines. Labeled axons most frequently course medially to enter a fiber bundle traversing GP. Some axons emit collaterals within 50µm of the soma which arborize within the dendritic field of the parent cell and contain several boutons en passant. Cell bodies, dendrites and axons of 2 labeled neurons were examined in serial sections. Most dendrites and cell bodies are covered by closely packed axonal endings. At least five types of axonal endings are observed. The most numerous are small (0.5-1.5µm) type 1 endings containing large pleomorphic vesicles. These interdigitating terminals form symmetrical contacts on cell bodies and all along the lengths of dendritic shafts and have been shown to be of striatal origin by Chang et al, (1980). Synapsing less frequently and only on distal dendrites are small (1-2µm) type 2 endings filled with small oval vesicles and forming asymmetric contacts. The bulbous type 3 ending (2-4µm) is the least frequently encountered ending. It contains small, loosely packed pleomorphic vesicles and makes multiple symmetrical contacts with distal dendritic shafts and vesicle-free spines. Dome-shaped type 4 endings (0.8-1.2µm) are presynaptic only to proximal dendrites, are filled with pleomorphic vesicles and each makes multiple symmetrical contacts. Large type 5 endings (3-4µm) make symmetrical contacts only on cell bodies and contain small oval and numerous large dense core vesicles. Labeled axons and their collaterals are unmyelinated within GP. Labeled boutons en passant correspond to type 4 axonal endings and contact unlabeled proximal dendrites. They have never been observed to synapse on labeled proximal dendrites of the parent cell. (Supported by USPHS Grant NS 14866).

64.2 HIGH-MAGNIFICATION GOLGI STUDY OF AGED CAT CAUDATE. A.B. Scheibel, A.S. Kaplan, and J.P. McAllister. Depts. of Anatomy and Psychiatry; Brain Research Institute; and Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

Prior data from our laboratory (Scheibel & Tomiyasu, in press) indicate that substantial age-related changes occur in the dendrospinous systems of the medium spiny cells in the aging (89-101 yr.) human caudate nucleus. These cells, when compared to those from young adults (23-35 yr.), show dramatic decreases in number of dendritic spines, in dendrospinous area, and in dendritic area exclusive of spines.

These findings have now been duplicated in old (15-18 yr.) vs. young adult (19 mo.) cats. Five Golgi-impregnated medium spiny Type I neurons were selected from the head of a caudate of each of two old and two young adult cats. The longest, and most complete dendrite of each of these 20 cells was indicated by computer analysis (McAllister, et al., this meeting). All subsequent measures were done blindly. A terminal branch was chosen from each of the indicated dendrites. A 50µ-long segment, beginning 25µ from the start of the branch, was drawn at 8800x apparent magnification, using a modified camera lucida system. (R. Coss, personal communication). Planimetric analysis of these drawings yielded the following results:

MEASURES PER 50µ-LONG DENDRITIC SEGMENT

	YOUNG	OLD	SIGNIF.
Total area (μ^2)	118.8 ± 9.3	88.9 ± 1.5	*
Dendrite area (w/o spines) (μ^2)	77.2 ± 5.3	62.4 ± 4.2	*
Average branch width (µ)	1.55 ± 0.11	1.25 ± 0.08	*
Number of spines	52.9 ± 3.5	32.5 ± 10.3	*
Area of all spines (μ^2)	41.6 ± 4.0	26.5 ± 5.7	*
Average area per spine (μ^2)	0.79 ± 0.03	0.87 ± 0.09	-

mean ± S.D.; sig: * = $p<.05$; - = N.S.

Additionally, spines from old animals showed a much wider range of morphological patterns compared to those from the young adults. The medium spiny cells are now known to be the main receptive element for caudatopetal afferents from cortex, thalamus, and midbrain. Their axons also constitute the major efferent channel from the caudate. Marked decreases in the synaptic surface area of this important cell system must certainly restrict caudate function, with consequent impairment of motor performance and the inception of voluntary activity.

64.3 MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL CHARACTERISTICS OF IDENTIFIED MEDIUM-SIZED SPINY NEURONS IN THE CAUDATE NUCLEUS OF KITTENS AND ADULT CATS. R.S. Fisher, M.S. Levine, C.D. Hull, and N.A. Buchwald. Mental Retardation Research Center and Brain Research Institute, School of Medicine, UCLA, Los Angeles, CA 90024.

Intracellular neuronal records of evoked responses to cortical (Cx), thalamic (Th), and nigral (SN) electrical stimulation were obtained from neurons in the caudate nucleus (Cd) of kittens and adult cats. After evoked response records were obtained, neurons were marked for subsequent anatomical identification by intracellular iontophoresis of horseradish peroxidase (HRP). After transcardial perfusion with aldehyde fixatives followed by 10% sucrose, brains were cryoprotected by immersion in 30% sucrose. Coronal serial frozen sections (100µm thick) of each brain were processed for peroxidase activity with either DAB or TMB chromagens. Intact marked neurons were correlated with their electrophysiological records. To date, we have identified 7 cells in 4 kittens (16-35 days old) and 10 cells in 4 adult cats as medium-sized spiny neurons. The resting membrane potentials of these neurons were lower in kittens than in adults ($\bar{x}$ = 31mV vs. 44mV) but action potential amplitudes were equivalent in both age groups ($\bar{x}$ = 23mV vs. 25mV). All tested neurons responded to ipsilateral Cx stimulation. In kittens, only 1 of 3 tested neurons responded to Th stimulation while 3 of 3 responded to SN stimulation. In adults, 5 of 5 tested cells responded to Th stimulation and 6 of 6 to SN stimulation. In identified adult Cd neurons, evoked responses always consisted of an EPSP followed by a long-duration IPSP (50-200 msec duration). In contrast, identified neurons in young kittens, as reported previously (Morris, et al, Br. Res., 1979) responded to stimulation only with EPSPs. IPSPs rarely followed these initial EPSPs. Morphologically, kitten neurons had smaller dendritic field radii than adult neurons (200-300µm vs. 400-700µm) and fewer apparent dendritic spines. Dendritic varicosities were present in the neurons of younger kittens. Axons of both kitten and adult Cd neurons were thin, collateralized, highly convoluted and could occasionally be followed for long distances.

The reasons for the lack of the IPSP in neonatal kittens could not be totally accounted for by our morphological data. They may be related to delayed maturation of inhibitory interneuronal or axonal collateral systems synapsing on medium-sized spiny neurons.

64.4 QUANTIFICATION OF MORPHOLOGICAL ALTERATION OF "MEDIUM" SPINY NEURONS IN CAUDATE NUCLEUS OF AGED CATS. M.S. Levine, J.P. McAllister C.D. Hull, A.M. Adinolfi, and N.A. Buchwald. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, CA 90024.

These experiments utilized computer-assisted quantitative techniques to assess alterations in somatic and dendritic morphology of "medium" spiny neurons in the caudate nucleus of aged cats. To date, we have examined tissue from 4 adult cats (55 cells, 1-2 yrs) and 2 aged cats (30 cells, 15-18 yrs.). Tissue was impregnated using the Rapid Golgi method. Spiny neurons were drawn with a camera lucida. Three dimensional analyses of aspects of somatic and dendritic morphology were performed with the aid of a PDP-11/40 computer. Neuronal somata diameter and area decreased slightly in aged cats. The short and long axes of these somata decreased from 14.5 ± .5 (group mean ± s.e.) to 12.2 ± .5µm and 23.3 ± 1.3 to 21.4 ± 4µm in adult and aged neurons, respectively. Similarly, somatic area decreased from 362 ± 9µm^2 to 300 ± 27µm^2. Caudate neurons in aged cats showed marked reductions in dendritic length. Total dendritic length decreased from 3765 ± 335 to 1897 ± 207µm, while average dendritic length decreased from 777 ± 81 to 493 ± 29µm. The average radius of the dendritic field decreased from 220 ± 19 to 133 ± 4µm. The decreases in dendritic length measurements ranged from 25 to 50% for different parameters. The number of dendrites per neuron decreased from 5.12 ± .07 to 4.30 ± .10. Average number of branches per dendrite did not change (9.97 ± .44 to 9.80 ± .74 for adult vs. aged caudate neurons, respectively). These relationships were confirmed by comparing the same measurements from only the longest (optimally impregnated) dendrite of each cell, a procedure that helps to correct for branches that are truncated as they pass out of the section. Counts of dendritic spines indicate spine loss on distal dendritic segments (1.056 ± .163 to .390 ± .190 spines/µm). Spine density increases slightly on proximal segments in aged cats (.008 ± .022 to .019 ± .033 spines/µm). Analysis of branch ordering patterns indicated that branch ordering was not markedly rearranged in aged cats. However, length decreases occured at all orders and were greatest in the higher order segments. An analysis of length of free endings and closed endings indicated that virtually all dendritic length decreases in aged cats occured in free endings (113 ± 3 to 67 ± 0.4µm). Closed endings branch lengths were similar for both groups (28 ± 2 for adults vs 27 ± 2µm for aged cats). These results indicate that medium spiny neurons in the cat caudate nucleus undergo marked decreases in dendritic length and spine density (on distal segments) during aging. Decreases in dendritic length appear to be confined to free endings. In contrast, the number of branches per dendrite and dendritic branch ordering patterns remain relatively unaltered.

64.5 AN AUTORADIOGRAPHIC STUDY OF NEOSTRIATAL EFFERENT PROJECTIONS IN KITTENS. A.M. Adinolfi, M.S. Levine and J.A. Cospito. Dept. of Anatomy and Mental Retardation Research Center, University of California, Los Angeles, California 90024.

This study traces autoradiographically the general topography and terminations of striopallidal and strionigral pathways in kittens. Five kittens (2 at 2 days, 2 at 28 days and 1 at 68 days of age) received single injections into the left caudate nucleus of equal mixtures of tritiated leucine and proline reconstituted in sterile saline (0.3-06µl for total radioactive concentrations of 22-45 µCi.) Animals were sacrificed by vascular perfusion with 10% neutral formalin at 24 hrs, 48 hrs, and 6 days depending on their age. Frozen sections were cut at 50 µm in the transverse plane. Every third section was mounted and dipped in Kodak NTB-2 emulsion, exposed for 6 wks, developed in Kodak D-19, and stained with thionin. Injection sites within the caudate head were mapped in bright and dark field illumination. Total caudate volume increased by 2.8 from 2-68 days. While injection sites were comparable in size, they occupied 26% of caudate volume at 2 days and 9% at 68 days. In the youngest animals labelled amino acids diffused further within the caudate nucleus and spread into the rostral putamen. In all kittens, labelled fibers from the caudate head project ipsilaterally as discrete bundles through the anterior limb of the internal capsule and course in a ventrocaudal direction within the capsule. Fibers enter the rostral globus pallidus near the anterior commissure and terminate diffusely. Silver grains in linear configurations were considered as axonal bundles and those in random or diffuse array as axonal terminals. Further caudally, discrete bundles are found among capsular fibers dorsomedial to the entopeduncular nucleus. The medial two-thirds of this nucleus contains a moderate to heavy projection but only scattered terminals are found in the lateral entopeduncular and pallidal regions at these levels. Labelled efferent projections proceed in a caudal direction along the ventral border of the subthalamic nucleus. Fiber bundles traverse this nucleus but no terminals are found in this region. At midbrain levels, the strionigral pathway occupies the medial portion of the cerebral peduncle and enters the substantia nigra. Terminal fields are labelled heavily in the rostromedial part of the pars reticulata. The caudal and lateral parts of the pars reticulata and the pars compacta contain fewer labelled terminals. No neostriatal projections are found caudal to midbrain nigral levels. This study concludes that caudate neurons in newborn kittens project prominently and exclusively to ipsilateral pallidoentopeduncular and nigral regions. (Supported by USPHS grant no. HD-05958.)

64.6 DEVELOPMENT OF SPONTANEOUS AND EVOKED UNIT ACTIVITY IN THE VENTRAL ANTERIOR AND VENTRAL LATERAL THALAMIC NUCLEI (VA-VL) IN CATS. S.W. Kiefer, M.S. Levine, C.D. Hull, and N.A. Buchwald. MRRC and BRI, UCLA School of Medicine, Los Angeles, CA 90024.

We have analyzed the development of neurons in the VA-VL complex, a thalamic region receiving major afferents from both the basal ganglia and the cerebellum. VA-VL cells are also reciprocally connected with the pericruciate cortex. Animals were anesthetized with a Halothane-N_2O respiratory mixture, paralyzed with flaxedil and artificially respirated. Extracellular single unit data were obtained from 14 cats in four age groups (1-10 days, n=4; 11-20 days, n=4; 31-40 days, n=3; adult > 1 year, n=3). For each cell, spontaneous firing and responsiveness to stimulation of ipsilateral pericruciate cortex (Cx), caudate nucleus (Cd), and contralateral deep nuclei of the cerebellum (Cbl) were determined. Spontaneous activity has been analyzed in 262 VA-VL neurons. In 1-10 day old kittens VA-VL cells fired infrequently ($\bar{x}$ ISI=2,490 msec). Spontaneous firing increased with age (11-20 days, $\bar{x}$ ISI=1,670; 31-40 day, $\bar{x}$ ISI=1,210). However, even by 40 days, the rate of spontaneous firing did not equal that of adults ($\bar{x}$ ISI=460 msec). Burst occurence (at least 2 successive intervals < 10 msec) also increased with age. 12% of the units in 1-10 day kittens; 18% in the 11-20 day group, and 65% in the 31-40 day group showed bursting activity. Adult levels (93%) were not reached by 40 days. Evoked responses: 1) Cbl stimulation evoked responses in about 25% of neurons tested regardless of developmental age. About half of these responses were initially excitatory, the remaining inhibitory both in the youngest kittens and in adults, b) Cd stimulation- Responsiveness of VA-VL neurons to Cd stimulation increased as a function of age: 15% (10/66 cells) in the 1-10 day group; 41% (23/56) in adults. In the 1-10 day old kittens 60% of the cells responded with initial inhibition; the others with initial excitation. In adults, the proportion of initial inhibition increased to 78% (18/23), c) Cx stimulation- Responsiveness to Cx stimulation also increased with age: 25% (15/60 units) in 1-10 day old kittens; 77% (44/57) in adult cats. As with Cd, the percentage of initially inhibitory responses to Cx stimulation increased with age: 47% (7/15) in the 1-10 day group showed initial inhibition; in adult cats, 84% (37/44). The data suggest that VA-VL neurons in the neonatal kitten are immature and must go through further postnatal development before achieving adult levels of function.

64.7 CONNECTIVITY OF THE CAUDATE NUCLEUS IN NEWBORN KITTENS AND ADULT CATS. N.A. Buchwald, R.S. Fisher, M.S. Levine, R. Gazzara, and C.D. Hull. Mental Retardation Research Center and Brain Research Institute, School of Medicine, UCLA, Los Angeles, CA 90024.

Retrograde and orthograde neuronal transport of lectin-bound horseradish peroxidase (WG-HRP) were used to demonstrate the connectivity of the caudate nucleus (Cd) in 7 newborn kittens and in 4 adult cats. A 2.5% solution of WG-HRP was pressure injected into the left Cd of each animal (.05 - .20µl, .87% NaCl vehicle). After 24-48h animals were killed and perfused with aldehyde fixatives followed by 10% sucrose. The tissue was immersed in 30% sucrose for cryoprotection. Adjacent sets of frontal or parasagital serial frozen sections (100µ thick) were processed for peroxidase activity with DAB, TMB, and BDHC chromagens and counterstained with neutral red.

The location and cytological characteristics of neurons labelled retrogradely (Cd inputs) and fibers/terminal fields labelled orthogradely (Cd outputs) were similar in newborn and adult cats. Labelled neuronal cell bodies were prominent in four anatomical sites: 1) cortex (bilateral in the cingulate, pre- and postsigmoid, proreus, and anterior gyri; ipsilateral input in the posterior sylvian gyrus), 2) ventral thalamus (ipsilateral in the centromedian, parafascicular, central medial, dorsomedial, ventral anterior, and rhomboidal nuclei), 3) ventral midbrain (ipsilateral in all regions of the substantia nigra, ventral tegmental area, and retrorubral fields), and 4) dorsal raphe (bilateral). Smaller aggregations of labelled neuronal cell bodies were found in the contralateral substantia nigra in both kittens and adults. In adults, labelled neurons were also observed in the ipsilateral globus pallidus and basolateral amygdala. No cell bodies were labelled in the entopeduncular nucleus. Orthogradely labelled fibers and terminal fields were evident in three ipsilateral locations: globus pallidus, entopenduncular nucleus and substantia nigra. There was considerable overlap of labelled cell bodies and strionigral terminal fields in the pars compacta. Labelled cell bodies tended to be smaller in kittens than adults.

The density of the WG-HRP reaction product was characteristic of each anatomical location. Cortical neurons (small pyramidal figures prominent in layer 3; scattered through layers 4-6) were very lightly labelled; thalamic and raphe neurons (small-to medium stellate figures) had moderate label density; nigral neurons (medium-to-large fusiform figures) were heavily labelled.

These results are consonant with the major findings of our previous studies of electrophysiological development. Inputs and outputs of the Cd are present and functional throughout postnatal life.

64.8 AN ELECTRON MICROSCOPIC STUDY OF GOLGI-IMPREGNATED MEDIUM SPINY NEURONS IN CAT CAUDATE NUCLEUS. J.P. McAllister, D.S. Hayes and A.M. Adinolfi (SPON: Russell A. Gazzara). Dept. of Anatomy and Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

In cats, medium spiny neurons (homologous to Type I spiny neurons in primates) are distributed throughout the caudate nucleus and constitute the largest proportion of neurons impregnated by the Rapid Golgi method. In this study, we describe the cytological features and synaptic organization of Golgi-impregnated medium spiny neurons after gold toning and deimpregnation, according to the method of Fairen, Peters and Saldanha (1977). Single neurons were drawn from Epon-embedded deimpregnated sections before serial thin sectioning for electron microscopy. The selected neurons had ovoid cell bodies and proximal dendrites which were smooth, spine-free and uniform in diameter. These gave rise to intermediate and distal branches, richly covered with short, pedunculated and often, bifurcated spines. Dendritic varicosities were absent and distal branches with free endings tapered slightly to their terminations. In thin sections of medium spiny neurons, metablic gold is concentrated beneath the plasma membrane. These fine particles outline the periphery of the perikaryon and proximal dendrites. Cell bodies are characterized by a pale nucleus containing a prominent nucleolus and surrounded by scant cytoplasm with few formed organelles. Occasional small arrays of rough endoplasmic reticulum extend into the proximal dendrites and are situated among parallel microtubules. Somatic and dendritic surfaces are contacted symmetrically by few axon terminals containing pleomorphic vesicles. Most of the proximal surfaces are apposed by astroglial processes. Intermediate and distal spiny dendrites were followed in serial thin sections. Gold particles are much more coarse and, except for large mitochondria, tend to fill smaller dendrites. These particles also fill the thin stalks and expanded heads of the spines. When present, the spine apparatus is not obscured by the gold. Small dendrites and dendritic spines are contacted asymmetrically by axon terminals containing spherical vesicles. Less often, the dendritic profile or thin stalk of a spine is contacted symmetrically. Initial segments and preterminal portions of axons have been followed for short distances and are contacted symmetrically. This study confirms the distribution of symmetrical and asymmetrical synaptic contacts on spiny neurons in cat neostriatum. (Supported by USPHS Grant HD 05958).

64.9 TWO SPATIALLY SEPARATE STRIOPALLIDAL AXONAL ARBORIZATIONS ARE LABELED BY SMALL AMINO ACID INJECTIONS IN RAT NEOSTRIATUM. K.D. Phelan* and C.J. Wilson* (SPON: D. Tanaka). Department of Anatomy, Michigan State University, East Lansing, Michigan 48824.

In a previous study, single intracellularly labeled neostriatal projection neurons were shown to exhibit two separate axon collateral arborizations in globus pallidus. To examine the topographical organization of the striopallidal pathway in the rat, patterns of axonal distribution of small populations of neostriatal projection neurons were demonstrated autoradiographically following stereotaxic placement of iontophoretic injections of tritiated amino acids in various parts of the neostriatum. Two distinct regions of labeled axonal processes were found in globus pallidus after such injections in ipsilateral neostriatum. In sagittal sections, label was seen over fiber bundles of the internal capsule coursing from the injection site into globus pallidus. As they penetrated the border of globus pallidus, these fibers gave rise to a sharply bounded region of concentrated autoradiographic labeling in the pallidal neuropil. The dorso-ventral and medio-lateral extent of this region varied with the size of the neostriatal injection site. However, its rostro-caudal dimension remained relatively constant (50-100μm) and corresponded with that previously seen for individual striopallidal axons. The position of this labeled zone along the neostriatal-pallidal border depended upon the position of the injection site, being centered on the point of penetration of labeled capsular bundles. Labeled bundles of fibers continued caudally past this region and through a variable region of relatively sparse labeling before forming a second arborization in the pallidal neuropil. Labeling in this more caudal pallidal region was more diffuse and irregular in shape than that seen in the rostral zone. It varied in size according to the size of the injection site, and exhibited a rostro-caudal topographic relationship with the neostriatum. These results suggest that the striopallidal pathway in the rat is more precisely organized than previous suspected, and that there may exist at least two distinct topographical representations of neostriatum within globus pallidus.

64.10 A STRIATO-STRIATAL CONNECTION IN RATS. I. J. Bak, C. H.Markham, and E. S. Morgan* Dept. Neurology, Sch. Med., UCLA, Los Angeles, Ca. 90024.

It has been shown in previous studies that herpes simplex virus (HSV) can be used as a tracer in the study of neural pathways in the neostriatum. When HSV is injected into the neostriatum, it is transported retrogradely along afferent nerve fibers and labels their cell bodies outside of the neostriatum. In the present study, particular attention was focused on possible neural connections between left and right striatum.

1 μL of HSV wild type 1 (10,000 plaque forming units per microliter) was injected into the rostral medial part of the head of the left caudate nucleus. Three to four days after microinjection of HSV, the brain was perfused with glutaraldehyde fixative and further prepared for light and electron microscopy.

Injection of HSV into the left neostriatum results in selective labelling of large neurons in the contralateral side of the neostriatum. These large neurons were easily identified not only under the electron microscope but also with light microscopy. There were numerous virus particles (nucleocapsids) in the nucleus and matured virus (virions) in the cytoplasm. There was also a distinct migration of chromatin substance towards the nuclear membrane and a loss of nucleoli.

These large HSV labelled neurons are morphologically characterized by a diameter ranging from 30μm to 50μm. Usually two or three primary dendrites extend from the neuron in opposite directions. The cells contain rich cytoplasmic organelles such as ribosomes, rough endoplasmic reticulum, mitochondria and lysosomal granules. The nuclear membrane usually appears lobulated. Further careful observation reveals that these HSV labelled large neurons are spiny neurons. Approximately 1% of the total neuronal population of the neostriatum is made up of this cell type.

Present results strongly suggest that one class of large striatal neurons terminate in the contralateral side of the neostriatum.

64.11 DIFFERENTIAL DISTRIBUTION OF NEURONES IN THE HEAD OF THE CAUDATE NUCLEUS. Y. Estrada-Palma*, J.A. Roig, I. Zarco-Coronado* and H. Brust-Carmona. Depto. de Fisiología, Div. de Investigación, Fac. de Medicina, Univ. Nal. Autónoma de México, México 20, D.F.

Previous work has suggested an anatomicofunctional organization of the caudate nucleus (CN). However, morphological descriptions do not agree with this suggestion. To elucidate this possible organization of the CN we performed acute experiments in both intact cats and after bilateral injections of 6-Hydroxydopamine (6-OHDA) into the substantia nigra (SN) or dorsal to it (ZI). The extracellular unitary activity was recorded with microelectrodes in one CN or simultaneously in both. We chose only those units appearing spontaneously and being twice as big as the background activity and which remained invariant for 2 min before being fed into a magnetic tape recorder for further analysis by a PDP 11/40 computer. At the end of the recordings the cats received a lethal anesthetic dose and their brains were perfused. Thereafter histological sections were stained (Nissl). Microscopically we counted in each mm the neurones observed along the microelectrode tract and measured their greatest somatic diameter. The best analyzed region corresponded to the A 16-17 coordinates (Jasper and Ajmone Marsan Atlas). In the dorsal regions the potentials were small and iterative at almost constant intervals. In the ventro-lateral regions they were big and appeared in bursts. The dorsal units were hardly affected by electrical stimulation of the n. centralis medialis (NCM), the SN, or the radial nerve, while the ventral ones were modified. The response pattern was usually one of inhibition-excitation for the SN and of excitation-inhibition for the NCM. The analysis of the field potentials, obtained with the same microelectrode, seem to support these observations. At the medial tracts (L 3-4 mm) we found in each mm starting at the dorsal border of the CN the following mean diameters: 1st = 12.86μ, 2nd = 13.64μ, 3rd = 13.59μ, 4th = 13.24μ. At the lateral tracts (L 5 mm) the mean diameters were: 1st = 13.70μ, 2nd = 16.08μ, 3rd = 16.25μ, 4th = 16.44μ. The differences (t test) between the dorsal and ventral regions were statistically significant ($P < 0.05$). In the cats with SN lesions the greatest diameters were also observed in the ventral regions. Furthermore, the mean diameter observed in the second mm was of 15.71μ which differs statistically from those observed in the intact animals as well as the ZI lesioned. These data indicate a differential neuronal distribution according to size and sensibility to electrical stimulation of other cerebral structures, shedding more light on the proposed anatomicofunctional organization of the CN.

64.12 CROSSED CONNECTIONS OF THE SUBSTANTIA NIGRA IN THE RAT. C.R. Gerfen, Wm.A. Staines*, G.W. Arbuthnott* and H.C. Fibiger. Div. of Neurological Science, U.B.C., Vancouver, B.C., Canada.

The existence of crossed multisynaptic pathways that allow for the interdependent control of activity in the two substantia nigrae have been inferred from a number of recent investigations (see Cheramy et al., Nature 289 (1981) 537). This prompted a reexamination of the connections of the substantia nigra (SN) with an emphasis on crossed inputs to and crossed projections from that nucleus. Male albino rats received 20-50 nl pressure injections of a 1% wheat germ agglutinin conjugated horseradish peroxidase (WGA-HRP) solution into the SN or into surrounding areas as controls. Following a 24 hr survival period the animals were anaesthetized and processed according to the tetramethyl benzidine (TMB) protocol of Mesulam (J. Histochem. Cytochem. 26 (1978) 106) for the visualization of HRP.

The pattern of anterograde transport of WGA-HRP after SN injections, confirming for the most part previous reports, demonstrated ipsilateral nigral efferent projections to the striatum, globus pallidus (GP), subthalamic nucleus (SUT), thalamic nuclei including the paralamellar mediodorsal (MD), ventromedial (VM), and parafascicular (Pf) nuclei, central grey, midbrain reticular formation, superior colliculus (SC) and parabrachial area including the pedunculopontine nucleus (PB-PPN). Additionally, the nigral projections to the paralamellar MD and VM thalamic nuclei and to the SC were demonstrated to be bilateral. Previous reports of HRP injection into the SC have indicated that only 2-3 contralateral SNr neurons provide crossed nigro-tectal fibers (Beckstead et al., J. Neurosci. 1 (1981) 121). However, in the present study WGA-HRP injections into the rostral ventral lateral SC, the area in which terminal labelling was seen contralateral to SN injections, labelled as many as 200 contralateral SNr perikarya.

Confirming previous reports, SN WGA-HRP injections retrogradely labelled neurons located in the following ipsilateral brain areas: 1) prefrontal cortex, 2) motor cortex, 3) striatum, 4) GP, 5) central nucleus of the amygdala, 6) anterior hypothalamic area (2-3 neurons), 7) SUT, and 8) dorsal raphe. Additionally, labelled perikarya were observed in the ipsilateral Pf thalamic nucleus, in the contralateral posterior lateral hypothalamic area (LHp) and in the ipsi- and contralateral PB-PPN area. These nigral afferents were confirmed with complimentary WGA-HRP injections into each of these brain regions. While bilateral PB-PPN innervation of the SN has been reported in the cat there has been no previous demonstration of a crossed nigral afferent system from the contralateral LHp area.

Supported by the MRC and NIH.

64.13 THE PALLIDOHABENULAR AND PALLIDOTHALAMIC PATHWAYS ARISE LARGELY FROM TWO DIFFERENT CELL POPULATIONS WITHIN PRIMATE GLOBUS PALLIDUS. L. De Bellefeuille*, A. Parent and R. Boucher. Lab. of Neurobiology, Fac. Med., Laval Univ., Québec, Canada, G1K 7P4.

The double fluorescent retrograde labelling technique (Van der Kooy et al., '78) was used in an attempt to disclose the exact sources at pallidal levels of the projections to the habenula (Hb), and to the ventral anterior (VA)-ventral lateral (VL) thalamic nuclei in primate. A total of four squirrel monkeys (Saimiri sciureus) were used. Injections of a mixture of DAPI-Primuline (DP) in quantities ranging from 0.2 to 0.6 µl were made in Hb, whereas Evans blue (EB) was injected in similar quantities within the VA-VL nuclei on the same side of the brain. The animals were allowed to survive from 6 to 7 days and the brain sections were examined with the help of a Leitz Ploemopak fluorescence microscope.

After these injections a multitude of DP-labelled neurons was found within the anterior lateral hypothalamic area which stands out as the main source of forebrain afferents to Hb. A lesser number of DP cells occurred in the substantia innominata beneath the globus pallidus (GP). No EB-labelled cells were disclosed in these two peripallidal sites. Within the GP itself the DP cells were much less numerous than the EB cells and both were differently distributed. The DP (Hb-projecting) cells were most abundant in the rostral pole of the internal segment of GP (GPi) where they merge indistinctly with the large population of DP cells present in the adjoining lateral hypothalamus. As we proceed caudalward, the DP cells become less numerous and are mostly found at the periphery of GPi where they surround a multitude of EB (VA/VL-projecting) cells which are uniformely distributed within the core of the internal pallidum. The EB cells were extremely abundant all along the rostrocaudal extent of GPi except within the rostral and caudal poles of this structure where only DP cells can be found. Only a few double-labelled cells were observed in the present experimental material. They occurred just caudal to the rostral pole of GPi where there was a certain intermingle of DP and EB cells.

These findings suggest that the primate GPi is organized according to a complex pattern basically consisting of various concentric cell layers. The VA/VL projecting neurons being located within the core of GPi are nearly completely surrounded by a shell of Hb-projecting cells. Furthermore, the entire GPi is enveloped by a neuronal network consisting of large and strongly-reactive acetylcholinesterase (AChE)-containing neurons. However, these AChE cells do not project significantly to either Hb or VA/VL but instead are seemingly related to peripallidal limbic structures, particularly the nucleus basalis (Parent et al., '81), which project to neocortex.

(Supported by grant MT-5781 of the MRC of Canada).

64.14 THREE DIMENSIONAL QUANTITATIVE MORPHOLOGY OF SUBTHALAMIC NEURONS INTRACELLULARLY LABELED WITH HRP. C. Hammond*, J. Yelnik*, J.M. Deniau*, M. Kalia, and S.T. Kitai (SPON: A. Foley). Dept. of Anatomy, Michigan State University, E. Lansing, MI and Lab. Physiol. CTR Nerv and U3 INSERM France.

Responses of rat subthalamic nucelus (STN) neurons following cortical stimulation were intracellularly recorded and subsequently labeled with HRP. After fixation, the brains were cut serially (50µm) in sagittal plane and processed by the $CoCl_2$-DAB procedure. Sections containing labeled neurons were post-fixed in osmium and section embedded in plastic. Morphology of the neuron is described by means of algebraic and geometric parameters following light microscopic examination and three-dimensional computer reconstruction. Twenty-two labeled neurons were identified as Golgi type I (projection) neurons with branched axons. The somata were ovoidal in shape and had a few somatic spines. Four dendritic stems (3.70 ± 0.75) arose from the soma and gave rise to 25.0 ± 4.1 dendritic tips. The dendritic field had the shape of a flat ellipsoid, and was 1000µm long, 600µm wide and 250µm tall. Its long axis was parallel to the rostral-caudal axis of the nucleus. The total dendritic length was 6000 µm (6148 ± 692) and the longest dendrite measured 750µm (753 ± 158µm). Some dendrites extended beyond the borders of the nucleus and terminated in the cerebral peduncle, internal capsule and zona incerta. The dendrites were thin and had spines and protrusions of various sizes and shapes. The axon emerged from the soma or a proximal dendrite and divided within or close to the STN into two branches, one going rostrally and the other caudally. The caudal-going branch of one neuron was followed into the substantia nigra (SN), where it divided into two branches which gave rise to several thin collaterals running dorso-ventrally. The rostral-going branch of another neuron gave rise to a collateral terminating within the dendritic field of the parent cell before dividing into two branches, running rostrally. These observations suggest that rat STN neurons could receive afferent inputs other than those terminating within the nucleus. Axons of the STN neurons are collateralized within the nucleus and the main axon branches into two major axons before or immediately after they emerge from the nucleus.

(Supported by NIH Grant NS 14866 and Min. Aff. estrang grant DGRST 78/7/2764.).

64.15 EM-AUTORADIOGRAPHY OF NIGROTHALAMIC TERMINALS IN THE CAT. I.A. Ilinsky, K. Kultas-Ilinsky, S. Warton*, and K.R. Smith. Depts. of Anatomy and Surgery, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

The ultrastructural features and synaptic sites of nigrothalamic afferents were described in a degeneration study in the cat by Kultas-Ilinsky et al. (Exp. Brain Res., 1978). Degenerative changes in synaptic boutons, however, limit the possibilities of ultrastructural analysis as well as identification of the degenerating boutons with their counterparts in the normal neuropil. Thus an EM-autoradiographic study was undertaken to overcome these difficulties. 0.2-0.4 µl of 2,3,4,5[3]H-leucine (ICN) in concentration 70 µCi/µl was injected into the pars reticularis of substantia nigra in seven cats. The animals were allowed to survive for 4-6 days, then they were perfused and the tissue was processed for EM and LM autoradiography as described previously (Kultas-Ilinsky et al., Brain Res., 1980). The exposure time for EM-autoradiography was 4-6 months.

A large number of labelled boutons and myelinated fibers were found in the ventral medial nucleus of the thalamus (VM). The diameter of labelled myelinated fibers ranged from 0.5 to 1.4 µm. The mean of the largest and smallest diameters of labelled boutons were 2.93 µm and 1.39 µm respectively. Some terminals, however, reached a length of 3.7 µm. The boutons were characterized by large numbers of long mitochondria, very distinct neurotubules and a population of synaptic vesicles of extremely variable shapes and sizes. Preliminary measurements indicate that the mean diameter of synaptic vesicles is in the range of 40 nm with ratio of longest to shortest diameter being 1.46. In all labelled boutons 3-4 large (103 nm) dense core vesicles were observed also. Synaptic junctions were of the symmetrical type with a relatively long contact area. Labelled nigral boutons formed synaptic contacts on large and small diameter dendritic branches of thalamocortical projection neurons as well as on vesicle-containing dendrites which presumably belong to local circuit neurons. In several instances the same labelled nigral bouton was observed contacting both types of dendrites. Some of the nigral boutons seemed to be of the en passant type. Labelled terminals were found either singly in the neuropil or in complex synaptic arrangements in glomeruli. Quantitative analysis of the density of nigral boutons on the dendrites of projection and local circuit neurons is currently in process. Supported by a grant from American Parkinson Disease Association.

64.16 A BASAL GANGLIA-THALAMIC-TELENCEPHALIC PATHWAY IN PIGEONS. Cheryl A. Kitt and Steven E. Brauth, Department of Psychology, University of Maryland, College Park, Maryland 20742.

One of the major pathways by which the mammalian basal ganglia influence motor functions is via projections to nuclei of the thalamic ventral tier. Ventral tier nuclei, in turn, project upon portions of the frontal cortex including the motor and premotor cortices. Previous studies (Brauth, Ferguson and Kitt, 1978; Reiner, Brauth, Kitt and Karten, 1980) have suggested that similar pathways may exist in birds via the thalamic nucleus dorsointermedius posterior (DIP). In the present study the afferent and efferent connections of DIP were traced by horseradish peroxidase histochemistry and autoradiography.

HRP injections centered within DIP labeled neurons within the ipsilateral paleostriatal complex (avian basal ganglia), ipsilateral dorsal reticular nucleus (RSd) and bilaterally within the lateral cerebellar nucleus (CL). Within the paleostriatum, large cells of the paleostriatum primitivum (PP) and ventral paleostriatum (VP) were labeled as well as occasional small neurons of the lobus parolfactorius (LPO). Previous studies have considered the PP comparable to the mammalian globus pallidus, VP comparable to the mammalian substantia inominata and LPO comparable to portions of the mammalian striatum such as the caudate nucleus and nucleus accumbens.

The results of the autoradiography studies indicate that DIP fibers enter the telencephalon via the lateral forebrain bundle. Silver grain accumulations were found in the region ventral to PP including the VP and nucleus intrapeduncularis (INP). DIP efferents pass through the paleostriatum augmentatum (PA) to terminate within a small crescent shaped field of neurons lying in the rostromedial portion of the neostriatum intermedium (NI).

These results suggest that DIP neurons, like those of the mammalian ventral tier, may provide a pathway by which the basal ganglia influence motor functions in birds. The neostriatum intermedium (NI) has been shown to project to a more caudal field of neurons within the lateral neostriatum, the neostriatum intermedium pars lateralis (NIL)(Ritchie and Cohen, 1977). The NIL, in turn, projects to the avian archistriatum. While no direct counterpart to the mammalian motor cortex has been identified in birds, the avian archistriatum is the source of a long descending telencephalic efferent system called the occipitomesencephalic tract (OM). In pigeons, OM fibers reach the lateral reticular formation and lateral pontine nucleus, structures which, in mammals, are in receipt of descending projections from the motor cortex.

64.17 AUTORADIOGRAPHIC STUDY OF THE EFFERENT FIBERS OF THE ENTOPEDUNCULAR NUCLEUS AND SUBSTANTIA NIGRA IN THE CAT.

M. Giguère and L.J. Poirier, Lab. de neurobiologie, Hôpital de l'Enfant-Jésus, 1401, 18e Rue, Québec G1J 1Z4.

Following injections of ^{3}H-leucine in different parts of the entopeduncular nucleus (EP) and the substantia nigra (SN) it was observed that both structures project to a common terminal area. This area corresponds to the ventral anterior, ventral lateral and ventral medial thalamic nuclei and the nucleus tegmenti pedonculopontinus (TPP). Furthermore, a specific group of efferent fibers arising from each structure (EP and SN) was also disclosed: the EP sends axons to the lateral part of the lateral habenular nucleus and to the centro-median-parafascicular complex and the pars reticulata of the SN projects to the superior colliculus.

Projections to the thalamic nuclei (VA-VL-VM) follow a topographical pattern which suggests that the EP and the pars reticulata of the SN may be regarded as being morphologically interrelated. The pars compacta of the SN projects profusely to the striatum and more so in a restricted area corresponding to the rostral part of this structure.

64.18 ACETYLCHOLINESTERASE-RICH PROJECTION FROM THE BASAL GANGLIA TO NEOCORTEX IN THE CAT.

A. Parent, R. Boucher and J. O'Reilly-Fromentin*. Lab. of Neurobiology, Fac. Med., Laval Univ., Québec, Canada, G1K 7P4.

In the brains of cats prepared according to the DFP pharmacohistochemical procedure for the demonstration of acetylcholinesterase (AChE)-producing neurons, the entopeduncular nucleus (EN) was found to be composed of small to medium-sized (maximum diameter: 28.2 ± 0.3 um) neurons staining only weakly for AChE. In contrast, the globus pallidus (GP) comprises a mixted neuronal population. There is (1) weakly-stained cells (27.3 ± 0.4 um) which are morphologically very similar to those in EN, and (2) large (40.3 ± 0.6 um) and intensely reactive AChE cells which are topographically related to similar multipolar AChE cells located in various peripallidal limbic structures, particularly the substantia innominata (SI). Large (40.2 ± 0.5 um) and strongly stained AChE neurons are also scattered throughout the putamen (PUT) amongst a multitude of smaller and weakly reactive cells. The large and strongly-stained AChE cells in PUT are morphologically similar to the voluminous AChE neurons present in GP and often there is no clear boundary between these two cell populations.

In an attempt to find out if some of these AChE neurons project toward neocortex, multiple WGA-HRP injections were made within the auditory cortex (AI and AII) in 15 cats and the brain sections processed according to the combined HRP-AChE method (Mesulam, '76). These injections resulted in a retrograde labelling of numerous large and strongly-stained AChE cells within GP and of a smaller number of similar neurons in PUT.In PUT the AChE-HRP labelled cells were found most abundantly along the medial border, and in the caudoventral aspect of this structure. These double-labelled PUT cells often appear continous with those in GP. No HRP material could be detected in the smaller and weakly reactive AChE cells present in EN, GP or PUT after cortical injection. In contrast, HRP injections into the various subcortical target structures of the basal ganglia (including substantia nigra, VA/VL thalamic nuclei and EN) label only the smaller pale cells and not the large and intensely reactive AChE cells within the basal ganglia (Parent et al., '80).

These findings suggest that in regard to its output elements the feline basal ganglia may be subdivided into two fundamental cellular compartments: 1. the parvocellular neurons which stain only weakly for AChE, project to the main subcortical target structures of the basal ganglia, and appear to represent the typical "striatal" elements, 2. the magnocellular neurons which stain strongly for AChE, project widely upon neocortex and appear to represent the "limbic" elements of the basal ganglia.

64.19 ORGANIZATIONAL FEATURES OF THE CORTICOSTRIATE PROJECTION IN THE MONKEY.

P. J. Eslinger, G. W. Van Hoesen and E.H. Yeterian, Depts. of Anat. & Neurol., Univ. of Iowa, Iowa City, IA 52242.

Previous anatomical studies in the monkey have revealed that two areas of the cerebral cortex with reciprocal interconnections project in part to the same specific subdivisions of the neostriatum. These results imply that the topography of a given corticostriate projection can be understood on the basis of the intrahemispheric association connections of the cortical area. The present investigation was undertaken to ascertain the extent of communality in the corticostriate projections of three non-adjacent cortical areas known to have substantial reciprocal corticortical connections with each other.

Injections of tritiated amino acids (^{3}H - leucine and ^{3}H - lysine) were made in the posterior one-half of the cingulate gyrus (area 23), the posterior parahippocampal area (area TF) or the inferior parietal lobule (area 7) in 9 rhesus monkeys. Conventional autoradiographic methods were used to reveal the distribution of label. The sections were studied and charted with darkfield illumination and light microscopic procedures. Prior to analyzing the corticostraite projections, it was confirmed that areas 23, TF and 7 are indeed interconnected, as previous results had indicated. The corticostriate projections of these areas to the head, body and tail of the caudate nucleus were then examined. It was observed that all three cortical areas project to widespread parts of the caudate nucleus, and overall, have a unique topography. However, at numerous locations a communality was observed in the terminal labeling of corticostriate projections. This was most conspicuous in the dorsal and lateral parts of the head of the caudate nucleus, in the body and in the middle and dorsal parts of the tail. In three other monkeys control injections of labeled amino acids in the foot region of area 4, the posterior orbitofrontal cortex (area 13) or the medial temporal polar cortex (area TG or 38) revealed few if any corticocortical projections from these areas to areas 23, TF and 7. Additionally, there was little or no communality in their corticostriate projections.

The results further establish the fact that corticostriate and corticocortical projections are correlated closely. They imply that a given part of the caudate nucleus receives corticostriate projections from multiple areas of the cerebral cortex and that these areas are interconnected with each other via corticocortical connections. One interpretation of this organization might be that the information carried in the corticostriate projection is more related to corticocortical circuits than to specific cortical loci. (Supported by grant NS 14944 to G.W. VH.)

64.20 ORIGINS OF SUBCORTICAL PROJECTIONS TO THE NEOSTRIATUM OF THE OPOSSUM.

James C. Hazlett and Diane L. Schanz*. Dept. Anatomy, Wayne State University, Detroit, MI 48201.

While studies in several eutherian forms have detailed the origins of thalamic and mesencephalic projections to the neostriatum, similar information is not presently available for any example of the marsupial radiation. Accordingly, we have utilized retrograde axon transport techniques to examine the origin of neostriatal afferents in the opossum. Furthermore, since several of these systems are reported to be topographically organized, rostral, middle and caudal portions of both the caudate and putamen were targeted for injection. At thalamic levels placements in the body of the caudate resulted in moderate retrograde labelling throughout the intralaminar complex (parafascicular posterolateral, parafascicular and paracentral nuclei) and one midline cell group, nucleus centralis thalami. Comparable putamen placements resulted in a similar distribution but with fewer numbers of reactive cells. Caudal caudate or putamen injections were marginally effective in labelling thalamic cells. However, the few reactive cells which were observed occupied the appropriate loci. Injections in the head of the caudate produced a considerably more extensive distribution of labelled thalamic cells. As expected, this included the intralaminar complex and nucleus centralis. Moreover, it appeared that almost every neuron in these locations contained at least some reaction product. In addition, labelled thalamic cells appeared in the anterior and posterior paraventricular, intermediodorsal, interanterodorsal, mediodorsal and rhomboid nuclei. A few reactive neurons were also observed in the anterior thalamic complex. At mesencephalic levels only the rostral caudate (head) injections resulted in labelling of the nucleus raphe dorsalis and ventral tegmental area. In contrast, all caudate and putamen injections yielded retrograde labelling in the substantia nigra. On the basis of mid caudate and mid putamen injections we suggested that most neurons in the pars compacta and a few cells in the adjacent p. reticulata projected to the caudate, while certain cells in the p. lateralis (well developed in the opossum) together with a few neurons in the adjacent p. reticulata projected to the putamen (Hazlett, '80). Subsequent placements at the rostral and caudal extremes of both neostriatal subdivisions further confirm the presence of a medial to lateral nigrostriatal topography and provide additional evidence suggesting an anterior to posterior representation and gradient. (Supported by the National Science Foundation - Grant #BNS 80-22312.)

64.21 NEUROCHEMICAL CHARACTERIZATION OF THE NIGROTEGMENTAL PROJECTIONS IN THE RAT. J.A. Childs* and K. Gale (SPON: F.G. Standaert). Department of Pharmacology, Georgetown University, Schools of Medicine and Dentistry, Washington, D.C. 20007.

Complete cerebral hemitransection placed rostral to substantia nigra (SN) did not prevent the contralateral circling behavior induced by intranigral microinjection of muscimol (50 ng); under these conditions, specific GABA receptor binding in SN was unchanged. In contrast, transections placed caudal to SN caused a marked loss (50%) of GABA receptors in SN, and, at the same time, reduced glutamic acid decarboxylase activity in the caudal mesencephalic tegmentum by 20%.

To determine whether the projections from SN to the caudal mesencephalon might be GABA-containing, ^{3}H-GABA was microinjected in combination with a GABA-transaminase inhibitor (gamma-vinyl-GABA, 2ug) into SN and the transport of the ^{3}H-GABA was followed over 1-5 hours. Of the radioactive GABA remaining in the brain, the highest concentration (outside of the injection site) was found in the ipsilateral caudal mesencephalic tegmentum, at the midcollicular level, just ventral to the region of the central grey. When ^{3}H-GABA was injected into this region, a significant portion appeared in the ipsilateral SN.

These data suggest that some of the descending efferent projections from the SN to the caudal mesencephalic tegmentum may be GABAergic. These pathways may be subject to GABA-receptor-mediated inhibitory influences in SN.

65.1 PROPERTIES OF CALCIUM UPTAKE AND SEROTONIN RELEASE IN RAT PLATELETS. L. Toll and S.H. Snyder. Johns Hopkins University, Sch. of Med., Dept. of Neuroscience, Pharmacology and Psychiatry, Baltimore, MD 21205.

It has been shown that under certain conditions extracellular calcium is required for serotonin release from platelets (Bennett, W.F., Belville, J. and Lynch, G., 1979, Neuroscience 4:1203). Studies were undertaken to determine if factors which block serotonin release from platelets could do so by inhibiting stimulus induced calcium influx. In this manner platelets were used as a model system to study the properties of stimulus induced calcium entry and neurotransmitter release.

Rat platelet rich plasma was incubated with [^{3}H]5-HT to allow incorporation into platelets. After washing, platelets were incubated with ^{45}Ca in the presence of thrombin. Thrombin stimulation of ^{45}Ca entry and [^{3}H]5-HT release were then measured simultaneously by filtration. Both processes occured rapidly, being virtually complete by 3 min at 30°C. At 0°C or in the presence of EDTA the level of ^{45}Ca uptake and [^{3}H]5-HT release is similar to that in the absence of thrombin. Both thrombin induced ^{45}Ca uptake and [^{3}H]5-HT release were inhibited by divalent cations with the order of potency being $Cd^{2+} > Ni^{2+} > Mn^{2+} \geq Co^{2+} > Ba^{2+} = Mg^{2+}$. This is similar to the divalent ion potency in inhibiting depolarization induced Ca^{2+} entry into nerve terminals.

Serotonin release from platelets is inhibited by agents which increase intracellular cAMP levels (Friedman, F. and Detwiler, T.C., 1975, Biochemistry, 14:1315) We have found that phosphodiesterase inhibitors theophylline, isobutylmethylxanthine and papavarine as well as dibutyryl-cAMP and PGE_1, all of which increase intracellular cAMP levels, inhibit both ^{45}Ca entry and [^{3}H]5-HT release in a dose dependent manner. Theophylline, dibutyryl-cAMP and PGE_1, require preincubation to produce inhibition, indicating the accumulation of cAMP is necessary. Papavarine inhibits instantaneously indicating a more direct blockage of ^{45}Ca entry. ^{45}Ca uptake was also inhibited by dinitrophenol and FCCP, uncouplers of oxidative phosphorylation, as well as by mitrochondrial ATPase inhibitors oligomycin and dicyclohexylcarbodimide. This indicates the requirement for energy for thrombin induced calcium flux. Of these compounds only oligomycin inhibited release of [^{3}H]5-HT. The other compounds probably interfere with serotonin storage in intracellular vesicles and thus, allow its unstimulated efflux from the platelets.

65.2 EVIDENCE THAT LECTIN-BINDING SITES ARE PRESENT ON ISOLATED HYPOTHALAMIC GRANULES CONTAINING LHRH. A. Barnea, and G. Cho*. Depts. Ob-Gyn and Physiology, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

Luteinizing hormone releasing hormone (LHRH), stored in granule-like particles within hypothalamic neurons, is known to be released into the hypophysial portal system. It is reasonable to assume that fusion of the LHRH granules with the neuronal plasma membrane is an important step in this release process. Since glycoproteins, particularly their terminal carbohydrate moeities, have been implicated in membrane-membrane interactions, we wished to ascertain if tightly-bound carbohydrates are present on the surface of hypothalamic granules containing LHRH. LHRH granules, isolated from hypothalami of adult male rats by means of hypo-osmotic shock and differential centrifugation, were passed through columns of Sepharose to which a lectin (a carbohydrate-binding protein) has been covalently attached. LHRH was eluted from the columns, and the amount present in the unbound and bound fraction was measured by RIA. Using this procedure, we evaluated the binding of LHRH granules to two immobilized lectins: Concanavalin A (Con A; a lectin binding molecules having α-D-mannopyranosyl and sterically related residues) and wheat germ agglutinin (WGA; a lectin binding molecules having N-acetyl-glucosaminyl residues). When LHRH granules were chromatographed on columns of Con A-Sepharose, 80% of the total LHRH was recovered in the unbound fraction and 20% in the bound fraction. The total recovery of LHRH from the columns was 96 ± 2% (mean ± SE; N = 21). When the unbound fraction was passed again through another column, 32% of the total LHRH was bound to the columns. Synthetic LHRH, added to the LHRH granules before chromatography, did not bind to the Con A-Sepharose. To examine the specificity of the binding of the LHRH granules to Con A, LHRH granules were chromatographed on columns of Con A-Sepharose, WGA-Sepharose, or Sepharose-4B. Of the total LHRH recovered from the columns, 21.4 ± 1.6% (N = 9) was bound to Con A-Sepharose, 10.5 ± 0.5% to WGA-Sepharose, and none was bound to Sepharose-4B. These findings are indicative that LHRH granules bind to immobilized lectins, and that the degree of binding is dependent on the binding specificity of the lectin. We propose that tightly-bound carbohydrates (lectin binding sites) are present on the surface of the LHRH granules and that such binding sites may be involved in the release of LHRH from hypothalamic neurons.

65.3 MONOVALENT ION REQUIREMENTS FOR THE MgATP-STIMULATED RELEASE OF LHRH FROM ISOLATED HYPOTHALAMIC GRANULES. G. H. Burrows and A. Barnea. Depts. Ob-Gyn and Physiology, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

We have previously demonstrated that MgATP stimulates the release of luteinizing hormone releasing hormone (LHRH) from isolated hypothalamic granules by a mechanism which requires KCl. In the present study, we have examined the concentration dependence and specificity of the KCl requirement for the MgATP-stimulated release of LHRH by replacing first the K^+ and then the Cl^- with other monovalent ions. LHRH granules were isolated from homogenates of adult male hypothalami by differential centrifugation and then incubated in buffered media containing the various salts with or without MgATP. LHRH released into the medium was separated from that remaining in the granules by affinity chromatography and then quantified by radioimmunoassay. When LHRH granules were incubated in the absence of KCl, LHRH release was not stimulated by MgATP. However, when KCl was included in the incubation medium, LHRH release was stimulated by MgATP. Moreover, the magnitude of the stimulation was found to be a saturable function of KCl concentration and maximal stimulation was observed at 80 mM KCl. When granules were incubated in the presence of 60 mM LiCl, NaCL, KCl, CsCL, choline chloride or tetraethylammonium chloride, the MgATP-stimulated release of LHRH was 12.1, 8.5, 9.1, 8.5, 5.3, or 0%, respectively. Inclusion of anion transport inhibitors (SITS, phloretin, probenecid, or pyridoxal phosphate) in the incubation mixture did not inhibit the stimulation of LHRH release by MgATP. The finding that the MgATP-stimulated release of LHRH can occur in the presence of each of the monovalent anions tested or in the presence of anion-transport inhibitors, is indicative that an active site selective for monovalent anions is not involved in the MgATP-stimulated release of LHRH. On the other hand, the findings that the MgATP-stimulated release of LHRH cannot occur in the presence of each of the monovalent cations tested and that the stimulated release was inversely related to the crystal radius of the cation, are indicative that an active site selective for monovalent cations is involved in the MgATP-stimulated release of LHRH from isolated hypothalamic granules.

65.4 REGULATION OF NOREPINEPHRINE UPTAKE BY THE INTERACTIONS OF SYNAPTOSOMES WITH DIVALENT CATIONS AND ATP. E.D. Hendley, S.R. Whittemore* and Y.H. Ehrlich. Depts. Physiol. Biophys, Psychiatry and Biochem. Univ. Vermont Coll. Med., Burlington, VT 05405.

The high affinity uptake of norepinephrine (NE) in brain has been thoroughly characterized pharmacologically, and has been shown by us and others to be subject to rapid and reversible alteration during altered behavioral states in rats and mice. Other studies in our laboratories have demonstrated alterations in the phosphorylation of synaptosomal proteins following similar behavioral manipulations. In the present study we have investigated the possibility that membrane protein-phosphorylation/dephosphorylation systems play a role in the regulation of transmitter uptake. This was done by measuring the high affinity uptake of ^{3}H-l-NE under phosphorylating conditions (in the presence of Ca^{+2} Mg^{+2} and ATP), conditions previously shown to cause phosphorylation of specific neuronal membrane proteins, and under non-phosphorylating conditions (omission of Ca^{+2}, Mg^{+2} and/or ATP). High affinity uptake of NE was determined by adding synaptosomes (P_2) of rat cerebral cortex to prewarmed media, and incubating them for 1 min at 30°C in Krebs-bicarbonate Ringer (KRB) containing ^{3}H-l-NE at 5 concentrations from 0.1 to 1.0 uM. Cocaine, 10 uM, was used to define specific uptake. Samples were filtered under vacuum and ^{3}H-l-NE uptake was measured by liquid scintillation counting. The kinetic constants, apparent Km and Vmax, were determined by regression analysis of Lineweaver-Burk plots. Under these assay conditions, control uptake exhibited an apparent Km of 0.18 uM and Vmax of 83 fmol/mg/min. When ATP, 200 uM, was added, uptake rates markedly increased; Vmax increased 2-fold and Km also increased. Under non-phosphorylating conditions uptake markedly decreased as Km was elevated with no change in Vmax.

In a second series, phosphorylating conditions were maintained during 5 min preincubation at 30°C in normal KRB, following which P_2 was pelleted and resuspended in isotonic sucrose, and then NE uptake was determined as described above. This procedure led to marked increases in uptake rates (elevated Km and Vmax) as seen previously with addition of ATP during the one min uptake measurement. Preincubation for 5 min in the absence of Ca^{+2} and Mg^{+2} led to decreased uptake rates, however, this decrease was caused by reduced Vmax with no change in apparent Km. Inclusion of γ-P^{32}-ATP during these preincubation or incubation procedures revealed that varying conditions which result in altered uptake rates also cause changes in the pattern of phosphorylation of specific proteins. Ongoing studies are examining the possible functional relationships between these systems. The changes in uptake rates observed here under phosphorylating conditions are similar to those we observe in vivo following stress, aggression, electroconvulsive shock and genetic hyperactivity. (USPHS MH 25811)

65.5 HIGH-AFFINITY GLUTAMATE AND GABA UPTAKE IN HUMAN BRAIN: NEUROCHEMICAL CHARACTERISTICS AND ULTRASTRUCTURAL CORRELATES. William O. Whetsell, Jr. and Robert Schwarcz. Division of Neuropathology, University of Tennessee and Memphis V.A. Hospital, Memphis, Tenn. 38163 and Maryland Psychiatric Research Center, Baltimore, Md. 21228

Following a recent report on the effects of freezing and tissue storage on glutamate uptake in rat brain (Schwarcz, Life Sci., 28, 1147, 1981), uptake of both glutamate and GABA was examined in human brain tissue collected at autopsy. The brains of all subjects (age range 38-85; no history of neurologic or psychiatric disorders) were dissected and quick-frozen at -80°C within 7 hr post mortem. Tissues were subsequently thawed and P_2-fractions prepared according to conventional differential centrifugation steps. Uptakes were routinely determined at $3x10^{-7}$M glutamate and 10^{-6}M GABA, respectively. Portions of the P_2-fractions were also examined by electron microscopy.

The data demonstrated the presence of strictly sodium-dependent uptake systems for both amino acids. Accumulation of both glutamate and GABA was abolished by sonicating the P_2-suspension prior to incubation, indicating a dependency of the processes on intact brain elements. Frozen brain samples could be stored up to 3 months (but not longer) without appreciable changes in experimental data. Regional differences in glutamate uptake were pronounced (N=7-9): cortical areas=hippocampus>caudate=putamen=thalamus=cerebellum>hypothalamus>globus pallidus=substantia nigra>medulla - the last showing less than 15% of the uptake found in cortical specimens. Kinetic analysis of high-affinity glutamate uptake in caudate tissue (N=5) demonstrated a K_m of 2.6±1.3μM and a V_{max} of 166±53 pmol/min/mg prot - in excellent agreement with figures obtained from frozen and thawed rat striata. Pharmacological assessment of both glutamate and GABA uptake substantiated these similarities: the selectivity of the uptake processes (a wide range of drugs did not interfere at 1mM) and the absolute and relative potencies of a spectrum of specific uptake inhibitors were virtually identical in human caudate and rat striatum.

Ultrastructural examination of P_2-preparations from the frozen human caudate tissue clearly demonstrated the presence of synaptosomes identical to those observed in fresh rat striatum.

Our combined neurochemical and morphological data support our previously expressed view that uptake measurements in quick-frozen and thawed human brain samples 1) are technically feasible 2) reflect functional properties of glutamatergic and GABAergic nerve terminals in the human brain and 3) may provide a tool for examination of these mechanisms in neuropathological states.

This work was supported by USPHS grant 16941 and a grant from the Wills Foundation.

65.6 PHOSPHATIDYLSERINE ENHANCEMENT OF [^{3}H] GABA UPTAKE BY RAT WHOLE BRAIN SYNAPTOSOMES. Andrew Y. Chweh* and Steven W. Leslie. Department of Pharmacology and Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

[^{3}H] GABA binding to purified lipids has been examined in an organic solvent-aqueous partition system. In addition, [^{3}H] GABA binding capacity in the partition system was compared with the ability of the lipids to alter sodium-dependent [^{3}H] GABA uptake into synaptosomes isolated from rat whole brains. For the binding study, three ml aliquots of $CHCl_3$-CH_3OH (2:1, v/v) containing 0.5 mg of each lipid and 1.0 ml of Ringer's solution (NaCl, 116 mM; KCl, 2.5 mM; $CaCl_2$, 1.0 mM, Tris base, 2 mM; pH adjusted to 7.4 with concentrated HCl) containing 0.1 μCi of [^{3}H] GABA with or without drug (nipecotic acid or bicuculline) and/or cations (Ca^{2+}, Na^+) were added to 15 ml capped culture tubes. Tubes were vortexed thoroughly for 1 min. at room temperature. After centrifugation at 500 g for 5 min. 200 μl of a lower organic phase was evaporated and counted for the radioactivity. [^{3}H] GABA was found to bind to all of the lipids studied in the organic solvent-aqueous partition system (phosphatidic acid, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine, gangliosides and sulfatide), although phosphatidylserine exhibited by far the greatest binding capacity. [^{3}H] GABA uptake into synaptosomes was enhanced by phosphatidylserine (0.1 mM) (48.0 percent), but was not altered by any other lipid. Phosphatidylserine enhancement of [^{3}H] GABA uptake required the presence of sodium and was blocked by nipecotic acid (10 μM). These results suggest that phosphatidylserine may play a role as a GABA carrier in the sodium-dependent GABA uptake process in the presynaptic nerve end. (Supported by NIAAA grant AA05132-02).

65.7 IN VITRO RELEASE OF ENDOGENOUS DOPAMINE AND 3,4-DIHYDROXYPHENYLACETIC ACID FROM RAT STRIATUM. R.S. Flint*, J.M. Murphy, M.T. Ciancone* and W.J. McBride (SPON: M.B. Waller). Depts. of Psych. & Biochem., Inst. Psych. Res., Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The release of endogenous dopamine (DA) and 3,4-dihydroxyphenylacetic acid (DOPAC) from 300x300 μm prism-shaped tissue slices of the rat striatum was studied. The tissue slices were suspended in G50 coarse Sephadex in polypropylene colums. After a suitable washout period with physiological medium, the release, induced by 55 mM K^+ or 100 μM veratridine, of endogenous DA and DOPAC was measured in the superfusate by HPLC procedures. Initial studies using 55 mM K^+-stimulation in the presence of 2.5 mM Ca^{+2}, resulted in the release of DA (54 ± 6 pmole/mg prot/min) as well as DOPAC (31 ± 3 pmole/mg prot/min). Addition of an MAO inhibitor ($8x10^{-6}$M pargyline) to the medium throughout the superfusion reduced the stimulated, Ca^{+2}-dependent amount of DOPAC released by 93% while increasing the amount of DA released to 62% above control values. Addition of pargyline, only at the time stimulated release (induced by 55 mM K^+ plus 2.5 mM Ca^{+2}) occurred, did not alter the amount of DA and DOPAC released. When 10^{-5}M cocaine was included throughout the superfusion (which should prevent uptake nearly 100%), there was no effect on the K^+-stimulated, Ca^{+2}-dependent release of DA or DOPAC. When α-methyl-β-tyrosine, a tyrosine hydroxylase inhibitor, was present during the superfusion, the amount of stimulated release of both DA (20% of control) and DOPAC (10% of control) was reduced. One hundred μM veratridine (in the absence of Ca^{+2}) stimulated the release of DA and DOPAC to the same extent as that found for 55 mM K^+ plus 2.5 mM Ca^{+2}. The peak release of DA occurred 5 min after changing the superfusion medium to one containing 55 mM K^+ plus 2.5 mM Ca^{+2} whereas the peak release of DOPAC occurred 10 min after changing the medium. Addition of 16 mM Mg^{+2} to the medium had no effect on the K^+-stimulated, Ca^{2+}-dependent release of either DA or DOPAC. In fact, substituting 16 mM Mg^{+2} for 2.5 mM Ca^{+2} markedly stimulated the release of both DA (21 ± 5 pmoles/mg prot/min) and DOPAC (23 ± 7 pmoles/mg prot/min) above baseline levels, although the amount released was less than that obtained for Ca^{+2} (40% of control for DA and 74% of control for DOPAC). The data indicate that (1) both DA and DOPAC are formed within dopaminergic terminals in the in vitro system; (2) little or no uptake of released DA occurred in the superfusion columns; (3) 55 mM K^+-stimulated release of DOPAC occurs nearly as well in the presence of 16 mM Mg^{+2} as in the presence of 2.5 mM Ca^{+2}; and (4) approximately half the DA releasable pool can be released by Mg^{+2}, suggesting the possible existence of a nonclassical release mechanism in the DA terminals. (Supported by MH00203).

65.8 THE EFFECT OF AN IN VIVO ADMINISTRATION OF PHENCYCLIDINE ON HIGH AFFINITY CHOLINE UPTAKE IN RAT HIPPOCAMPUS AND STRIATUM. G.C. Haggerty*, J.A. Richter and R.B. Forney* (SPON:J.I. Nurnberger), Dept. of Pharm. & Tox. & Inst. Psych. Res., Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

Phencyclidine (PCP) has been reported to interact with the cholinergic nervous system primarily in an antagonistic manner. Since other anticholinergic drugs such as atropine and scopolomine have been reported to increase high affinity choline uptake (HACU) in whole brain (Atweh et al., Life Sci. 17: 1535-1544, 1975) we wanted to determine if the anticholinergic properties of PCP extended to a similar effect on HACU.

Experiments were carried out in male Wistar rats 250-350g. They were injected with saline, 7.0, 26.0 or 54.4 mg/kg PCP i.p. 30 min before decapitation. Synaptosomes (P_2 fraction) were prepared from hippocampus and striatum and incubated with 0.5 μM ^{3}H-choline at 30°C. Preliminary studies demonstrated that uptake was linear with time and protein concentration. Blanks were incubated in sodium-free medium so that the values reported are for sodium dependent high affinity choline uptake.

TREATMENT mg/kg PCP	HACU HIPPOCAMPUS pmoles/4 min/mgP	HACU STRIATUM pmoles/3 min/mgP
0	21.3	38.0
7.0	23.1	33.7
26.0	21.8	34.0
54.4	19.6	28.1

Analysis of variance demonstrated that PCP caused a significant decrease in HACU in the striatum but no significant change in the hippocampus. In parallel studies atropine (40 mg/kg i.p.) caused the expected increase in HACU in both brain regions. These data suggest that PCP does not act similarly to classical anticholinergic agents on this parameter. Behavioral studies in our laboratory have shown that at 30 min after a 54.4 mg/kg dose of PCP, rats are very ataxic and exhibit extreme rigidity of the body and often fine tremors. On the other hand, atropine caused hyperactivity and irritability at the dose used. Further studies will look at the temporal effects of the high dose of PCP on HACU for comparison with long-term behavioral effects.

65.9 ENHANCED IN VITRO NOREPINEPHRINE (NE) UPTAKE BY ISOLATED HYPOTHALMIC STORAGE VESICLES OF SPONTANEOUSLY HYPERTENSIVE RAT (SHR). J.H.Rho*, K. Hough*, B. Newman and N. Alexander. Clin. Pharmacol., Dept. of Med. and Dept. of Anatomy, Sch. of Med. and Pharm. Univ. of Southern California, Los Angeles, CA 90033

The in vitro uptake of ^{3}H-NE by storage vesicles from the hypothalamus of age-matched SHR and Wistar-Kyoto (WK) rats has been studied. An improved isolation technique for controlling the hypo-osmotic lysing of the synaptosomes, adjustments of the suspending medium and alterations of the centrifugation procedures have been devised. The result has been an improved procedure for the isolation of biochemically active NE storage vesicles from rat hypothalamus and rat whole brain. Differences between samples do not exceed 4%. Electron-microscopic examination of these samples confirms the concentration of synaptic vesicles.

The uptake mechanisms of storage vesicles of both SHR and WK rats exhibit a marked temperature dependence and the absolute requirement for ATP-Mg^{++} (90%). A complete inhibition of NE uptake by reserpine or dicyclohexylcarbodiimide (DCCD) was also documented. NE uptake is linear for 5 min. at 30°C, is saturable and does not level off for in excess of 20 min. Although the kinetics of the NE uptake by the hypothalamic samples of the two rat strains were the same, the amount of uptake was consistently different. The average ^{3}H-NE uptake by 15 hypothalamic samples of SHR was 46.75 p mol per mg protein of storage vesicles (5 min incubation) while that of age-matched WK was 35.21 p mol per mg protein. These differences are highly significant ($p < 0.0005$).

65.10 IN VITRO RELEASE OF ENDOGENOUS MONOAMINES AND AMINO ACIDS FROM NINE CNS REGIONS. W.J. McBride, R.S. Flint*, M.T. Ciancone* and J.M. Murphy. Depts. of Psych. & Biochem., Inst. Psych. Res., Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The K^+-stimulated, Ca^{+2}-dependent release of norepinephrine (NE), dopamine (DA), serotonin (5-HT), GABA, glutamate (Glu), aspartate (Asp), glycine (Gly), taurine (Tau) and alanine (Ala) was measured in the superfusate of tissue slices prepared from cerebral cortex (CTX), striatum (STR), hippocampus (HIP), hypothalamus (HYPO), midbrain (MB), thalamus (THAL), nucleus accumbens (ACC), pons-medulla (PM) and spinal cord (SC) of the rat. Each region was chopped into 300x300 µm prism shaped sections and suspended in G50 coarse Sephadex in polypropylene columns. After a suitable washout period in physiological medium, the release of endogenous monoamines and amino acids, induced by 55 mM K^+ in the absence and presence of 2.5 mM Ca^{+2}, was measured. Portions of each fraction were assayed by HPLC for monoamine content (reported as pmoles/mg protein/min) while another aliquot was used for determining amino acid values (reported as nmoles/mg protein/min) by GLC procedures, except for Tau which was measured spectrofluorometrically. NE, DA and 5-HT were released from all 9 regions. The release of NE was greatest from the HYPO (2.7 ± 0.3) and ACC (1.8 ± 0.6), while the release of DA was highest from the STR (33 ± 5) and ACC (8 ± 2). The release of 5-HT was nearly uniform (0.1 - 0.3) from all regions studied with the exception of the HYPO which exhibited the highest amount released (0.9 ± 0.3). The release of GABA was highest from the HYPO, MB and THAL (0.7 - 1.1). The release of Glu varied over a wide range and had its highest value in the STR (2.1 ± 0.6). Compared to the amount of Glu released, the amount of Asp released was small (0.09 - 0.17 in STR, CTX and THAL). There was no stimulated release of Gly, Tau or Ala observed for any of the CNS regions studied with two exceptions. The two exceptions were that a significant release of endogenous Gly was detected from the spinal cord (0.03 ± 0.01) and pons-medulla (0.14 ± 0.01). The finding that there was no K^+-stimulated, Ca^{+2}-dependent release of taurine under conditions where GABA, and other transmitters, are released is evidence against a transmitter function for this amino acid. The selective release of Gly from only the SC and PM is in accord with the evidence supporting a transmitter function for this amino acid in these 2 regions. The high release of Glu and DA in the STR; GABA, NE and 5-HT in the HYPO; and DA in the ACC support a significant transmitter role for these compounds in these regions. (Supported in part by MH00203 and NS13925).

65.11 HIGH AFFINITY BINDING OF [^{3}H] DESIPRAMINE TO RAT BRAIN LABELS NORADRENERGIC UPTAKE SITES. M. Rehavi*, F. K. Goodwin, P. Skolnick*, and S. M. Paul*. (SPON: J. Axelrod). Clinical Psychobiology Branch, NIMH, Laboratory of Bioorganic Chemistry, NIAMDD, Bethesda, MD 20205.

High affinity binding sites for [^{3}H] imipramine have been characterized in rat brain, human brain, and human platelets. Recent evidence has shown that these high affinity binding sites for [^{3}H] imipramine selectively label serotonin uptake sites in brain and platelets (Paul et al., Life Sci. 26:953, 1980; Langer et al., Science 210,:1133, 1980; Paul et al., Life Sci. 28:2753, 1981). Since secondary amine tricyclic antidepressants were found to be relatively weak inhibitors of [^{3}H] imipramine binding, we set out to determine whether "high affinity" binding sites for [^{3}H] desipramine are also present in rat brain. In the present study high affinity binding sites (K_D = 1.5 nM) for [^{3}H] desipramine have been demonstrated and characterized in membranes of rat brain. The binding of [^{3}H] desipramine was found to be saturable, reversible, heat sensitive and regionally distributed in the brain. High concentrations of [^{3}H] desipramine binding sites were found in the septum, cerebral cortex, and hypothalamus and low concentrations in the medulla, cerebellum and corpus striatum. A good correlation ($r = 0.81$, $p < 0.001$) was observed between the potencies of a series of drugs in inhibiting high affinity [^{3}H] desipramine binding and their ability to block norepinephrine uptake into synaptosomes. In general, the secondary amine tricyclic antidepressants desipramine and nortriptyline were much more potent than the tertiary amine antidepressants. In 6-OHDA-lesioned rats there was a marked decrease in [^{3}H] NE uptake and [^{3}H] desipramine binding with no significant alterations in [^{3}H] 5HT uptake and [^{3}H] imipramine binding.

Our results indicate that high affinity binding of [^{3}H] desipramine is pharmacologically and biochemically different from the high affinity binding of [^{3}H] imipramine in rat brain and that there is a close relationship between the high affinity binding sites for [^{3}H] desipramine and the uptake site for norepinephrine. Labelling of norepinephrine uptake sites with [^{3}H] desipramine may be a valuable tool for studying the mechanism of presynaptic transport of norepinephrine.

65.12 XYLAMINE, A NITROGEN MUSTARD, SELECTIVELY INHIBITS NE UPTAKE BY A Na+ DEPENDENT MECHANISM. R.W. Ransom* and A.K. CHO* (SPON: S. BUTCHER). Dept. of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024

In this laboratory xylamine (XYL)(N-2'-chloroethyl-N-ethyl-2-methylbenzylamine) has been shown to be a long-lasting inhibitor of norepinephrine (NE) transport across the plasma membrane of noradrenergic neurons. We have further studied XYL's selectivity and mechanism of action in efforts to develop it as a specific labelling agent for the NE uptake carrier. The incubation protocol used in these experiments is designed to measure XYL's irreversible inhibitory actions. Rat cortex is finely minced and exposed to XYL for 10 min at 37°C in Krebs bicarbonate buffer. Washed P_2 fractions are then prepared from control and drug treated minces and used as the source of synaptosomes for determining [^{3}H]NE uptake. Using this incubation protocol XYL exhibits an ID_{50} of 0.1 µM as an NE uptake inhibitor. This effect can be blocked by coincubating cocaine (10 µM) with XYL. When Na^+ is removed from the Krebs buffer and replaced by either Li^+ or choline, uptake inhibition is also prevented. This Na^+ dependency and cocaine protection indicate that XYL requires interaction with the carrier to inhibit NE uptake. XYL's selectivity was evaluated in studies of its ability to inhibit choline uptake into striatal synaptosomes and 5-HT uptake into cortical synaptosomes. While NE uptake is inhibited maximally at 1 µM XYL, neither choline or 5-HT uptake was inhibited at 10 µM XYL. XYL is also effective when administered in vivo and maximal uptake blockade in synaptosomes prepared from injected rat occurs after a 40 mg/kg (i.p.) dose. After this treatment choline transport and 5-HT transport into striatal and cortical synaptosomes, respectively, were unaffected. These results indicate XYL's selectivity and show that it is not an indiscriminate alkylating agent.

65.13 GABA UPTAKE BY GRANULE CELLS OF THE RAT OLFACTORY TUBERCLE. N.R. Krieger, J.R. Megill* and P. Sterling. (SPON: M. Selzer). Depts. of Pharmacology and Anatomy, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

The rat olfactory tubercle is suited to neurochemical studies by its laminar organization and rich complement of transmitters and related enzymes. It contains high concentrations of GABA and its synthetic enzyme, glutamic acid decarboxylase (GAD). Using techniques of laminar localization we previously demonstrated that GABA and GAD are most concentrated in the deeper polymorphic layers of the tubercle and relatively absent from the superficial plexiform and pyramidal layers (J. Neurochem. 33 (1979) 299-302). Here we report that the granule cell population (the islands of Calleja) of the polymorphic layer of the tubercle accumulates ^{3}H-GABA.

^{3}H-GABA (34.5 Ci/mMole; 1.5 µl) was injected into the tubercle, and an hour later the rat was perfused with a mixture of paraformaldehyde and glutaraldehyde. The tissue was osmicated, dehydrated and embedded in epon. Serial sections were prepared as EM autoradiograms with Ilford L-4 emulsion.

Silver grains were sparse over the pyramidal and polymorphic cell bodies, but numerous over the granule cell bodies in the islands of Calleja. Grain densities (grains/µm^3) for the granule cells were 0.41 compared to 0.024 and 0.089 respectively for the pyramidal and polymorphic cells. Within the island, all the granule cells appeared to be labeled.

These results, combined with our previous demonstration of the presence in this region of endogenous GABA and GAD, suggest that the granule neurons of the rat olfactory tubercle are gabaergic. Supported by NIH grant MH 31820.

65.14 A PROSPECTIVE METHOD FOR THE QUANTITATIVE DETERMINATION OF NEUROTRANSMITTER COMPARTMENTATION. James V. O'Fallon and Joseph W. Harding. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164.

The Na^+, K^+-ATPase generates and maintains the membrane potential in nervous tissue. The Na^+ gradient that is established by this enzyme has been linked to the transport of compounds, including neurotransmitters and amino acids, across synaptic membranes. It has been further suggested that the Na^+, K^+-ATPase may be a trigger for a neurotransmitter release [e.g., Vizi, Neuroscience 3, 367-384 (1978)]. We have recently presented evidence that 20 µM ouabain, a specific inhibitor of the Na^+, K^+-ATPase, induces the release of cytoplasmic neurotransmitters exclusively [O'Fallon et al., J. Neurochem. 36, 369-378 (1981)].

In the present report advantage was taken of our observation that 20 µM ouabain induced the release of cytoplasmic transmitters in the development of a method to quantify the release of transmitters from neuronal-vesicular, neuronal-cytoplasmic, and glial compartments. In the method, 20 µM ouabain was used in parallel with two other neuroactive agents, 60 mM K^+ and 20 µM veratridine. The effects of these three agents on neurotransmitter release can be summarized by three simultaneous equations which contain the three transmitter compartments as variables. Coefficients for the fractional amount of transmitter released from each compartment by each agent were obtained from model transmitter-region combinations. After the coefficients had been empirically established, the equations were applied to the data obtained on the release of eight transmitters from eight mouse brain regions. The results provided a quantitative evaluation of compartmentation for each transmitter in each brain region examined. This methodology that was developed in this work should be generally applicable to studies involving both compartmentation and transport of neurotransmitters.

65.15 INHIBITION OF γ-AMINOBUTYRIC ACID TRANSPORTER BINDING BY THE POTENTIAL PHOTO-AFFINITY LABEL 4(4'-AZIDOBENZOIMIDYLAMINO)BUTANOIC ACID. G. Tunnicliff* (SPON: H. C. Stanton). Laboratory of Neurochemistry, Indiana University School of Medicine, Evansville, Indiana 47712.

The sodium-dependent binding of [^{3}H]γ-aminobutyric acid to synaptic membranes from rat cerebral cortex exhibited a high affinity component (K_d = 1.2 µM) and a low affinity component (K_d = 35 µM). Concentrations of γ-aminobutyric acid above 40 µM produced an inhibition of binding (substrate inhibition).

4(4'-Azidobenzoimidylamino)butanoic acid (ABBA) competitively inhibited [^{3}H]γ-aminobutyric acid binding to both the high affinity and low affinity binding systems. The K_i values were 11.2 µM and 49.1 µM respectively. Nipecotic acid was more effective in inhibiting both binding systems. K_i values were 4.3 µM and 10 µM. Similar results were obtained for the inhibition of [^{3}H]γ-aminobutyric acid uptake by cortical synaptosomes in the presence of ABBA or nipecotic acid. This supports the idea that sodium-dependent binding is indeed binding to the γ-aminobutyric acid transporter.

ABBA contains an azide group which could make the molecule a useful photo-affinity label for the transporter. Moreover, since ABBA possesses a benzene ring this compound might possibly cross the blood-brain barrier and thus could have important in vivo effects on the uptake of γ-aminobutyric acid.

65.16 EFFECTS OF ACUTE ADMINISTRATION OF PHENCYCLIDINE ON SERUM PROLACTIN CONCENTRATIONS IN THE RAT: DOPAMINERGIC OR CHOLINERGIC? D.F.Kirksey* and C.M. Kuhn. Department of Pharmacology, Duke Univ. Sch. Med., Durham, NC 27710.

Recent studies have suggested that phencyclidine (PCP) may produce its clinical symptomotology via direct or indirect interactions with the central dopaminergic and/or cholinergic systems. PCP reportedly inhibits: 1) amine uptake systems (Smith et.al., Biochem. Pharmacol. 26: 1435, 1977), 2) acetylcholine receptor-regulated ion conductances (Tsai et.al., Mol. Pharmacol. 18:159, 1980), 3) cholinesterase activity (Maayani et.al., Eur. J. Pharmacol. 18: 167, 1974), and 4) ^{3}H.QNB binding to central muscarinic receptors (Aronstam et.al., Mol. Pharmacol. 18: 179, 1980). In the present experiments the pharmacological effects of acute administration of PCP on basal and elevated serum prolactin concentrations in the rat were compared with effects of cholinergic agents and a variety of indirect- acting dopaminergic agonists, agents which facilitate release or block reuptake of neurogenically released dopamine.

Adult male rats (175-200g), sham-injected with saline for 3 consecutive days prior to each experiment, were divided equally into experimental groups and injected i.p. with either saline (0.9%), reserpine (5 mg/kg), or alpha-methyl-p-tyrosine (150 mg/kg). Alpha-methyl-p-tyrosine (AMPT) or reserpine was injected 90' and 300'prior to sacrifice, respectively. One hour prior to sacrifice animals received a second injection of either saline, PCP (10 mg/kg), amphetamine (5 mg/kg), methylphenidate (10 mg/kg), cocaine (20 mg/kg), pilocarpine (10 mg/kg), or atropine (20 mg/kg). All rats were decapitated 5 hours after initial injection of reserpine groups and trunk blood collected, allowed to clot at 4°C, and centrifuged. Serum was collected and assayed for prolactin by radioimmunoassay kits supplied by NIAMDD.

Basal levels of serum prolactin (15 ± 5 ng/ml) were reduced slightly but significantly by PCP, methylphenidate, and amphetamine. Reserpine pre-treatment produced marked increases in serum prolactin levels (51 ± 13 ng/ml) which were completely antagonized by PCP, amphetamine, methylphenidate, and cocaine. In contrast, the cholinergic drugs, atropine and pilocarpine, exhibited no effects on either basal or elevated prolactin levels. Pre-treatment of animals with AMPT, which inhibits dopamine synthesis resulted in an approximate four-fold increase in serum prolactin levels (69 ± 20). PCP and the indirect-acting dopaminergic agonists were all ineffective in reducing these AMPT-induced prolactin elevations. These data suggest that the pharmacological effects of PCP on prolactin release are mediated through an enhancement of tuberoinfundibular dopaminergic neuronal transmission rather than effects on cholinergic systems.

65.17 THE GADOLINIUM ION: A POTENT BLOCKER OF CALCIUM CHANNELS AND CATECHOLAMINE RELEASE FROM CULTURED CHROMAFFIN CELLS. J. M. Trifaró* and G. W. Bourne (SPON: B. Esplin). Dept. Pharmacol. & Ther., McGill Univ., Montreal, Canada.

Gadolinium (Gd^{3+}) is trivalent ion of the lanthanide series which has a high charge to density ratio but a similar ionic radius to Ca^{2+}. Therefore, the effects of gadolinium ions on [^{3}H]noradrenaline output and ^{45}Ca fluxes during resting conditions and stimulation were investigated in cultured bovine chromaffin cells.

Chromaffin cells isolated from bovine adrenal medullae were plated on collagen-coated dishes (10^6 cells/dish) in DMEM containing 10% fetal calf serum as previously described (J. M. Trifaró & R. W. H. Lee, Neuroscience, 1980, 5, 1533-1546). Seven day-old cells were used in all studies and noradrenaline stores were labelled by incubating for 5 min with amino acid-free DMEM containing 10^{-7}M [^{3}H]noradrenaline (specific activity = 1 µCi/0.1 nmole) as described elsewhere (R. L. Kenigsberg & J. M. Trifaró, Neuroscience, 1980, 5, 1547-1556).

Exposure of chromaffin cells to 0.05 mM Gd^{3+} produced 80 ± 5% and 81 ± 4% inhibition of the release of [^{3}H]noradrenaline in response to 10^{-4}M acetylcholine and 56 mM K^+ respectively. Doubling of the extracellular concentration of Gd^{3+} (0.1 mM) produced a 87 ± 3% and 100 ± 2% inhibition of the secretory responses to acetylcholine and K^+. Gd^{3+} (0.05 mM) also produced a parallel shift to the right in the dose-response relationship between the extracellular Ca^{2+} concentration and [^{3}H]noradrenaline output during acetylcholine stimulation, this observation suggests a competitive antagonism of the Ca^{2+} effects by Gd^{3+} in stimulus-secretion coupling.

Gd^{3+} (0.05 mM) was an effective inhibitor (92.3 ± 0.7%) of the uptake of ^{45}Ca into chromaffin cells induced by a depolarizing concentration (56 mM) of K^+. Furthermore, Gd^{3+} also inhibited the increase in both Ca^{2+}-Ca^{2+} exchange mechanism and [^{3}H]noradrenaline output observed in chromaffin cells upon the re-introduction of Ca^{2+} into a Ca^{2+}-free incubation medium.

The present results, which were obtained using low concentrations of Gd^{3+}, indicate that gadolinium is a powerful inhibitor of the Ca^{2+} movements which are required for triggering amine release from chromaffin cells by different secretagogues. Moreover, the results also suggest that Gd^{3+} might be a useful tool for release and electrophysiological studies in other Ca^{2+}-dependent systems.

66.1 OLFACTORY BULBECTOMY AND CHRONIC AMITRIPTYLINE TREATMENT. J.A. Jesberger* and J.S. Richardson. Depts. of Pharmacology and Psychiatry, University of Saskatchewan, Saskatoon, Sask., S7N 0W0.

Bilateral abalation of olfactory bulbs produces a number of behavioral and biochemical changes that are normalized by chronic antidepressant therapy. We have used this preparation as an animal model of depression to examine the biochemical events associated with chronic treatment with the tricyclic antidepressant (TCA), amitriptyline (AMI). Recent investigations have shown that chronic treatment with TCA's will result in a decrease in the density of high affinity binding sites for the beta-adrenergic antagonist ^{3}H-dihydroalprenolol (^{3}H-DHA) and the TCA, ^{3}H-imipramine in several regions of the brain. We have investigated the binding of these two ligands to brain membranes from sham and bulbectomized male Sprague Dawley rats that have received either saline or AMI for 28 days (10 mg/kg i.p.) followed by a 5-day drug free period. Behavioral testing (stepdown passive avoidance and emotionality rating) was conducted after the 5-day drug washout period. The animals were then sacrificed, trunk blood was collected and the brain was excised and dissected. Regions dissected out and investigated were the hypothalamus, midbrain, hippocampus and pons medulla.

Olfactory bulbectomy resulted in an increase in the number of trials for acquisition of the stepdown passive avoidance task, increased irritability scores and elevated 11-hydroxycorticosteroid levels, all of which were returned to near sham values by AMI treatment. Membrane preparations from sham-operated amitriptyline treated animals exhibited a decreased binding for the beta-adrenergic antagonist ^{3}H-DHA relative to that of saline treated shams. Lesioned-saline treated animals did not show any significant decrease in the binding of ^{3}H-DHA relative to saline treated shams nor did the AMI treated lesioned animals exhibit any altered binding relative to that found in saline treated lesioned animals. Chronic treatment with amitriptyline resulted in a decrease in binding for ^{3}H-imipramine in sham-operated animals. Binding studies of ^{3}H-imipramine in bulbectomized subjects are in progress.

These studies suggest that olfactory bulbectomy indirectly or directly alters the noradrenergic response potential to chronic AMI treatment.

66.2 STUDIES ON THE EFFECTS OF INTRAVENTRICULAR INFUSIONS OF (-)-NICOTINE ON BEHAVIOR MAINTAINED UNDER FIXED RATIO SCHEDULES, V. J. DeNoble* and L. Carron*. Behavioral Pharmacology Laboratory, Philip Morris Research Center, Richmond, VA 23261.

Intraventricular infusion of (-)-nicotine produces a prostration syndrome that is prevented by intraventricular pretreatment with derivatives of nicotine but not by anticholinergic drugs (Abood et al., 1979). Present studies investigated 1) intraventricular infusions of (-)-nicotine on behavior maintained under fixed ratio (FR) schedules of food reinforcement, 2) effect of repeated infusions and, 3) effect of nicotinic-cholinergic antagonists on prostration.

In exp. 1 eight male albino rats, each implanted with a cannula in the lateral ventricle were maintained under FR 16 until response rates were stable (<10% variance in responses/sec for 5 consecutive sessions). Sessions were two consecutive 15-min periods with a 5-min time-out (TO) in between. All infusions were separated by 5 days. Rats were first infused with saline (5µl) and repetitive 15-min sessions were run until response rate was at preinfusion levels. Latency to complete the first FR following infusions was recorded. Next, rats were infused with 5µg of (-)-nicotine. This was repeated with the rats maintained under FR 32 and 64. In exp 2 (N=6) rats were maintained under FR 32 and tested as follows: 1) saline infusion, 2) (-)-nicotine (10µg) 3) saline/presession injection (sc) of mecamylamine HCL (0.05, 1.5 and 3.0) or hexamethonium Cl (0.5, 1.0, 1.5 mg/kg/sc) 4) (-)-nicotine/presession injection of the antagonists, and 5) (-)-nicotine retest.

Results of exp 1 showed that latency to complete the first ratio under FR 16 following a saline infusion was $\bar{X}$ = 0.8 min (.02 SE) whereas the latency following (-)-nicotine was $\bar{X}$ = 10.9 min (1.6 SE). Latencies were inversely related to FR size (FR 16, 11.0 min (7.6 SE), FR 32, 7.7 min (1.5 SE), FR 64, 4.3 min (0.9 SE). To determine if this inverse relationship was due to repeated (-)-nicotine infusions independent of the FR schedule the rats in exp 1 were tested with (-)-nicotine twice under FR 32. No significant difference was found between the latencies. Latency following a 10µg infusion of (-)-nicotine (exp 2) was $\bar{X}$ = 13.0 min (1.4 SE). Mecamylamine had no effect during saline infusions, however, it did produce a dose dependent decrease in the latency following a (-)-nicotine infusion (0.05, 1.5 and 3.0 mg/kg/sc; latency - 6.8, (1.2 SE), 2.0, (0.7 SE), 0.6, (0.1 SE) min. Hexamethonium injections had no effect. These results suggest that: 1) duration of the effect of intraventricular infusions of (-)-nicotine extended beyond the observed prostration, 2) duration of suppression varies as a function of the FR size, 3) there is a lack of tolerance with repeated infusions and 4) mecamylamine but not hexamethonium antagonized the effects of (-)-nicotine on FR responding suggesting that the effects are mediated by central nicotinic-cholinergic receptors.

66.3 THE EFFECTS OF STRYCHNINE, 5-METHOXY-N,N-DIMETHYLTRYPTAMINE AND CLONIDINE ON ACOUSTIC AND ELECTRICALLY-ELICITED 'STARTLE' RESPONSES IN THE RAT. R.L. Commissaris* and M. Davis (SPON: M. Bowers). Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508.

Although many neuropharmacological agents have been shown to alter the acoustic startle response, the site(s) of action for many of these agents has not been defined. This study used electrical stimulation within the startle circuit in combination with selected drug treatments as a technique to localize the site(s) of action for these agents.

Previous work has suggested that the primary acoustic startle circuit in the rat is: auditory nerve, ventral cochlear nucleus, nuclei of the lateral lemniscus, nucleus reticularis pontis caudalis (RPC), spinal interneuron, lower motor neuron, muscles. Electrical stimulation of sites within this circuit produces a response similar to the acoustic startle response (Gendelman and Davis, Neurosci. Abstr. 5: 494, 1979). In the present study male rats (350-400 g) received bilateral, single-pulse (100 µA per electrode, 1 msec duration) stimulations of the RPC alternating with acoustic noise bursts (115-db, 4-20 kHz band-width, 90 msec). The interstimulus interval between the two types of stimuli was 10 sec. Both acoustic and RPC-elicited 'startle' responses were measured for forty minutes following intraperitoneal administration of strychnine (1.0 mg/kg), 5-methoxy-N,N-dimethyltryptamine (5-MeODMT; 4.0 mg/kg), clonidine (80 µg/kg) and saline. These drugs were chosen because previous studies in which they were injected directly into the lumbar region of the spinal sub-arachnoid space (intrathecal administration) have indicated that their excitatory (strychnine, 5-MeODMT) and inhibitory (clonidine) effects on acoustic startle are mediated at least in part through the spinal cord (i.e., "downstream" from the RPC). As expected, strychnine and 5-MeODMT increased and clonidine decreased acoustic startle. Consistent with the spinal actions of these agents in modulating acoustic startle, RPC-elicited 'startle' was also increased by strychnine and 5-MeODMT and decreased by clonidine.

These results indicate that the 'startle' elicited by electrical stimulation of the RPC can be altered by treatments which act in the spinal cord to modulate acoustic startle. Furthermore, these results suggest that the 'startle' response produced by electrical stimulation of various sites within the acoustic startle circuit may be used to elucidate the site(s) of action for agents which modulate the acoustic startle response in the rat.

66.4 COCAINE POTENTIATES KETAMINE-INDUCED LOSS OF RIGHTING REFLEX AND SLEEP TIME. Christina VanderWende, Marie T. Spoerlein and Judy Lapollo*. College of Pharmacy, Rutgers.The State University, Box 789, Piscataway, N.J. 08854.

Ketamine has dissociative anesthetic properties and unlike the parent compound, phencyclidine (PCP), is still used as an anesthetic in the human. However, it does have post anesthetic sequelae which resemble the psychotomimetic effects of PCP. Because of these mind-altering effects, ketamine has now gained acceptance as a street drug. There is the potential that ketamine will be used in combination with other drugs such as cocaine, amphetamine and caffeine which are at times used as adulterants of ketamine powders. We have found that cocaine modifies ketamine-induced loss of the righting reflex and sleep time.

Cocaine caused a shift to the left of the dose-response curve of ketamine for the loss of righting reflex in a dose-dependent manner. Cocaine administered simultaneously with ketamine reduced the ED_{50} to 48(30-76) and 86(61-120) mg/kg when given in doses of 30 and 15 mg/kg, respectively, as compared to 115 mg/kg in the ketamine controls. Sleep time with 150 mg/kg of ketamine was significantly increased by 56% when administered simultaneously with 30 mg/kg of cocaine. This effect of cocaine was not a generalized effect with CNS depressants since cocaine had no effect on loss of righting reflex or sleep induced by pentobarbital, phenobarbital or hexobarbital. Conversely, Metrazol (55 mg/kg) antagonized ketamine sleep as would be anticipated for a CNS stimulant.

Since ketamine has a cocaine-like effect on catecholamines (CA), we examined the possibility that CA systems may underlie the cocaine potentiation of ketamine. Mice were treated with alpha-methyl-p-tyrosine (∝MPT), 400 mg/kg, to deplete the CA's. At various times after the pretreatment, the cocaine effect was again reexamined. Although the sleep time with ketamine (100 mg/kg) was significantly increased with ∝MPT itself, the administration of cocaine had no further effect on sleep. Thus, the effect of cocaine was blocked by ∝MPT. Attempts to further study the CA involvement using adrenergic and dopaminergic receptor modifying drugs were more difficult to interpret. Generally DA agonists increased while DA blockers antagonized the effect of cocaine, although they, in themselves, potentiated ketamine. The results with alpha and beta agonists and antagonists were less clear.

66.5 EFFECTS OF INTRASEPTAL GABAERGIC AND SEROTONERGIC AGENTS ON MURICIDE. M. Potegal, B. Yoburn* and M. Glusman, N.Y. State Psychiatric Institute, New York, NY 10032.

Electrical stimulation of the septal region of hamsters, rats, cats and monkeys inhibits various forms of aggressive behavior (Potegal, et al Physiol Behav., 24:863, 1980). The neurotransmitter systems mediating this effect have not yet been established although it has been shown that dopamine, norepinephrine, acetylcholine and glutamate are not specifically involved (Albert & Chew, Behav Neural Biol., 30:357, 1980). A GABA involvement is suggested by the moderately high concentration of the GABA synthesizing enzyme glutamate decarboxylase (GAD) in lateral septum and the effectiveness of the GABA agonist muscimol in altering the muricidal (mouse-killing) behavior of rats when injected intracranially (Mandel, et al, 1978). Serotonin is a possibility because raphe lesions dramatically facilitate muricide while systemic administration of the agonist quipazine and antagonist metergoline alter the threshold for septal muricide-inhibitory electrical stimulation (Gibbons et al, Soc. Neurosci. Abstr. 6: 366, 1980).

In our first experiment 5 muricidal male Long-Evans hooded rats were implanted with a chronic intraseptal cannula. In each of 8 sessions a drug was injected intraseptally after a baseline muricide latency had been obtained. Mice were presented at 5,20, 40 and 60 min following administration of counterbalanced muscimol (0.5, 0.05, 0.005 µg), thiosemicarbazide (a GAD inhibitor; 7.5, 2.5, 0.75 µg) or saline. Muscimol significantly facilitated muricide in a dose-dependent manner while thiosemicarbazide (TSC) had a significant dose-dependent inhibitory effect. Both drugs increased activity moderately. Muscimol increased irritability; TSC had no effect on irritability.

In a second experiment the effects of these GABAergic agents on muricide and eating were compared to those of quipazine and metergoline in 3 rats. The respective effects of muscimol and TSC on muricide were replicated while quipazine and metergoline appeared to have no major effects. None of the drugs affected eating. These results suggest that GABA may suppress the aggression-inhibitory neuronal elements of the septum resulting in a disinhibition of muricide. Muscimol-induced increases in irritability may indicate that this effect occurs across different types of aggression. Serotonin-receptive neural tissue is not directly involved at the septal level but may be activated through septal-raphe pathways. The lack of differential effects of muscimol and TSC on activity and eating suggest that septal GABAergic systems may have a specific role in aggressive behavior. (This research was supported in part by a grant from the Harry F. Guggenheim Foundation.)

66.6 LOCUS OF ACTION OF ANTIPSYCHOTIC DRUGS. A. D. Sherman* and F. Petty. Dept. of Psychiatry, Univ. of Iowa, and Veterans Adm. Med. Cent., Iowa City, IA 52242.

Inhibition of the conditioned avoidance response (CAR) by neuroleptics correlates well with their antipsychotic potency. Stereotactic injection of chlorpromazine (CPZ, 1.0µg in 0.2 µl) delayed acquisition of a one-way CAR when injected into the amygdala, septum, or caudate, but was without behavioral effect in the anterior neocortex, hippocampus, globus pallidus, n. accumbens, thalamus, hypothalamus, substantia nigra, entorhinal cortex, or lateral geniculate body. Haloperidol (HDL) also inhibited CAR acquisition in the three CPZ-sensitive areas.

Atropine, given intraperitoneally, diminished the CAR-inhibitory effect of intracranial CPZ in septum and caudate, but not in amygdala. IP atropine blocked the CAR-inhibition of HDL in caudate, but not in septum or amygdala. Atropine had no effect on CAR-inhibition of either drug injected IP.

When CPZ at the ED_{50} for CAR inhibition (2.3 mg/kg) was injected IP, tissue levels of CPZ in septum, caudate, and amygdala, but not in other areas, demonstrated a significant correlation with behavioral effects.

A series of putative neurotransmitters, dopamine (DA), norepinephrine (NE), serotonin (5-HT), γ-amino butyric acid (GABA), glutamic acid (GLU), aspartic acid (ASP), and acetylcholine (ACh) were then injected into the septum, caudate, and amygdala at a dose of 1 µg in 0.2 µl. In the amygdala, both GABA and ACh delayed acquisition of the CAR. This effect was also found with injection of NE or ASP into the septum, and with injection of GABA, ASP, or ACh into the caudate.

These findings demonstrate the significant interaction of neuroleptics and the acetycholine system in the caudate, an interaction that was also present for CPZ but not HDL in the septum. This, plus the higher potency for CAR inhibition found for HDL vs. CPZ in the amygdala support the hypothesis that the anti-avoidance actions of neuroleptics may derive from an action in the amygdala.

The data also suggest a potential role for the amino acid neurotransmitters, and support the hypothesis of Janssen (Int. J. Neuropsychiat. 4:10, 1967) that GABA is involved in the action of neuroleptics. The finding that ASP in the septum inhibits CAR is of particular interest as this putative neurotransmitter has not previously been thought to play a role in the mechanism of action of psychotropic drugs.

66.7 ^{3}H BENZODIAZEPINE BINDING SITE DISTRIBUTION FOLLOWING ICSS. M. Sano*, F. Gimino*, S.Steiner, A. Lippa* and B. Beer*. Behavioral Physiology Lab., City College of New York, New York, N.Y. 10031.

As a means of examining the relationship between classical central reward mechanisms and more recently discovered brain mechanisms of anxiety, the techniques of ICSS and high affinity radioactive binding prodedures have been conducted concurrently. The C-T monophasic pulse pair procedure is well established as a tool for delineating site-specificity of reward mechanisms in discrete brain regions. This technique has been coupled with a radioactive binding assay using ^{3}H Flunitrazepam as a ligand to characterize the distribution of benzodiazepine binding sites in specific brain regions. These binding sites appear to be related to behavioral measures of anxiety.

Albino Sprague-Dawley rats were implanted with an indifferent skull electrode and with 2 bipolar electrodes bilaterally placed in discrete ICSS reward sites. Animals were shaped at one site for a maximum of 15 daily sessions at a variety of current intensities. The crude homogenates of several brain areas including cortex, hippocampus and diencephalon were incubated with ^{3}H Flunitrazepam alone or in the presence of clonazepam to determine non-specific binding. The results evaluate binding in tissue after exposure to ICSS. Kinetic analysis will permit the evaluation of B max and KCl values in specific brain regions.

66.8 EVIDENCE THAT ANTI-ACETYLCHOLINE RECEPTOR ANTIBODIES DO NOT INTERACT WITH HYPOTHALAMIC BUTX SITES IN VIVO AND IN VITRO. P.F. Strang-Brown and B.J. Morley. The Boys Town Institute for Communication Disorders in Children, Omaha, NE 68131.

The cross-reactivity between whole brain BuTX binding sites and antibodies to peripheral receptors is negligible (Speth et al., Soc. Neurosci. Abst., 3:339, 1977; Morley and Kemp, Soc. Neurosci. Abst., 5:1013, 1979, Morley and Kemp, Brain Res. Rev., 2, 1981) but Block and Billiar (Brain Res., 117:381, 1979) demonstrated cross-reactivity between antisera to peripheral receptors and rat brain hypothalamic BuTX sites. Recently, Tarrab-Hazdai and Edery (Exp. Neurol., 67:670, 1980) have reported that intraventricular injections of anti-Torpedo IgG into rabbits resulted in a depression of water and food intake. The concentration of BuTX binding was also shown to be decreased substantially in the hypothalamus but not in the hippocampus or cerebral cortex. These latter two studies suggest that there are regional variations in the cross-reactivity of peripheral antibodies with brain BuTX sites. The following studies tested this hypothesis.

For our studies, purified nAChR from Narcine brasiliensis was injected into rats to produce anti-Narcine antibodies. The titer was calculated to be 5×10^{-8}M. Cannulas were stereotaxically implanted bilaterally into the hypothalami of 20 anesthetized male albino rats. After a recovery period of 5 days, the animals were given daily injections of anti-Narcine antisera or normal rat sera. Injections were proportioned so that 5 µl of sera was injected into each cannula 4 times daily for a total of 40 µl sera daily. Food and water intake and body weight were monitored daily. The hypothalamus, hippocampus, and cerebral cortex were assayed biochemically as described by Morley et al. (Brain Res., 134:161, 1977) for specific BuTX binding. Additionally, the cross-reactivity of Triton extracts of rat hypothalamic ^{125}I-BuTX sites was investigated using anti-Torpedo, anti-Electrophorus, and anti-Narcine antisera in radioimmunoassays.

The chronic administration of anti-Narcine antisera for 7 or 14 days resulted in no effect on either food or water intake in the rats. Results of the biochemical assays of hypothalamus, cerebral cortex, and hippocampus showed no alterations in the concentration of BuTX binding in any area. Peripheral antibodies did not significantly immunoprecipitate BuTX sites in radioimmunoassays.

These results support the hypothesis that there is little or no cross-reactivity between antibodies to peripheral receptors and brain BuTX sites.

66.9 PSYCHOMOTOR STIMULANTS, SOCIAL ISOLATION AND PLAY IN YOUNG RATS. W. W. Beatty, A. M. Dodge*, L. J. Dodge*, K. White* and J. Panksepp. Depts. of Psychology, North Dakota State Univ., Fargo, ND 58105 and Bowling Green State Univ., Bowling Green, OH 43403.

Brief social isolation (8-24 h) profoundly stimulates play fighting in juvenile rats (Panksepp & Beatty, Behav. Neural Biol. 30: 197, 1980). To begin the study of the neurochemical mechanisms that regulate play the effects of ip injections of d-amphetamine sulfate (0.125-1.0 mg/kg) or methylphenidate HCl (0.5-4.0 mg/kg) were determined. Both agents suppressed play fighting in a dose-dependent fashion regardless of whether the animals were housed in pairs (social housing) or alone (isolation). At the highest doses tested both drugs increased the time the rats spent in social investigation (mutual grooming and sniffing), but only if the animals had been socially isolated. Neither agent affected rearing under the present conditions. Thus, low doses of psychomotor stimulants lead to a redistribution of social behavior, at least when animals have been socially isolated. Play fighting is suppressed while social investigation is enhanced.

66.10 THE EFFECTS OF PARA-CHLOROAMPHETAMINE AND A MONOFLUORINATED ANALOGUE ON THE BEHAVIOR OF RATS AND ON BRAIN AMINE LEVELS. C.H.M. Beck, H. Chow*, W.G. Dewhurst*, G.B. Baker and R.T. Coutts*. Neurochemical Research Unit, Dep't. of Psychology, Dep't. of Psychiatry, Fac. of Pharmacy and Pharmaceutical Sciences, Univ. of Alberta, Edmonton, Alberta, T6G 2E1.

The clinical value of the serotonin depletor para-chloroamphetamine (pCA) as an antidepressant is limited by its toxic effect on serotonin neurons. The monofluorinated analogue of pCA, namely 2-amino-1-(4-chlorophenyl)-3-fluoropropane or FpCA, like pCA reduces brain 5-HT levels, although higher doses are required and the 5-HT concentrations return to normal faster than with pCA (Baker, G.B. et al., Neuropharmacology, 1980, 19:1255). The purpose of the present study was to compare the short term effects of pCA and FpCA on brain amine levels and on open field behavior of rats. Male Sprague Dawley rats received, one hour before recording, injections of pCA (5.2 mg/kg, i.p.) or FpCA (5.6 mg/kg, i.p.) or saline (2 ml/kg, .9%, i.p.) having been pretreated, 24 hours earlier, with saline (2 ml/kg, .9%, i.p.) or reserpine (1 mg/kg, i.p.). Behavioral observations were made prior to the first injection and in the second hour after the second injection. The rats' behavior was recorded continuously by a trained observer during 15 two-minute observation periods interpolated over the one hour sessions. The observer used a checklist of comprehensive, mutually exclusive behavioral categories. In 9 sessions the rat was alone and in 6 sessions the rat was paired with another rat. Immediately after the second observation session at 2 hours after the second injection, the rats were decapitated and their brains fluorimetrically assayed for norepinephrine, dopamine and serotonin. Relative to saline controls, the whole brain levels of serotonin were reduced in rats given pCA (to 54% of controls), and these levels were further reduced (to 28% of controls) by pretreatment with reserpine. The dose of FpCA used did not reduce serotonin levels following saline pretreatment, however, serotonin levels were reduced to 49% of controls in animals given FpCA with reserpine pretreatment. This was a reserpine effect since reserpine alone depleted serotonin levels to a similar degree (to 36% of controls). All reserpine pretreated animals had similar reductions in whole brain levels of norepinephrine (to 33% of controls) and of dopamine (to 58% of controls). Animals given FpCA and pCA with saline pretreatment showed brain norepinephrine levels increased to 114% of controls and increased dopamine levels to 144% of controls. The general effect on behavior of the injections in the experimental groups compared to either saline injections or the effect of no injections at all (predrug) was to increase the likelihood of the rat being immobile.

66.11 "OFF" RESPONDING IN THE SHUTTLEBOX SELF-STIMULATION TEST: EFFECTS OF ANXIOLYTICS AND d-AMPHETAMINE. S. Gerhardt*, J. Prowse and J. M. Liebman. (SPON: M. Roffman). Res. Dept., Pharma. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

In Atrens' shuttlebox self-stimulation procedure (Psychopharmacol. 49:97, 1976), rats interrupt a photocell beam to initiate brain stimulation, then terminate it by interrupting another beam at the opposite end of the shuttlebox. Latency to initiate stimulation (the ON latency) is considered to correlate inversely with reward value of stimulation, while the latency to terminate stimulation (the OFF latency) has been used as an indicator of concomitant, nonspecific performance disruption. We now report that the OFF latency is differentially elevated by anxiolytic agents and, in contrast, reduced by d-amphetamine.

Rats with lateral hypothalamic electrodes were trained to interrupt an infrared beam to initiate continuous biphasic square-wave stimulation. Interruption of a beam at the other end of the shuttlebox terminated stimulation but left the animal free to re-initiate current. Test sessions lasted 10 min, during which ON and OFF latencies were compiled by computer. Drugs were administered i.p. and were given 30 min before testing except for pentobarbital (15 min).

Moderate doses of diazepam (2.5 and 5 mg/kg) and chlordiazepoxide (3 and 10 mg/kg) increased OFF latencies significantly more than ON latencies. A similar effect was noted after pentobarbital (10 mg/kg). At a lower dose, each of these agents reduced ON latencies slightly at the same time that OFF latencies were slightly elevated.

The effects of d-amphetamine (0.1-1 mg/kg) were compared with those of pipradrol (1-10 mg/kg), another psychomotor stimulant, and buproprion (10-100 mg/kg) a dopamine uptake blocker. All three agents reduced the ON latency, as expected from their facilitatory effects on bar-pressing self-stimulation rates. However, only d-amphetamine concurrently reduced OFF latencies. Pipradrol reduced ON latencies with a magnitude comparable to d-amphetamine, yet failed to alter OFF latencies. It is possible that d-amphetamine differs from other stimulant drugs in a manner which may reflect anxiomimetic properties. Alternatively, psychomotor activation caused by d-amphetamine may account for its ability to reduce OFF latencies.

That OFF responding may reflect an aversive component of stimulation is suggested by these results, by informal observations of performance, and by the proximity of electrode placements to the medial hypothalamus. Further pharmacological characterization of OFF responding may aid in understanding the substrates of aversive motivation and anxiety.

66.12 EFFECTS OF VARIOUS CATECHOLAMINE ANTAGONISTS AND NONSPECIFIC MOTOR DISRUPTION ON SHUTTLEBOX SELF-STIMULATION PERFORMANCE: A SYSTEMATIC COMPARISON. J. M. Liebman, J. Prowse* and S. Gerhardt*. Res. Dept., Pharma. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

The shuttlebox self-stimulation procedure developed by Atrens has been proposed as a means of dissociating drug effects on "reward" from nonspecific motor effects. We systematically evaluated this hypothesis by comparing the effects of: (a) several dopamine antagonists, (b) disruption of noradrenergic rather than dopaminergic neurotransmission, and (c) nonspecific disruption of motor performance.

Rats with lateral hypothalamic electrodes were trained to interrupt an infrared beam at one end of a shuttlebox to activate a stimulator that delivered continuous biphasic square-wave brain stimulation. Interuption of a beam at the other end terminated stimulation but left the animal free to re-initiate current. Test sessions lasted 10 min, during which "ON" and "OFF" latencies were compiled by computer. Drugs were administered i.p. 30 min before testing. Changes in ON latencies are thought to correlate with changes in reward value of stimulation. The absence of concurrent changes in OFF latencies is taken to indicate that changes in ON latencies are not attributable to nonspecific motor effects.

In agreement with Atrens et al. (Psychopharmacol. 49:97, 1976), we found that clozapine (1-10 mg/kg) elevated ON latencies more strongly than OFF latencies. This profile was not unique among dopamine antagonists, however, as metoclopramide (1-10 mg/kg) had very similar effects. Haloperidol (0.03-1 mg/kg) also elevated ON latencies more strongly than OFF latencies, but the differentiation between latencies was weaker than with clozapine or metoclopramide. Prazosin (0.3-10 mg/kg), an α-1 adrenergic antagonist, had effects very similar to those of haloperidol. Thus, although various catecholamine receptor antagonists elevated ON latencies more strongly than OFF latencies, they were not readily discriminated from each other using this procedure. Moreover, the same profile was produced by methocarbamol, a muscle relaxant with sedative properties.

Clonidine (0.03-0.3) mg/kg very clearly differentiated ON from OFF latencies, elevating the former markedly while only slightly altering the latter. The reason for clonidine's unusually selective effect on ON latencies remains to be explored further, but such an effect parallels findings from other laboratories.

66.13 ANTAGONISM OF NICOTINE EFFECT BUT NOT TOLERANCE DEVELOPMENT BY HEXAMETHONIUM. Glenn Daniel Todd* and John A. Dougherty. Depts. Psychiatry and Pharmacology, Univ. of Kentucky Medical Center and Veterans Admin. Medical Center, Lexington, Ky.

In a previous study (Soc. Neurosci. Abstr., 5:665, 1979) we found that tolerance to a suppressant effect of nicotine on a fixed-ratio schedule of lever-pressing developed within one hour and was still present 8 hours later. The duration of suppression after the second injection was often 75% shorter than after the first injection (4.1 vs. 14.2 min). To evaluate the mechanism of this tolerance development, the effect of hexamethonium upon the suppression of responding produced by nicotine was examined in 10 Wistar rats. A saline injection (control) or a nicotine injection (200 ug/kg, BASE, i.p.) was given immediately before each of two daily lever-pressing sessions conducted four hours apart. Each session lasted 30-minutes with every fiftieth press reinforced by water presentation, with the rats maintained at 80% of ad lib weight by limitation of water access.

Hexamethonium (1 or 5 mg/kg, BASE, s.c.) given 1 hour prior to the start of the first daily session produced no change in responding in either of the two daily saline control sessions. Hexamethonium, 1 mg/kg, did not affect the suppression of responding produced by the first nicotine injection (13.3 vs. 14.2 min) and did not affect the development of tolerance to the second daily injection of nicotine (4.8 vs. 4.1 min) 4 hours later. Hexamethonium, 5 mg/kg, given 1 hour prior to the first daily nicotine injection did antagonize the suppression of responding normally produced by the first daily nicotine injection (3.4 vs. 14.2 min). However, when the effect of the second nicotine injection was assessed 4 hours later, the development of tolerance was found to be unchanged (4.6 vs. 4.1 min).

The possibility that a prolonged effect of hexamethonium antagonized the suppressant effect of nicotine in the second daily session was ruled out by a study in which 5 mg/kg hexamethonium was given 5 hours before the first daily lever-pressing session. Hexamethonium had no effect on the normal 14-15 min suppression produced by nicotine in the first daily session.

Thus, 5 mg/kg hexamethonium antagonized the suppressant effect of nicotine but had no effect on the development of tolerance to that suppressant effect 4 hours later. Therefore, tolerance occurred to the effect of nicotine even though the effect of nicotine had been antagonized. This suggests that the development of tolerance to the behavioral suppresant effect of nicotine may be independent of cholinergic receptor blockade.

66.14 EFFECTS OF TRIETHYLTIN ON SCHEDULE DEPENDENT AND SCHEDULE INDUCED BEHAVIORS USING A FIXED INTERVAL OR FIXED RATIO SCHEDULE OF REINFORCEMENT. D. L. DeHaven, S. M. Evans*, M. J. Wayner and F. C. Barone. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210

The effects of the demyelinating agent triethyltin (TET) on operant responding using a FR-30 schedule of reinforcement and on schedule dependent and schedule induced behaviors using a FI-1 min schedule of reinforcement were assessed. TET (0.5, 1.0 and 1.5 mg/kg IP in 15% ethanol, immediately pre-session) was administered twice a week for two weeks following an established stable baseline of responding during the same regimen of vehicle administration. Response rate under the FR-30 schedule was decreased following 1.5 mg/kg TET. Schedule induced licking and water intake and schedule dependent lever pressing under the FI-1 min schedule were significantly decreased following 1.0 and 1.5 mg/kg TET. Rats on the FI-1 min schedule were also allowed to recover to ad lib feeding body weight and were retested in the same operant chambers on the same schedule. Baseline responding and subsequent vehicle-injection baseline measures were again determined. TET was then administered as described above. Decreases in schedule induced licking and water intake and schedule dependent lever pressing were observed following 0.5 and 1.0 mg/kg TET. Results indicate that operant responding and particularly schedule induced behavior are sensitive to low doses of TET. Schedule induced behavior which occurs in animals at ad lib feeding body weight is most sensitive to the behaviorally toxic effects of TET. (Supported by NIH Grant NINCDS USPHS No. 13543.)

66.15 A SIMPLE AND RAPID METHOD FOR IMPLANTATION OF A CHRONIC CANNULA INTO THE MOUSE CEREBROVENTRICULAR SYSTEM. D. L. Colbern*, P. J. Syapin, and E. G. Zimmermann. Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024, and Department of Neurology, USC School of Medicine, Los Angeles, CA 90033.

Cannulation of the lateral ventricle in two strains of mice (Swiss-Webster and C57) was accomplished by modifying a rat implantation method previously described by Brakkee, et al. (Lab. Animal Sci., 29:78-81, 1979). Major advantages of the present technique include the accurate, non-stereotaxic placement of an easily-made polyethylene cannula, and the extremely secure attachment of dental cement to the fragile mouse skull without the use of jeweler's screws. A metal guard placed around the exposed portion of the cannula permits post-operative group housing of mice. Using pentobarbital anesthesia, sequential cannulation of 20 mice by one person routinely takes 4 hours (10-15 min per mouse). Surgeries performed in parallel on a number of mice anesthetized by other means would require less time.

This technique allows quick and painless injection of microliter volumes of chemicals into the cerebrospinal fluid of unanesthetized mice. ACTH 1-24 injected via these cannulae produced expected excessive grooming behavior when compared to saline injections. Repeated injections through the cannulae have been made for 2-3 weeks after implantation. The simplicity of the cannulation procedure and subsequent non-stressful injection make this a valuable technique for evaluating the effects of intracerebroventricularly applied drugs on behavioral and neurochemical parameters.

Support: USPHS Grant NIAAA-03513 and DHHS Grant S07 RR05356.

67.1 ATTENUATION OF DOPAMINE AGONIST EFFECTS OF CHRONIC PERGOLIDE ADMINISTRATION. D. Jiang*, A. Reches*, H.R. Wagner*, S. Fahn, Dept. Neurology, College of Physicians and Surgeons, Columbia University, New York, NY 10032.

The dopamine agonist properties of pergolide, an N-propyl-ergoline derivative, were studied in the rat. At low dosage (0.1 mg kg^{-1} i.p), pergolide depressed motor activity, while at higher doses (0.5-4.0 mg kg^{-1}) motor activity was increased and stereotypy appeared. Increased motor activity at higher doses was both preceded and followed by a decrease in motor activity. A reduction in the deaminated dopamine (DA) metabolites, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), was found in the striatum during periods of increased motor activity. No significant change in metabolite levels was noted during the initial hypoactive phase. During the period of motor hyperactivity, decreases in HVA and DOPAC levels were dose independent between the range of doses investigated (0.5-2.0 mg kg^{-1} pergolide). In rats treated chronically with pergolide (0.5 or 1.0 mg kg^{-1}, i.p., on alternate days for two weeks), the duration of the heightened behavioral responses (hyperactivity and stereotypy) decreased while the enusing hypoactive phase increased in both duration and magnitude. The decrease in the levels of DA metabolites (DOPAC and HVA) was also reduced following chronic pergolide treatment; after two weeks, levels were no longer significantly different from controls. A similar attenuation of behavioral response occurred in rats previously injected unilaterally in the substantia nigra with 6-OHDA. Turning behavior in such rats persisted in excess of 36 hrs following initial pergolide injections but seldom lasted beyond 24 hrs following two weeks of repeated injections. The increase in motor activity, stereotypy and turning behavior at higher drug doses and the decrease in DA metabolite levels (DOPAC + HVA) are consistent with a DA agonist role for this ergot derivative. The attenuation of these reponses with repeated drug exposure suggests the development of tolerance.

67.2 INHIBITION OF DOPA UPTAKE AND METABOLISM IN RAT STRIATUM BY O-METHYLDOPA A. Reches*, and S. Fahn, (SPON: R.E. Barrett). Dept. Neurology, College of P & S, Columbia University, New York, NY 10032.

A major part of DOPA given to parkinsonian patients is methylated by COMT to 3-O-methyldopa (OMD) which is inactive therapeutically. Clinical studies indicate that OMD may antagonize the beneficial effect of DOPA; for example, patients treated with DOPA deteriorate when OMD is added to their regimen. We have therefore studied the effect of OMD on DOPA metabolism. Rats were injected with OMD (400 mg·kg^{-1} i.p.) and 2 h later with DOPA (100 mg·kg^{-1} i.p.); control rats received DOPA only. Rats were sacrificed 15 min after DOPA injection. In OMD pretreated rats DOPA, dopamine, DOPAC and HVA levels in the striatum were significantly lower than control rats: 0.89 ± 0.2 vs. 1.58 ± 0.19, $p< 0.05$; 18.5 ± 2.6 vs. 23 ± 1.25, $p<0.05$; 6.3 ± 0.9 vs. 9.6 ± 0.16, $p<0.02$; and 1.39 ± 0.14 vs. 1.82 ± 0.06, $p<0.05$, respectively. No effect was observed on 5-HIAA levels; 0.616 ± 0.11 vs. 0.663 ± 0.13. (All results were determined by HPLC, and are expressed as mean ng/mg tissue ± S.E.M. of n=5, statistics by two-tailed student t-test.) Control and OMD pretreated rats were injected with NSD-1015 (100 mg·kg^{-1} i.p.) and were sacrificed 20 min later. In OMD pretreated rats the accumulation of DOPA in the striatum was significantly lower compared with the control group: 1.3 ± 0.04 (n=9) vs. 1.65 ± 0.117 (n=9), $p<0.025$. Control and OMD pretreated rats were injected with gamma-butyrylactone (750 mg·kg^{-1} i.p.) and sacrificed 40 min later. Dopamine accumulation in OMD pretreated rats was lower, compared with control group 24.5 ± 1.1 (n=11) vs. 28.2 ± 1.1 (n=10), $p<0.05$. It is concluded that OMD interferes with dopamine synthesis in the striatum, possibly either by decreasing brain uptake of precursors or by inhibiting tyrosine hydroxylation. 67.3 DO CATECHOLAMINE SYNTHESIZING ENZYMES SHARE COMMON GENE CODING SEQUENCES? T.H. Joh, E.E. Baetge, B.B. Kaplan, M.E. Ross, M.J. Brodsky, V.R. Albert*, D.H. Park and D.J. Reis. Departments of Neurology and Anatomy, Cornell University Medical College, New York, N.Y. 10021.

The biosynthesis of epinephrine in adrenal medulla requires three specific enzymes: tyrosine hydroxylase (TH), dopamine B-hydroxylase (DBH) and phenylethanolamine N-methyltransferase (PNMT). These enzymes are regulated together, usually by control of their biosynthesis. Conceivably, these enzymes might be coded for by a single gene, or by several genes that have evolved through gene duplication. To test this hypothesis, we sought to determine whether the three enzymes, as similar gene products, structurally resemble one another.

All three enzymes were purified to homogeneity from bovine adrenal and their molecular weights (MWs) determined by SDS-urea PAGE. MWs of the enzymes are: DBH=75,000; TH= 60,000; PNMT= 30,000; and the trypsin-digested form of TH (tTH)=35,000. Antibodies (Abs) to all three enzymes and tTh were raised in rabbits or by hybridoma techniques.

To determine whether the enzymes can be identified as similar proteins in mRNA translation products, poly(A)mRNA was purified from fresh bovine adrenal medulla,and translated in vitro in a reticulocyte cell-free protein-synthesizing system. Individual enzymes were identified from the translated products by immunoprecipitation and SDS-PAGE. All four Abs precipitated similar proteins. That is, DBH-Ab precipitated DBH and TH; TH-Ab precipitated TH, DBH, and a small quantity of PNMT; PNMT-Ab precipitated PNMT, TH, and a small quantity of DBH;and tTH-Ab precipitated PNMT and TH.

Peptide analysis of purified PNMT and of tTH using Staphlococcus aureus protease digestion and SDS-PAGE for identification of peptides showed that both enzymes produced eight identical peptides. The amino acid composition of all three enzymes indicated that the molar ratios of the major amino acids are similar, the major amino acids being: leu, glu, asp, ala, val, and gly, respectively. Serine is a major amino acid in both DBH and TH, but not in PNMT and tTH.

These results indicate that all three enzymes have protein domains with similar primary structure. This is consistant with the hypothesis that the three enzymes are coded for by a single gene or genes evolved from a common ancestral precurser. (Supported by NIH grant, MH24285 ,HL 18974, and HD 11392).

67.4 MESOCORTICAL DOPAMINE NEURONS: UNIQUE RESPONSE TO HALOPERIDOL EXPLAINED BY ABSENCE OF AUTORECEPTORS. M. J. Bannon and R. H. Roth. Depts. Pharmacology & Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

Haloperidol markedly accelerates dopamine (DA) turnover in the striatum and olfactory tubercle following acute administration. This effect is due to multiple sites of haloperidol action, including (a) the blockade of postsynaptic DA receptors with a subsequent increase in dopaminergic impulse flow through neuronal feedback mechanisms, and (b) the blockade of nerve terminal DA autoreceptors. In the prefrontal cortex, haloperidol elicits a much smaller increase in DA turnover. This difference may be explained by the recent finding that mesocortical DA neurons lack nerve terminal autoreceptors (Mol. Pharmacol. 19: 270-275, 1981).

In the present experiments, acute haloperidol challenge (1 mg/kg, i.p.) to rats dramatically increased both striatal and olfactory tubercle α -methyltyrosine-induced DA depletion (319% and 241% control depletion, respectively) and dihydroxyphenylacetic acid levels (DOPAC; 401% and 243% control DOPAC, respectively). In contrast, in the prefrontal cortex only small changes in α -methyltyrosine-induced DA depletion and DOPAC levels were observed following haloperidol challenge. It has been previously demonstrated that the small haloperidol-induced increase in prefrontal cortical DA synthesis is totally prevented following the blockade of dopaminergic impulse flow (Mol. Pharmacol. 19: 270-275, 1981). These data strongly suggest that the effects of haloperidol on mesocortical DA neurons are dependent on alterations in neuronal impulse flow and do not involve nerve terminal autoreceptors.

Following chronic haloperidol treatment (0.5 mg/kg/day, i.p. X 28 days), significant tolerance to the DOPAC-elevating effect of a haloperidol challenge (1 mg/kg) developed in both the striatum and olfactory tubercle. No tolerance to haloperidol was observed in the prefrontal cortex. In additional experiments with chronically treated rats, no evidence of DA autoreceptor function was revealed in the prefrontal cortex. It is suggested that tolerance to the effects of haloperidol may be mediated in part by nerve terminal DA autoreceptors. In fact, in brain regions where haloperidol tolerance was seen (i.e. striatum and olfactory tubercle), the development of DA autoreceptor supersensitivity was also demonstrated. (Supported in part by USPHS Grants MH-14092, MH-25642 and the State of Connecticut.)

67.5 LONG-TERM EFFECTS OF A SINGLE DOSE OF AMPHETAMINE ON STRIATAL DOPAMINE NEURONS IN IPRINDOLE-TREATED RATS: TIME-COURSE AND TIME-DEPENDENT INTERACTIONS WITH AMFONELIC ACID. L. R. Steranka. Dept. of Pharmacology and Physiology, Northwest Center for Medical Education, Indiana University School of Medicine, Gary, IN 46408.

The administration of a single dose of (+)-amphetamine sulfate (9.2 mg/kg, i.p.) to rats treated with iprindole hydrochloride (10 mg/kg, i.p.) produced marked decreases in the striatal concentrations of dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), and homovanillic acid (HVA) one week after drug administration. Significant changes were not observed in striatal 5-hydroxyindoleacetic acid (5HIAA) nor in norepinephrine, DA, DOPAC, HVA and 5HIAA concentrations in frontal cortex and a limbic forebrain sample containing primarily nucleus accumbens and olfactory tubercles. In time-course experiments, decreases in striatal DA were apparent by 12 hours after amphetamine plus iprindole administration and persisted for at least 4 weeks. Decreases in striatal DOPAC and HVA followed a similar time course, except decreases in these parameters were observed at 6 hours as well. The administration of amfonelic acid (5 mg/kg, i.p.), a potent DA uptake inhibitor, up to 8 hours, but not at 12 hours, after amphetamine administration prevented the decreases in striatal DA, DOPAC and HVA at one week after the administration of the drug to iprindole-treated rats. These data indicate that the actions of amphetamine which are necessary and sufficient for the production of the long-term decreases in striatal DA, DOPAC and HVA are dependent upon the integrity of the neuronal uptake mechanism for DA and occur within 12 hours after the administration of amphetamine to iprindole-treated rats.

Although amfonelic acid prevented the long-term effects of amphetamine on striatal DA neurons, it did not alter the decrease in DOPAC produced by amphetamine at 6 hours after the administration of amphetamine plus iprindole. This finding suggests that the ability of amfonelic acid to prevent the long-term effects of amphetamine on striatal DA neurons in iprindole-treated rats is not due to a blockade of the entry of amphetamine into the neuron and, thus, suggests that the access of amphetamine to the inside of the neuron is not sufficient for the production of its long-term, possibly neurotoxic, effects on striatal DA neurons.

67.6 PLASMA HOMOVANILLIC ACID AS AN INDEX OF CNS DOPAMINE METABOLISM: ENHANCEMENT WITH A PERIPHERAL MONOAMINE OXIDASE INHIBITOR. D.E. Sternberg*, G.R. Heninger, and R.H. Roth. Yale University School of Medicine, New Haven, CT 06508.

Plasma homovanillic acid (HVA) may be a useful measure of CNS HVA production by central dopamine (DA) systems. Even though there is a significant peripheral contribution to plasma HVA, experimental manipulations that alter brain HVA also change plasma HVA. In rodents, electrical stimulation or lesions of DA pathways, and pharmacologic treatments that increase or decrease brain HVA, produce parallel changes in plasma HVA levels. The present study was designed to assess whether the relationship between haloperidol induced increases in brain and plasma HVA levels could be strengthened by reducing the contribution to plasma HVA from peripheral sources. Debrisoquin sulfate, a monoamine oxidase inhibitor which does not enter the brain, decreases the production of HVA from peripheral sources and can be safely used in humans. Experiments were conducted in rats to determine an effective dose and time schedule for debrisoquin administration which would reduce the peripheral contribution to plasma HVA and MHPG. A minimum dose schedule of debrisoquin (.5 mg/kg x 3 days, 1 mg/kg x 1 day) produced a significant 27% and 37% decrease in plasma HVA and MHPG, respectively, but no change in brain HVA or MHPG. Using this schedule, rats were pretreated with either debrisoquin or vehicle. Two hours prior to sacrifice, they were administered either vehicle or various doses of haloperidol (0.2,0.1,0.05 mg/kg). A significant plasma HVA increase following haloperidol was observed at a lower dose (0.05 mg/kg) in the debrisoquin pretreated rats. In this group, a 71% increase in brain HVA was accompanied by a 60% increase in plasma. In the vehicle pretreated group, twice the dose of haloperidol (0.1 mg/kg) was required, producing a 131% increase in brain HVA and a 51% increase in plasma. Debrisoquin had no effect on the magnitude of the haloperidol-induced brain HVA increase. These data indicate that debrisoquin pretreatment improves the reliability of plasma HVA as a measure reflecting changes in CNS DA metabolism. Plasma HVA samples obtained in humans following debrisoquin treatment may provide a clinically applicable method for assessing brain DA systems in neurologic and psychiatric illness. (Supported by MH25642, MH14092 and MH30929).

67.7 TETRABENAZINE AND RESERPINE MAY AFFECT DIFFERENTLY THE PHENCYCLIDINE, COCAINE AND AMFONELIC ACID ACTIONS ON SYNAPTOSOMAL DOPAMINE. S. P. Bagchi and M.A. Reilly* Rockland Research Institute, Orangeburg, NY 10962.

We have observed that the stimulants phencyclidine (PCP), cocaine (CO) and amfonelic acid (AA) may enhance the synthesis and release of synaptosomal (P_2) DA (Biochem. Pharm. 29, 2957 (1980); Neuropharmacology (in press)) from phenylalanine (PHE); also, the presence of reserpine may not only block such synthesis stimulation by either PCP, CO or AA but reveal their inhibitory effects on DA formation. We have now tested the influence of tetrabenazine (TBZ), another amine depletor and an antipsychotic, upon the actions of these stimulants for comparative purposes. The methods consisted of incubating rat caudate nucleus P_2 in tris buffer (10 mM; pH 7.4) containing salts, pargyline (0.08 mM), glucose (10 mM), sucrose (0.32 M) and labelled PHE substrate at 37° for 10 min with/without a drug. Postincubation separation of the particulates from the medium was by filtration on a 0.8μm Millipore filter. The separated fractions were then analyzed for labelled DA and for the particulate labelled PHE substrate uptake. The sum of particulate and medium contents indicated the total formation of labelled DA and its synaptosomal release was expressed by dividing the ratio medium/total labelled DA in the presence of a drug by the same ratio from the control incubation. The results indicated that both Res and TBZ inhibited the total formation of labelled DA and stimulated its release; also their effects on the synthesis and release were quantitatively similar over a wide concentration range (22 to 1800 nM). The presence of either PCP, CO or AA stimulated the synthesis as reported before and a coaddition of Res with any of the stimulants blocked such synthesis increase and furthermore revealed their inhibitory effects. The presence of TBZ however maintained the synthesis stimulations by the same drugs. The releasing actions of these stimulants however were not affected differently by Res and TBZ. Tyramine (TA), another releasing agent, also inhibited the synthesis and stimulated the release of labelled DA; but a coaddition of TA with any of the stimulants also failed to block their synthesis enhancing effects. The results suggest, a) TBZ and Res may act on different DA pools, b) the DA synthesis stimulations by either PCP, CO or AA may be due to their actions on synaptic vesicles but not synaptosomal reuptake and c) Res influence on PCP, CO and AA actions may have a specificity beyond its simple releasing action. (Kindly supported by the Office of Mental Health, State of New York).

67.8 Lumbar Elimination Mechanism for Homovanillic Acid Which is Probenecid Insensitive. R. Stanley Burns*, Susan A. Cosgrove* and Michael H. Ebert* (SPON: Chuang C. Chiueh). Lab. of Clin. Sci., NIMH, Bethesda, MD 20205.

The level of homovanillic acid (HVA) in cerebrospinal fluid (CSF) is used as an index of brain dopamine metabolism. The kinetics of HVA in lumbar CSF was studied in the Rhesus monkey.

In 4 animals, 50 μg of deuterium-labeled (d_2-) HVA alone or combined with 5 μCi of ^{14}C-inulin, a marker of bulk flow of CSF, was administered in 100 μl of saline as a bolus injection into the subarachnoid space one vertebral level above an indwelling lumbar sampling catheter. A second group of 3 animals were pretreated with an intravenous infusion of probenecid at a dose (120 mg/Kg over 1 hour followed by 20 mg/Kg/hour X 6 hours) which produces maximal inhibition of acid transport at the choroid plexus. Timed 100 μl CSF samples and sequential blood samples were obtained over the 6 hour post-injection period. Endogenous HVA and d_2-HVA were determined by gas chromatography-mass spectrometry and ^{14}C-inulin by liquid scintillation counting.

The d_2-HVA concentration in lumbar CSF decreased with a mean half-life ($t_{1/2}$) of 40 minutes, while the $t_{1/2}$ of ^{14}C-inulin was 6-7 hours. Endogenous HVA levels remained constant with a CSF:serum ratio of about 10. d_2-HVA was detected in blood at 15 minutes and reached peak levels 90 minutes after intra-lumbar injection. The rate of elimination of d_2-HVA from lumbar CSF was not altered by probenecid pretreatment. The level of HVA in lumbar CSF is determined not only by the delivery rate from the ventricular system, but also by its local clearance rate.

67.9 EFFECTS OF VARYING INTENSITIES OF WHITE LIGHT ON DOPA ACCUMULATION IN RAT RETINAS. Melissa A. Proll*, Cylia W. Kamp and William W. Morgan. Dept. Anat., Univ. Texas Health Sci. Ctr., San Antonio, TX 78284.

It is well established that light activates the retinal dopamine (DA) neurons in rats, but the parameters controlling this response are ill-defined. The objective of this study was to determine the effects of different intensities of white light on the activity of the retinal DA neurons. Dihydroxyphenylalanine (DOPA) accumulation following an injection of NSD 1015 (hydroxybenzylhydrazine), a L-aromatic amino acid decarboxylase inhibitor, was used as an index of DA neuron activity. Groups of six to eight male rats, dark adapted for approximately fifteen hours, were exposed either to no light (other than a photographic red light) or to 0.7, 5.3, 32.2, or 570.3 lux in a specially designed light box with illumination provided by Sylvania Cool White fluorescent bulbs. The bulbs were covered with black plastic, and light intensity was controlled by varying the number of slits cut in the plastic. Light intensity was measured with a Tektronix J16 Digital Photometer. All rats received NSD (100 mg/kg, i.p.) fifteen minutes prior to sacrifice by decapitation. This was immediately prior to light exposure in groups receiving light. Concentrations of DOPA and DA were measured by high performance liquid chromatography with electrochemical detection. DOPA accumulation in rats exposed to no light or to 0.7 lux did not differ significantly from each other. In rats receiving no light, DOPA accumulation was significantly less than that measured in rats exposed to either 5.3 ($p<0.05$), 32.2 or 570.3 lux ($p<0.01$). DOPA accumulation after exposure to only 0.7 lux was also significantly less than the accumulation after 5.3, 32.2 or 570.3 lux ($p<0.05$). DOPA accumulation in rats receiving 5.3, 32.2, or 570.3 lux did not differ significantly. These results suggest that the threshold of white light required for the activation of the retinal DA neurons is between 0.7 and 5.3 lux. Supported by DA 00755 and NS 14855 to WWM.

67.10 DOPAMINE TURNOVER AS ESTIMATED BY SIMULTANEOUS LCEC ASSAY OF DOPAMINE AND DOPAMINE METABOLITES. C.H. Cheng and G.F. Wooten, Depts. of Neurol. and Pharmacol.; Wash. Univ. Sch. Med.; St. Louis, MO 63110

Estimation of the ratio of dopamine (DA) to dihydroxyphenlacetic acid (DOPAC) is a useful index of DA turnover. However amphetamine (Amph), a DA-releasing drug, produces paradoxical changes in the DA/DOPAC ratio (J. Pharmacol. Meth. 5:165-173, 1981) probably as a result of the ability of Amph. to both block DA reuptake and inhibit monoamine oxidase activity. In order to fully characterize the effects of drugs, particularly amph, on DA turnover and release, we have developed a method for simultaneous assay of DA, DOPAC, 3-methoxytyramine (3MT), and homovanillic acid (HVA) using liquid chromatography with electrochemical detection. Brain samples were homogenized in $HClO_4$ 0.1N containing GSH 5mM, centrifuged, and aliquots of the supernatant were injected directly. Samples were separated on a μBondapak C_{18} reverse phase column with the amperometric detector set at 760 mV. The assays were performed at a flow rate of 1.5 ml/min. at ambient temperature. The mobile phase consisted of methanol 10%, acetic acid 1%, EDTA 1mM, and heptane sulfonic acid 4mM. Sensitivity of the assay defined as twice the amplitude of the background noise was 30 pg for DA and DOPAC and 300 pg for HVA and 3-MT. The assay was highly specific as the retention times for each compound were sufficiently different so that each peak was totally resolved on the column. Dihydroxybenzylamine was used as the internal standard. The assay was linear in the concentration ranges that were studied. Control values in striatum (μg/g) were as follows: DA 10.4±0.82, DOPAC 1.57±0.12, 3-MT 0.27±0.07, and HVA 1.03±0.06. Thirty minutes after Apomorphine (0.5 mg/kg SC) striatal DOPAC levels were 59% and HVA 40% of control with no change in DA. One hour after administration of haldol (1 mg/kg SC) DOPAC levels were 356% and HVA 1700% of control, again with no change in DA. One hour after amph (2.5 mg/kg SC) striatal levels of DA were 154% of control, DOPAC 59%, 3-MT 144%, and HVA 61% ($P < 0.05$ for all changes reported).

These data suggest that changes in levels of DA and 3-MT reflect the release of DA induced by amph administration. The reduction of DOPAC and HVA are consistent with the ability of amph to competitively inhibit monoamine oxidase activity.

67.11 PURIFICATION AND CHARACTERIZATION OF RAT STRIATAL TYROSINE HYDROXYLASE. N. M. Richtand* and R. Kuczenski. Departments of Biochemistry and Pharmacology, Vanderbilt University School of Medicine, Nashville, TN 37232.

Recent experiments have shown that the kinetic properties of rat striatal tyrosine hydroxylase (TOH) and its activation by the polyanion heparin are sensitive to the presence of specific monovalent cations (R. Kuczenski, J. Neurochem., in press). For example, activation of TOH by heparin, which proceeds through a decrease in Km of the enzyme for its reduced pterin cofactor, is preferentially prevented by increasing concentrations of KCl or NaCl as compared to TrisCl or tetramethylammonium chloride (TMACl). Thus, heparin can still effect a two-fold decrease in Km of TOH for cofactor in the presence of 0.35M TMACl or TrisCl, but fails to alter the activity of the enzyme in the presence of an equal concentration of KCl or NaCl. These and other data suggest that K^+ or Na^+, but not Tris or TMA^+, may stabilize or promote a conformational state of TOH which has a lower affinity for heparin.

Based on these observations, rat striatal TOH has been purified to apparent homogeneity. The pivitol step in the purification protocol involves differential monovalent cation elution of enzyme activity from a heparin-substituted Sepharose 4B affinity column. Crude extracts of rat striatum are applied to the column, and a substantial portion of contaminating proteins is removed during extensive washing with high ionic strength TMACl. Subsequently, TOH is eluted with a KCl gradient. This procedure yields a 130-fold purification of TOH in a single step with near 50% recovery of enzyme activity.

The purification protocol is notable in two respects. First, it provides a simple procedure for the rapid purification of rat striatal TOH in sufficient yield to allow for physicochemical characterization of the enzyme. Second, the success of the specific monovalent cation elution of TOH from the heparin-substituted Sepharose provides support for the suggestion that monovalent cations can modify the conformational state of the enzyme.

Purified TOH has been examined for protein-bound phosphate, and the kinetic properties of the purified enzyme have been detailed and compared to the enzyme in crude homogenates. The susceptibility of the purified enzyme to kinetic activation by heparin, phospholipids and phosphorylating conditions has been assessed. Finally, studies of the effects of activating conditions on the physico-chemical properties of the enzyme have been initiated.

67.12 EVIDENCE FOR DOPAMINE DEFICIENCY IN THE WEAVER MOUSE. M. J. Schmidt, B. D. Sawyer, * K. W. Perry,* R. W. Fuller, M. M. Foreman and B. Ghetti. The Lilly Research Laboratories, Indianapolis, IN 46285, and Indiana University Medical Center, Indianapolis, IN 46223.

Dopamine (DA) deficiency is a contributing factor in the symptomatology of Parkinson's disease. Weaver (WV) mice display a number of motor impairments reflecting cerebellar abnormalities. However, they also exhibit neurologic changes that might be due to DA deficiency. These mice are hyperactive when stimulated and intermittently exhibit a fine tremor. We undertook a thorough study of the DA system in the WV by using biochemical, pharmacological and anatomical approaches, since preliminary evidence indicated that DA in the whole brain of WV mice was reduced (Lane et al., 1977). WV mutant mice (CBA Aw-J/A) and heterozygous littermates were obtained from Jackson Lab. (Bar Harbor, ME) or raised from stock in our facilities.

Monoamine levels in the olfactory tubercle, frontal cortex and striatum were determined using high-pressure liquid chromatography and electrochemical detection. Dopamine was 27 percent lower in the olfactory tubercle, 77 percent lower in the frontal cortex and 75 percent lower in the striatum of WV mice. Norepinephrine and serotonin were not lower in these brain areas. Tyrosine hydroxylase activity in the striatum was measured with a radiometric assay and was 70 percent lower in WV mice. Examination of mice from 11-270 days-of-age revealed that the DA system failed to develop in WV mice. Motor activity was assessed in individual animals using circular photocell activity cages with minimal illumination. Apomorphine and pergolide, direct DA agonists, increased activity more in WV than in normal littermates. Amphetamine, which releases endogenous stores of DA, was less active in WV mice. These findings provide suggestive evidence that post-synaptic DA receptors in WV mutants might have become supersensitive as a result of lower levels of DA in motor areas of the brain.

Anatomical evidence of DA system abnormalities was found in WV mice. Serial sections were cut from the midbrain of WV and control mice and stained alternatively with gallocyanin for Nissl substance or with hemotoxylin-eosin. The pars compacta of the substantia nigra in WV appeared hypocellular when compared with the corresponding sections from controls. Fewer large neurons were seen in the affected animals.

This study illustrates that WV mice have specific deficiencies in the DA system. As such, they might prove useful as a model for the treatment of Parkinson's disease.

67.13 CONTINUOUS AMPHETAMINES:SWITCH FROM STEREOTYPICAL TO HALLUCINOGEN-LIKE BEHAVIORS CORRELATED WITH FLUCTUATIONS IN CAUDATE BUT NOT ACCUMBENS DOPAMINE RECEPTORS. **G. Ellison, W. Morris, and P. Schwartz. Dept. Psychology and Neuroscience, UCLA, Los Angeles 90024.**

Following implantation with slow-release d-amphetamine pellets rats and monkeys initially enter a phase of motor stereotypies or bouts of staring, then become inactive, and finally enter a late-stage during which behaviors usually elicited only by hallucinogens appear. These stages are correlated with cyclical alterations in caudate dopamine receptors. During the initial (stereotypy) phase, there is a potentiation in caudate dopaminergic receptor tone. This is evidenced both by an increased potency of d-Amp to induce motor stereotypies, and by increased in vivo and in vitro spiroperidol binding in caudate. Spiroperidol accumulation is not increased in nucleus accumbens at this time. During the late-stage, the number of receptors in caudate decreases. Continuously administered d-Amp is especially effective (compared to repeated daily injections) in inducing both of these alterations in caudate, and in producing long-term damage to dopamine terminals in caudate but not accumbens. From these observations we hypothesize that the selective neurotoxic action which amphetamines have on caudate but not accumbens dopamine terminals is correlated with an early proliferation of caudate dopamine mechanisms. Supported by DA 02312.

67.14 EFFECTS OF THE PUTATIVE AUTORECEPTOR AGONISTS, 3-PPP AND TL-99 ON CENTRAL DOPAMINERGIC MECHANISMS. M. Williams, G. E. Martin and D. R. Haubrich. Merck Institute for Therapeutic Research, West Point, PA 19486.

The effects of two putative dopamine (DA) autoreceptor agonists, 3-PPP (Hjorth et al., Abst. Amer. Col. Neuropsychopharm., 1979) and TL-99 (Goodale et al., Science 210: 1141, 1980) were examined together with the reference DA agonists, N-n-propylnor-apomorphine (NPA), apomorphine (APO) and pergolide (PERG) in three dopaminergic test procedures; ^{3}H-APO binding (I), antagonism of gammabutyrolactone stimulation of DA synthesis (II) and production of stereotypy in rats (III). The activity in I was NPA > APO ≅ TL-99 > PERG ≫ 3-PPP. Preferential interactions with pre- and postsynaptic receptors were assessed in tests II (pre) and III (post). 3-PPP and TL-99 failed to produce stereotypies at nonlethal doses (ED_{50}'s >50 mg/kg i.p.) while NPA, PERG and APO had ED_{50}'s <1.0 mg/kg. All five compounds were active in test II with ED_{50}'s <2 mg/kg i.p., the ED_{50} ratios III:II being; NPA: 1.8; APO: 1.0; 3-PPP: >9.7; TL-99: >21; and PERG: 24. The results support the concept that TL-99 and 3-PPP are selective DA autoreceptor agonists and would also indicate that PERG at low doses preferentially interacts with autoreceptors.

67.15 SELECTIVE DOPAMINERGIC AUTORECEPTOR ACTIVATION: AN IN VIVO TEST SYSTEM. G. E. Martin and R. J. Bendesky*. Merck Institute for Therapeutic Research, West Point, PA 19486.

A pharmacological test will be described which uses the locomotor activity (LMA) of the mouse for assessing dopamine (DA) receptor activation. Apomorphine, in low doses, has been shown to decrease the mouse's LMA presumably due to activation of the DA autoreceptor, whilst greater doses activate the postsynaptic DA receptor causing an increase in LMA. Since apomorphine exerts effects on both DA receptors depending on the dose administered, it generates a U-shaped dose response curve (Carlsson, 1975). Hence, selectivity for the DA autoreceptor would be indicated in this LMA test if a test drug satisfied three criteria. The drug should: 1) produce a dose-related inhibition of LMA with no excitation as the dose is increased; 2) the inhibition should be reversed by sulpiride; and 3) the test drug should inhibit LMA throughout its duration of action.

Using these criteria, 13 reported dopamine agonists were examined in this test. A wide range of doses of each drug was given to 20-30 mice (i.p.) and LMA was recorded automatically in donut-shaped activity chambers and compared with LMA of a control group. The results are outlined in the table. 3-PPP, TL-99, ADTN prodrug and CF 25-397 have a profile of activity consonant with selective DA autoreceptor activity. The first three compounds have been proposed as selective DA autoreceptor agonists by other investigators which suggests that mouse LMA may be a useful measure of DA autoreceptor activation.

Drug	Dose Range(s) (mg/kg i.p.)	(1) Δ LMA	(2) Sulpiride	(3) Duration
3-PPP	0.6-100	↓	+	+
TL-99	0.16-1.28	↓	+	+
ADTN(pro)	8.1-100	↓	+	+
CF25-397	0.019-20	↓	+	+
DPI	0.08-50	↓	-	+
Bromocriptine	5-160	↓	+	-
Lergotrile	0.08-20	↓	+	-

67.16 INTERACTION OF CATIONS AND ASCORBIC ACID IN [^{3}H]-SPIROPERIDOL BINDING IN RAT BRAIN . L. L. Coughenour* (SPON: J. Abelson) Warner-Lambert/Parke-Davis Pharmaceutical Research Division, Ann Arbor, Michigan 48105.

Numerous studies have been done on the binding of [^{3}H]-dopamine agonists and [^{3}H]-dopamine antagonists to the striatal membranes of rats and other species. In most of these studies ascorbic acid and either a mixture of ions or EDTA was added to the incubation mixture. Recently, it has been reported that in the presence of ascorbic acid, $MnCl_2$ ($1x10^{-4}$ M.) and NaCl ($1x10^{-1}$ M.) increase the binding of [^{3}H]-spiroperidol, a dopamine antagonist, to rat striatal membranes by 192% and 178% of control, respectively (Usdin, et al, 1980). However, others have reported that ascorbic acid inhibits the binding of the dopamine agonist [^{3}H]-ADTN to rat striatal membranes (Kayaalp and Neff 1980) and the binding of the dopamine antagonist [^{3}H]-haloperidol to guinea pig brain membranes (Leslie, et al, 1980). In the present study ascorbic acid (0.001%, 0.01%, 0.1%) was found to inhibit the binding of [^{3}H]-spiroperidol to rat striatal membranes by 50-70% when no ions were present in the incubation mixture. However, when a mixture of ions (120 mM NaCl, 5 mM KCl, 2 mM $CaCL_2$, 1 mM $MgCl_2$) was present in the incubation mixture, ascorbic acid (0.1%) did not inhibit the binding of [^{3}H]-spiroperidol to these membranes. The binding in the presence of both ions and ascorbic acid was not different from the binding in the absence of both ions and ascorbic acid.

When no ascorbic acid was present, NaCl ($1x10^{-1}$ M.) increased the binding of [^{3}H]-spiroperidol by 18% and MnSO4 ($1x10^{-4}$ M.) decreased the binding by 12% while no significant change occurred with EDTA ($1x10^{-4}$ M.) In addition NaCl, MnSO4, and EDTA in the above concentrations could prevent but not reverse the inhibition by ascorbic acid (0.1%). The inhibition by ascorbic acid was time dependent with 50% inhibition occurring after 10 minutes and virtually 100% inhibition occurring after 30 minutes at 25°C. These findings indicate that ascorbic acid may be altering the kinetics of the binding of [^{3}H]-spiroperidol to striatal dopamine receptors. Ascorbic acid also may be modulating or masking the effects of cations on dopamine receptor binding systems. These parameters should be re-evaluated to account for the effects of ascorbic acid in dopamine binding assays.

68.1 EFFECT OF ELECTRICAL STIMULATION OF THE C1 ADRENERGIC CELL GROUP AND THE KOLLIKER-FUSE NUCLEUS ON SYMPATHETIC VASOMOTOR ACTIVITY AND ADRENAL MEDULLARY CATECHOLAMINE SECRETION IN RAT. C.A. Ross, A. Del Bo*, D.J. Reis Lab. of Neurobiology, Cornell Univ. Med. Coll. New York, NY 10021

Segments of the thoracic spinal cord which innervate the adrenal medulla receive afferents from several brainstem presumably autonomic nuclei. In the present study we investigated the effect of electrical stimulation of two of these--the C1 adrenaline containing cell group of the medulla oblongada and the Kolliker-Fuse nucleus (KFN) of the parabrachial complex in the pons (Ross et al. Neurosci. Lett. 1981; Saper and Loewy, 1980). We sought to establish whether neurons in these nuclei excite or inhibit release of adrenal medullary hormones, and if so, whether they act upon the adrenal medulla, or sympathetic vasomotor nerves, or both. Stimulation of both C1 and KFN in chloralose (60mg/ kg) anesthetized, paralyzed, artificially ventilated rats (n=55) with 10 sec trains evoked stimulus-locked pressor responses and tachycardia. Thresholds were 8-15 μa and the responses were graded; at 5x threshold, the elevation of arterial pressure was approximately 80 mm and the increase in heart rate 60 bpm. The optimal stimulus frequencies in the C1 region were 150-300 hz, while those in the KFN were 70-150 hz. Pressor responses and tachycardia from both regions were blocked by spinal cord transections or by phentolamine (5mg/kg, i.v.), but not by acute midbrain transection, nephrectomy, or adrenalectomy. After abolition of vasomotor responses by pretreatment with 6OHDA (100mg/kg) electrical stimulation of both C1 and KF nuclei elicited pressor responses with a delayed onset (15-20 sec) and a prolonged duration (2-5 min), accompanied by vagal bradycardia. Stimulus thresholds and frequency optima were similar to those in untreated rats. The pressor responses were almost completely abolished by phentolamine or bilateral adrenalectomy and therefore resulted from release of adrenal medullary catecholamines. The areas from which maximal responses were elicited corresponded closely with the locations of neurons of C1 and KFN retrogradely labelled after injections of HRP into the lower thoracic spinal cord. The pressor responses from both areas were unaffected by prior ipsilateral midbrain hemitransection, and thus were not dependent on fibers of passage descending from the hypothalamus (Saper et al, 1976). We conclude: (a) excitation of neurons of the C1 adrenergic group and the Kolliker-Fuse nucleus elicits release of adrenal medullary catecholamines and excites sympathetic vasomotor nerves via direct projections from each nucleus to the intermediolateral cell column; (b) within each nucleus, representation of the vasomotor fibers and the adrenal medulla are admixed.

68.2 CNS CONTROL OF THE SYMPATHETIC NERVOUS SYSTEM IN THE DOG: SITE OF ACTION OF BOMBESIN AND A SOMATOSTATIN ANALOG. Marvin Brown, Laurel Fisher* and Victoria Webb*. (SPON: E. Battenberg). Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Bombesin, mammalian bombesin (gastrin releasing peptide) and somatostatins (SS), SS-28 and oligo-SS's,given intracisternally or intracerebroventricularly to rats influence epinephrine (E) secretion by the adrenal medulla. Each of these two classes of peptides are distributed in several brain regions thought to participate in regulation of the sympathetic nervous system. Studies to determine the CNS site(s) of action of bombesin and the SS-analog, desAA^{1,2,4,5,12,13}[D-Trp^{8}]-SS (ODT8-SS) to affect plasma levels of E, norepinephrine (NE), glucose (CHO) and glucagon (G) and mean arterial blood pressure (MAP) have been carried out. Adult 10-12 kg male Beagle dogs were used. Multiple, chronic brain ventricular and/or parenchymal cannulae and carotid artery and jugular vein catheters were placed one week prior to experiments. Studies were carried out in unanesthetized dogs placed in a Pavlov sling. Bombesin (5-50 nmoles) placed into the lateral ventricle did not influence plasma levels of E, NE, CHO, G or MAP. Bombesin (5 nmoles) placed into the anterior hypothalamus, dorsal medial hypothalamus (DMH), interpeduncular nucleus, interstitial nucleus of the midbrain and subcumiform nucleus resulted in significant elevations of plasma E, G and CHO and increased MAP. Plasma NE was elevated only in animals with extremely high E levels (> 2 ng/ml). Control injections into these same sites did not result in alteration of E, G, CHO, or MAP. Bombesin placed into the lateral hypothalamus and ventral lateral thalamus resulted in significant elevations of MAP without change of plasma E or CHO. Placement of bombesin into the lateral preoptic area, ventral medial hypothalamus, ventral lateral thalamus, amygdala, hippocampus, several cerebral cortical areas, putamen, bed nucleus of the stria terminalis, posterior hypothalamus, red nucleus, substantia nigra, parabrachial nucleus, and dorsal motor nucleus of the vagus did not result in significant changes of plasma levels of E, NE, or CHO or of MAP. Elevations of plasma E and MAP induced by bombesin placed into the DMH were abolished by simultaneous placement of ODT8-SS into the same site. In contrast, ODT8-SS placed in other brain regions, i.e. hippocampus, amygdala, and red nucleus did not prevent bombesin elevations of plasma E. Conclusions: Bombesin stimulation of specific sites within the dog brain results in elevation of plasma E, G, and CHO and increase in MAP. While overlap between sites at which bombesin elevates E and MAP exist, there are sites where increases in MAP occur without signigicant elevations of plasma E. Likewise, elevation of plasma E is not always associated with increased MAP. ODT8-SS acts in the DMH to prevent bombesin actions.

68.3 BRAIN CONTROL OF GLUCOREGULATION: INVOLVEMENT OF THE RENIN-ANGIOTENSIN SYSTEMS? Laurel Fisher* and Marvin Brown. Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Stressful stimuli (e.g. ether, surgery) and several chemical substances placed inside the brain (e.g. bombesin, β-endorphin, carbachol, 2-deoxyglucose) produce hyperglycemia. This effect results from activation of the adrenomedullary sympathetic nervous system. Enhanced sympathetic outflow could elevate circulating Angiotensin II (AII) levels via stimulation of renin secretion. AII is reported to act directly on the adrenals to release catecholamines and thus could in part mediate the response to stress or to centrally-acting hyperglycemic agents. The following studies explored the possible involvement of peripheral and central AII in the neural control of blood glucose levels.

Adult male Sprague-Dawley rats (200-250 g) anesthetized with ether were used in all experiments. Intravenous injection of AII (10 μg) produced hyperglycemia which was blocked by concomitant treatment with the AII receptor antagonist, [Sar^{1},OMeThr^{8}]-AII (20 μg, iv). Insulin levels also were elevated after AII administration, suggesting a hyperglycemic mechanism other than by stimulation of adrenal epinephrine secretion. Consistent with this notion is the fact that adrenalectomy or intracisternal injection of ODT8-SS (1 μg) failed to abolish AII-induced hyperglycemia. Peripheral administration of [Sar^{1},OMeThr^{8}]-AII (20 μg, iv) did not modify the hyperglycemic effects of surgical stress or of intracisternal injections of bombesin (100 ng), β-endorphin (50 μg), carbachol (10 μg), and 2-deoxyglucose (3 mg). Further, intracisternal bombesin (100 ng) produced hyperglycemia in nephrectomized animals and in rats pretreated with propranolol (0.4 and 4 mg, sc). Thus, circulating AII plays a minimal role, if any, in mediating the glucose response to stress or to centrally-acting hyperglycemic substances.

Intracisternal injection of AII (10 μg) also increased blood glucose levels and this effect was blocked by intracisternal injection of [Sar^{1},OMeThr^{8}]-AII (20 μg) or ODT8-SS (1 μg). In contrast, the hyperglycemia observed after intracisternal injections of bombesin, β-endorphin, carbachol, and 2-deoxyglucose (same doses as above) was not antagonized by intracisternal injection of [Sar^{1},OMeThr^{8}]-AII. Hence, these compounds' actions on blood glucose levels probably are not mediated via central AII receptors. However, centrally-administered AII may share the same final pathway as these other substances to produce hyperglycemia in that ODT8-SS is a potent antagonist in all cases. This idea is supported further by preliminary data suggesting that intracranial injection of AII stimulates adrenomedullary epinephrine secretion in unanesthetized rats.

68.4 REGULATION OF ADRENAL MEDULLA BY ALPHA RECEPTORS FOLLOWING CAROTID OCCLUSION IN NORMOTENSIVE RATS. M. Bouvier and J. de Champlain*. Centre de Recherche en Sciences Neurologiques and Dept of Physiology, Université de Montréal, Montréal, Québec, Canada.

The regulation of the sympatho-adrenal tone was studied during bilateral carotid occlusion (CO) in vagotomized normotensive rat. The sympathetic activity was estimated by measuring the plasma concentration of norepinephrine (NE) and epinephrine (E), using a differential radioenzymatic assay. Baseline values under chloralose anesthesia were: NE: 0.111 ± 0.009 ng/ml; E: 0.036 ± 0.010 ng/ml. Following a one-minute carotid occlusion, a rise in mean blood pressure (MBP) simultaneously with a significant ($p < 0.01$) increase in circulating E (+ 0.024 ± 0.006 ng/ml were observed without any change in circulating NE. To eliminate any change in the reuptake during that procedure, the effects of carotid occlusion were studied after an injection of desmethylimipramine (1 mg/kg i.v.). As expected, the baseline values of NE raised significantly to 0.187 ± 0.017 ng/ml but the E values remained unchanged. Following that treatment, it was not possible to detect any elevation of NE following the stimuli, whereas the elevation of E induced by the occlusion remained unchanged. Moreover, the pressor response to occlusion was found to be greatly reduced by acute bilateral adrenalectomy (from 22 ± 3 mmHg to 10 ± 2 mmHg) but the response tended to be potentiated by chemical sympathectomy (6-OHDA, 100 mg/kg i.v. 24 hrs previously) indicating the participation of adrenal CA liberation in this response. The pressure response was partially blocked by treatment with a mixed alpha-1, alpha-2 adrenergic blocker (phenoxybenzamine, 1 mg/kg i.v.) which tended to potentiate the increase of circulating E during that manoeuvre. Furthermore, the injection of a selective alpha-2 adrenergic blocker (Yohimbine, 0.5 mg/kg i.v.) did not change the pressor response but potentiated by more than three folds the increase in circulating E whereas this treatment did not change the catecholamine basal values. These results suggest that an acute stimulation of the carotid reflex arc induces a preferential increase of adrenal medullary activity. Moreover, these results suggest the participation of adrenergic receptors in the regulation of adrenal medulla. The potentiation of E liberation could be mediated by the blockade of alpha-2 adrenergic receptors located on adrenal chromaffin cells. These "auto-receptors" might regulate the liberation of adrenal medullary CA by mediating a negative feedback mechanism as suggested by several in vitro studies.

68.5 GLUCOCORTICOID RECEPTORS IN RAT ADRENAL MEDULLA: IMMUNOCYTOCHEMICAL LOCALIZATION. P.A. Bernard*, G. Teitelman, D.J Reis and T.H. Joh (SPON: R.A. Ross). Laboratory of Neurobiology, Cornell University Medical College, New York, N.Y. 10021.

The cellular responses to glucocorticoids are mediated by binding to specific cytoplasmic proteins in target cells. The steroid-receptor complexes are then "activated". It has been proposed that these activated receptors are then translocated into the nucleus where they associate with chromatin leading to the production of specific mRNA's. To directly examine the distribution of the activated glucocorticoid receptor (GR) in cells of the adrenal medulla, a target of glucocorticoids, we have raised Abs to the GR and localized them by immunocytochemistry. GR, identified on the basis of triamcinolone acetonide binding and affinity for DNA, was purified from rat liver cytosol. Nonactivated GR, concentrated by protamine sulfate precipitation, was first separated from DNA-binding proteins by DNA-cellulose column chromatography. The receptor preparation was then heat-activated, applied to a second DNA-cellulose column, and washed with low ionic strength (50 mM NaCl) buffer. The DNA-binding form of GR was eluted with high ionic strength (450 mM NaCl) buffer. GR was identified on PAGE on the basis of retention of ^{3}H-steroid in calcium-containing gels. Gel slices containing GR were injected into rabbits. and antibody was harvested. In a radioimmunoassay for GR, antibody reacted with the activated (DNA-binding) but not the non-activated form of GR.

Rat adrenal medullae were immunocytochemically stained for GR by the PAP method in frozen tissue sections. Almost all adrenal medullary cells were specifically stained in two distinct subcellular patterns: In some clusters of cells staining was exclusively nuclear, in others, cytoplasmic. No cells stained in both cytoplasm and nucleus. Administration of low doses of dexamethasone (10^{-7}M) increased (40 min later) only the intensity of cytoplasmic staining, while high doses (10^{-5}M) dramatically increased the number of cells with nuclear staining and markedly reduced the number of cells showing cytoplasmic staining. The present study is the first demonstration of cellular localization of GR and provides direct evidence that the adrenal medulla contains these receptors. The presence of activated GR in the cytoplasm of some cells suggests nuclear translocation is regulated by factors other than high affinity binding and subsequent activation of the receptor. The presence of GR in either nuclei or cytoplasm in untreated rats suggests that in life the GR is in a dynamic state.

68.6 TRIFLUOPYRAZINE-INDUCED INHIBITION OF CATECHOLAMINE SECRETION BY ISOLATED ADRENAL CHROMAFFIN CELLS. Jack C. Brooks and Suzanne Treml*. Dept. of Basic Sciences, Marquette Univ., Sch. Dent., Milwaukee, WI 53233.

Excitation-secretion coupling in chromaffin cells is known to be regulated by the intracellular calcium concentration and might, therefore, involve the calcium dependent regulator calmodulin. It has been demonstrated that calmodulin can be inactivated in vitro by the drug trifluopyrazine (TFP). We have examined the effect of TFP on catecholamine secretion by isolated chromaffin cells as part of studies designed to determine if calmodulin plays a role in secretion. A dose-response curve was constructed for cells incubated for 5 min. with various concentrations of TFP followed by stimulation with acetylcholine. The drug had no significant effect on secretion at a concentration of 0.01μM, while higher concentrations produced a biphasic effect on secretion. Secretion was reduced to the level of unstimulated control cell suspensions at 1.0μM TFP concentration. Higher TFP concentrations (10 to 100μM) produced an apparent increase in catecholamine release. At the 100μM TFP concentration catecholamine release was five-fold greater than that of cells stimulated in the absence of the drug. However, since dopamine also appeared in the medium, the enhanced release might be due to cell damage. The percentage of norepinephrine, out of the total catecholamine released, was also different for this drug concentration. TFP could not be removed from the cells by repeated washing with drug-free medium. It appears, therefore, that the effect of TFP on secretion is time dependent and either permanent, or the drug can not be removed from the treated cells. Preliminary experiments also indicate that the inhibition of secretion by TFP can not be reversed by increasing the extracellular calcium concentration to 5mM calcium, again indicating a lasting effect of the drug on the secretory system.

As is the case with other secretory cells, these data imply a role for calmodulin in catecholamine secretion by adrenal chromaffin cells.

68.7 RELATIONSHIP BETWEEN Ca^{++} UPTAKE AND CATECHOLAMINE SECRETION IN CULTURES OF ADRENAL MEDULLARY CHROMAFFIN CELLS. R.W. Holz, R.A. Senter*, R.A. Frye*, and T. Blok*. Dept. of Pharmacology, Univ. of Michigan Medical School 48109.

Carbachol or elevated K^+ stimulated $^{45}Ca^{++}$ uptake into chromaffin cells 2-4 fold. The uptake was stimulated by cholinergic drugs with nicotinic activity but not by those with only muscarinic activity. Ca^{++} uptake and catecholamine secretion-induced by the mixed nicotinic-muscarinic agonist carbachol were inhibited by the nicotinic antagonist mecamylamine but not by the muscarinic antagonist atropine. Significant Ca^{++} uptake occurred within 15 sec. of stimulation by carbachol or elevated K^+ at a time before catecholamine secretion was readily detected. At later times the kinetics of secretion induced by carbachol or elevated K^+ paralleled that of Ca^{++} uptake. There was a close correlation between the Ca^{++} uptake from the medium and catecholamine secretion in various concentrations of Ca^{++} which stimulated both processes and Mg^{++} which inhibited both processes. Thus, there is an excellent pharmacological and kinetic correlation between Ca^{++} uptake and catecholamine secretion. This correlation provides strong support for the notion that Ca^{++} entry and a presumed increase in cytosolic Ca^{++} concentration initiates and maintains secretion. Furthermore, these studies also suggest that a number of different stimuli can control the Ca^{++} permeability of these cells.

68.8 BOVINE CHROMAFFIN CELLS IN CULTURE: CHANGES IN PHENOTYPE INDUCED BY ORGAN EXTRACTS, ELEVATED POTASSIUM AND SERUM WITHDRAWAL, BUT NOT BY NERVE GROWTH FACTOR. K. Unsicker and H.-D. Hofmann*. Dept. of Anatomy and Cell Biology, Philipps University, D-3550 Marburg, FRG.

Rat and human adrenal chromaffin cells have the capacity to express a neuronal phenotype by forming axons and growth cones when cultured in the presence of NGF (Tischler et al., Lab. Invest. 43:339, 1980; Unsicker et al., Proc. Natl. Acad. Sci. USA 75:3498, 1978). Recent studies have provided contradictory results regarding effects of NGF on cultured bovine chromaffin cells. The present investigation was undertaken to define the conditions favouring extension of processes of bovine chromaffin cells. The cells were isolated and grown as previously described (Unsicker et al., Neurosci. 5: 1445, 1980).

In the presence of non-chromaffin (fibroblast-like) cells a small proportion of chromaffin cells (approx. 15%) formed processes within 2 weeks that were longer than the 3-fold cell diameter. Elimination of non-chromaffin cells by rigorous differential plating, γ-irradiation or treatment with FdU inhibited the formation of processes. Addition of a cell-free extract from non-chromaffin cells, but not conditioned medium, re-established process formation. Treatment of cultures with extracts of bovine seminal gland, which contains a NGF-like activity (Hofmann and Unsicker, Neurosci. Letters Suppl. 6, 1981), caused extension of processes from about 30% of chromaffin cells within 2 days. Extracts from bovine liver, kidney and brain, mouse submaxillary gland NGF (50ng to 5μg/ml) and the purified NGF-like fraction from bovine seminal gland had no effect.

Process formation was extensively stimulated by elevating K^+ in the medium (11 to 55 mM) and to a lesser extent by serum withdrawal. However, processes rarely resembled the long, varicose axons formed by rat and human chromaffin cells in vitro.

These results suggest that process formation of bovine chromaffin cells, in contrast to rat and human chromaffin cells, is a rather unspecific phenomenon. These processes resemble cytoplasmic extensions rather than neurites. Consequently, bovine chromaffin cells may be considered not to be the most suitable model to study early events of axon formation and the mechanisms underlying neuronal plasticity of chromaffin cells.

68.9 OPIOID PEPTIDES AND NARCOTIC ANALGESICS MODULATE THE BASAL RELEASE OF CATECHOLAMINES FROM ADRENAL CHROMAFFIN CELLS IN CULTURE.

Deanne M. Dean* and Bruce G. Livett. Division of Neurology, The Montreal General Hospital and McGill University, Montreal, Canada.

We have recently examined the effects of various opioid peptides (enkephalins, enkephalin analogues, β-endorphin, dynorphin) and narcotic analgesics (morphine, levorphanol) on both the basal and nicotine-mediated release of catecholamines (i.e. ^{3}H-NE) from bovine adrenal chromaffin cells in culture. Although these agents inhibit the release of ^{3}H-NE induced by nicotine ($5x10^{-6}$M), the inhibition is non-specific (1).

In contrast, these agents appear to modulate the basal release of catecholamines from adrenal chromaffin cells in culture. At concentrations between $1x10^{-6}$M to $1x10^{-3}$M, these agents enhanced the basal release of ^{3}H-NE. The enhancement of basal release by morphine ($5x10^{-4}$M) was dependent on the presence of Ca^{++} in the medium. The enhancement was stereospecific since levorphanol, but not dextrorphan was active. The enhancement produced by morphine ($1x10^{-4}$M, $5x10^{-4}$M) and levorphanol ($1x10^{-3}$M) was reversed by naloxone and naltrexone. The ability of naloxone to reverse the enhancement of basal release of ^{3}H-NE by dynorphin and β-endorphin was also examined.

Lower concentrations ($1x10^{-8}$M, $1x10^{-7}$M) or many of these agents (e.g. the enkephalins, dynorphin, morphine) inhibited the basal release of ^{3}H-NE from adrenal chromaffin cells in culture. Although the inhibition produced by morphine ($1x10^{-8}$M) was reversed by naloxone ($1x10^{-7}$M, $1x10^{-6}$M), the effect was not stereospecific since dextrorphan was active while levorphanol was not.

These results support earlier studies demonstrating a direct stimulatory effect of morphine on the adrenal gland (2,3) and suggest that endogenous opioid peptides in the adrenal medulla (4) may modulate basal secretion of catecholamines.

69.1 UNMYELINATED SPLANCHNIC FIBERS OF PREGANGLIONIC AND POSTGANGLIONIC TYPES - AN ELECTRON MICROSCOPIC STUDY. Grace C.H. Yang*, Dwayne S. Yamasaki*, George M. Krauthamer and David C. Kuo. Department of Anatomy, College of Medicine and Dentistry of New Jersey, Rutgers Medical School, Piscataway, New Jersey 08854.

It is commonly believed that most autonomic preganglionic fibers are finely myelinated. In the present investigation, electron microscopic analysis of the unmyelinated fiber component of the left major splanchnic nerve (MSPLN) of the cat indicates that the majority of these fibers are, in fact, preganglionic. The ratio of unmyelinated to myelinated fibers of preganglionic type is approximately two to one. In the normal MSPLN there are 10,000-15,000 unmyelinated fibers. Following a left ventral root rhizotomy (T3-L1)**, unmyelinated fiber counts in the left MSPLN dropped precipitously (see table). A second significant finding in this study is that a large number of unmyelinated fibers in the MSPLN are postganglionic. This is contrary to the generally accepted view that this nerve is primarily sensory and preganglionic. Many undegenerated, unmyelinated fibers were identified in the MSPLN after left spinal nerve cuts (T3-L1) immediately lateral to the dorsal root ganglion (see table). A few neuronal cell bodies were also identified in one MSPLN specimen. Conceivably, some postganglionic fibers may originate from these aberrant cells. In different experiments, the cells of origin of splanchnic postganglionic fibers were studied. Retrograde transport of HRP from the central cut end of the MSPLN labeled a substantial number of paravertebral postganglionic sympathetic neurons, largely located in the region of the sympathetic chain from which the MSPLN has its origin.

Fiber Counts of Normal and Partially Degenerated MSPLN
(UM - unmyelinated; MY - myelinated)

Cat	Normal	Ventral Rhizotomy (T3-L1)	Spinal Nerve Cut (T3-L1)
1	15359(UM) 3801(MY)	-	-
2	9620(UM) 2655(MY)	-	-
3	-	4697(UM) 315(MY)	-
4	-	2609(UM) 284(MY)	-
5	-	-	1643(UM) 13(MY)
6	-	-	7619(UM) 38(MY)

**The spinal levels which contained preganglionic neurons of the MSPLN have been previously defined by HRP method (Kuo et al., Neurosci. Letts., 17(1980) 11-16). (Supported by NS 10922.)

69.2 FINE STRUCTURE OF SUBSTANCE P-LIKE IMMUNOREACTIVE NERVE TERMINALS IN THE CELIAC GANGLION OF GUINEA PIGS. H.Kondo* and R.Yui*. (SPON:T.Chiba). Niigata Univ. Sch. of Med., Niigata, JAPAN

The fine structural localization of substance P-immunoreactive nerve fibers and their synaptic relations to other neuronal elements in the celiac ganglion of guinea pigs were studied by means of the peroxidase-antiperoxidase(PAP) method in electron microscopy. The immunoreactive nerve fibers contained abundant small clear spherical vesicles, 45 nm in diameter, and a few large granular vesicles with a halo, 90 nm in mean diameter. The immunoreactive materials were localized around cytoplasmic components including vesicles and mitochondria and on the inside of the plasma membrane. The immunoreactive nerve fibers directly apposed to unlabelled dendrites of postganglionic principal neurons and also presumably preganglionic axons. Some of the unlabelled axons contained abundant small clear vesicles, 45 nm in means diameter, while others contained abundant large granular vesicles, 90 nm in mean diameter. At sites of apposition, the apposed plasma membranes parallel to each other were separated by a space of about 20 nm. The accumulation of vesicles was observed in the immunoreactive fibers and a cytoplasmic density was slightly observed on the apposed plasma membrane of unlabelled dendrites, but no distinct electron density together with the accumulation of vesicles was seen underneath the apposed membrane of unlabelled axons. No cellular components showing features of SIF(small intensely fluorescent) cells were found in relation to the immunoreactive nerve fibers. The present study shows that substance P-fibers form axodendritic synapses on the principal neuron, which could be the synaptic site where substance P is related to induce the non-cholinergic slow EPSP. This study also suggests the presence of the presynaptic interaction between substance P-fibers and some preganglionic axons in the celiac ganglion.

69.3 INVESTIGATION OF CERTAIN INTRINSIC PROPERTIES OF FELINE CELIAC GANGLION (CG) NEURONS. D. L. Decktor* and W. A. Weems, Dept. Physiol. and Cell Biol., Univ. Texas Med. Sch. at Houston, Houston, TX. 77025

Neural commands that regulate the function of the abdominal viscera are synthesized within the prevertebral ganglia of the solar plexus from both peripheral and central preganglionic inputs. Intrinsic properties of each ganglionic neuron are prime determinents of its ability to integrate these preganglionic inputs and synthesize an output command. The purpose of this study was to investigate some of the intrinsic properties of CG neurons. Solar plexus ganglia were studied in vitro. Transmembrane potentials of neurons were monitored by intrasomatic electrodes. The input resistance and membrane time constant were measured for each neuron. From these values the total input capacitance was calculated. The amplitude and duration of the afterspike hyperpolarization (ASH) was measured and the rhythmic firing mode of the neuron assessed. All of the neurons tested fired in a rhythmic firing mode. Fifty-nine percent were phasic and 41% were tonic. Input resistance ranged from 5 to 58MΩ. This large range of values may be indicative of differences in either the size or the specific membrane resistance of the individual neurons. The mean value for phasic neurons (21MΩ) was significantly less than that calculated for tonic neurons (36MΩ). Time constant ranged from 9 to 21 msec with a mean of 13.8 msec. Input capacitance ranged from 286 to 2750 picofarads. If it is assumed that specific membrane capacitance is relatively constant, then the large range of values for input capacitance would reflect differences in neuron size. ASH durations ranged from 21 to 267 msec and were distributed bimodally with peaks at 60 and 140 msec. It was concluded from these studies that neurons within the celiac ganglion cannot be represented as a single population with similar intrinsic properties. The wide range and non-Gaussian distribution of values reported may reflect functional differences in the physiological role of individual neurons. (Supported by N.I.H. grant HL21351)

69.4 SLOW RHYTHMIC MEMBRANE POTENTIAL CHANGE IN HAMSTER PARASYMPATHETIC NEURONS. T. Suzuki* and K. Kusano. Neurophysiology Lab. Dept. of Biol., Illinois Inst. Technology, Chicago, IL.60616.

Previously we have reported that postganglionic neuron excitability is modulated by hyperpolarizing potentials associated with action potentials and synaptic potentials, and by rhythmic hyperpolarizing potentials (RHP's) activated either spontaneously or by caffeine application. We have concluded that these hyperpolarizing potentials are all due to Ca-activated K-conductance increase. Recently, we have found another cellular activity, namely the slow rhythmic membrane potential change (SRMPC),which is much slower in time scale than the "caffeine-induced" RHP's. The SRMPC is roughly sinusoidal and occurs spontaneously in some neurons. The average membrane potential change from peak to bottom is 9.7±5.7 mV (mean±S.D., range: 4-32 mV) with an average interval of 5 min (range: 2.5-11.5 min). The most negative level of the SRMPC observed is -90 mV in some neurons, but the average is -80±5.6 mV (n=41). The membrane resistance is higher at the most positive E_m level than at the most negative E_m level. The SRMPC can be triggered by applying preganglionic repetitive stimulation. Postganglionic repetitive stimulation, direct stimulation of the neuron by injecting depolarizing current, and bath-applied ACh or Carb are also effective. When the median level of the SRMPC is close to -90 mV the amplitude of SRMPC becomes very small and is hardly seen. The median E_m level of the largest amplitude of the SRMPC is between -60 and -70 mV, and for E_m's lower than this the SRMPC amplitude decreases. The frequency of the SRMPC is not clearly affected by the temporal displacement of the E_m between -50 and -85 mV. The SRMPC is abolished reversibly by 2.5 mM 4-aminopyridine, an agent which reduces membrane K-conductance. In Ca-free saline the amplitude of the SRMPC decreases, and conversely, in the presence of up to about 5 mM Ca the amplitude of the SRMPC increases. In higher than 5 mM Ca the E_m has been found to be more stable near the E_K level. Caffeine of 2-5 mM induces characteristic RHP's on top of SRMPC. When caffeine induces E_m hyperpolarization, the SRMPC decreases gradually. In some neurons, both amplitude and frequency of SRMPC are attenuated by caffeine. Ruthenium red of 10^{-4} M reduces the SRMPC slightly after treatment for 1 hr. Intracellular injection of Ca induces a large transient hyperpolarization when the E_m of the preinjection state had been between -45 and -60 mV. When the E_m had been close to E_K, such transient hyperpolarization is not prominent. Injection of Ca during SRMPC reduces its amplitude and finally the E_m becomes stable at the lower level of the SRMPC. It is concluded that the SRMPC is generated endogenously in these neurons by slow intracellular Ca activity changes which modulate K-conductance. (Supported by NIH Grant, NS12275).

69.5 AN ANALYSIS OF THE INHIBITORY EFFECTS OF LEUCINE ENKEPHALIN ON TRANSMISSION IN VESICAL PARASYMPATHETIC GANGLIA OF THE CAT. August M. Booth*, Nancy Ostrowski*, Sean McLinden*, Irene Lowe* and William C. de Groat. Dept. of Pharmacology, School of Medicine, Univ. of Pittsburgh, Pgh., PA 15261.

Previous studies in situ have shown that transmission in parasympathetic ganglia on the surface of the urinary bladder (UB) is depressed by intra-arterial injections of leucine enkephalin (ENK). In the present investigation the mechanisms underlying this depression were examined with intracellular recording techniques in vitro. Ganglia were removed from the serosal surface of the UB of cats and pinned out in a chamber perfused with Krebs solution at 35-37°C. Activity of ganglion cells was recorded intracellularly with micropipettes. Preganglionic fibers were stimulated with suction or hook electrodes. Stable resting potentials of more than 50mV and action potentials exceeding 70mV were obtained from the majority of cells.

When cell firing was elicited with preganglionic stimulation the application of ENK in concentrations between 12 and 50 μM depressed cell firing by 30-100%. The inhibition was clearly evident within 2-3 min following drug application and lasted 10-20 min following the offset of the drug. More than 80% of those cells tested showed ENK-inhibition. Increasing drug concentrations to 160 μM did not result in demonstrable inhibition in cells that showed no inhibition to 12-50 μM concentrations of ENK.

When cell firing was blocked by hyperpolarizing pulses or when stimulus intensity was reduced to produce epsps that were below the threshold for cell firing ENK reduced the average amplitude of epsps in responsive cells 30-60%, increased the number of epsp "failures" 75-400% and reduced the frequency of spontaneous miniature potentials 40-60%. ENK did not reduce the amplitude of miniature potentials. ENK did not change membrane conductance, resting potential or threshold for cell firing.

To demonstrate the presence of ENK in UB ganglia the FITC indirect immunoflorescence technique was used. ENK immunoreactivity was seen between and surrounding ganglion cell soma. This ENK was presumably contained in terminals of sacral preganglionic neurons which provide the cholinergic, excitatory input to these ganglia and which were shown to contain ENK by Glazer and Basbaum (1980).

In summary, ENK inhibits cholinergic transmission in UB ganglia by a presynaptic mechanism. Since ENK terminals are present in these ganglia, it seems possible that ENK coexists with acetylcholine in the same terminal endings and may modulate ganglionic transmission.

69.6 ORIGIN OF AXONS IN THE BLADDER NERVES. Claire E. Hulsebosch and Richard E. Coggeshall, Depts. of Anatomy and of Physiology and Biophysics and the Marine Biomedical Institute, The University of Texas Medical Branch, Galveston TX 77550.

There are three main nerves which innervate the bladder: the pelvic nerve, the hypogastric nerve and the pudendal nerve. Previous studies using selective surgery determined the number and origin of myelinated (M) axons in these nerves but did not consider the unmyelinated axons (UN) which are more numerous than the myelinated axons. The present ultrastructural study uses selective surgery to determine the number and origin of the unmyelinated as well as the myelinated axons in the bladder nerves of the rat. These data are presented in the following table in which each datum, displayed as a mean value of several rats, represents the number of fibers of ventral root origin (VR), dorsal root origin (DR) or sympathetic origin (SYM):

ORIGIN	PUDENDAL		HYPOGASTRIC		PELVIC	
	UN	MY	UN	MY	UN	MY
VR+SYM	742	53	1353	206	2613	158
DR+SYM	3000	1354	1124	148	1556	444
SYM	165	5	836	141	546	70
VR+DR	2884	1595	644	45	3814	756

In summary, these data suggest the following: 1) 85% of the axons in the pudendal nerve are sensory, 10% are somatic motor and 5% are sympathetic, 2) 55% of the axons in the hypogastric nerve are sympathetic, 30% are somatic motor and 15% are sensory, 3) 50% of the axons in the pelvic nerve are somatic motor, 35% are sensory and 15% are sympathetic, 4) the unmyelinated axons make a substantial contribution in each category. Therefore, it is desirable to characterize the electrophysiological response properties of the unmyelinated fiber population in order to understand the innervation of the bladder. Supported by NIH grants NS 10161, NS 06246, NS 07377 and NS 11255.

69.7 ULTRASTRUCTURE AND SYNAPTIC COVERAGE OF PHYSIOLOGICALLY IDENTIFIED NEURONS OF THE GUINEA PIG SMALL INTESTINE: DOUBLE LABELING BY INTRACELLULAR INJECTION OF HORSERADISH PEROXIDASE AND EM RADIOAUTOGRAPHY WITH ^{3}H-SEROTONIN. S.M. Erde, D.M. Sherman*, and M.D. Gershon, Department of Anatomy, Columbia Univ. P.&S., New York, NY 10032.

Studies of the morphology of neurons of the myenteric plexus of the guinea-pig small intestine, physiologically identified and marked by the intracellular injection of Lucifer Yellow, have previously been reported (Neuroscience Vol. 6:101.1, 1980). We have extended these observations by injecting horseradish peroxidase (HRP; Sigma type VI) into physiologically identified neurons to permit examination of the cells, their processes, and their synaptic inputs by electron microscopy. Electrical activity of myenteric neurons was recorded using intracellular glass micropipettes, filled with HRP [0.2M solution of potassium acetate, 0.1M Tris buffer (pH 8.6), and 5% HRP]. The micropipettes were beveled to a resistance of 150 to 200 megohms. Neurons were categorized as S cells if they fired repetitively on injection of depolarizing current, and as AH cells if they failed to fire repetitively and an after-hyperpolarization, associated with a decreased membrane conductance, followed an action potential. HRP was injected into cells iontophoretically by passing depolarizing rectangular current pulses. Following physiological characterization and injection of HRP, preparations were incubated with tritiated serotonin (0.5uM) for 15-30 minutes in the presence of a 100-fold excess (50uM) of norepinephrine in order to specifically label serotonergic axon terminals. Tissue was fixed with 2.5% glutaraldehyde. HRP was demonstrated with Hanker-Yates reagent and the ^{3}H-serotonin by light and electron microscopic radioautography. Injected ganglia were cut out and HRP-filled cells were sectioned throughout their extent. Morphology was well preserved for electron microscopy despite the long incubation in vitro. Simultaneous identification of HRP-filled neurons and ^{3}H-serotonin proved to be feasible. This double labeling technique, therefore, permits identification of neurons receiving a serotonergic input and the regional localization of that input on those cells. Supported by NIH Grant #NS12969.

69.8 SYMPATHETIC AUTONOMIC NEUROPATHY IN THE HEART IN EXPERIMENTAL DIABETES. S. Y. Felten*, R. G. Peterson, P. A. Shea, and D. L. Felten. Departments of Anatomy and Psychiatry, Indiana University School of Medicine, 1100 W. Michigan, Indianapolis, IN 46223

Diabetes was induced with streptozotocin in male Sprague-Dawley rats at 1, 2, and 4 months of age. Within each of these groups, the animals were allowed to survive with diabetes for periods of 1, 2, and 4 months. Blood glucose levels for diabetes ranged from 550-650 mg% (controls 85-110 mg%) with HbA_1C levels from 4.5-7.5 %Hb (controls 1.9-2.5 %Hb) indicating the presence of diabetes. Motor conduction velocities measured in the sciatic nerve were decreased in all groups of diabetics when compared to controls.

Norepinephrine (NE) levels were measured in the right atrium and the ventricles of the heart using reverse phase, ion-paired HPLC with electrochemical detection. Patterns of sympathetic innervation were studied using glyoxylic acid histofluorescence.

In rats made diabetic at one month of age, atrial and ventricular NE levels were increased over controls at both one and two months of diabetes. At four months of diabetes, both atrial and ventricular NE levels were decreased. In rats made diabetic at two months of age, atrial and ventricular NE levels were increased at one month of diabetes and had returned to or slightly below control levels at two and four months of diabetes. In rats made diabetic at four months of age, atrial NE levels were normal at one month of diabetes, decreased at two months of diabetes, and returned to normal at four months of diabetes. In contrast, ventricular NE levels remained elevated at one, two and four months of diabetes.

Histofluorescence studies of the patterns of distribution of noradrenergic fibers in the heart were done on rats with diabetes of one month duration and have shown overall increases in the density of noradrenergic innervation with no change in the actual patterns of distribution. These findings are in agreement with the HPLC measurements showing an early increase of NE tissue levels in the diabetic rat heart.

This preliminary evidence demonstrates a two phase change in noradrenergic innervation of the heart in diabetes, agreeing with previous findings from this laboratory in diabetic rat penile corpora. The present findings suggest that during the early phases of diabetes the noradrenergic nerves are still intact and may be susceptible to pharmacologic manipulations. The later fall of NE back to or below control levels may indicate actual neuronal damage, suggesting that early intervention may be necessary to protect these nerves from degeneration.

This work was funded by the Juvenile Diabetes Foundation and the American Diabetes Association - Indiana Affiliate.

69.9 ABNORMAL BIOPHYSICAL PROPERTIES OF AUTONOMIC NEURONS IN SPONTANEOUSLY HYPERTENSIVE RATS. P. Yarowsky, D. Weinreich, and R. Snow. Dept. Pharmacol. & Exp. Therap., Univ. of MD, Sch. Med., Baltimore, MD, 21201.

Previous physiological and pharmacological investigations have shown that there is increased sympathetic nerve activity in Spontaneously Hypertensive rats (SHR) (Judy et al., Circ. Res. 38 (supp. II):21, 1976; Juskevich et al., Europ. J. Pharmacol. 51:429, 1978). It is not known whether the altered sympathetic nerve activity is due to changes in the biophysical properties of the postganglionic sympathetic neurons. We have recorded from the in vitro superior cervical ganglion (SCG) from the adult (7-10 wks of age) SHR with standard intracellular techniques. A remarkable feature of these neurons was that they showed repetitive action potentials (n = 36/40) during a depolarizing pulse or following anodal break; a behavior rarely observed in normotensive Sprague-Dawley or Wistar rats. In addition, some cells displayed spontaneous action potentials for prolonged periods of time. Furthermore, addition to Locke's solution of tetrodotoxin (TTX;1 μM) and TEA (5mM) did not abolish the repetitive action potential discharge. Multiple action potentials could be blocked, however, by the addition of any of the following Ca^{++} antagonists to Locke's solution: Co^{++} (5mM), Cd^{++} (3mM), or Ni^{++} (1mM). The remaining single action potential could be eliminated by adding TTX to the Locke's solution containing the Ca^{++} antagonists. These results indicate that the first spike is mediated by Na^{+} current, while the subsequent multiple action potentials are produced by regenerative Ca^{++} currents.

Examination of the membrane properties of SCG neurons in the SHR consistently revealed a lower resting membrane potential (-50mV vs. -60mV), yet they displayed normal input conductance, spike amplitude, spike threshold, and after hyperpolarization (C & K currents). The contribution of M-currents (Brown and Adams, Nature 283:673, 1980) to the electrogenesis of the observed repetitive spiking in SHR neurons was tested by using Ba^{++} (4 mM), a blocker of M-currents (Constanti et al., Brain Res. 206:244, 1981). Ba^{++} treatment of SHR ganglion cells yielded a slight decrease in the resting slope conductance (-15%) at or around resting potential and accentuated repetitive spiking. The % change in slope conductance produced by Ba^{++} was much smaller than is expected, based upon the values reported by Brown and Constanti (Br. J. Pharmac. 70:593, 1980). These data suggest that the postganglionic neurons of the SHR possess fewer or less efficacious M-channels than are present in cells from normotensive animals. (Supported by The Homer & Martha Gudelsky Foundation, Inc.)

69.10 PARASYMPATHETIC PREGANGLIONIC NEURONS AND PRIMARY AFFERENT PROJECTIONS IN THE SPINAL CORD OF THE RHESUS MONKEY. I. Nadelhaft, J. Roppolo, W. de Groat, C. Morgan, and S. Ames*. VA Medical Cent. & Depts. of Neurosurgery and Pharmacology, Univ. of Pgh. Medical School, Pittsburgh, Pa.

Horseradish peroxidase (HRP) applied to the central stump of the transected pelvic nerve of anesthetized Rhesus monkeys labeled afferent and efferent neurons innervating the pelvic viscera. Preganglionic neurons forming the sacral parasympathetic nucleus (SPN) were located in a narrow band 150-200 μm wide on the ipsilateral border of the intermediate gray matter. The SPN contained an average of 800 neurons (range: 330-1300) and characteristically extended over two or three sacral segments with the majority of cells in S2. The average length of the SPN was 13.2 mm (range: 9.1-18.2). The SPN was composed of medium sized elongated somata (17.5x32.0 μm) with their major axes in the transverse plane and oriented parallel to the lateral border of the gray matter. Dendrites extended deep into the lateral funiculus, horizontally into the medial posterior commissure, and dorsolaterally along the lateral edge of the dorsal horn. Preganglionic axons followed the lateral border of the ventral horn to the ventral rootlets.

Pelvic nerve afferent axons carried HRP to the dorsal root ganglion (DRG) neurons and by transganglionic transport to the spinal cord. The average number of labelled DRG cells was 3066 (range: 2224-4363) with the largest fraction (80%) in S2. The segmental frequency of DRG cells correlated with the frequency of SPN cells in corresponding spinal cord segments. Within the spinal cord labelled primary afferent fibers were prominent in the sacral segments and were also observed in decreasing numbers within two to three segments beyond the rostral and caudal limits of the SPN. In transverse sections, primary afferents were found throughout Lissauer's tract (LT) and in the lateral half of the dorsal columns. A prominent collateral fiber bundle from LT was located along the lateral edge of the dorsal horn. This bundle extended into the SPN and a few collaterals continued medially into the posterior commissure and the contralateral side of the cord. A much less prominent collateral fiber group from LT passed medially over the apex of the dorsal horn and descended along the midline into the posterior commissure. Horizontal sections revealed that these two collateral pathways were organized into periodically spaced bundles of fibers about 250 μm apart. HRP reaction product in terminal fields related to these afferent collateral projections were found in the lateral marginal zone, along the dorsal medial septum, and bilaterally in the medial region of the posterior commissure. In summary, the most striking observation of this investigation is prominent projection of visceral afferent fibers directly into the sacral parasympathetic nucleus.

69.11 GUANETHIDINE-INDUCED DESTRUCTION OF PERIPHERAL SYMPATHETIC NEURONS: AN AUTOIMMUNE PHENOMENON. P. T. Manning, C. W. Powers* and E. M. Johnson, Jr. Wash. Univ. School of Medicine, Dept. of Pharmacology, St. Louis, MO 63110.

Guanethidine (GUAN), a guanidinium adrenergic neuron blocking agent which, when chronically administered at high doses to newborn or adult rats (other species are not affected), causes destruction of peripheral sympathetic neurons. Neuronal destruction is preceded by small cell infiltration of the sympathetic ganglia, and is suggestive of an immunologically-mediated mechanism. We have demonstrated that administration of immunosuppressive agents prevents the sympathectomy produced by GUAN administration. Adoptive transfer experiments using spleen and bone marrow cells obtained from naive donors transferred to lethally irradiated recipients were thus carried out to demonstrate that GUAN-induced destruction occurs by an immunologically-mediated mechanism. To determine the dose of irradiation necessary to protect against neuronal cell death induced by GUAN, 3-week-old Lewis rats were treated with either 600, 750, or 900 rads of γ-irradiation six hours prior to the initiation of GUAN treatment. Rats received 50 mg/kg of GUAN sulfate for 5 days, were killed 2 days later, and the superior cervical ganglia (SCGs) dissected for assay of tyrosine hydroxylase (TOH) activity and for histological evaluation. Irradiation protected against GUAN-induced destruction in a dose-related manner with virtually complete protection afforded by doses of 900 rads. Similar results were obtained using neonatal Sprague-Dawley rats. Adoptive transfer recipients (3-week-old Lewis rats) were irradiated with 850 rads immediately prior to cell transfer. Adoptive transfer experiments involved 4 groups of animals: Group A (GUAN only); Group B (irradiation only), Group C (irradiation + GUAN); and Group D (irradiation + $5x10^6$ spleen and bone marrow cells + GUAN). Spleen and bone marrow cells were obtained from naive adult Lewis rats of the same sex. Sympathetic ganglia from animals in Groups B and C were normal, whereas ganglia from animals in group A showed the usual massive small cell infiltration and cell destruction. Animals in Group D, in contrast to Group C, showed clear small cell infiltration of the ganglia and neuronal destruction. These results indicate that small cell infiltration and neuronal destruction due to GUAN treatment require immune competency. The specific antigen that induces this autoimmune response as well as the specific immune mechanism responsible for the neuronal destruction remain to be elucidated. Supported by NIH grant HL-20604 and NIH Cardiovascular Training Grant 5-T32-HL-07275. EMJ is an established investigator of the American Heart Association.

69.12 LEVELS OF PLASMA NOREPINEPHRINE AND EPINEPHRINE FOLLOWING STANDARD HYPOTHALAMIC STIMULATION IN THE AWAKE CAT. S.L. Stoddard-Apter, A. Siegel, and B.E. Levin. Dept. of Neurosciences, N.J. Medical School, Newark, N.J. 07103, and Dept. of Neurology, V.A. Medical Center, East Orange, N.J. 07019.

This study was designed to map areas in the hypothalamus which were capable of activating the peripheral adrenergic fiber (plasma norepinephrine) and adrenal medullary (plasma epinephrine) components of the sympathetic nervous system. Hypothalamic sites were stimulated in 13 adult, ovariectomized, female cats, while the unanesthetized animal was restrained in a headholder; the standard stimulus was a 5-sec train of biphasic, square-wave pulses (0.4 mA; 60 Hz). Blood samples were withdrawn through an indwelling venous cannula prior to stimulation, and at 0.25, 0.5, 1, 2, 3, 4, and 5 min following stimulus onset. Plasma levels of norepinephrine (NE) and epinephrine (Epi) were determined by radioenzymatic assay. Cardiovascular (CV) parameters of heart rate (HR) and mean arterial blood pressure (MAP) were monitored continuously through an indwelling arterial cannula. The pooled data from 120 diencephalic sites were mapped from AP: 14.5-7.5 and L: 0.0-4.0. Since no correlations were found between baseline levels of plasma catecholamines (CAs) and the absolute levels reached following hypothalamic stimulation, sympathoadrenal (SA) responses were classified on the basis of the absolute level of NE or Epi within the first 75 sec after stimulation. Maximal responses were defined as levels of NE > 7.0 ng/ml and Epi > 10.0 ng/ml. The results of this study were as follows: (1) Sites which maximally activated the SA system were located throughout the rostro-caudal extent of the hypothalamus, with the most effective areas in the dorsomedial preoptic area and the medial tuberal hypothalamus. (2) Several sites were found which differentially increased one component of the SA system (NE or Epi). (3) Significant increases in plasma CAs were elicited from hypothalamic sites, primarily in the preoptic area, without coincident increases in HR and MAP. (4) Conversely, stimulation of numerous lateral hypothalamic sites elicited maximal CV activation (increases in MAP > 50 mm Hg and HR > 65 beats/min) without concomitant increases in plasma CAs. These results suggest that the hypothalamic systems which control or modulate the sympathetic nervous system exhibit a degree of divergence in the control of the CV, sympathetic nervous, and adrenal medullary components of the peripheral nervous system.

(Supported by NINCDS grant NS-07941-12 and the V.A. Medical Research Service.)

70.1 TANYCYTES IN ESTROGEN-TREATED LONG-TERM OVARIECTOMIZED EWES DISPLAY ULTRASTRUCTURAL EVIDENCE SUGGESTING HEIGHTENED CELLULAR ACTIVITY. Penelope W. Coates and Steven L. Davis*. Dept. Anatomy, Texas Tech Univ. Health Sciences Center, Lubbock, TX 79430 and Dept. Animal Science, Univ. Idaho, Moscow, ID 83843.

Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) was used to analyze fine structure changes in tanycytes lining the floor of the third ventricle of 17β-Estradiol ($E_2β$)-treated long-term ovariectomized (OVX) female sheep (ewes) compared to tanycytes from OVX ewes alone. Eight mature ewes were OVX, maintained for 8½ months, at which time four ewes received daily injections of 10 µg $E_2β$/kg over a two week period while the remaining control ewes (OVX) received daily injections of vegetable oil. At the end of this time, blood was drawn from each animal for radioimmunoassay (RIA) of luteinizing hormone (LH), and tissues were prepared for SEM and TEM by procedures previously employed (Coates and Davis, Biol. Reprod. 17: 567-573, '77). LH concentration in the OVX group was 45.1 ± 28.7 ng/ml, compared to 2.2 ± 1.3 ng/ml for the $E_2β$-OVX group. SEM revealed that most tanycytes from OVX ewes displayed a characteristic lack of surface features, especially microvilli compared to the $E_2β$ - OVX group. Those structures that were present appeared prominent by virtue of the absence of surrounding features. This contrasted with the appearance of tanycytes from the $E_2β$-OVX ewes where long, slender branching microvilli were consistently seen, giving an overall fuzzy appearance to the floor of the third ventricle. Miniblebs were also evident. TEM of the OVX group showed that tanycytes presented a more heterogeneous appearance than suggested by SEM alone, possibly due to limited sampling. Tanycytes which lacked microvilli did not exhibit the rich development of internal organelles characteristic for tanycytes with microvilli from the $E_2β$-OVX group: i.e., numerous mitochondria, Golgi complexes and ribosomes, profiles of r.e.r. filled with an electron dense substance, microfilaments and microtubules, and prominent nucleoli. RIA showed that LH in OVX ewes was 20 fold greater than LH in the $E_2β$-OVX group, indicating the latter was strongly under the negative feedback influence of $E_2β$. These data are highly reminiscent of the appearance of tanycytes in wethers (castrate rams) and testosterone propionate treated wethers reported earlier (Coates & Davis, SEM/1979/III:497-504). Taken as a whole, the ultrastructural evidence suggests a positive correlation between tanycytes displaying morphological characteristics suggesting increased synthetic, secretory and/or absorptive activity and the presence of gonadal steroid hormones.

70.2 IN SITU NUCLEAR RETENTION OF ^{3}H-ESTROGEN BY NEURONS IN HYPOTHALAMUS AND AMYGDALA: TEMPORAL ASPECTS. Donald A. Keefer, Department of Anatomy, University of Virginia Medical School, Charlottesville, Va. 22908.

Certain neurons in the phylogenetically old regions of the brain contain cytoplasmic estrogen receptors. Upon entering these neurons estrogen binds to the receptor and translocates to the nucleus where the estrogen-receptor complex becomes associated with chromatin. In this study the quantitative dry autoradiographic-immunocytochemical method was used to analyze and compare the temporal parameters of nuclear retention of radioactivity in several different neural regions after ^{3}H-estradiol administration. Sixteen adult female rats, ovariectomized for four days were given i.v. injections of 5.4 µg ^{3}H-estradiol/kg. body weight. The brain and other tissues were removed 15m, 1h, 3h or 7h after injection and were frozen in toto in liquid freon at -150° C. Six micron-thick sections were cut in a cryostat at -30° C and thaw mounted onto desiccated emulsion coated slides (Kodak NTB-2). After 40 days exposure at -20°C the autoradiograms were photographically processed (Keefer, D.A., J. Histochem. Cytochem. 29: 167, 1981). Silver grains were counted over nuclei of neurons in the medial preoptic (MPO) arcuate (ARC), ventrolateral ventromedial (VLVM) and medial amygdaloid (MA) nuclei. Classification of neurons as "labeled" and "unlabeled" was determined by the Poisson distribution (Arnold, A.P., J. Histochem. Cytochem. 29: 207, 1981). Silver grain counts were maximal in neurons of all four regions at 15m after injection. Counts in the ARC and VLVM were very similar at all time intervals, decreasing almost linearly from 15m to 7h. Uptake by POA neurons remained constant from 15m to 1h then decreased from 1h to 7h. MA neuron uptake dropped rapidly between 15m and 1h, and slowly between 1h and 7h. The labeling indices of POA and VLVM neurons remained at .80 to .90 over all time intervals. Indices for MA and ARC neurons dropped from .75 to .85 at the early times to .50 at 7h. These data indicate that the temporal aspects of nuclear retention of radioactivity after ^{3}H-estradiol injection may vary for target neurons in different regions of the brain.

Supported by NIH grants HD12173 and RCDA HD00243.

70.3 MODIFICATIONS IN THE OLFACTORY BULD ANTIDROMIC FIELD POTENTIALS BY 17 β- OESTRADIOL. M. de la Rosa-Viejo*, H.U. Aguilar-Baturoni, and R.Guevara-Aguilar. Depto. de Fisiología, Div. de Investigación, Fac. de Medicina, Univ. Nal. Autónoma de México, México 20, D.F.

In previous papers we reported modifications in the electroencephalographyc activity of the olfactory structures by stimulation of the posterior hypothalamus after subcutaneus administration of 17 β- oestradiol in castrated famale cats. Furtheremore the components of the olfactory pathway potentials evoked by posterior hypothalamus stimulation increase following topical application of 200 µg of 17 β-oestradiol. The purpose, of this study was to elucidate if there results could be explained by changes in the exitability of the olfactory bulb. We recorded in rats anaesthetized with chloral hydrate (450mg/Kg) the antidromic field potentials in the olfactory bulb produced by stimulation of the lateral olfactory tract. The rats had been oophorectomized two weeks before. The I.V. administration of 50 µg of 17 β- oestradiol produced an increase of both components of the antidromic potentials. The fast components (originated in the Mitral cells) increase in a 158%, while the slow components (fromthe granulose cells) in a 495% with respect to the control. This results suggest that the sexual hormones exert modulatory influences upon the exitability of the olfactory bulb.

70.4 MEDIAL PREOPTIC-SEPTAL AREA (mPO-S) AND MIDBRAIN CENTRAL GRAY (MCG) UNIT RESPONSES TO ESTROGEN IONTOPHORESIS AND GENITAL STIMULATION. J.T. Haskins and R.L. Moss. Dept. of Physiology, University of Texas Health Science Center, Dallas, TX 75235.

The mPO-S and MCG concentrate radiolabeled estrogen and are important in regulating the release of luteinizing hormone (LH). The present study investigates neuronal responses in the mPO-S and MCG to the iontophoresis of 17B-estradiol (17B-E_2S) and to vaginocervical stimulation. Female Sprague-Dawley rats (200-400g) in either late diestrus (LD) or late proestrus (LP) were anesthetized with urethane (1.2g/kg) and prepared for extracellular, single unit recording. Genital stimulation was accomplished by means of light-pressure applied to the uterine cervix with a cotton swab soaked in mineral oil.

The spontaneous activity of 87 neurons in the mPO-S and 79 neurons in the MCG was recorded. The activity of mPO-S neurons was significantly lower ($p<.05$) on LP (3.08±0.41 spikes/second; n=51) than on LD (4.27±0.42; n=36), while spontaneous activity of MCG neurons was significantly lower ($p<.05$) on LD (2.26±0.27; n=29) than on LP (4.14±0.57; n=50). The iontophoretic deposition of 17B-E_2S onto mPO-S and MCG neurons evoked both excitatory and inhibitory responses. However, most neurons in both areas failed to respond to the iontophoresed 17B-E_2S. No significant differences in the numbers or types (excitations or inhibitions) of estrogen responsive neurons were found in either the mPO-S or MCG.

Genital stimulation also had marked excitatory and inhibitory effects on the unit activity of neurons in both the mPO-S and MCG. These same neurons did not respond to toe or tail pinch or to stroking of the back fur. No significant differences were found in the number or types of neuronal responses to genital probing in either the mPO-S or MCG. However, unlike iontophoresed 17B-E_2S, some responses were slow in onset and outlasted the probing stimulus for seconds or, in some cases, minutes. Latencies and durations of inhibitory responses recorded from mPO-S neurons in LD were significantly longer than those recorded in LP ($p<.025$). We believe prior exposure to high endogenous estrogen levels during early proestrus may account for the differences in spontaneous neuronal activity in both areas, i.e. faster activity in the mPO-S during LD and slower activity in the MCG during LD. Similarly, endogenous estrogens may alter the integrative properties of mPO-S or MCG neurons prior to and during the period of sexual heat such that mating, if necessary, could insure the release of sufficient LH to cause ovulation. In view of these results it seems reasonable that the mPO-S and MCG are central nervous system centers important in integrating sexual stimuli and that this integration is modulated throughout the estrous cycle by fluctuating estrogen levels.

70.5 THE VENTROMEDIAL MIDBRAIN AND LORDOSIS BEHAVIOR IN THE GOLDEN HAMSTER. J. D. Rose and M. D. Havens*. Dept. of Psychology, Univ. of Wyoming, Laramie, WY 82071.

In sexually-receptive female golden hamsters, lordosis can be elicited and maintained by continuous application of lumbosacral tactile stimuli. Previous single-unit recording work in hamsters (Rose, J. D., Exp. Neurol., 60: 499, 1978) identified neurons responding to lordosis-triggering forms of stimuli in various midbrain locations, especially deep tectum. The present investigation reexamined the midbrain to locate neurons with the strongest and most sustained responses to lumbosacral tactile stimuli. Single neurons were recorded from the midbrain in urethane-anesthetized, ovariectomized hamsters under four different hormonal conditions: pretreatment with estradiol benzoate (EB) and progesterone (P), at 44 and 4 hrs before recording, respectively; EB alone; P alone and oil vehicle alone. Neurons were sought which displayed changes in firing of more than two times their spontaneous rates throughout a 20 sec application of lumbosacral tactile stimulation. Such cells were found most often in the deep superior colliculus, the central gray, in scattered locations in the reticular formation and in a ventromedial region including the interpeduncular nucleus, median raphé nucleus and adjacent tegmentum. The ventromedial cluster of strongly-responsive cells was of particular interest since it lay in a region having a high progesterone binding capacity (Wade, G. N., et al., Brain Res., 61:357, 1973). To evaluate the potential significance of the ventromedial region in lordosis, ovariectomized hamsters were prepared with electrolytic lesions placed there. Each hamster received a series of three pre-lesion and three post-lesion behavioral tests, following appropriate injection of EB and P, to assess lordosis in response to a male and to manual lumbosacral stimuli. The lesions were highly effective, producing either a complete abolition of lordosis or a reduction in the lordosis-eliciting capacity of lumbosacral tactile stimuli. In the latter case, lordosis was elicited by males but not by manual stimulation alone. These lesion effects may have been due to destruction of neurons responsive to lumbosacral tactile stimuli and/or to damage of the midbrain neuronal substrate for P uptake. In addition, some of the more dorsal lesions may have interrupted descending tectal efferents, thereby impairing the contribution of the superior colliculus to the control of lordosis (Muntz, J. A., et al., Brain Res. Bull., 5: 359, 1980). It is unlikely that the most ventral of the lesions, such as those confined to the interpeduncular nucleus, produced their effects by interrupting tectal efferents.

70.6 CHRONIC HYPERPROLACTINEMIA DOES NOT INCREASE STRIATAL DOPAMINE RECEPTOR BINDING. P. C. Doherty*, S. Lane*, K. Pfeil*, W. W. Morgan, A. Bartke*, and M. S. Smith* (SPON: L. F. Mercer). Depts. of Anat. and Ob.-Gyn., Univ. of Tex. Hlth. Sci. Ctr., San Antonio, TX 78284, and Dept. of Physiol., Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

Hyperprolactinemia (hyperPRL) induced by grafting 4 ectopic pituitary grafts under the kidney capsules suppresses copulatory behavior in male rats. Recent reports have indicated that short-term hyperPRL induced by 2 pituitary grafts or prolactin administration can induce increases in copulatory behavior (Drago et al., Physiol. Behav. 26:277, 1981) and increases in stereotyped behavior and in the number of dopamine (DA) receptors in the striatum (Hruska et al., Abstr., Soc. Neurosci. 6:441, 1980). Thus experiments were performed to investigate the short-term effects of 4 grafts on copulatory behavior and the chronic effects of 4 grafts on DA receptor binding in the striatum. Adult sexually-experienced male rats were observed for copulatory behavior at 4 day intervals after induction of hyperPRL. No changes were observed until day 8, when the post-ejaculatory interval (PEI) was found to be significantly increased in the grafted animals (5.34±0.35 vs 4.21±0.20 min.; $\bar{x}\pm SE$; $p<0.02$). By day 16, when the grafted animals showed the complete pattern of behavioral suppression, the PEI was no longer increased, in agreement with previous findings from this laboratory. Similar results were obtained in a second experiment with two additional groups of animals. To determine if chronic hyperPRL results in changes in DA receptor binding in the corpus striatum, the binding of ^{3}H-spiroperidol to homogenates of the caudate-putamen (Fields et al., Brain Res. 136:578, 1977) was assessed in animals which had been grafted for 11 months. No differences in binding were observed between the grafted and sham-operated groups either in K_d for the receptor site (23.4±1.9 vs 25.4±4.0 pM) or in the maximum number of binding sites (39.2±2.2 vs 39.8±3.4 pmoles/g-tissue). At autopsy, the grafted animals had significantly larger adrenal glands and accessory reproductive organs, indicative of their hyperprolactinemic state. Previous reports of increases in behavior and DA receptor binding were not confirmed under the conditions of these experiments. These results do not exclude the possibility of early increases in behavior or receptor sensitivity, but rather indicate that at a time when the suppression of copulatory behavior occurs in hyperprolactinemic animals, striatal dopamine receptor binding is not increased or has returned to pre-treatment levels. The early increase and then return to normal in the PEI may be indicative of such a change. Supported by NIH grants HD-12671 and NS-14855.

70.7 PROLACTIN INCREASES THE DENSITY OF STRIATAL DOPAMINE RECEPTORS IN NORMAL AND HYPOPHYSECTOMIZED MALE RATS. K.T. Pitman*, R.E. Hruska, L.M. Ludmer*, and E.K. Silbergeld (SPON: P.D. Thut). Neurotoxicology Section, NINCDS, NIH, Bethesda, MD 20205.

We previously reported (Neuropharm. 19: 923, 1980) that estrogen administered to adult male rats significantly increases the density of the striatal dopamine (DA) receptors. In hypophysectomized (Hypox) rats this effect is blocked. We now report that administration of ovine prolactin (oPRL) to normal male or Hypox male rats increases the density of the striatal DA receptors. oPRL was administered to male rats by two methods. First, oPRL was dissolved in sesame oil and injected s.c. daily at doses from 8 to 1000 µg/d for 4 to 6 days. Second, oPRL was dissolved in saline and placed in Alzet osmotic mini-pumps. The concentration was adjusted so that either 120 or 6000 ng/h of oPRL was continuously injected s.c. for 7 days. Hypox rats were obtained from Taconic Farms and maintained on a drinking solution of dextrose and balanced salts. The rats were killed by decapitation. Hypox rats were inspected for complete absence of the pituitary, and in appropriate rats the pumps were removed and inspected. Striatal DA receptors were measured in our standard ^{3}H-spiroperidol binding assay. The daily administration of oPRL by s.c. injection to normal male rats did not alter the density of the striatal DA receptors at doses of 8 to 100 µg/d. While a dose of 250 µg/d had a tendency to increase the density, a significant increase was obtained only with the 1000 µg/d dose. In Hypox rats administration of 1000 µg/d of oPRL did not alter the density of the striatal DA receptors. The lack of effect in Hypox rats may result from the need for larger amounts of exogenous oPRL because the endogenous supply is gone. The continuous infusion of oPRL via mini-pumps also increased the density of the striatal DA receptors in normal male rats, but at a much lower dose of oPRL (120 ng/h for 7 days). This dose was not effective in Hypox male rats. Increasing the dose 50-fold to 6000 ng/h did increase the striatal DA receptor density in Hypox rats. Evidently, continuous s.c. administration of oPRL allows a lower dose to be used than is necessary by single large daily s.c. injections. In addition rat PRL (from the Rat Pituitary Hormone Distribution Program, NIADDKD) was active in normal male rats to increase the density of the striatal DA receptors. The affinity of the receptors was not changed in any experiment by prolactin administration. These results suggest that PRL alone can increase the density of the striatal DA receptors and that PRL could be the common mediator of the increase in striatal DA receptor density produced by estrogen, haloperidol, and other chemicals or drugs.

70.8 ESTROGEN POTENTIATES HALOPERIDOL-INDUCED CATALEPSY/AKINESIA IN MALE RATS. M. De Ryck*, R.E. Hruska and E.K. Silbergeld. (SPON: W. Himwich) Neurotoxicology Section, NIH, NINCDS, Bethesda, MD.

Estrogen may modulate behaviors controlled by the basal ganglia. In ovariectomized rats estrogen modifies behaviors induced by drugs acting, at least in part, on the nigrostriatal dopamine (DA) system. In male rats, a single injection of estrogen produces 6 days later a 20 percent increase in the number of striatal DA receptors and enhances DA agonist-induced stereotyped behaviors (Hruska and Silbergeld, Eur. J. Pharm., 1980, 61:397). Similar in vitro and in vivo changes are typical of DA receptor supersensitivity following chronic DA receptor blockade by haloperidol (HAL). Chronic HAL also causes tolerance to the catalepsy/akinesia induced by its acute administration. In contrast, as we show below, estrogen, rather than attenuate, actually potentiates HAL-induced catalepsy/akinesia.

Adult male rats were injected s.c. with 125 µg 17 Beta-estradiol valerate (EDV) in sesame oil (n = 40) or, as controls (CON), with sesame oil (n = 38). Six or 7 days later, catalepsy was rated by means of multiple measures (see De Ryck et al., Brain Res., 1980, 201:143): (1) Akinesia: crouched posture; freezing/shivering reaction; and latency till movement; (2) Bracing reactions; (3) Ptosis; (4) Blepharospasm; (5) Leaning; (6) Clinging; (7) Tonic grasp; (8) Righting; and (9) Tremor. These measures were separately analyzed and converted into a catalepsy index (CI; range = 0-100). EDV and CON groups were compared once before (saline) and repeatedly up to 7 hrs after a suprathreshold dose of .25 mg/kg HAL. Other EDV and CON groups were similarly tested up to 12 hrs after a threshold dose of .10 mg/kg HAL. Rats were also used as their own controls by running EDV and CON animals once before and for 5 hrs after saline, followed by 3 hrs after the threshold dose of .10 mg/kg HAL. Without HAL, repeated tests induced a neuroleptic-like catalepsy in 30 percent of drug-free controls. Chronic EDV reduced such "learned" catalepsy (acute EDV had no effects). In contrast, after HAL treatment, EDV rats became significantly more cataleptic than CON rats. After .25 mg/kg HAL, the CI of EDV rats was enhanced by 25 percent over control. Between- and within-animal comparisons showed that EDV lowered the catalepsy threshold after .10 mg/kg HAL. These results may not fit a simple model of DA receptor function after chronic estrogen. It is unclear whether decreased drug metabolism is responsible for these results. Alternatively, estrogen, known to enhance somatosensory inputs, could increase the gain of reflexive mechanisms underlying DA-mediated catalepsy and stereotypy.

70.9 COMPARISON OF THE BIOCHEMICAL AND BEHAVIORAL EFFECTS OF ESTROGEN IN MALE AND FEMALE RATS. R.E. Hruska, K.T. Pitman*, L.M. Ludmer*, M. De Ryck*, and E.K. Silbergeld. Neurotoxicology Section, NINCDS, NIH, Bethesda, MD 20205.

In striatal tissue from male or female rats, the addition of estrogen, in vitro, does not alter the binding of ^{3}H-spiroperidol to DA receptors. Similarly, in striatal tissue from male or female rats the inhibition of binding by d-butaclamol (an antagonist) or DA (an agonist) is the same and not altered by the addition of estrogen.

In vivo, estrogen administration (125 µg/rat of 17ß-estradiol valerate in sesame oil, injected 6 days before s.c.) increases the density of the striatal DA rceptors in adult male rats. This treatment does not affect the density of striatal DA receptors in adult female rats. Ovariectomy (ovex) also does not alter the density of the striatal DA receptors. However, estrogen administration to ovex rats significantly increases the density of striatal DA receptors as well as the dissociation constant (Kd). Therefore, rats without estrogen present (i.e. male or ovex rats) respond similarly to the administration of estrogen and have an increase in the density of the striatal DA receptors.

Behavioral stereotypy results are measured in grouped rats and are more complex. Normal female rats display more stereotyped behavior after apomorphine administration than normal male rats. The amount of stereotyped behavior in the female rat does not vary with the stage of the estrous cycle. Male rats administered estrogen show increased amounts of stereotyped behavior after apomorphine treatment (Eur. J. Pharm. 61: 397, 1980). If female rats have more stereotyped behavior than male rats, and male rats administered estrogen have more stereotyped behavior than normal male rats, it may be expected that ovex rats would have less stereotyped behavior than female rats. Paradoxically, ovex rats have more stereotyped behavior than normal female rats, and this is decreased to levels of normal female rats by administration of estrogen. Stereotypy regulation is probably complex in both male and female rats. In male rats there is a correlation between increases in stereotyped behavior and increases in density of striatal DA receptors. In female rats there is a dissociation. Possibly estrogen acts at other sites which regulate stereotyped behavior, such as at acetylcholine or GABA neurons. It might be expected that male and female rats exhibit different responses after hormone treatment, especially since the sexual differentiation and hormonal environment of the brains are dissimilar. Indeed, it may be serendipitous to find a correlation in male rats, while in female rats other effects are more important.

70.10 SEX DIFFERENCES IN RESPONSE TO CONFLICT: BEHAVIORAL AND PITUITARY-ADRENAL EFFECTS. J. Weinberg, M.R. Gunnar, L.P. Brett, C.A. Gonzales and S. Levine. Dep't. of Psychiatry and Behavioral Sciences, Stanford Univ. Sch. of Med., Stanford, CA 94305

Behavioral and pituitary-adrenal responses of male and female rats were compared in an approach-avoidance conflict situation. Animals were exposed to a novel (milk) solution, and a conditioned taste aversion was produced by pairing drinking with LiCl injection. Reexposure to milk then occurred following 72 hr of ad lib food and water or 72 hr of food and water deprivation. Thus avoidance tendencies were produced by aversive conditioning and approach tendencies were produced by deprivation prior to reexposure. No consistent sex differences were observed during the pretoxicosis phase of testing. At the end of the deprivation period females exhibited greater plasma corticoid elevations than males. On the first reexposure day males maintained elevated corticosterone levels while females showed a significant suppression of corticoids below presession levels. However, males and females showed similar suppressions in drinking on this day. If ad lib access to food and water was then reestablished and daily reexposures to milk were continued, sex differences in behavior appeared. Males showed a greater initial suppression of intake than females and females recovered to pretoxicosis intake levels faster than males. Gonadectomy eliminated these sex differences. Presession corticosterone levels were lower in ovariectomized females and higher in castrated males than they were in intact animals. When reexposed to milk castrated males exhibited a response pattern similar to that of the females: i.e. a corticoid suppression on the first reexposure day and an accelerated recovery to pretoxicosis intake levels. These data indicate that intact males and females respond differently to conflict. That females showed a greater corticoid response to deprivation suggests that the deprivation regimen might be more aversive for females than males. An increased response to deprivation should increase motivation to approach the milk, and if approach tendencies become stronger than avoidance tendencies, conflict and hence arousal, should decrease. The finding that females exhibited a corticoid suppression upon reexposure, as well as less suppressed intake and faster recovery to pretoxicosis drinking levels suggests that females experienced less conflict than males. Furthermore, in this situation testosterone has primarily an activational effect. The sexual dimorphism in both behavioral and pituitary-adrenal responsiveness appeared to depend upon the presence of testosterone in the adult male.

70.11 EFFECTS OF COPULATION ON FOOD INTAKE IN MALE RATS. A. A. Nunez, L. I. Siegel* and G. N. Wade. Department of Psychology, Michigan State University, East Lansing, Michigan 48824 and Univ. Massachusetts, Amherst, MA 01003.

In adult male rats, repeated mating tests or cohabitation with intact females reduces body weight gain and carcass fat (Neuroscience Abstracts, 4: 182, 1978). Two lines of evidence suggest that copulation-induced changes in body weight and adiposity may be mediated by testicular testosterone. First, it has been reported that male rats increase their secretion of testosterone when exposed to receptive females. Second, prolonged treatment of castrated male rats with high doses of testosterone propionate (TP) reduces weight gain and body fat (Neuroscience Abstracts, 6: 45, 1980). This decrement seems to be mediated by a reduction in adipose tissue lipoprotein lipase (LPL) activity. In addition to changes in body weight and adiposity, high doses of TP reduce caloric intake. Dietary self-selection experiments have shown that this reduction in total calories is the result of a specific reduction in carbohydrate intake.

The present experiment aimed to further investigate the effects of copulation on behavioral and physiological endpoints that are sensitive to testosterone. Sexually active and sexually deprived male rats were given access to a pair of isocaloric diets that were equal in fat, but that contained differing amounts of carbohydrate and protein. Body weight and food intake were measured twice weekly for six weeks. Copulation (2 mating tests/ week) significantly reduced body weight. However, sexual activity failed to reduce caloric intake and did not affect the intake of protein or carbohydrate. Using the same self-selection paradigm, daily injections of 2 mg of TP produced a selective increase in protein intake, and reduced carbohydrate and caloric intake. Adipose tissue LPL activity is reduced by doses of TP that reduce food intake, body weight and carcass fat content in castrated rats. We found no evidence for changes in LPL activity in sexually active males that were gaining significantly less weight than controls.

In summary, although copulation and TP treatment produce similar effects on body weight and adiposity, these effects do not seem to share a common mechanism. (Supported by Grants NS 10873, NS 05854-01 and NS 00090 from NINCDS, by Grant AM 20785 from NIAMDD and by Training Grant MH 11823 from NIMH).

70.12 THE EFFECTS OF o,p'-DDT ON NEUROENDOCRINE PARAMETERS IN FEMALE RATS. Anne M. Etgen. Dept. Biology, Livingston College, Rutgers University, New Brunswick, NJ 08903.

Previous research has shown than 1-(o-chlorophenyl)-1-(p-chlorophenyl)-2,2,2-trichloroethane (o,p'-DDT), a contaminant in technical DDT, possesses potent estrogenic properties. It stimulates uterine growth, induces the synthesis of specific estrogen-inducible uterine protein, and has a low affinity for uterine estrogen receptors. Since chlorinated insecticides have been reported to produce reproductive disorders in both humans and animals, it seemed possible that o,p'-DDT might also have estrogenic activity at the level of the central nervous system and that disruption of neuroendocrine interactions might contribute to the observed reproductive dysfunction. As a preliminary test of this possibility, the effects of o,p'-DDT on sexual behavior, gonadotropin release, and body weight, three estrogen sensitive neuroendocrine responses, were tested.

For sexual behavior tests, ovariectomized adult female Sprague Dawley rats received sc injections of 50, 200, 350 or 500 mg/kg of o,p'-DDT followed 48 hr later by 500 ug of progesterone (P). Tests for lordosis behavior began 4 hr after P treatment. On successive weeks, animals received a given dose of DDT either alone or in combination with an optimal (2 ug) or suboptimal (1 ug) dose of estradiol benzoate (EB), or they received 1 or 2 ug of EB alone. The order of treatments was randomized, and no consistent treatment order effects were noted. DDT failed to facilitate lordosis when given alone or combined with 1 ug of EB, regardless of the dose. When given with 2 ug of EB, no dose of DDT significantly antagonized EB-induced sexual behavior.

Another group of female rats with equivalent body weights was unilaterally ovariectomized (left ovary) and given daily sc injections of vehicle, 0.1 ug of estradiol (E_2), 200 mg/kg of DDT, or 0.1 ug of E_2 plus 200 mg/kg of DDT. After 15 days, the body weights of the animals were recorded and the remaining (right) ovary was removed. The weight of the right ovary was compared to that of the left to determine if any of the treatments had attenuated gonadotropin secretion. Animals receiving DDT alone or in combination with E_2 had significantly lighter right ovaries than did animals receiving vehicle or E_2 alone; the latter two groups did not differ. In addition, both groups which received DDT had significantly lower body weights than the control or E_2-treated animals. DDT thus appears to mimic estrogen depression of body weight and gonadotropin release but to neither facilitate nor inhibit estrogen-induced lordosis behavior. The interaction of DDT with pituitary and hypothalamic estrogen receptors will be compared with its effects on these neuroendocrine responses.

70.13 CHANGES IN BRAIN IRON DURING THE ESTROUS CYCLE. Joanna M. Hill* (SPON: P.D. MacLean). Laboratory of Brain Evolution and Behavior, National Institute of Mental Health, Bethesda, MD 20205.

Iron is unevenly distributed in the brain with the highest levels occurring in the ventral pallidum (VP), globus pallidus (GP), and substantia nigra (SN). With the use of the sensitive diaminobenzidine intensification of the Perl's histochemical method for iron and measurement of tissue ferritin iron concentration by spectrophotometry, a sex difference in brain iron, with females having the greater iron reserves, recently has been demonstrated (Hill, Neurosci. Abstr. 6, 131, 1980). A sex difference brought about by sex steroids occurs in many aspects of iron metabolism. This study was undertaken to determine if brain iron changes with the naturally occurring fluctuations of ovarian hormones during the estrous cycle. Using the sensitive methods outlined above, this study demonstrates that: 1) iron is localized histochemically not only in the high-iron areas of the VP, GP, and SN but also in the organum vasculosum of the lamina terminalis (OVLT), the tanycytes, and in granules in the arcuate nucleus and median eminence (sites known to contain luteinizing hormone releasing hormone, LHRH); and 2) total non-heme iron concentration in the VP, GP, and SN, measured by spectrophotometry, fluctuates during the estrous cycle with levels at proestrus significantly higher than at other stages of the cycle.

	μg Fe/g wet weight ± S.E.M.
Proestrus	43.48±5.55*
Estrus	25.44±5.11
Diestrus	23.02±4.73
Metestrus	15.40±2.49

*F=6.24, df=3,27 p<0.005

The increase of endogenous iron in the VP and GP during proestrus could be: 1)directly influencing the activity of the adjacent medial preoptic area and thus causing ovulation (iron salts or or electrochemical stimulation with steel electrodes of the medial preoptic area causes luteinizing hormone (LH) release and ovulation), 2) reflecting the endogenous iron changes occurring in the high-iron areas of the hypothalamus, thus influencing LHRH directly through the association of iron with LHRH in the OVLT, tanycytes, the arcuate, and median eminence or 3) indirectly affecting gonadotropin release through the effects of iron on monoamines (iron is required for the synthetic and degradative enzymes as well as, perhaps, the storage and receptor mechanism of brain monoamines which, in turn, are involved in gonadotropin release and sexual behavior).

70.14 EXERCISE REINSTATES ESTROUS CYCLES IN HAMSTERS MAINTAINED IN SHORT PHOTOPERIOD. K.T. Borer, C.S. Campbell, L. Gordon*, K. Jorgenson* & J. Tabor*. Dept. Phys. Educ., Univ. Mich., Ann Arbor, MI 48109 & Dept. Biol. Sci., Northwestern Univ., Evanston, IL 60201.

Exposure to short photoperiod renders female hamsters anestrous (Seegal, R.F. & Goldman, B.D., Biol. Reprod. 12:223-231, 1975) and reduces their volume of daily running activity (Widmaier, E.P. & Campbell, C.S., Physiol. Behav. 24:923-930, 1980), while exposure to running reinstates rapid growth in adult hamsters (Borer,K.T. & Kelch,R.P., Amer. J. Physiol. 234:E611-E616, 1978). To determine whether the photoperiod would affect exercise-induced growth and whether exercise would affect photoperiodically-induced anestrus, we subjected four groups of 7 hamsters to: short day and exercise (10L:14D-EX); long day and exercise (16L:8D-EX); short day and sedentary (10L:14D-SED); long day and sedentary existence (16L:8D-SED). Five consecutive estrus cycles were monitored before exposure to different photoperiods, and seven cycles were monitored after ten weeks of exposure to a given photoperiod. After ten weeks in a given photoperiod, EX groups were given a 4-week exposure to running activity in rotating wheels. Hamster length was determined at the start and at the end of the experiment. In addition, on the last day of the experiment, blood was collected by decaptiation between the second and third hour after the onset of light. Serum was used for measurements of growth hormone (GH) and prolactin (PRL) with homologous radioimmunoassays. Percentage of body fat was determined by petroleum ether extraction of freeze-dried homogenates of hamster carcasses.

Our findings are: (1) Photoperiod had no effect on exercise-induced growth or serum GH concentration, but short photoperiod abolished or reduced (to 29 and 71%) estrous cycles and was associated with significantly lower serum PRL concentration ($p < 0.05$); (2) Exercise resulted in significant elongation of the body (41% $p < 0.001$), in complete or partial (14-86%) reinstatement of estrus cycles in short-day hamsters ($p < 0.001$), and in significantly higher levels in serum GH concentration ($p < 0.05$); (3) Exercise was associated with significant reduction in the percentage of body fat in animals of both photoperiods ($p < 0.005$).

We conclude that the neuroendocrine changes associated with the exposure to voluntary running activity interfere with the neuroendocrine consequences of exposure to the short photoperiod. Photoperiodically-induced neuroendocrine changes, however, have no impact on the exercise-induced facilitation of growth.

70.15 DIFFERENCES BETWEEN ANDROGEN-RESISTANT RAT AND MOUSE MUTANTS. K. L. Olsen* and T. O. Fox. Long Island Research Institute, State Univ. of New York, Stony Brook, NY 11794 and Dept. Neuropathology, Harvard Med. Sch. and Dept. Neuroscience, Mental Retardation Research Center, Children's Hosp. Med. Cntr., Boston, MA 02115.

To assess the possible involvement of androgen receptors in behavior, androgen-resistant mutants that are deficient in androgen receptors have been analyzed. We have compared some aspects of the phenotypes of rats (tfm) and mice (Tfm) which have the syndrome of testicular feminization. Both rat and mouse mutants exhibit profound deficiency in responsiveness to androgen. Correlated with this deficit, each exhibits only 10 - 20% of the level of the putative androgen receptors of the respective wild-types. We report that these two mutants are distinguishable from their wild-type controls and from one another with regard to spontaneous male sexual behavior and to DNA-cellulose elution patterns of putative androgen receptors from brain.

Both wild-type rats and mice spontaneously display the full copulatory sequence of behaviors. The spontaneous behavior of the mutants is reduced relative to that of the wild-type males. Androgen-resistant rats mounted receptive females and 20% even exhibited the ejaculatory pattern. In contrast, none of the mutant mice displayed any spontaneous male sexual behavior.

The residual androgen receptors from both the rat and mouse mutants were chromatographed on DNA-cellulose to compare them qualitatively and thus obtain a biochemical characterization of the mutational effects. Receptors from mutant rat brain eluted with the same pattern, but at a uniformly lower level, compared with wild-type rats. In contrast, receptors from mutant mice eluted with an altered pattern as compared with wild-type mice. This revealed a virtual lack of a detectable major receptor form from the mouse, with the residual receptor being either a minor or mutant form. Thus, the receptor deficiencies in the two mutants appear to be non-identical. The levels and elution patterns of estrogen receptors were the same in mutant and wild-type mice and rats.

These experiments indicate that these two mutations differentially affect behavior and androgen receptors, and this must be taken into account when using, or comparing, these mutants in genetic experiments.

70.16 ANDROGEN AND ESTROGEN RECEPTORS IN HAMSTER BRAIN. C. C. Vito, J. F. DeBold and T. O. Fox, Dept. of Neuropathology, Harvard Med. Sch., and Dept. of Neuroscience, Mental Retardation Res. Ctr., Children's Hosp. Med. Ctr., Boston, MA 02115; and Dept. of Psychology, Tufts Univ., Medford, MA 02155.

Among hamsters, mice and rats, there are both species and sex differences in the behavioral responsiveness of adults to androgens and estrogens. We are investigating the possible relevance of sex hormone receptor mechanisms to such differences.

Using ^{3}H-dihydrotestosterone (DHT), ^{3}H-estradiol and DNA-cellulose affinity chromatography, we have demonstrated that putative receptors for both androgens and estrogens are present in cytosol extracts of hypothalamus-preoptic area (HPOA) and remaining brain (whole brain minus HPOA = RB) from gonadectomized adult male and female hamsters. By all qualitative and quantitative criteria tested to date, both the androgen and estrogen receptors in cytosols of male HPOA and RB are indistinguishable from those of female HPOA and RB. Moreover, the androgen and estrogen cytosol receptors in hamster (male and female) HPOA and RB are qualitatively similar to those in both mouse and rat brain as evidenced by their ability to adhere to DNA, characteristic behaviors during elution from DNA-cellulose with a linear gradient of [NaCl], affinity for their respective hormones, specificity of hormone-binding, and tissue specificity. Cytosols of HPOA and RB contain DHT-binding activity which adheres to DNA-cellulose and elutes below 150 mM NaCl, saturates between 5 and 10 nM DHT, and binds testosterone; the concentration of putative androgen receptor in HPOA is about 5-fold greater than that in RB. Cytosols of HPOA and RB also contain estradiol-binding activity which adheres to DNA-cellulose and elutes above 150 mM NaCl, saturates between 5 and 10 nM estradiol, and binds the synthetic estrogen diethylstilbestrol; the concentration of putative estrogen receptor in HPOA is about 10-fold greater than that in RB.

Our data suggest that there is a quantitative species difference in both the androgen and estrogen receptor systems in HPOA. The ratio of androgen receptor to estrogen receptor is higher in adult hamster HPOA (male and female) than that observed in either adult mouse or adult rat HPOA; in adult male and female hamsters, this ratio is higher by virtue of the fact that androgen receptor concentrations are about 4-fold higher and estrogen receptor concentrations are about 2-fold lower than in either mouse or rat HPOA. These observations correlate with a generally lowered estrogen sensitivity of female hamsters and heightened DHT sensitivity of male hamsters relative to mice and rats.

70.17 INHIBITION OF ANDROGEN BINDING BY ATD AND FLUTAMIDE. J. F. DeBold, T. O. Fox and K. L. Olsen* Dept. Psychol., Tufts Univ., Medford, MA 02155; Dept. Neuropathol., Harvard Med. Sch. and Dept. Neurosci., Mental Retardation Res. Ctr., Boston, MA 02115; Long Island Res. Inst., S.U.N.Y., Stony Brook, NY 11794.

The extent to which androgen action in the brain is mediated by androgen receptors or by estrogen receptors after aromatization of androgen to estrogen is currently uncertain. ATD (1,4,6-androstatriene-3,17-dione), an inhibitor of aromatization of androgen to estrogen, and flutamide (4'-nitro-3'-trifluoromethylisobutyrylanilide), an antiandrogen, are often used to assess pharmacologically the mode of androgen action. Thus, if ATD is found to block androgen action in a particular system it is generally concluded that aromatization is important; however, if flutamide blocks androgen action it is thought to reflect direct action on androgen receptors. We have tested biochemically some of the assumptions behind these conclusions.

Cytosol extracts from the hypothalamus-preoptic area (HPOA) and kidney of castrated male rats were incubated (4° C) for 1 hr with 5 nM ^{3}H-DHT alone or with 100 nM or 1 uM ATD, flutamide or DHT. Bound ^{3}H-DHT was measured after filtration with Sephadex G-25. Although less effective than unlabelled DHT, ATD and flutamide both reduced the apparent amount of specifically bound ^{3}H-DHT.

	Inhibition by ATD		Inhibition by Flutamide	
	100 nM	1 uM	100 nM	1 uM
HPOA	16.3%	32.9%	17.0%	29.4%
Kidney	32.0%	59.6%	31.0%	48.3%

This effect was greater in kidney cytosols than HPOA but was concentration-dependent in both. In a preliminary study we found similar effects of ATD in mouse kidney.

Possible competition by flutamide and ATD for androgen binding was also assessed with DNA-cellulose affinity chromatography. Kidney and HPOA extracts were incubated (4° C) for 1 hr with 10 nM ^{3}H-DHT alone or with 1 uM ATD, flutamide or DHT. The labelled extracts were layered onto DNA-cellulose columns and further incubated at 22° C for 1 hr. ATD reduced androgen *binding (eluted at 100 - 150 mM NaCl) by 12% in HPOA and 34% in* kidney, while flutamide had little effect in HPOA (2%) and inhibited kidney by 12%. The difference in degree of inhibition with Sephadex vs DNA-cellulose chromatography may reflect differences in kinetic vs equilibrium conditions.

Clearly, in vitro ATD can interfere with androgen binding; in fact better than flutamide, an antiandrogen. Although conditions in vivo are different, some caution must be used in interpreting ATD effects as purely inhibition of aromatization.

71.1 SYMPATHETIC INNERVATION OF THE RABBIT APPENDIX: FURTHER EVIDENCE FOR NEURAL INPUT TO LYMPHOID TISSUE. J.M. Overhage*, S. Y. Felten *, J.F. Schmedtje*, and D.L. Felten. Department of Anatomy, Indiana University School of Medicine, 1100 W. Michigan St., Indianapolis, IN 46223

Recent morphological and functional studies (J.M. Williams et al., Brain Res. Bull., 6:83-92, 1981) have demonstrated sympathetic noradrenergic innervation of parenchymal lymphoid tissue in murine thymus and spleen, and an inhibitory control by these fibers over response to sheep red blood cell antigen. The well documented existence of lymphoid tissues in the wall of the appendix of the rabbit prompted us to search for sympathetic innervation. The vermiform appendix from 17 New Zealand white rabbits (five 21 day old, five 42 day old, seven adults) was prepared for sucrose-phosphate-glyoxylic acid (SPG) histofluorescence. In the appendix (J. Schmedtje, J. Morph., 166:179-195, 1980), domes with a central core of B-lymphocytes and a surface epithelial zone of migrating T-lymphocytes, and intradomal regions with a subepithelial layer of immunoglobulin-secreting plasma cells are found. The moats surrounding the domes separate elements of the cellular immune system on one side from the humoral immune system on the other. A dense sympathetic innervation was found in specific regions of the appendix in rabbits of all three ages. Fluorescent plexuses were found in the outer muscular layer, mainly in association with blood vessels. From the muscular layer, radially oriented clusters of fluorescent fibers coursed inward between the domes. Upon reaching the floor of the moats surrounding the inner portion of the domes, these sympathetic fibers arborized into an extensive plexus in the intradomal regions. A dense component of these intradomal plexuses traveled parallel to the furface of the epithelium in the subepithelial plasma cell zone. Viewed from the luminal surface, these fibers surrounded the domes, separated from them by the moats. Associated with the intradomal adrenergic plexuses were yellow fluorescent cells which did not demonstrate metachromatic staining. We suggest that the sympathetic innervation of the intradomal plasma cell zone and the proximity of fibers across the moats from the surface epithelium of the domes may represent further evidence for neural input to lymphoid tissue. In the rabbit, the appendix represents an important lymphoid structure. In humans, the appendix is not as highly organized or important a lymphoid structure as in the rabbit, but still may play a role in immune responsiveness. We suggest that the rabbit appendix is a well organized and readily accessible model for sympathetic-lymphoid tissue interactions in the gastrointestinal tract, and may represent another important functional link between the nervous and immune systems. Supported by an Alfred P. Sloan Fdn. Fellowship (D.L.F.)

71.2 MODULATION OF LYMPHOPROLIFERATIVE T-CELL RESPONSES BY THE CEREBRAL CORTEX. K. Bizière, P. Bardos*, D. Degenne*, G. Renoux*. C.R.C.M., rue du Pr. Blayac, 34082 Montpellier Cedex, France. Lab. d'Immunologie, Fac. Med., 37032 Tours Cedex, France.

Surgical lesions of the left cerebral cortex have been shown to impair immunological responses by depressing T-cell mediated responses and spleen NK activity (Renoux, G., Bizière, K., Renoux, M., Guillaumin, J.M. C.R. Acad. Sci., 290 D : 719 ; Bardos, P., Degenne, D., Lebranchu, Y., Bizière, K., Renoux, G. Scand. J. Immunol., 1981 in press). In the present report we describe the effets of surgical lesions of cerebral cortex on lymphoproliferative T and B-cell responses.

Similar lesions were performed on either the left or the right cerebral cortex of 6-7 week old female C_3H/He mice. Animals were anaesthetized by i.p. administration of 0.085 ml/g of a 5 % solution of chloral hydrate ; the skull overlying the cortex was removed and the cortex was ablated by shallow knife cuts ; the ablated area was gently packed with sterile gelfoam and the scalp was apposed with sutures. The lesion involved the dorsal and lateral aspects of the frontal, parietal and occipital cortex, without penetrating the corpus callosum. Animals with a left cortical lesion served as controls for the surgical trauma induced by lesioning the right cortex, and vice versa. Sham operated mice in which the cortex was not lesioned during surgery, were also used as controls. Eight weeks after surgery phytohemagglutinin, (PHA), concanavaline A, (CON A) and pockweed, (PWM) induced responses were measured by $|^3H|$- Thymidine incorporation. The allogenic antigen response was measured in a one way mixed lymphocyte culture (MLC) using allogenic spleen cells.

A surgical lesion of the left cortex resulted in a significant 30 % decrease of $|^3H|$- Thymidine incorporation in T- Lymphocytes in response to PHA and Con A, but did not affect the response to PWM (a B cell response in mice). In contrast a surgical lesion of the right cortex caused a significant 30 % increase of $|^3H|$- Thymidine in response to PHA, but did not affect the reponse either to Con A or to PWM. The kinetics of the MLC response were deeply modified after either left or right cortical lesions, the maximum response occurred at seven days as compared to five days in controls and was significantly greater than that observed in controls.

These results bring new evidence that the cerebral cortex may be involved in the elaboration of immune responses by modulating T-cell mediated events.

71.3 SEXUAL DIMORPHIC AND STRAIN DIVERSITY IN ANTIGEN SPECIFIC HUMORAL IMMUNITY: NORMAL ENDOCRINE MODULATION OF IMMUNITY. P. Trefts*, K. Bulloch[1] and R.N. Hamburger*,(Spon: T. Melnechuk), Pediatric Immunology and Allergy Div., Dept. of Pediatrics, Univ. of Ca., School of Med., LaJolla, Ca. 92093. [1]Div. of Neuroimmunology, Dept. of Neurology, SUNY at Stony Brook, N.Y. 11794

Many human diseases show definite patterns of susceptibility based on sex, age and the major histocompatibility complex. In order to determine if certain aspects of normal immunity express a hierarchy of responses based on these same parameters, a study was undertaken to examine antigen and class specific humoral responses of 5 strains of mice. Aged matched wildtype staggerer (C3H and B57Bl/6J mixed background), inbred BIOS as well as BALB/c, C57Bl/6J, A/J and their Fl crosses were used in these experiments. The mice were injected i.p. either with DNP-OVA, DNP-KLH or DNP - ascaris in 0.5 ml. of normal saline with 2 mg. aluminum hydroxide $Al(OH)_3$ as the adjuvant. Retro-orbital sinus bleeds were collected from individual animals on day 10 and day 23 and the serum fraction prepared. All injections and serum collections were carried out at the same time in every experiment. Dilutions of individual serum were then tested in a solid phase radioimmune assay for the class and antigen specific response to the hapten DNP. Standards for IgG_1 & IgA were tested in each assay to quantify the class specific responses to DNP. The results of these experiments show that in all strains and Fl crosses regardless of the carrier used, female mice elicited higher antigen specific IgA and IgG_1 responses on day 10 and day 23 than males, regardless of age. The magnitude of the sexual dimorphic responses ranged from 6-9 fold differences for the BlOS and staggerer wildtype, to 2-4 fold differences for the A/J BALB/c and C57Bl/6J. Fl showed intermediate responses. These data demonstrate a consistent difference between male and female class specific response to a given antigen (hapten-carrier complex) that is related to the strain. Although age did not appear a factor in these experiments, others (Murphy, W.H.,Prog. in Neurol. Res. 175, 1979) have shown that age dependent loss of immune function is a viable factor in susceptibility to some viruses in certain strains independent of sex. Testosterone and progesterone treatment of the male and female wildtype staggerer (Bulloch, K., Trefts, P. and Hamburger, R.N., man. in prep.) show there is not a qualitative difference between male and female immune cells since the sexual dimorphism can be abrogated with the appropriate hormone. It is clear from the experiments "normal immunity" is under endocrine modulation. The data presented here provides a model system to evaluate the exact nature of these mechanisms and a basis for interpreting the aberrant diseased state.

71.4 EVIDENCE FOR A CNS-THYMUS AXIS INVOLVING THYMOSIN PEPTIDES. N. R. Hall, E.W. Palaszynski*, T. W. Moody and A. L. Goldstein*. Dept of Biochemistry, George Washington Univ. Sch. of Med., Washington, D. C. 20037.

Peptide hormones produced by the thymus gland play a central role in T-cell dependent immunity. The possibility that these thymosin peptides may also play a regulatory role as part of a CNS-thymus gland axis is suggested by two types of experimental evidence: 1) The presence in rat hypothalamus and pituitary gland of the peptide, thymosin α_1, and 2) differential effects of intracerebral thymosin administration upon immunologic and endocrine parameters.

Discrete rat brain regions were extracted and assayed for thymosin-like peptides using a RIA capable of detecting as little as 50 pg of thymosin α_1. The density of endogenous thymosin-like peptides was 20-fold greater in high regions such as the hypothalamus and pituitary than in low regions such as the cortex and spinal cord. Intermediate peptide densities were present in the striatum, midbrain, thalamus and hippocampus. In all brain regions assayed, one major peak of immunoreactivity was present which had a molecular weight similar to that of thymosin α_1 and a minor peak which may represent a low molecular weight metabolite which is derived from the major peak.

The biological effects of thymosin α_1, thymosin α_7 and the partially purified thymosin fraction 5 were evaluated following intracerebral injection into unanesthetized adult mice through stereoxatically positioned guide cannulas. Antibody titers to SRBC were found to be significantly depressed in animals that received thymosin fraction 5 or thymosin α_7 when compared with saline injected control animals. In contrast, mice that received intracerebral thymosin α_1 had elevated antibody titers. No significant differences were observed in the mixed lymphocyte response or spleen cell response to LPS. However, spleen cell responsiveness to PHA and Con-A were significantly depressed in animals that received thymosin fraction 5. The possibility that some of these immunologic changes might have been due to an altered neuroendocrine axis was suggested by the observation that the pituitary glands and ovaries were slightly enlarged in the thymosin fraction 5 treated animals, but not in those that received thymosin α_1 or thymosin α_7.

Consequently, it is proposed that the endocrine thymus is part of a neuroendocrine axis that may play a prominent role in the mechanism by which the brain might influence the course of disease.

73 SYMPOSIUM

CNS DEVELOPMENT IN INVERTEBRATES. J.G. Hildebrand (Chairman, Columbia Univ.), C.S. Goodman (Stanford), J.W. Truman (Univ. Washington), and D.A. Weisblat (U.C. Berkeley).

Much interest in developmental neurobiology focuses on the genesis of populations of neurons and the mechanisms that direct their interactions and sculpture them to form the CNS. This symposium samples recent advances resulting from efforts to probe cellular events in the development of the CNS in experimentally advantageous invertebrate preparations. Studying the leech CNS, D. Weisblat and coworkers have determined the embryonic origins of cells by injecting cell-lineage tracers into blastomeres early in development. Normally each of 4 bilateral pairs of ectodermal precursor blastomeres contributes distinct, stereotyped subpopulations of cells to the 32 segmental ganglia of the ventral nerve cord. Departure from the normal pattern follows ablation of specific blastomeres and can also result from fundamental ambiguities in the identity of certain blastomeres. To study the sequential choices made by growth cones of developing neurons, C. Goodman and associates examine living grasshopper embryos with Nomarski optics to observe early neuronal growth cones as they establish the first axonal pathways and subsequent growth cones as they choose between different axonal pathways. Experiments under way include manipulation of identified growth cones and the individual guide fibers they follow as well as use of monoclonal antibodies to explore cell surfaces of the neurons that lay down the early axonal pathways. J. Truman and coworkers explore the role and control of programmed neuronal death in shaping the developing adult CNS. The metamorphosis of moths is followed by a stereotyped program of death among mature neurons within the CNS. Both steroid and peptide factors influence the time of onset of this program, although neuronal interactions can selectively alter the time-course of the degeneration of certain cells. Sexual dimorphism in the CNS suggests plasticity in the development of ensembles of neurons. J. Hildebrand and coworkers find that sexually dimorphic neurons and neuropil structures in the olfactory pathway of the male moth brain develop as a consequence of direct interactions with olfactory afferents from male antennae. Surgical gynandromorphs reveal that male afferents can "masculinize" the female antennal lobe while a male lobe receiving innervation from a transplanted female antenna fails to show the characteristic, sexually dimorphic male elements.

74 SYMPOSIUM

MECHANISM OF ACTION OF ANTIDEPRESSANTS. E. Costa (Chairman, NIMH); S.Z. Langer* (Cochairman, L.E.R.S.); F. Goodwin (NIMH); F. Sulser (Vanderbilt Univ.); K. Fuxe* (Karolinska Inst.); and S.H. Snyder (Johns Hopkins Univ. Sch. of Med.)

F. Goodwin will introduce current neurobiological theories on the etiology and pathogenesis of endogenous depression. Symptoms of depression will be analyzed in the light of these theories.

F. Sulser will discuss the basis for the belief that chronic treatment with typical or atypical antidepressants will decrease density and reduce responsiveness of β-adrenergic receptors located in brain. He will show that changes in density or function of α-adrenergic receptors are inconsistent responses to chronic antidepressants, that the reduced function of β-adrenergic receptors involves uncoupling from adenylate cyclase and actual loss of receptors, and that iprindole fails to produce subsensitivity in absence of signal input due to lesion of locus coeruleus. He will discuss the implications on psychobiology and pharmacotherapy of affective disorders.

K. Fuxe will show that subchronic treatment with zimelidine, desipramine, imipramine, alaproclate and mianserin leads to adaptive changes in 5HT receptor mechanisms. The major finding seems to be the induction of large numbers of low affinity binding sites for 5HT-1 receptors leading to a possible stabilization of 5HT neurotransmission at the 5HT-1 receptors, while a reduction at 5HT-2 receptors is induced. Long-term treatment with zimelidine, desipramine, and imipramine also reduces 5HT dependent behavior in mice and rats. Thus, it is speculated that 5HT neurotransmission may be reduced and mainly switched over to 5HT-1 receptors following subchronic antidepressant treatment.

S. Langer will report the progress of the study of high affinity labeling of specific receptors with various antidepressants. The relationship between imipramine binding and 5HT uptake indicates an involvement of presynaptic 5HT mechanisms in the action of antidepressants.

E. Costa will show that the high affinity binding sites for desipramine are not located exclusively on 5HT presynaptic mechanisms. Moreover, mianserin, an atypical antidepressant, lacks presynaptic binding on 5HT neurons. Based on the simultaneous binding of antidepressants to various synaptic mechanisms, he suggests that the action of synaptic modulator(s) acting as receptor regulators in a number of synapses may be modified by antidepressants.

S. Snyder will stress that the antidepressants because of their clinical similarities may act on a final pathway though the specific mechanisms to attain the pathway may vary. Common themes seem to be down-regulation of NE dependent cyclase, the number of β-adrenergic receptors, the number of 5HT-2 receptors, and 5HT uptake mechanisms.

75.1 SPINALLY PROJECTING, SEROTONIN STAINED NEURONS CO-EXIST WITH ONE OR MORE PEPTIDES. R.M. Bowker*, K.N. Westlund, and J.D. Coulter. Depts. Psychiat. and Physiol. and Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX. 77550.

The origins of spinally projecting neurons that stain for serotonin, substance P, leucine- and methionine-enkephalin and somatostatin immunoreactivity were localized in rats using a combined method of the retrograde transport of HRP and the immunocytochemistry. Injections of HRP were made into different spinal cord levels of anesthetized rats. The spinally projecting neurons were identified by incubating the tissue sections in $CoCl_2$ and diaminobenzidine prior to the immunocytochemical staining for the respective antisera using the unlabeled antibody, peroxidase-antiperoxidase (PAP) method of Sternberger (Brain Res. 211, 1981). Serotonin stained neurons which projected to all spinal cord levels were distributed throughout the medullary raphe nuclear complex in the nucleus raphe obscurus, raphe pallidus, raphe magnus and the ventral parts of the nucleus gigantocellularis. The locations of these descending serotonin stained neurons correspond to cell groups B_1-B_3 of Dahlström and Fuxe (Acta Physiol. Scand., 1965). The quantitative data to date indicate that over 85% of the retrogradely labeled cells in the raphe nuclei and ventral reticular formation were found to be positively stained for serotonin. In colchicine treated animals large numbers of neurons stained positively for substance P, enkephalin and somatostatin immunoreactivity were distributed in these same midline raphe and ventral reticular nuclear groups. Other medullary cell groups, such as spinal nucleus of the trigeminal complex and nucleus of the solitary tract, were also found to contain positive peptidergic neurons. Of the spinally projecting neurons in the raphe nuclei and ventral nucleus gigantocellularis over 60% and nearly 50% were found to be stained for substance P, and enkephalin-like immunoreactivity, respectively. Fewer spinally projecting neurons contained positive immunoreactivity for somatostatin. These findings suggest that a large fraction of the spinally projecting neurons in the raphe nuclear complex and ventral reticular formation have serotonin co-existing with one or more neuropeptides.

(Supported by NIH Grants NS 12481 and NS 11255).

75.2 DISTRIBUTION OF ENKEPHALIN, SUBSTANCE P AND SEROTONIN IMMUNOREACTIVITY IN THE VISUAL SYSTEM OF THE LOBSTER, CRAYFISH AND HORSESHOE CRAB. Jorge Mancillas*, Jacqueline McGinty+ and Allen Selverston++ (SPON: W. Kristan). Depts. of Neuroscience* and Biology++, Univ. Calif., San Diego and Salk Institute+, La Jolla, CA

Neuroactive peptides first characterized in mammalian nervous systems have been recently detected in invertebrates. We report that immunoreactivity for enkephalin, substance P and the indoleamine serotonin can be localized to specific neural elements in the visual system of the spiny lobster, crayfish and limulus.

The indirect immunocytochemical technique was used. Frozen sections of lobster and crayfish eyestalks and the lateral eyes of limulus were incubated in leu-enkephalin (at 1:1000), substance P (1:100) and 5-HT (1:1000) antisera, which was then localized with an FITC labelled IgG. Specificity of the immunoreactive staining was tested by incubation with antisera previously absorbed with their respective synthetic antigen (at 0.1, 1, 10 and 100 micromolar concentrations) and by substituting the primary antibody with non-immune serum or PBS.

The patterns of immunoreactive staining were almost identical in the crayfish and lobster. Enkephalin-like immunoreactivity (lir) was observed in the primary photoreceptors (retinular cells) and their projections to the lamina ganglionaris, as well as in the medulla interna and terminalis. Additional enkephalin-lir terminals and cell bodies were observed in the medulla externa of the crayfish. Substance P-lir was present in perikarya, fibers and terminals of identifiable cell types in the lamina, medulla interna, externa and terminalis. Substance P-lir was also observed in cell bodies of the medulla terminalis X organ and in neurosecretory terminals in the sinus gland. 5-HT-lir was present in cell bodies, terminals and fibers in the medulla terminalis, interna and externa. All three substances were also present in the optic nerve. Interestingly, enkephalin and substance P-lir was observed in synaptically related cells, the retinular cells and the "neurosecretory" cells of the lamina, both of which terminate on the ganglion cells. The role of these substances as possible neurotransmitters (especially enkephalin in the photoreceptors) and their possible interactions are currently under study.

In the limulus lateral eye, only substance P-lir was observed in centrifugal fibers travelling through the optic nerve, the lateral plexus and ending around the edges of the ommatidia and the cornea. Preliminary evidence suggests that substance P can induce morphological changes in the ommatidia that may be associated with centrally controlled circadian changes in sensitivity or environmentally induced light-dark adaptation. These possibilities are being tested neurophysiologically.

75.3 COEXISTENCE OF GLUTAMATE DECARBOXYLASE IMMUNOREACTIVITY AND SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN NEURONS OF NUCLEUS RETICULARIS THALAMI OF THE CAT. W.Oertel$^{\Phi}$,A.M.Graybiel+,E.Mugnaini$^{\Omega}$,R.Elde+,D. Schmechel*@ and I.Kopin$^{\Phi}$.NIMH$^{\Phi}$,MIT+,U.Conn$^{\Omega}$,U.Minn.+,Duke Univ.@

Several instances of coexistence of neuropeptides and biogenic amines have been reported in peripheral and central neurons (Hökfelt et al,Nature 284,1980;285,1980).To date, however,no peptide has been localized in neurons that release the inhibitory neurotransmitter γ-aminobutyric acid(GABA). In the present study we investigated by immunocytochemical methods the possibility that glutamate decarboxylase (the biosynthetic enzyme for GABA) immunoreactivity(GAD) and somatostatin-like immunoreactivity(SOM) coexist in neurons of the feline nucleus reticularis thalami. Nine young cats were perfused with buffered(pH7.4) 4% paraformaldehyde with or without 0.1% glutaraldehyde. Vibratome or frozen sections (25μm) were processed either according to the preembedding unlabeled antibody enzyme method of Sternberger or the immunofluorescence technique with specific antisera against somatostatin(Elde and Parsons,Am.J.Anat.144,1975) and GAD(Oertel et al,Neuroscience,in press). On light microscopic examination of adjacent sections most of the neurons appeared to react for GAD (Houser et al,Brain Res.200,1980) and SOM(Graybiel et al,Anat.Rec 199,1981).In the electronmicroscope strong SOM was localized exclusively in the Golgi-apparatus; weak GAD was found in the cytoplasm and proximal dendrites,medium GAD in the Golgi-apparatus and very strong GAD in boutons. To demonstrate coexistence of these two antigens which have a different intracellular distribution,a sequential double staining method was employed:Sections were incubated in rabbit anti-somatostatin,followed by fluorescein coupled swine anti-rabbit. After fluorescence photography the sections were incubated in sheep anti-GAD,donkey anti-goat, goat peroxidase anti-peroxidase complex and 3',3-diaminobenzidine (DAB).Many neurons were stained for SOM(cytoplasmic skeins,green) and GAD (rather homogeneous reaction product,brown). In addition a double immunoperoxidase method was used to simultaneously visualize SOM with 4-chloro-1-naphthol(blue) and GAD with DAB (brown) with bright field microscopy. Despite the weak cross-reactivity of the two linking antibodies (control experiments), the differential distribution of SOM and GAD allowed the use of these sequential protocols without antibody elution.

This study strongly suggests that in the nucleus reticularis thalami of the cat,most neurons are GABAergic and also contain a compound immunohistochemically indistinguishable from the inhibitory neuropeptide somatostatin.

Supported by grant#0e95/1,Deutsche Forschungsgemeinschaft,West Germany(W.O.),NSF grant#BNS78/10549(A.M.G.),US-PHS grant#09904 (E.M.) and NIDA grant#02148 and the MCKnight Foundation(R.E.)

75.4 NEUROTENSIN IMMUNOREACTIVE SYSTEMS IN THE CENTRAL NERVOUS SYSTEM OF RAT. L. Jennes*, W.E. Stumpf, W.C. Beckman*, S.K. Burgess, D. Luttinger, C.B. Nemeroff and A.J. Prange, Jr. Dept. Anatomy and Biological Science Research Center, Univ. North Carolina, Chapel Hill NC 27514.

The distribution of neurotensin (NT)-containing structures in the central nervous system has been studied with immunohistochemical techniques. Male and female adult Holtzman rats received an intraventricular injection of colchicine (50 μg/100g body weight) 48 h before sacrifice by intracardiac perfusion with 4% paraformaldehyde. Immunohistochemistry was performed on vibratome and thick frozen sections using Mason's single bridge technique. The primary antiserum was shown to react with the C-terminal portion of the NT molecule by radioimmunoassay analysis of the binding of NT analogues with single D-amino acid substitutions. The antiserum was purified on a Protein-A column or on a DE 52 ion exchange column and exhibited no cross-reactivity in the radioimmunoassay with GnRH, β-endorphin and bombesin. Highest accumulations of NT immunoreactive cell bodies are found in the lateral portion of the lateral septum, the bed nucleus of the stria terminalis, the diagonal band, the nucleus (n.) paraventricularis pars parvocellularis, n. arcuatus, n. periventricularis thalami and the medial and central amygdala. Dispersed NT-containing neurons exist in the lamina fibrosa of the olfactory bulb, septo-preoptic region including the n. triangularis septi, medial forebrain bundle, zona incerta, n. ventralis thalami and central gray. In the lower brainstem, NT-containing neurons are seen in the n. raphe dorsalis and centralis, locus ceruleus, n. tractus solitarii, n. tractus mesencephali and formatio reticularis. A few neurons are located in the substantia gelatinosa and in the area surrounding the central canal. Neurotensin positive nerve fibers are seen in all regions which contain immunoreactive neurons. In addition NT fibers are present in the olfactory bulb in the n. olfactorius anterior, in different layers of the cortex, claustrum, caudate-putamen, globus pallidus, n. accumbens, amygdala with highest concentrations in the n. centralis and medialis, certain thalamic structures and in sensory projections of the trigeminus and the substantia gelatinosa, as well as other layers in the dorsal and central spinal cord. In addition to neurons, certain cells in the pituitary and in the subrachoroid space react positively with the antibodies. The results demonstrate that the neurotensinergic system is an extensive neuropeptide system, probably involved in the regulation of neuroendocrine, autonomic, sensory, and motor functions. Supported by PHS NS09914, NIMH MH-32316, 34121, NICHHD HD-03110 and Deutsche Forschungsgemeinschaft Je 105/2.

75.5 PRO ACTH/ENDORPHIN ANTIGENICITIES IN MEDULLARY NEURONS OF THE RAT[1]. D.G. Schwartzberg* and P.K. Nakane* (SPON: R. Lasher). Department of Pathology, University of Colorado Health Sciences Center, Denver, CO 80262.

Immunohistochemically, neurons containing pro ACTH/endorphin antigenicities (PACTH-Ag) have been reported to be confined to the basal hypothalamus (Krieger, D.T., New England J. Med. 304: 876, 1981). Antigenicities found outside of the diencephalon (Watson, S.J. et al., Nature 275:226, 1978) are thought to be derived from hypothalamic neurons. In the course of the investigation of the morphogenesis of neurons containing PACTH-Ag, a group of neurons in the medulla also containing PACTH-Ag was demonstrated immunohistochemically.

For this study the indirect peroxidase-labeled antibody method was used. Affinity purified rabbit antisera against (1-9) β-endorphin, N-terminal ACTH, and rabbit anti-16K fragment, all donated by Drs. Mains and Eipper, and rabbit anti-tyrosine hydroxylase (TH), donated by Dr. J.K. Stephens, were used as the first antibody; affinity purified peroxidase-labeled Fab' fragment of sheep anti-rabbit IgG was used as the second antibody.

Perikarya immunoreactive for all 3 major determinants of PACTH-Ag exist within the medulla adjacent to TH-containing neurons of the A2 system, and contribute axons to superficial basolateral tracts. The medulla is not a known site of action for ACTH-related peptides. However, noradrenergic neurons of the A2 cell group have been implicated in the regulation of sexual function (Sar, M., Nature 289:500, 1981), and β-endorphin exerts central effects on luteinizing hormone secretion (Parvizi, N., Nature 286:812, 1980). The anatomic association of medullary neurons containing PACTH-Ag, with A2 neurons suggests that these two systems may interact to control sexual function.

75.6 THE PRESENCE OF SUBSTANCE P-LIKE AND SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE ABSENCE OF UNMYELINATED PRIMARY AFFERENT INPUT IN THE SPINAL CORD OF THE STINGRAY. Teresa C. Ritchie and R.B. Leonard, Marine Biomed. Inst. and Dept. of Physiology and Biophysics, the Univ. of Texas Med. Branch, Galveston TX 77550.

Previous studies in mammals have indicated the presence of substance P or substance P-like immunoreactivity in various regions of the spinal gray horns, and emphasis has been placed on its association with the primary afferent input to the spinal cord. Specifically, substance P (SP) and somatostatin (SS) have been localized in small neurons of the DRG's and fibers in Lissauer's tract. Terminal labeling is dense in the superficial laminae of the dorsal horn, the targets of fine myelinated and unmyelinated fibers. This study was undertaken to examine the distribution of SP and SS in the spinal cord of the Atlantic stingray, Dasyatis sabina, an animal in which unmyelinated axons comprise only 0.4% of the total population of primary afferent fibers in spinal nerves and roots. However, despite the virtual absence of unmyelinated primary afferents, histological examination of the spinal cord reveals a large structure of the superficial dorsal horn resembling the substantia gelatinosa of mammals.

In this study, the distribution of SP-like and SS-like immunoreactivity was studied with antibodies to these peptides, using the unlabelled antibody, PAP technique of Sternberger. Controls consisted of preabsorption of the antisera with excesses of their respective antigens.

Sp-like immunoreactivity was found in a band occupying approximately the outer one-half of the substantia gelatinosa. The labeling was most dense in the lateral third of this structure, around the root entry zone. Scattered label also occurs in deeper regions of the dorsal horn and in the ventral horn. Preliminary results indicate a reduction in labeling in the substantia gelatinosa following multiple dorsal rhizotomies.

SS-like immunoreactivity also occurs in the stingray spinal cord. Fascicles of labeled fibers are seen running through the nucleus proprious and substantia gelatinosa, and a narrow band of presumptive terminals is seen along the superficial margin of the substantia gelatinosa. These fibers may originate from either the dorsal root or from a prominant tract in the dorsolateral funiculus. In addition, some fibers turn ventrally to distribute in the ventral horn.

These findings demonstrate the presence of both SP-like and SS-like immunoreactivity in the spinal cord of an elasmobranch which is characterized by a virtual absence of unmyelinated primary afferents. Additionally, preliminary results indicate that a portion of the labeling is associated with dorsal root input. Supported by grants NS 16093 and NS 11255.

76.1 ELECTROPHYSIOLOGY OF CULTURED HYPOTHALAMIC NEURONS: CA-DEPENDENT PLATEAU POTENTIALS. P. Legendre *, I. Cooke and J.D. Vincent. (SPON: B. Bioulac). INSERM U. 176, 33077 BORDEAUX-CEDEX, France.

All-or-none plateau depolarizing responses with durations of mins are recorded intracellularly (KCl electrodes) from the largest neurons (type (a), Theodosis et al., this vol.) of antibiotic-free primary cultures of dispersed fetal mouse hypothalamus 40 days or more old. During recording, the culture is continuously perfused with Hank's medium supplemented with Ca (final conc., 4 mM), glucose (50 mM), and HEPES (10 mM, pH 7.1), 32° C. The neurons exhibit a constant barrage of depolarizing synaptic activity. From this, or in response to depolarizing current arise three types of regenerative response: 1) overshooting action potentials (APs) of 2-5 msec (at 1/2 ampl.). 2) APs having a short plateau on their falling phase. This has variable duration, up to 2 sec, and reaches a depolarized level of -30mV. 3) Plateau responses of long duration. These arise from the falling phase of an AP or the short plateau potential, and take 50 msec to depolarize to the plateau, during which up to 8 impulses of declining amplitude may occur. The plateau level, -20mV, is constant from neuron to neuron and independent of cell holding potential (V_h), -50 to -60mV. Duration of the response varies from 1/2-5 min. During the plateau, cell input resistance (80-150 MΩ) is decreased 85%. The plateau gradually declines to -25mV, then a rapid (5-10 sec) repolarization to within 10mV of V_h follows with a parallel increase in resistance. The final repolarization requires 1/2-2 min. During slow repolarization, synaptic activity or current evokes type 2 responses; the amplitude and duration of their short plateau become progressively larger until a long plateau is again evoked. In some neurons having strong synaptic input, long plateaus are driven to recur regularly. The period (1/2-7 min) is correlated with the duration of plateau. Some neurons show plateaus only in response to brief (10 msec) depolarizing current. TTX reversibly blocks synaptic input and impulses, but does not change the amplitude or time course of plateaus. Presence of Co or Cd reversibly blocks plateaus. Ejected during a plateau, they provoke repolarization. If applied briefly and early during the plateau the plateau may redevelop. TEA doubles the duration of plateaus. Thus plateaus are endogenous, regenerative depolarizing responses involving a voltage-dependent Ca-conductance increase. Their regular recurrence and duration is remeniscent of patterned activity of vasopressin (VP) neurons in vivo (Poulain et al., Proc. R. Soc. B 196: 367, 1977). Long plateaus have only been observed in neurons of the morphological type (a) which sometimes react with VP antisera (Theodosis et al., this vol.).

76.2 DENDRITIC AND SOMATIC ACTION POTENTIALS IN SINGLE PURKINJE CELLS CHANGE $[K^+]_o$ and $[Ca^{2+}]_o$. J. Hounsgaard* and C. Nicholson (SPON: R.P. Kraig). Dept. of Physiol. and Biophys., New York Univ. Med. Ctr., 550 First Avenue, New York, N.Y. 10016.

While syncronous activation of large aggregates of neurons substantially changes $[K^+]_o$ and $[Ca^{2+}]_o$ (Nicholson, 1980; Neurosci. Res. Prog. Bull 18: 177-322) little is known about the ion changes around single neurons under normal levels of impulse activity. We have recorded the $[K^+]_o$ and $[Ca^{2+}]_o$ in the vicinity of visually identified Purkinje cell bodies in guinea pig cerebellar slices (Llinás and Sugimori, 1980; J. Physiol. 305: 171-195) using ion selective microelectrodes.

Intermittantly active cells were selected for the experiments. Spikes of somatic and dendritic origin were clearly distinguishable when monitored with the reference barrel of an ion-selective electrode positioned close to the cell body. Na^+-mediated somatic spikes with frequencies of 30-40 Hz in the early phase of an active period were associated with an increase of $[K^+]_o$ to a steady level approaching 1mM above base line (6mM). The onset of Ca^{2+}-mediated dendritic spikes in the terminal phase of an active period produced a dramatic increase in $[K^+]_o$ in the soma region reaching levels 3-4mM above baseline. The K^+ activity returned to the 6mM level of the superfusing medium within the first 10s of a silent period.

In addition to spike frequency, the amplitude of the K^+ signal was clearly related to the distance between the tip of the electrode and the cell membrane since it changed in parallel with the amplitude of the action potentials when the electrode was moved. The duration of the action potentials also seemed to be an important determinant of the K^+ signal. Single somatic spikes lasting 0.5 msec gave no measurable increase in $[K^+]_o$ while single dendritic spikes lasting 10 ms were associated with a distinct transient increase in $[K^+]_o$. These long duration spikes and associated K^+ signal were insensitive to tetrodotoxin. Spikes lasting several seconds appeard when 1mM Ba was substituted for 1mM Ca in the bathing solution. These Ba^{2+}-mediated spikes evoked an increase in $[K^+]_o$ of several mM.

Spike activity also changed the $[Ca^{2+}]_o$ level around Purkinje cell bodies, but the changes were small (≤ 0.2mM) and in the opposite direction to the K^+ changes.

The possible functional significance of the results and the capability of ion selective electrodes to determine the location of ion conductances will be discussed.

76.3 MODIFICATION OF GABA RESPONSE BY REPETITIVE ACTIVATION IN THE HIPPOCAMPUS. D.J. Watkins and R.K.S. Wong. Dept. of Physiol. LSU Med. Ctr. Shreveport, LA 71130.

There is now a considerable amount of neurochemical and pharmacological data suggesting that GABA may function as an inhibitory neurotransmitter in the hippocampus. Our recent studies showed that GABAergic inhibition activated during orthodromic stimulation suppressed the elicitation of endogenous burst firing in the soma-dendritic regions of the hippocampal pyramidal cell. Recent studies also suggest a decrease in the efficacy of the inhibitory process may occur upon repetitive stimulation of the efferent pathways at frequencies of 10/sec or higher. The present study is designed to examine whether modification of the inhibitory process induced by repetitive activation could in part be accounted for by alterations in the postsynaptic response to GABA. The in vitro hippocampal slice preparation was used in the study. GABA was applied by pressure pulses onto the slice. Typically 3 msec pulses of 30 psi amplitude were used to eject GABA (10^{-3} M) from a 30 MΩ pipette. The amount of GABA ejected in this fashion was calculated to be about 10^{-15} M. Intracellular recordings from CA1 pyramidal cells showed that a pulse of GABA applied at the somatic region typically produced an increase in membrane conductance with an associated hyperpolarization and a suppression of spontaneous firing at the resting potential. Hyperpolarizing the cell by current injection reduced the amplitude of the GABA induced hyperpolarizing (H) response and revealed an additional depolarizing (D) response. These responses exhibit interesting use-dependent changes. When paired pulses of GABA was applied at short intervals (up to 12 sec), the H response to the second application decreased in amplitude and the D response appeared to facilitate. These changes in the second GABA response could be observed for intervals up to 12 seconds following the initial GABA response. Additional experiments showed that similar changes could also be induced in the CA1 pyramidal cell by tetanic stimulation of the Schaffer Collateral pathway. The D response could increase 3-4 folds while the H response attenuated following tetenic shock. This alteration of the GABA response could last up to a minute following the tetanic stimulation. Our data demonstrate that a phasic application of GABA produces sustained changes in the response of the hippocampal pyramidal cell to GABA such that the inhibitory action of GABA to a subsequent application is attenuated. These changes in GABA response could also be induced by tetanic stimulation suggesting that they may play a physiological role in regulating the efficacy of the inhibitory transmission in the hippocampus. 76.4 GENERATION OF SYNCHRONIZED BURSTING IN POPULATIONS OF HIPPOCAMPAL NEURONS. R.K.S. Wong and R.D. Traub. Dept. of Physiol. LSU Med. Ctr. Shreveport, LA 71130 and IBM Watson Res. Ctr. Yorktown Hts. NY 10598.

When the GABAergic inhibitory process is blocked by pharmacological agents in the hippocampus, spontaneous and evoked synchronized oscillations are often recorded in populations of neurons. The present study represents an initial attempt to define some of the cellular processes underlying these synchronized oscillations. The in vitro hippocampal slice preparation was used. Extracellular recordings in the CA1 region showed that upon disinhibition, stimulation of the Schaffer Collateral pathway often elicited two phases of synchronized bursting. A first phase followed the stimulus at short, fixed latencies (5-10 msecs) and a second phase occurred at longer, more variable latencies (50-150 msec). These two phases of synchronized bursting could be further differentiated by the fact that while the first phase activity could follow the stimulus input in a 1:1 fashion up to 5Hz, the second phase activity had much longer refractory periods and could follow the stimulus frequency only up to about 0.3Hz. Intracellular recordings showed that burst firing was elicited in CA1 pyramidal cells during both phases of synchronization. The data also suggest that both phases of bursting were triggered by underlying excitatory postsynaptic potentials (EPSPs). The EPSP triggering the first phase bursting was elicited directly by the electrical stimulation of the Schaffer Collaterals. The EPSP underlying the second phase bursting followed the occurrence of synchronized bursting in the CA2-CA3 region of the hippocampus. Additional data showed that synchronized bursting could be elicited by orthodromic activation of neurons in a surgically isolated CA2 region of the hippocampal slice. This synchronized bursts had the following characteristics: (a) They could be elicited nonspecifically by the stimulation of any excitatory afferent input or by antidromic activation. (b) Their latency of occurrence was prolonged (50-150 msec). Our results suggest that upon disinhibition orthodromic stimulation of the CA1 cells directly elicit a phase of short latency synchronized bursting of these cells. In addition, the excitatory volley also triggers long latency, intrinsically generated synchronized bursting of the cells in the CA2-CA3 region. The excitatory volley arising as a result of the synchronized activity in CA2-CA3 region in turn projects onto the CA1 neurons, producing a second phase synchronization in the CA1 population. The cellular mechanisms for the generation of synchronization in the CA2 cell group is discussed in a companion abstract (Traub and Wong, this volume). 76.5 MULTIPLE BINDING SITES FOR OUABAIN IN THE CENTRAL NERVOUS SYSTEM. R. Hauger*, H.M. Do*, F.K. Goodwin, and S.M. Paul*. (SPON: F. Bruns), Clinical Psychobiology Branch, NIMH, Bethesda, MD 20205.

[^{3}H]Ouabain has been previously shown to bind specifically to multiple brain areas in the cat with equilibrium dissociation constants (K_D) ranging from 510 to 2000 nM (Eur. J. Pharmacol. 56:297-304, 1979). Since [^{3}H]ouabain binding sites in the human erythrocyte exhibit a much higher binding affinity (K_D = 11.3 nM) (Clin. Pharmacol. Ther. 28:346-349, 1980), we examined whether "high affinity" binding sites for ouabain exist in rat brain as well. Specific binding of [^{3}H]ouabain was readily demonstrated in homogenates of rat brain incubated with varying concentrations of [^{3}H]ouabain (1 to 1000 nM) and 5 mM ATP for 30 min. at 37°C. Scatchard analysis revealed the presence of at least two distinct binding sites in all areas of the brain examined. In the rat striatum a "high affinity" site characterized by an apparent K_D of 17.4 nM and a binding capacity (B_{max}) of 12.0 pmoles/mg protein and a "low affinity" site with an apparent K_D of 400 nM and B_{max} of 36.0 pmol/mg were present. In contrast, the "high affinity" site was absent from heart (left ventricle) and kidney. Ouabain and strophanthidin competitively inhibited ouabain binding in the brain with potencies similar to their inhibition of Na^+ - K^+ ATPase. Following lesions of the rat striatum with kainic acid, a marked decrease (40-60%) of both the "high affinity" and "low affinity" ouabain binding sites was observed. These results suggest that both binding sites are localized to neurons. This hypothesis was further supported by studies on postmortem brain samples from patients with Huntington's disease; where a marked decrease in [^{3}H]ouabain binding was observed in the caudate nucleus when compared to matched controls. [^{3}H]Ouabain binding appears to be a useful biochemical probe of neuronal Na^+-K^+ ATPase activity.

76.6 ASSESSMENT OF INJURY IN INTRACELLULARLY PENETRATED NEURONS OF THE CAT MOTOR CORTEX. C.D. Woody, E. Gruen*, and K.McCarley*Depts. of Anatomy & Psychiatry, UCLA Medical Center, Los Angeles,CA 90024

Many investigators have employed intracellular recording to assess unit activity in conjunction with local membrane properties,yet few studies have been directed toward assessment of possible injury arising from cell penetrations. The present studies compared the response of penetrated neurons to repeated click stimuli with that of unpenetrated (extracellularly recorded) units of the same cortical region. Recordings were made in awake cats using methods described elsewhere (Woody and Black-Cleworth, J.Neurophysiol.,1973). Penetrated neurons were pressure-injected with HRP at the conclusion of each study. Of 92 HRP-injected neurons, 30 showed only dendritic processes on examination of serially sectioned core biopsies. All but one of these cells were characterized by action potentials (AP) of amplitude smaller than the recorded resting potentials (RP), i.e. spike undershoot. These recordings were thought to represent dendritic penetrations with electrotonic spread of the spike through passive cables. Analysis of the HRP-injected cells showed that the penetrations with dendritic recoveries had higher input resistances than those with recoveries of both somas and dendrites (24±11 MΩ, s.d., and 18±12 MΩ, respectively, $P < .01$,Student t). Increases in spike height at the time of pressure injection were greater in spike undershoot than in spike overshoot cells (13±7 mV versus 11±5 mV). Increases in spike height were also greater in recordings with only dendrites recovered (16±8 mV) than in recordings with somas and dendrites recovered (11±7 mV). The latter differences were significant at $P < .01$. Responses to click were obtained from 83 penetrated neurons. The data from these neurons were separated into four groups according to the size of the recorded action potential. The magnitude of the response to click was much the same in three of the groups (AP 50-60 mV, AP 40-50 mV, and AP 30-40 mV) and slightly greater in the group with AP 20-30 mV as was the level of spontaneous activity. The response profiles (PSTH to click) were comparable to those of extracellularly recorded units (Woody et al, J.Neurophysiol., 1970,72). Studies using K^+ ion-sensitive microelectrodes intracellularly found comparable values of E_{K^+} with either spike undershoot or spike overshoot penetrations. We conclude that whatever injury arose from the penetrations of cortical neurons performed herein was not sufficient to impair the ability of the cells to respond with spike activation to natural stimuli such as weak click. Many of the penetrations appeared to be of passive dendritic cables rather than of cell somata. (Supported by AGO - 1754 and BNS 78-24146)

77.1 CORRELATION OF NEUROMA ULTRASTRUCTURE WITH AUTOTOMY IN RATS. M.M. Bosma* and W.K. Dong. Dept. of Anesthesiology, School of Medicine, University of Washington, Seattle, WA 98195.

Experimental amputation neuromas, as a model of anesthesia dolorosa, are known to be accompanied by autotomy of the denervated portion of the foot. Changes in neural structure may contribute to the abnormal firing patterns underlying the putative pain-producing mechanisms.

Sciatic nerve neuromas were produced and the severity of autotomy scored as described by Wall et al. (Pain, 7:103, 1979). Rats paired for high (7-10) and low (1-4) scores were sacrificed at 3 wks, 3 mos, and 6 mos. The most distal portion of the neuroma was prepared for EM. Each sample was scanned at low magnification and a representative area chosen for morphometry. Pictures were systematically taken at 3290X and 6680X. The 3290X series was used to measure myelinated (M) axon size, and to compare total numbers of M and unmyelinated (U) axons. The 6680X series was used to measure U axon size. Equal areas were sampled in each rat. Only areas of the nerve perpendicular to the section were sampled, but axons shaped or oriented abnormally were not measured. About 150-300 axons were sampled at each magnification.
