221.3 LONGITUDINAL EVALUATION OF THE EFFECTS OF NEONATAL HIPPOCAMPAL X-IRRADIATION IN THE RAT. Dr. R. B. Wallace, Mary-Beth McLaughlin and John Gustafson (Spon: D. Oliver). Developmental Psychobiology Laboratories, University of Hartford, West Hartford, Ct. 06117. Studies employing fine-resolution thymidine H^3 autoradiography have established the existence of a pool of mitotically active cells in the subependymal layers of the ventricles in the brains of mammals, particularly altricial species. The technique of focal x-irradiation of the rat hippocampus provides a method to produce selective lesions of the granular cells of the dentate gyrus; one can then study the behavioral consequences of this manipulation. In a series of papers dealing with the effects of focal cerebellar irradiation (Wallace and Altman 1970) a number of qualitatively assessed motor deficits were noted in young adult rats and these were correlated with a massive reduction (80%) in the granular cells of the IGL. We then noted and reported in a later paper (Wallace, Daniels and Altman 1972) that some of these animals with 2 year survival times showed behavioral recovery. Histological analysis revealed in these animals a recovery of the IGL to within normal values. In an attempt to determine the recovery potential of the proliferative matrix of the hippocampus, the following experiment was conducted; 42 male Long-Evans rats from our animal colony were used. All animals received focal x-irradiation of the hippocampus according to the following schedule: irradiation treatment began on postnatal day 2. On the 2nd and 3rd days after birth, animals received 200 rads. Thereafter, irradiation received was 150 rads on alternating days (5th through 15th postnatally). Non-irradiated control subjects remained with their mothers throughout the period. To determine the long term effects of neonatal degranulation 3 experimental and 3 control animals were sacrificed and examined at ages 1 month, 2 months, 4 months, 6 months, 12 months, 18 months, and 24 months. Animals were sacrificed with an overdose of sodium pentobarbital and perfused with 10% buffered formalin transcardially. The brains were removed, embedded in paraplast and sectioned at 6μ in the coronal plane. Every 10th section was saved and stained with H&E for histological analysis. The number of granule cells in matched sections of the dorsal hippocampus was counted at 400X magnification. Results indicated approximately a 70% reduction in the granule cells of the dentate gyrus in the irradiated animals up to 6 months of age. Following this, however, there was a recovery to approximately a 45% reduction against the control level in the 24 month animals. Thus, the proliferative matrix of the hippocampus would appear to possess some reconstitutive capacity although not to the extent earlier shown in the IGL of the cerebellar cortex. The implications of this will be further examined.

221.4 FUSION OF SEVERED AXONAL STUMPS WITH POLYETHYLENE GLYCOL: AN ARTIFICIAL MECHANISM FOR AXONAL REGENERATION. George D. Bittner, Dept. of Zoology, Univ. of Texas, Austin, Tx. 78712.

Since neurons have long cytoplasmic processes (axons), some traumatic lesions to nervous tissue can result from axonal severance rather than cell body ablation. Repair (if any) of such lesions in all vertebrate and some invertebrate axons studied to date occurs via rapid (12-36 hour) degeneration of severed distal stumps together with slow (1-2mm/day) outgrowth of processes from proximal stumps to reform synases on denervated cells. In contrast, many invertebrate neurons initially repair severed axons by the slow outgrowth of processes from proximal stumps which functionally activate surviving distal stumps by gap junctions or ephaptic current spread. (Severed distal stumps may survive and be activated for days, months, or years). In such cases, the final repair mechanism appears to be the reformation of synapses on target tissues. We and others have now reported a great variety of distal stump survival times, distal stump activation mechanisms, and synaptic reformation times. However, in no case have we or others confirmed that any organism regenerates axons by morphological fusion of proximal stumps with surviving distal stumps. (See data or references given in Bittner, Comp. Biochem. Physiol., 68A: 299-306, 1981; Birse and Bittner, J. Neurophysiol., 45: 724-742, 1981; Bouton and Bittner, Cell Tiss. Res., in press, 1981.)

We (Bittner and Ballinger, manuscript submitted for publication) now report an ability to reconnect severed CNS axons in an invertebrate (crayfish medial giant axon) in vitro and axons from a vertebrate hybrid cell line (NG 108-15 mouse neuroblastoma/rat glioma: Nelson et. al., PNAS USA 73, 123-27, 1976) in tissue culture. In both preparations, severed axons were fused with 40-50% polyethylene glycol (PEG) solution focally applied to the lesion site for 30-60 seconds (PEG, $HOH_2C(CH_2OCH_2)_nCHOH$, has been used for some years to fuse various cell lines grown in tissue culture). Our results suggest that in ~ 5% of all trials PEG can produce axoplasmic continuity between two severed medial giant stumps, although axolemmal continuity is not complete. Our data also show that ~ 8% of severed NG 108-15 processes reconnected to the cell body using PEG survive at least 24 hours. Our initial in vivo trials using mammalian myelinated axons have not yet been successful, perhaps because PEG dissolves both the myelin and axolemmal membranes so that they flow together. However, the possibility exists that PEG or similar membrane-active compounds may be used in vivo to repair axonal severance much more rapidly than ever occurs via various mechanisms evolved by different organisms. Supported by NSF grants BNS 77-27678 and 80-22248 and NIH grant NS-17275.

221.5 MOLECULAR CHANGES IN REGENERATING RETINOTECTAL NERVE TERMINALS. L. I. Benowitz and K. Padda*. Dept. of Psychiatry, Harvard Medical School, McLean Hospital, Belmont, MA 02178, and Harvard College.

During the regeneration of the optic nerve in goldfish, the labeling spectrum of proteins in the rapid phase of axonal transport shifts radically from that seen in the intact state (Benowitz, Shashoua & Yoon, 1981, J. Neurosci. 1:300-307). The rapid phase of transport includes material which becomes incorporated into the developing nerve terminals, and might be expected to include proteins involved in axonal guidance, target recognition and synaptogenesis. In our previous studies, double-isotope labeling and 1-dimensional gel separation methods were used to contrast the protein labeling patterns of intact and regenerating optic nerves. More recently, we have used a modification of O'Farrell's two-dimensional procedure to be able to examine the metabolic shifts for individual molecular species. Differentially-labeled proteins from intact and regenerating optic nerves were co-separated first by isoelectric focusing, then by molecular weight on SDS-polyacrylamide slab gels. Labeled spots on the gels, identified by fluorography, were cut out and counted for [^{3}H] and [^{14}C] to measure the synthetic activity of proteins in the intact and regenerating sides, respectively. The labeling of a 44,000 dalton species with a pI of 4.3 was found to increase 50-fold during regeneration, while 5- to 10-fold increases were seen for proteins of 210,000 daltons (pI 5.3) and 24,000 (pI 5.7). Major decreases in labeling were also observed, particularly for several high molecular weight proteins. Using subcellular fractionation methods to separate various components of the optic nerve terminals in the tectum, the greatest overall labeling increases during regeneration appeared at the 0.6/0.8 and 0.8/1.0 M sucrose interfaces when a lysed P_2 pellet (17,000 x g ppt.) from tectal homogenates was separated on a discontinuous sucrose density gradient (53,000 x g, 2 h). Analyses of these fractions on gels showed that the same protein changes which had been found in the optic nerve also appear in the nerve terminal membranes. Thus, these proteins may be considered as potential candidates for mediating cell-cell interactions during development. Nearly identical results have been reported in the regenerating frog optic pathway and in the developing rabbit visual system (Skene & Willard, 1981, J. Cell Biol. 89:86-95, 96-103; J. Neurosci. 1:419-426). Current studies using lectin-affinity chromatography indicate that overall, glycoproteins containing α-D methyl mannoside, glc-NAc, sialic acid or galactose are not being turned on in regeneration over and above the overall protein synthetic changes. Supported by NINCDS grants NS 14674, NS 16943, and by a Fellowship from the Alfred P. Sloan Foundation.

221.6 EMBRYONIC CNS TISSUE IMPLANTED INTO ADULT SPINAL CORDS H. Nornes, A. Björklund* and U. Stenevi*. Dept. of Anatomy, Colorado State University, Ft. Collins, CO 80523, and Dept. of Histology, University of Lund, Sweden.

Embryonic CNS tissue was implanted into adult spinal cords of rats to replace missing supraspinal systems, or to make a tissue bridge for the regeneration of host spinal cord axons across a site of injury or transection.

In the first type of experiment, the supraspinal noradrenaline (NA) system was lesioned at level C_2 with bilateral injections of 6 hydroxydopamine (3μg in 2μl/injection). Embryonic NA tissue from the brain stem (locus coeruleus) was then implanted into the NA denervated cords. The donor tissue was dissected from rat fetuses with crown-rump lengths (CRL) of 14-24 mm (embryonic days 15-17) and implanted into subpial cavities in the dorsolateral aspect of level T_{11} in adult female rats (180-200 g.). Following a 3-4 month survival time, the implantation sites were analyzed by Falck-Hillarp histofluorescent methods. Tissue union formed between the embryonic implants and host tissues with little or no cavitation. Noradrenaline axons from the implants crossed the tissue junctions and grew up to 10-12 mm in the grey matter of the hosts.

In the second type of experiment, complete subpial transections were made in the lower thoracic regions of adult female rats (180-200 g.). Pieces of embryonic spinal cord (CRL 10-16 mm), brain stem (CRL 7-8 mm), or hippocampus (CRL 16-20 mm) were implanted into the 1-2 mm subpial gaps in the spinal cords. Following a 3-4 month survival, a fluorescent dye (propidium iodide or true blue, 0.5μL, 5% in saline) was injected into the distal stumps of the spinal cords 2-15 mm from the site of the implant. The host animals were finally processed by Falck-Hillarp histofluorescence methods 5-7 days post injection. Tissue union formed between the hosts and transplants, and in some cases, fluorescent dye had been transported retrogradely from the distal stump into cell bodies in the transplant. In these same animals, NA axons had regenerated from the rostral stump of the cord into the transplant.

These experiments show that embryonic CNS tissue survives when placed into subpial cavities or complete transections of adult spinal cords of rats; further, axons from the transplants grow into the gray matter of the spinal cord and axons from the host regenerate into the transplant to reconstruct a potential relay. (Supported by Paralyzed Veterans of America Fellowship NBR-101, and Swedish [illegible] grant 04X-3874).

221.7 EFFECTS OF NERVE GROWTH FACTOR AND ITS ANTISERUM ON NEURITE OUTGROWTH FROM GOLDFISH RETINAL EXPLANTS. James E. Turner, Martin Schwab and Hans Thoenen. Dept. of Neurochemistry, Max Planck Institute for Psychiatry, Martinsreid, West Germany.

Our previous in vivo studies have strongly suggested that the goldfish visual system is dependent in part on nerve growth factor (NGF) for a successful regenerative response to axotomy (Turner, J.E. et al., Brain Res., 197:319, 1980). This presentation compliments our earlier in vivo work and reports that NGF stimulates neurite outgrowth from goldfish retinal explants and that the antiserum inhibits this process.

Goldfish retinal explants, whose ganglion cells were primed in vivo by an optic nerve crush of varying periods prior to culture (ie, post crush interval) were found to respond to low nanogram levels of NGF (1-5 ng/ml). This in vitro response was dose dependent, specific for NGF and could be reduced by 80% with NGF antiserum treatment. The magnitude and sensitivity of the NGF response was dependent on the post crush interval. Without a prior crush there was no NGF response unless explants remained in culture 1-2 weeks before treatment. NGF elicited the greatest increase in neurite outgrowth when administered to explants with a 7 day post crush interval (ie, 7 DPA). With increasing post crush intervals (ie, 14 DPA) NGF demonstrated a decreased capacity to enhance neurite outgrowth until by 35 DPA no response could be elicited.

Dr. Turner is the recipient of an NIH Research Career Development Award. Dr. Turner's present address is the Dept. of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, N. C. 27103.

221.8 CORTICOSPINAL TRACT (CST) PLASTICITY IN THE EARLY POSTNATAL RAT. D.R. Bernstein and D.J. Stelzner, Dept. of Anatomy, SUNY Upstate Medical Center, Syracuse, New York 13210.

Animals received midthoracic spinal cord (T_8-T_{10}) "over-hemisection," including right hemicord and left dorsal funiculus (DF), at birth (N=13) or 21 dpn (N=14). In a second experiment, the right sensorimotor cortex (SMC) was ablated at the same time the midthoracic lesion was made at birth (N=6), 6 (N=3) or 12 dpn (N=7). All operates survived 3-12 mo. prior to stereotaxic unilateral ^{3}H-proline injection of either, or the intact, SMC. Similarly injected adult rats (N=6) served as controls. After 48 hrs., rats were sacrificed and the brain and spinal cord examined using standard autoradiographic techniques. In control rats, injections labeled the contralateral CST primarily in the DF, and sparsely in the dorsal lateral funiculus (dLF) and upper central gray.

Since the CST develops postnatally, spinal lesion at birth and 6 dpn severs the pathway through which most CST axons will traverse at a later stage, but at 12 and 21 dpn, CST axons are also cut. Following injection of the appropriate SMC, the right or left CST was studied. In neonatal operates, the left CST bypassed its severed pathway by growing through the remaining cord. The right CST also grew through the remaining tissue, but only in the double lesion neonatal and 6 dpn operates where growing left CST axons were absent. The misrouted axons were found only in the dLF and upper central gray, normal CST positions, and terminated bilaterally but to correct CST sites (Neurosci. Abst. 6: 683).

In 12 and 21 dpn operates, CST axons severed by the spinal lesion did not regenerate. Within 3-4 mm rostral to the lesion site, fibers sprouted to include nonspecific areas, especially near the scar border. Tightly-packed label concentrations, av. 8.5 μm diam., similar in size and location to reactive ends of cut axons (Anat. Rec. 193: 483), were common rostral to the lesion only in 21 dpn operates. Spared CST axons in the left dLF were more heavily labeled than normal and there was evidence of both collateral and terminal sprouting in the zone caudal to the lesion site. Evidence of labeled CST axons was usually not detectable in lumbar spinal cord.

Our data show that the availability of an intact matrix allows neogenic CST axons to grow around a lesion which destroyed their primary pathway. Growth is enhanced by CST axons being "channeled" into secondary CST routes and is limited by an interaction with opposite side CST axons. On the other hand, by 12 dpn there is axonal sprouting of the spared CST axons, but only regenerative sprouting of cut CST axons near the lesion site. (NS Grant 14096)

221.9 ANALYSIS OF 4S RNA IN REGENERATING OPTIC NERVES OF GOLDFISH. N.A. Ingoglia, Dept. of Physiology and Neurosciences, CMDNJ-New Jersey Medical School, Newark, NJ 07103

Previous experiments have demonstrated that 4S RNA is transported axonally during the reconnection period of optic nerve regeneration in goldfish (Ingoglia, Science, 206:73, 1979). The present experiments were performed to analyze further the characteristics of the RNA undergoing axonal transport.

In the first experiments, ^{3}H-uridine was injected into both eyes of fish 10 days after the right optic nerves were crushed. Fish were sacrificed 2, 3 or 5 days later and radioactivity in the normal and regenerating nerve tract complexes were analyzed for TCA soluble and insoluble radioactivity. Results indicated a several-fold increase in radioactivity in both fractions in regenerating nerves. In other experiments, the nature of the RNA present 2 days p.i. was determined by extracting nerves in cold phenol and fractionating the RNA by polyacrylamide gel electrophoresis (PAGE). Approximately 40% of the RNA in regenerating nerves was present as 4S RNA, whereas only 20% was present as 4S RNA in normal nerves, indicating that 4S RNA is transported axonally prior to reconnection of regenerating optic axons. In other experiments ^{3}H-uridine was injected into both eyes of fish 18 days (near the time of reconnection) after bilateral optic nerve crush and fish were sacrificed at various times up to 180 days p.i. ^{3}H-RNA was extracted from 24 pooled tecta and fractionated by PAGE. 70% of the ^{3}H-RNA is present as 4S RNA 12 days p.i., and 60 days p.i. this value is still approximately 50%. When nerves were cut 36 days p.i. (54 days post crush) and allowed to degenerate for 6 days before determining tectal ^{3}H-RNA, the majority of the ^{3}H-4S RNA was lost from the tectum indicating significant amounts of axonally transported 4S RNA are not transferred out of the axon to surrounding cells. In other experiments the time of sacrifice after injection was held constant and the time of injection after nerve crush was varied. Analysis of tectal ^{3}H-RNA showed that the major period of axonal transport of ^{3}H-4S RNA was in the early stages of regeneration. Further analysis of the data suggests a long 1/2 life for intra-axonal 4S RNA.

In conclusion, these experiments show that 4S RNA: 1) is present in growing axons prior to reconnection; 2) is transported maximally during early stages of regeneration; 3) remains intra-axonal following transport; and 4) turns over at a slow rate following transport.

221.10 FAILURE OF AXON FASCICULATION: A CLUE TO CNS REGENERATIVE FAILURE? S. Goldberg and B. Frank*. Department of Anatomy, University of Miami School of Medicine, Miami, Florida 33101.

We produced lesions in retinas of regenerating (newt, goldfish) and non-regenerating (mouse, rat, chick, rabbit) species and noted, via silver-stained flat mounts, the qualities of axonal sprouting from severed optic axons in the ganglion cell fiber layer of the retina.

In unoperated controls, all retinas had a bundled (fascicular) pattern of optic axons converging upon the optic nerve. Lesions in the regenerating species resulted in sprouts that formed fascicles as they grew. A fascicular pattern of growth has recently also been noted (Bohn and Reier, '80) following lesions in the optic nerve of Xenopus, another animal which regenerates.

Lesions in non-regenerating animals resulted in sprouts that had no tendency to adhere to one another as fascicles. Lack of fasciculation was also noted among axons that succeeded in bypassing the lesion site. On the other hand, adult mouse sciatic nerve axons (which do regenerate) formed fascicles when lesioned and diverted within the scarred region.

The absence of fasciculation among non-regenerating axons could reflect a lack of extracellular growing space in the CNS of these animals (see Krayanek and Goldberg, these meetings) or a deficiency in the mechanism of adhesive specificity between neuron and environment.

221.11 REGENERATIVE AXONAL ELONGATION IN THE ADULT MAMMALIAN CNS. S. David* and A.J. Aguayo. (SPON: M. Rasminsky). The Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Canada.

Using a new experimental technique that permits axonal growth to be directed into or from specific regions of the CNS, we have examined whether spinal and medullary neurons in the adult mammalian CNS are capable of extended axonal elongation. In a series of adult Sprague-Dawley rats and C57BL/6J mice, autologous segments of sciatic nerve (3.5 cms in rats and 2 cms in mice) were used as bridges to connect the medulla oblongata to the lower cervical or upper thoracic spinal cord. These bridging nerve grafts were placed extraspinally with one end inserted into the dorsolateral spinal cord and the other end inserted into the dorsolateral medulla. The spinal cord between these two levels was left intact. The animals survived without apparent neurologic deficits.

Grafts examined by light (LM) and electron microscopy (EM) 1-7½ months after surgery were well innervated by axons ensheathed by Schwann cells. The origin of these axons was determined by transecting the regenerated grafts and applying horseradish peroxidase (HRP) to the cut ends. LM of tetramethylbenzidine and H_2O_2 reacted sections showed retrogradely labelled neurons in the medulla and spinal cord. These neurons were located near the sites of insertion of the graft and their axons had elongated a maximum of 3 cms in rats and 1.5 cms in mice. The terminal course of axons in the graft was examined by anterogradely labelling the fibers with HRP. Using LM-HRP, anterogradely labelled fibers penetrated the CNS for approximately 2 mm. With EM-HRP (tissue reacted with diaminobenzidine and H_2O_2), these fibers were found to be ensheathed by CNS glia along their terminal course.

These results indicate that PNS bridges become innervated by axons from spinal and medullary neurons and that in this altered glial environment these CNS neurons are capable of marked axonal elongation. In addition, axons from the graft penetrate the CNS for short distances, where they are ensheathed by CNS glia.

221.12 REGENERATION OF OPTIC AND PERIPHERAL AXONS IN THE FROG OPTIC TECTUM. Elliot I. Kaplan and Carmine D. Clemente. Brain Research Institute, UCLA Sch. Med., Los Angeles, CA. 90024.

Previous reports from this laboratory (Neurosci. Abstr. 5:679, 1979; Anat. Rec. 196:92A, 1980) have described the successful regeneration of peripheral axons into the optic tectum of Rana pipiens. Aberrant axons derived from surface grafts of the mandibular nerve were found to invade the entire rostro-caudal extent of the dorsal tectum, primarily within superficial layers 8 and 9. Since these layers also play host to the retinotectal projection, it was of interest to ask: (1)does optic denervation have an effect upon the aberrant fiber pattern? (2)how does the regeneration pattern of aberrant axons compare with that of optic fibers? (3)how might optic and peripheral axons simultaneously regenerate into the same target tectum?

To answer these questions, 23 nerve-grafted and 6 sham operated frogs received a contralateral optic nerve crush or retinal enucleation. These lesions were made either before or after (-2 to +7 weeks) the graft/sham surgery. Following a graft survival of 6-67 weeks, regenerating peripheral or optic nerves were labelled with horseradish peroxidase. The present results are based on light microscopic analyses of 40 μ tectal sections treated with tetramethyl benzidine or Hanker-Yates reagent.

Removal of the optic input to the host tectum produced no significant effect upon the rostro-caudal or medio-lateral extent of aberrant growth, but it did influence the laminar distribution of peripheral axons. If the retinotectal projection underwent degeneration before or during the active phase of aberrant ingrowth, peripheral fibers were able to assume a wider field in layer 9 than if the optic fibers were left intact. However, peripheral axons which had already entered and established themselves in a fully innervated host were unaffected by subsequent optic lesions. These findings suggest that the intact optic fiber layers may serve as mechanical constraints for growing peripheral axons. The denervation effect, then, would reflect a breakdown of such "barriers".

Comparisons between optic and peripheral regeneration patterns revealed a number of disparities. While optic fibers formed many fascicles and reestablished discernible layers in the tectum, aberrant axons failed to form organized bundles or layers. Most peripheral fibers grew singly and in a tortuous manner, occasionally in close association with blood vessels and myelinated axons of the host. Even when both fiber projections regenerated concurrently, they each displayed their respective growth patterns. Thus, both types of axon are able to grow and survive in the same CNS environment, but they do so differently and independently of one another.

221.13 EVIDENCE THAT TRANSFER RNA IS TRANSPORTED AXONALLY IN REGENERATING OPTIC AXONS OF GOLDFISH. M. Zanakis*, G. Chakraborty* and N. Ingoglia (SPON: F.P.J. Diecke), Depts. of Physiol. and Neurosci., CMDNJ-New Jersey Medical School, Newark, NJ 07103

Experiments were designed to determine if 4S RNA, which is transported axonally in regenerating optic axons of goldfish, is transfer RNA.

Eighteen days following bilateral optic nerve crushes, ^{3}H-uridine was injected into both eyes of 12 fish (labe]ing axonal and perikaryal RNA in the tectum). Four days later, ^{14}C-uridine was injected intracranially (labeling only perikaryal RNA in the tectum). Two days later, fish were sacrificed, left and right tecta were removed and pooled, and RNA was extracted with phenol and precipitated by adding 2.5 volumes of ethanol. 4S RNA was obtained by DEAE cellulose chromatography. The individual transfer RNA species were then fractionated either by methylated albumin kieselguhr (MAK) or BD cellulose chromatography. Optical density profiles of labeled 4S RNA were similar to commercially obtained E. coli tRNA and to profiles already described in the literature. Radioactivity profiles for both ^{3}H and ^{14}C followed O.D. profiles, and comparisons of ^{3}H to ^{14}C showed no significant differences between the two, within the experimental error of this study. Since at least half of the ^{3}H-4S RNA is intra-axonal (Ingoglia, 1981, Neurosci. Abstr.) and all of the ^{3}H-4S RNA has the same chromatographic mobility as the perikaryal 4S RNA as well as the E. coli tRNA, we conclude that intra-axonal 4S RNA is likely to be tRNA. Furthermore, since there was no difference in the level of labeling of various tRNA species in regenerating axons compared with tRNAs in surrounding cells, we suggest that the tRNA in regenerating axons is composed of a variety of tRNA species and not a unique species of tRNA.

Since ribosomes are not present in axons, it is unlikely that axonal tRNA is participating in classical protein synthesis. However, it might be participating in non-ribosomal, post-translational protein modification as described by Soffer (Adv. Enzymol., 1974, 40:91-97). If this is the case, then the enzyme responsible for this reaction, peptidyl transferase, should be present in these axons. Preliminary data indicate the presence of this enzyme in rat and goldfish brain, in rat sciatic nerves and in regenerating optic nerves and tracts of goldfish. Further experiments are planned to determine if this enzyme is axonally transported.

(Supported by grant EI 02887 from NIH.)

221.14 NERVE GROWTH FACTOR PROMOTES GOLDFISH OPTIC NERVE REGENERATION. Henry K. Yip* and Bernice Grafstein. Dept. of Physiology, Cornell Univ. Med. Col., New York, NY 10021.

Previous studies have shown that NGF enhances the effects of axotomy on retinal ganglion cells in both the newt and in the goldfish (Turner, et al., Brain Res., 171:197, 1979; Brain Res., 197:319, 1980). These studies have demonstrated that following NGF treatment, there is a marked increase in perikaryal size and an acceleration of morphological changes. Cultured retinal ganglion cells pretreated with NGF also showed enhanced neurite outgrowth.

In the present study, we have further examined the role of NGF in promoting regeneration of goldfish optic nerve. NGF was administered by intraocular injection or by local application to the lesion site with silastic cuffs. The effects of NGF on the retinal ganglion cells were evaluated behaviorally and morphologically. The behavioral measure was the mean recovery time for the startle reaction to a sudden increase in illumination. Measurements of silver-stained regenerating axons were made by light microscopy. To determine whether the enhanced outgrowth was accompanied by changes in the cell body, we also examined the effects of NGF on nucleolar incidence and cell size.

Both β-NGF and 7S-NGF were effective in enhancing axonal outgrowth following optic nerve crush. The time for recovery of visual function was decreased by 20-40% as a result of NGF treatment. The number of regenerating axons and the mean axonal length were also significantly increased. The size of the retinal ganglion cell bodies and nucleolar incidence, however, did not change up to 14 days after the lesion. These results suggest that the outgrowth-promoting effect of NGF does not require a concomitant increase in RNA and protein synthesis above that which normally occurs during regeneration.

The effects produced by a single intraocular injection given at the time of the lesion were not improved by giving repeated injections throughout the experiment. The effect of NGF appeared to be dose-dependent, since doses smaller than 900 BU were not effective.

In a similar experiment, we have studied the effects of bovine brain gangliosides on regenerating goldfish retinal ganglion cells. Preliminary results indicate that gangliosides also have a promoting effect on axonal outgrowth.

Supported by NINCDS Grants NS-09015 and NS-14967 to BG and a Nat. Spinal Cord Injury Found. Fellowship to H.K.Y.

221.15 GLIAL CELL FACTOR(S) AFFECT REGENERATING GOLDFISH RETINA, IN VITRO. M. Schwartz, Y. Mizrachi*, A. Shahar*†and Y. Kimhi*. Dept. of Neurobiology, The Weizmann Inst. of Sci., Rehovot, Israel. Dept. of Virology, Israel Inst. for Biol.Res., Ness-Ziona, Israel.†

The regenerative capacity of the goldfish visual system is exhibited, in vitro, by the extensive outgrowth from retinal explants in the presence of 10% fetal calf serum (FCS), provided that the optic nerve had been crushed 10-14 days prior.

We have shown that neurotrophic factor in the goldfish brain can induce and maintain neuritic outgrowth from the explanted regenerating retina (Schwartz et al., submitted). The source of the neurotrophic factor(s) in the brain is not clear as yet.

As indicated in the present work, cloned rat glioma cells, in culture, release neurotrophic molecules that replace the ultimate need for FCS in the induction and maintenance of neurites from retinal explants. Light and scanning electron microscopy studies indicate that the morphology and the growth pattern of the neurites growing out of the goldfish regenerating retina in presence of glial factor(s) is different from that observed in FCS-containing media: The neurites in the former case are longer, have a lower tendency to fasciculate and show high density of varicosities. This observation may indicate that the glial conditioned medium does not provide all of the factor(s) participating either in the optic nerve regeneration in vivo or in the induction of outgrowth in vitro.

Preliminary results suggest that the active component is a protein of about 5.5S, that can be partially purified on a DEAE column. Addition of antibodies specific to mouse nerve growth factor (NGF) does not affect the growth induced by the glial factor.

The present work further supports the hypothesis that non-neuronal cells can supply their own neurons with trophic stimuli during development and during regeneration.

221.16 AXONAL CHANGES IN THE RETINAL STUMP OF THE TRANSECTED OPTIC NERVE. P. M. Richardson, V.M.K. Issa*, S. Shemie*, Dept. of Neurosurgery, McGill University & Neurosciences Unit, Montreal General Hospital.

The retinal stumps of rat optic nerves were examined by light and electron microscopy from one to 32 weeks after the nerves were cut intracranially. By one week, a zone of necrosis, perhaps due to infarction, had developed, extending from the cut end of the nerve approximately one half way to the globe but sparing the peripheral region of the nerve. During subsequent progressive degeneration, changes became evident sequentially in the intracranial portion of the nerve, the orbital segment, and finally the retina. At four weeks, the population of myelinated axons in the optic nerve was reduced to 10% normal; by 32 weeks, less than 1% remained. Ganglion cells in the periphery of the retina (identified by retrograde labelling with horseradish peroxidase) appeared to degenerate more slowly than those close to the optic disc. Although meagre compared to other fibre systems, some evidence of axonal outgrowth was seen. Single unmyelinated axons were scattered through the optic nerve stumps at all times after transection. Newly formed structures resembling synapses were found near the pial surface in some nerves.

Peripheral nerve grafts and cross-unions did not appear to enhance either the survival or regrowth of retinofugal fibres. Despite adverse local tissue conditions, some grafted cells survived and some optic nerve axons could be traced with radioautography to the tips of cut nerves. However, none of them have been seen yet to extend into a graft or become ensheathed by Schwann cells. The lack of response of optic nerve axons to peripheral nerve grafts may be due to intrinsic neuronal properties, poor local tissue perfusion or both.

221.17 EFFECTS OF LESIONS OF THE NEONATAL STRIATUM ON THE ORGANIZATION OF MIDBRAIN DOPAMINERGIC SYSTEMS. C.B. Jaeger, T.H Joh, and D.J. Reis. Lab of Neurobiology. Cornell Univ. Med. Coll. New York, NY 10021.

Unilateral lesions were placed in the corpus striatum (CS) in newborn rats to determine whether (a) the topographic organization of the nigrostriatal dopaminergic (DA) projection characteristic of adult rats (Moore & Bloom, Ann. Rev. of Neurosci. 2:113,1979) is established at a time when the striatum is still undergoing morphological and functional maturation; (b) neonatal injury would result in any reorganization of the pathway. The CS was ablated unilaterally by gentle aspiration in newborn rats, 6-24h of age, anesthetized with ether. At various times thereafter the distribution and connectivity of the mesencephalic DA neurons was studied by immunoctyochemical localization of tyrosine hydroxylase (TH), which catalyses the biosynthesis of DA, histochemical localization of acetylcholinesterase (ACHE) and retrograde transport of horseradish peroxidase (HRP). Lesions of the CS were varied. Complete ablation of the CS and ventral forebrain resulted in a unilateral loss of the majority of DA neurons in A9, A10 and A8. However, even after extensive unilateral lesions of the forebrain all of midbrain DA neurons did not disappear. Removal of the dorsolateral CS affected mostly A9 neurons. Lesions of the tail had no appreciable effect on DA neurons in the mesencephalon. ACHE, normally present in the neuropil of the zona compacta of the substantia nigra and ventral tegmentum of the midbrain, was strikingly absent in A9 and A10 regions coincident with loss of DA neurons. This observation indicates a close correspondence between neurons synthesizing ACHE and TH. HRP was injected into the unlesioned striatum of neonatally injured rats when they were adults. There was a small projection to the contralateral substantia nigra and mesencephalic tegmentum. Some of the retrogradely labelled neurons occupied similar positions as surviving DA neurons. However, HRP injected into unlesioned controls demonstrated a comparable cross nigrostriatal pathway of similar density. We conclude: (a) The topographic organization of the nigrostriatal projection is established prior to maturation of the target. (b) Interruption of this pathway in neonatal animals does not lead to evident reorganization of the remaining nigrostriatal system nor in hypertrophy, of a crossed collateral nigrostriatal pathway. (Supported by NIH grants HL 07379 and N.S.O. 3346).

221.18 AUTORADIOGRAPHIC TRACING OF TRITIUM-LABELLED CULTURED PERIPHERAL NON-NEURONAL CELLS IMPLANTED IN THE TRANSECTED CAT SPINAL CORD. J.R. Wrathall*, M.R. Braford and C.C. Kao*. Departments of Anatomy and Neurosurgery Georgetown University and Veterans Administration Medical Center, Washington, D.C. 20007.

Peripheral non-neuronal cells appear to provide support for regenerating PNS axons. Results from implantation of peripheral nerve segments into the spinal cord indicate that PNS non-neuronal cells may also facilitate regeneration of axons in the CNS. In order to further study the behavior of peripheral non-neuronal cells in the CNS, we prepared autologous cultures of such cells and labelled them in vitro with ^{3}H-thymidine so that they could be traced by autoradiography after implantation into the CNS. Each adult female cat was anesthetized and a segment of sciatic nerve removed, dissociated, and used to initiate cultures of autologous non-neuronal cells enriched in Schwann-like cells (J. Cell Biol. 83:97a, 1979). When sufficient cells had been generated, the cultures were exposed to ^{3}H-thymidine (0.33μCi/ml medium) for 72 hours, harvested, and a cell pellet ($\sim$2 x 10^{7}v.c.) taken to surgery. The cat was re anesthetized, a laminectomy performed, the dura opened and a "slit" transection performed through a small longitudinal incision in the pia-arachnoid at T10. In this microneurosurgical procedure, the spinal cord is completely transected but only about a 1mm gap is produced between the two spinal cord stumps. The labelled cells were then implanted to completely fill the gap and the wound closed in layers. In one group of cats, the exposed spinal cord was bathed in hypothermic saline ($<4^{\circ}$C) for 2 hours prior to and 1 hour post-transection, before the cells were implanted. Three or 7 days post-operatively the cats were perfused with saline and fixative and the cord processed for autoradiography. By 3 days after implantation the labelled PNS non-neuronal cells were observed to have penetrated 2-3 mm into the spinal cord stumps and were observed in areas of CNS axon terminals. Pre-implantation hypothermia had no observable effect on this rapid penetration by the peripheral cells into the cord but did reduce the later degeneration and cavitation within the spinal cord stumps. Thus, the cultured PNS non-neuronal cells appeared to rapidly move into the spinal cord and reach positions where interaction with spinal cord axons would be possible. (Supported by The Veterans Admin. & NINCDS NS 14413)

221.19 BEHAVIORAL ANALYSIS of SPINAL CORD REGENERATION in the SEA LAMPREY. Joseph Ayers, Gail A. Carpenter, Scott Currie* and James C. Kinch*. Marine Science Institute, Dept. of Biology and Dept. of Mathematics, Northeastern University, Boston, MA 02115

Recovery from complete transection of the spinal cord has been examined in ammocoete larvae, transforming larvae and fully transformed adults of the sea lamprey, Petromyzon marinus. The present investigation addressed two issues: (1). Do different behaviors recover with different time courses? and (2). How complete is the recovery of behavioral function?

The time course of behavioral recovery was ascertained by scoring animals for the reappearance of four behaviors in addition to forward swimming, including turning, backward crawling, burrowing and aversive withdrawal. Our findings indicate that some behaviors such as burrowing can appear prior to the reappearance of coordinated swimming, while others such as aversive withdrawal recover with even longer time courses. Thus, the processes which underly these different recoveries appear independent.

In order to assess the normalcy of recovered behaviors, computer algorithms which analyze digitized images from motion pictures (Abstr. Soc. Neurosci., 6: 466) were extended to calculate new movement parameters as well as measures of swimming performance. When compared to normal specimens, recovering transectees typically exhibit significant deficits in several of these parameters. Thus, while the regenerates appear normal in the quality of the behavior there are essential differences in quantitative aspects of the recovered motor output. Supported by an Alfred Sloan Foundation Fellowship and NSF Grant MCS 80-04021.

221.20 EFFECT OF OPTIC NERVE CRUSH ON RETINAL GANGLION CELLS IN HOODED RATS. L. Misantone, K. Barron, M. Gershenbaum*, V. Cipolla*, M. Zanakis* and M. Murray. Departments of Anatomy and Neurology, Phila. College of Osteopathic Med., Philadelphia; Albany Medial College, Albany, N.Y.: The Medical College of Pennsylvania, Philadelphia, PA. 19129

The failure of mammalian central neurons to regenerate after axotomy is a poorly understood phenomenon. One approach to defining the causes is to compare a mammalian central neuron with a successfully regenerating nonmammalian neuron. We compared the reaction to axotomy of non-regenerating retinal neurons (rat) with a regenerating retinal neuron (goldfish). Rat ganglion cells were axotomized by unilaterally crushing the optic nerve intracranially, and the rats were allowed to survive 1-28 days. The intact side served as a control. RNA content of retinal ganglion cells was measured cytophotometrically. Optic nerves were examined proximal and distal to the crush with LM and EM. Axonal transport was assessed in animals in which 25 uCi ^{3}H proline-leucine had been injected intraocularly 3-18 hr before sacrifice.

Cytophotometric examination of ganglion cells showed evidence consistent with a depletion of RNA content and cellular atrophy by 7d p.o. These changes became more pronounced at later times. Concurrently, the axons in the proximal nerve stump showed clear morphological signs of degeneration by 7d p.o. which becomes well defined by 14d. By 14d there was a significant loss of axons, a marked increase in glial cytoplasm and a noticable reduction in optic nerve diameter. By 28d few recognizably normal axons are observed. Distal to the crush degenerative changes are apparent within 7d p.o. and occur in the large diameter axons first. Reactive gliosis is well advanced by 14d. Transport studies over 1-28d p.o. demonstrate that the intraocularly labeled protein accumulates at the crush site, suggesting that axonal transport continues in proximal axons up to 28d p.o. In contrast to the rat, goldfish retinal ganglion cells show cellular hypertrophy and increased RNA metabolism after axotomy. There is also an increase in amount of axonally transported material. These changes are early and dramatic components of the regenerative response to axotomy. These events do not appear to occur in the nonregenerating rat optic neurons, although some morphologically normal axons persist for several weeks, and there is an indication that some degree of axonal transport continues.

221.22 AXON REACTION IN TRIGEMINAL NEURONS FOLLOWING MANDIBULAR NERVE GRAFTS TO THE FROG OPTIC TECTUM. Carmine D. Clemente and Elliot L. Kaplan. Brain Research Institute, UCLA Sch. of Med., Los Angeles, CA. 90024.

How does the cell body respond to aberrant regeneration of its axon? In an attempt to answer this question, the following experimental paradigm was used: the proximal stump of a transected mandibular nerve was grafted onto the surface of the optic tectum in adult Rana pipiens. Details of the procedure and of the non-specific peripheral fiber growth within the host tectum have been reported previously (Neurosci. Abstr. 5:679, 1979; Anat. Rec. 196:92A, 1980; this meeting). In the present study, parent neurons in the trigeminal motor (Mot V) and mesencephalic (Mes V) nuclei were analyzed morphometrically and in terms of cell numbers.

In response to nerve graft surgery, there was a dramatic axon reaction in cell bodies of the ipsilateral Mot V and Mes V. This was characterized by a transient increase in nucleolar, nuclear, and somal cross sectional areas, beginning within 1 week post surgery (WPS), peaking by 6 WPS, and gradually returning toward normal levels thereafter (followed for as long as 67 WPS). Although the recovery rates for the two nuclei were similar, Mot V neurons tended to reach their maximal response levels more rapidly than Mes V cells (2 WPS as opposed to 6 WPS). The most severely affected cell component was the nucleolus, which swelled by as much as three times in Mot V and two times in Mes V. At no time was chromatolysis observed. As a matter of fact, during the first 2-3 WPS, cytoplasmic basophilia increased somewhat over control levels.

These changes in neuronal morphology reflect a strong anabolic reaction, one which has a temporal coincidence with the regeneration of grafted axons. Also, the distinctions between Mot V and Mes V suggest that the motoneurons may be better equipped to respond effectively to nerve transection and translocation. However, the more vigorous Mot V response might instead be due to the fact that these neurons are situated closer to the nerve end than are the Mes V cells.

To test whether the nerve graft might provoke a loss of trigeminal neurons, cell counts were carried out from 1 day to 24 WPS. Whereas Mot V cells were maintained at all survival times studied, there was a delayed drop-out of 25-30% of Mes V cells between 12 and 24 WPS. This, taken together with a qualitative estimate of sensory cell loss in the trigeminal ganglion, suggests a greater viability of regenerating motoneurons. Whether the Mot V neurons are permanently stable and therefore correlated with the long term survival of peripheral axons in the host tectum is still under investigation.

221.23 DIMETHYL SULFOXIDE, TRYPSIN AND HYPERBARIC OXYGEN TREATMENTS FOLLOWING SPINAL CORD TRANSECTION IN RATS, J. B. Gelderd, D. E. Bowers, Jr.*, S. F. Deschner*, W. P. Fife*, and D. W. Welch*. Dept. of Anatomy, Coll. of Med. and Dept. of Biology, Coll. of Sci., Texas A&M University, College Station, TX 77843.

A previous study in our laboratory indicated a synergistic therapeutic effect between dimethyl sulfoxide (DMSO) and hyperbaric oxygen (HBO) following spinal cord transection in rats (Gelderd et al., Undersea Biomed. Res., 7:305, 1980). The present study was designed to assess the efficacy of combining trypsin, DMSO and HBO treatments in promoting regeneration and return of function following spinal cord transection.

Sixty, adult, female rats served as experimental animals. Following spinal cord transection at the T-8 vertebral level, animals were separated into groups of 15 each for treatment as follows: Group I received only normal postoperative care required for paraplegic animals; Group II received a 0.5cc subcutaneous injection of 20% DMSO in phosphate buffer (pH 8.0) over the lesion site every 12 hrs for 15 days; Group III received the identical treatments given animals in Group II, with the addition of 0.4mg trypsin included in each injection medium; Group IV received the identical treatments given animals in Group III, in addition to daily HBO treatments of 90 min. duration at 2.82 atmos. absolute. All treatments were initiated within 15 min. following spinal cord transection. Systematic behavioral testing was conducted at 30-day intervals to assess hindlimb function. All animals were sacrificed 180-200 days postlesion by intracardiac perfusion with fixatives. The spinal cords at the lesion sites were removed and processed for either transmission electron microscopy, scanning electron microscopy or light microscopy (Bodian silver stain, Gomori's trichrome).

No return of hindlimb function was observed during the postoperative period in any of the animals. Histological data revealed scar formation at the lesion site with cavitation formation rostral and caudal to the lesion. The rostrocaudal extent of these cavitations varied within and between treatment groups (3mm-11mm), with Group I revealing the most extensive cavitations. The walls of the cavitations were lined by occasional ovoid cells with branching processes. Nerve fibers were seen within the lesion in all animals at the light and electron microscopic levels with ultrastructural data revealing both myelinated and unmyelinated axon profiles. At this time, the origin and termination of these nerve fibers has not been determined. It was concluded that the combined trypsin, DMSO and HBO therapy used in this study did not produce a demonstrable, synergistic, therapeutic effect. Supported by a grant from Paralysis Cure Research.

222.1 TENSION OVERLAP IN SPLIT VENTRAL ROOTS OF SKELETAL MUSCLES OF THE CHRONIC SPINAL CAT. V. R. Edgerton, E. Eldred, L. A. Smith*. Dept. Kinesiology, Anat. and Brain Res. Inst., UCLA, CA. 90024.

In the developing soleus (SOL) of a kitten, the muscle fibers revert to slower contracting fibers of slow-twitch staining profile; during a comparable period the polyinnervation characteristic of the very young kitten gives way to a single anonal innervation of each fiber. Cutting the spinal cord prevents to some degree the conversion of fiber types, whether it also interfers with loss of polyinnervation is not known.

Tests with the tension occlusion method were made on SOL and medial gastrocnemius (MG) muscles of 8 cats cordotomized (C) at 2 or 12 wk and sacrificed at 14 to 18 wk of age. As controls 9 normal (N) kittens of 2 or 12 wk were tested. Other hindlimb muscles were denervated, the SOL and MG were freed of fascia and the tendons connected to a stiff myograph. Ventral roots L_7 and S_1 or portions thereof were placed on two bipolar electrodes so as to yield approximately equal tension responses at L_0 muscle length.

For the SOL no significant overlap of either twitch or tetanic tensions was found in either group of (C) cats, nor in the 12 wk intact kittens. In the MG, overlap was consistently noted in the 2 and 12 wk transected cats, as well as the intact 2 and 12 wk cats. These findings suggest that after cordotomy polyinnervation in the SOL disappears as in normal animals. The detection of MG tension overlap under near isometric conditions, even in the adult animal may be a result of the more, complex pennate arrangement of fibers in this muscle. In any case, in neither muscle did the cord transection appear to affect the picture of tension overlap presented.

222.2 FATIGUE PROPERTIES OF SINGLE MOTOR UNITS IN EXERCISED AND NON-EXERCISED CHRONIC SPINAL CATS. L.A. Smith*, V.R. Edgerton, E. Eldred. Depts. Kinesiology, Anat and Brain Res. Inst., UCLA Los Angeles, CA 90024

Spinalization in the cat results in a reduction in the contraction time (CT) of the soleus (SOL) as well as a conversion to a fast twitch staining profile of its fibers (Edgerton, Neurosci. Abst., 1979). It has also been reported that the alteration in CT was not related to the amount of neuromuscular activity the cat received.

The present study was made to determine the effects of chronic spinalization and exercise on fatigue of single motor units in the SOL and medial gastrocnemius (MG) muscles. Twelve cats were cordotomized at the T_{12} level at either 2 or 12 weeks (wk) of age. Six were exercised on a motor driven treadmill 15 to 20 min/day for 12 to 14 wk post-surgically. Normal animals were also studied as age group controls. Motor units (MU) were identified by the teasing of ventral root filaments.

The measn MU CT for the SOL for the non-exercised (NE), exercised (E) and normal (N) groups was 49 (± 1.901), 50 (± 1.307), and 62 (± 1.815) respectively. The mean values for the MG for the same groups was 37 (± 1.426), 32 (± 0.943) and 36 (± 1.078). Mean fatigue index (FI) values for the MU of the SOL were .89 (± 0.014), 0.84 (± 0.016), and 0.88 (± 0.009) for NE (n=28), E (n=60), and N (n=30). MG mean FI values were 0.39 (± 0.054), 0.30 (± 0.054), and 0.52 (± 0.073).

The figure below contrasts the FI for MU of MG and SOL. The FI of MU in both muscles were not appreciably affected by exercise. The persistence of a high index in the SOL muscle which shows a shortened CT and altered histochemical profile, supports the conclusion that the conversion of fibers is from SO to FOG. The properties responsible for changing the CT apparently are not the same as those that regulate the fatigue properties.

222.3 THE MYOELECTRIC SIGNAL VERSUS FORCE RELATIONSHIP IN DIFFERENT HUMAN MUSCLES. J. H. Lawrence*, C. J. De Luca, A. P. Xenakis* and R. S. LeFever* (SPON: G. Bilotto). Neuro Muscular Research Lab., Children's Hospital Medical Center, Harvard Medical School, Boston, MA 02115.

The present study has been initiated to investigate if the normalized surface myoelectric (ME) signal vs. normalized force relationship varies in different human muscles and if it is dependent on exercise. The data were obtained from a carefully controlled set of experiments which involved the biceps, deltoid and first dorsal interosseous muscles of three pianists, four long-distance swimmers, three powerlifters and six normals. This study presupposed that if type of training influences the ME signal - force relationship or if this relationship is muscle-dependent then this would be revealed through the ten "specialists". These specialists, chosen from among the world's best, exhibit varying degrees of fine motor control, endurance training and power training in different muscles. A total of 400 isometric linearly force-varying contractions peaking at either 40% or 80% of the maximal voluntary contraction (MVC) level were processed, grouped and averaged. The rms amplitude of the ME signal was smoothed with a Hamming window filter. The resulting data were normalized and plotted as a function of normalized MVC.

The results indicate that for the group-averaged data the shape of the ME signal - force curve is primarily determined by the muscle under investigation and is generally independent of the subject group and the force rate. Whereas this relationship is linear for the first dorsal interosseous ($r>0.98$), it is nonlinear for the biceps and deltoid. Paired t-tests revealed a significant ($p<.0001$) difference between these three curves at 20%, 40% and 60% of MVC. A large intersubject variation was noticed for the same muscle. The ME signal - force relationship may be associated with the different anatomical architecture, function and motor unit control properties of each muscle [R.S. LeFever and C.J. De Luca, Abstracts of the Soc. for Neuroscience, 1979].

(Supported in part by the Liberty Mutual Insurance Co. and the Insurance Institute for Highway Safety.)

222.4 POSSIBLE FIBER TYPING BY ANALYSIS OF SURFACE EMG SIGNALS. R.G. Rosenthal,* M.A. Sabbahi, R. Merletti* and C.J. De Luca. NeuroMuscular Research Laboratory, Children's Hospital Medical Center, Boston, MA., Liberty Mutual Research Center, Hopkinton, MA., and Politecnico di Torino, Italy.

Fast twitch muscle fibers have long been known to have higher conduction velocities than slow twitch muscle fibers. Furthermore, intramuscular conduction velocity has previously been reported to correlate with the median frequency of the EMG signal. This is possibly due to the association between the spectral compression of the EMG signal and the change in the muscle pH during a contraction. The median frequency of the EMG signal and the pH of the muscle have been observed to decline during a sustained contraction [F.B. Stulen, Ph.D. Thesis, M.I.T., 1980]. Yet, there have been no reports of the correlation between the surface EMG signal and the fiber composition of a muscle.

In this study, surface electrodes were placed on various muscles of 12 normal male subjects. They performed isometric contractions equivalent to 20%, 40%, 80% and 100% of their maximal voluntary contraction level. EMG signals were monitored from contractions of the soleus, medial gastrocnemius, vastus medialis, vastus lateralis and first dorsal interosseous muscles. The median frequency of the signals obtained was calculated on-line and in real-time using a newly developed analog Muscle Fatigue Monitor (MFM). The percentage changes of the initial median frequency of the EMG signal measured at the beginning of the muscle contraction was obtained at the various force levels.

Our preliminary results indicate that at higher levels of contraction, the percentage change of the initial median frequency was minimal in the soleus muscle, whereas in the other muscles, it gradually increased in direct correlation with the increased percentage of fast twitch fibers within these muscles.

Such a non-invasive technique for the detection of muscle fiber predominance in a given muscle has potential values in both physiological and clinical settings. (Supported in part by Liberty Mutual Insurance Co. and NIHR, grant #23-P-55854.)

222.5 ISOMETRIC TORQUE PRODUCED BY THE CAT HAMSTRINGS MUSCLE ABOUT THE ANKLE AS A FUNCTION OF HINDLIMB POSITION. Roger W. Wicke* and Felix E. Zajac (SPON: C.C. Boylls). Rehab. Eng. Res. Dev. Ctr.(153), VA Med. Ctr., Palo Alto, CA 94304.

Cuff electrodes were implanted around semitendinosus (ST) and posterior biceps (PB) muscle nerves in two cats anesthetized with pentobarbital. Each cat was placed in a frame which rigidly restrained the pelvis. To measure torque about the ankle, a pin through the tibia was rigidly fixed to the frame, and a force transducer was placed around the foot. The moment arm was measured from the force transducer to the ankle joint. Isometric torque was recorded during maximal simultaneous stimulation of the electrodes for a range of combinations of hip, knee, and ankle angles.

Torque is highly dependent on all joint angles. Maximum torques are produced at the physiological extremes of knee extension and ankle dorsiflexion, and torque approaches zero at opposite extremes. Active torque of up to 20 kg-cm about the ankle can be produced. This indicates that the hamstrings must be considered as a three joint muscle group in the cat. After the torque measurements had been obtained from the intact hindlimb, active torque was once again measured at *various stages of dissection of skin and fascia.* Almost all of the torque was produced by transmission of PB and ST force through their tendinous insertion on the calcaneus via the interconnecting fascial sheath. After additional dissection to isolate soleus muscle and nerve, we measured ankle torque generated by maximal stimulation of soleus at all ankle joint angles. Hamstrings can produce up to three times greater torque than soleus for certain hindlimb positions.

In the range of hindlimb positions occurring during the E2 phase of locomotion in the cat, the hamstrings are capable of producing 5 to 8 kg-cm of torque at the ankle in comparison with 6 to 7.5 kg-cm produced by soleus. The fact that ST and PB EMG activity occurs in E1 (Rasmussen et al, J. Morph. 155:253, 1978) suggests that ankle torque contributed by the hamstrings may be an important component during E2.

Supported in part by NIH grant NS 11971.

222.6 MECHANICAL INTERACTIONS OF FAST-TWITCH AND SLOW-TWITCH MUSCLES DURING PLANTAR FLEXION OF VARYING SPEEDS. R. S. Hutton and R. M. Enoka. Dept. of Kinesiology, Univ. of Washington, Seattle, WA 98195

It has been proposed that recurrent inhibition, which is presumed to act more powerfully on tonic than on phasic alpha motoneurons (Cullheim & Kellerth, J. Physiol., 281:301, 1978; Eccles et al., J. Physiol., 159:479, 1961), and selective recruitment order of synergistic motoneurons (Kanda et al., Exp. Brain Res., 29:57, 1977; Smith et al., J. Neurophysiol., 43:612, 1980) may function to prevent slowly contracting muscles from impeding rapid contraction. The possibility that such mechanical interactions do occur was investigated kinematically by analysis of plantar flexion in rat hind limb (Sprague-Dawley, 300-350g) under loaded and unloaded conditions. The left limb was denervated to isolate the LG-Sol nerve and muscles. Distal attachments of MG, PL, BF, ST and Q were cut. The knee was clamped at 98° (σ±9). Plantar flexion was induced before and after Sol denervation by posterior tibial nerve stimulation (100Hz) at 3x twitch threshold with the ankle in a 102° (σ±11) resting position (unloaded), 52° (σ±9) dorsi-flexed position (held by a stimulus-synced retractable bar) or with ankle position set by a 50-500g load applied in series to the intact Achilles tendon. Foot movements were filmed at 500 f/s, digitized, smoothed by digital filter, and differentiated to determine velocity and acceleration. Kinematic data before/after denervation are shown in the following table:

Load (g)	n	Peak Vel. rad/s (σ)	t-Peak Vel. ms (σ)	Peak Accel. rad/s/s	t-Peak Accel. ms (σ)
0	4	18±5/18±4	14±3/13±5	475/423	9±2/9±2
50	3	24±3/23±2	25±1/25±2	983/1176	15±6/12±2
100	4	21±3/18±4	36±4/32±2	851/782	20±3/17±3
200	4	17±3/15±4	44±6/41±5	591/552	18±4/17±4

With the ankle near maximal dorsi-flexion at stimulus onset, peak velocities associated with passive elastic muscle properties approached values achieved by active contractile mechanisms. Under unloaded and loaded conditions no evidence was found in support of mechanical interference by Sol of maximal contractile LG responses. Contributions of Sol tension to foot velocity and acceleration began to emerge under loaded conditions between 100-300g but did not become prominent until loads >300g were applied. Findings were in agreement with previous reports (Walmsley et al., J. Neurophysiol., 41:1203, 1978; Spector et al. J. Neurophysiol., 44:951, 1980) that the slow twitch Sol muscle, though fully activated, cannot contribute effectively to plantar flexion movements falling within a critical dynamic range.

Supported by GSRF Grant, University of Washington.

222.7 ELECTRICAL AND MECHANICAL FATIGUE PROPERTIES IN CAT MOTOR UNITS OF IDENTIFIED TYPE. H.P. Clamann and A.J. Robinson* Dept. of Physiology, Medical College of Virginia, Richmond, Va. 23298.

Although it has been suggested that muscle or motor unit fatigue may occur by failure in the electrical or the mechanical mechanism, only mechanical fatigue of the different motor unit types has been studied in detail. The present experiments were designed to compare the susceptibility to electrical fatigue of the three motor unit types and to relate electrical to mechanical fatigue in these same units. In cats single motor axons of medial gastrocnemius or soleus motor units were isolated in finely divided ventral root filaments. Force was recorded from the distal tendon of the appropriate muscle, and the electrical activity of motor units was led off from bare pins inserted into the same muscle. The electromyogram (EMG) was full-wave rectified and electronically integrated to permit recording the integral (IEMG) of individual motor unit potentials during stimulation of the motor axon. Motor units were classified as type FF, FR, or S according to criteria of Burke and others. Motor unit fatigue was induced by tetanic stimulation at 80 pps. This stimulus rate was greater than the tetanic fusion frequency of nearly all units including type FF, and was slow enough to prevent overlap of successive EMG waveforms. All motor units were stimulated at the same rate to allow direct comparison of fatigue properties.

Type FF motor units lost the ability to produce force after 10-15 seconds of stimulation; a smooth decline almost to 0 of the EMG waveform followed loss of force. Such a pattern of force fatigue followed by EMG failure is seen with other stimulus patterns also. Partial recovery of twitch force and full restoration of EMG amplitude occurred within seconds. FR units generally showed a smooth simultaneous decline of electrical and mechanical activity; force declined by over 75% in 45-60 seconds. S units showed marked changes in the EMG before any loss of force was measured. As with other unit types, the EMG waveform increased in duration and then began to decline smoothly in amplitude. After 30-45 seconds abrupt fluctuations in EMG amplitude (jitter) appeared and persisted. IEMG declined by over 50% before any force decrement occurred.

It is concluded that during fatiguing contractions, readily fatiguable motor units lose the ability to contract while the EMG is still virtually normal; EMG fatigue precedes mechanical failure in fatigue-resistant units. Electrically as well as mechanically, FF units are best suited to phasic use while S units respond best to tonic drive. Supported by Grant # NS-11677 from NIH, and a United Nuclear predoctoral grant to AJR.

222.8 EFFECTS OF STEROID TREATMENT ON PROPERTIES OF MOTOR UNITS IN RED AND PALE CAT HINDLIMB MUSCLES. A.J. Robinson*and H.P.Clamann (SPON: A.J. Szumski). Dept. of Physiology, Medical College of Virginia, Richmond, Virginia 23298

The administration of glucocorticoids has been shown to induce atrophy and weakness in whole skeletal muscle. These effects are more pronounced in pale muscle than in red muscle. The present study was designed to examine the effects of steroid treatment on the mechanical,electrical, and fatigue properties of single motor units in the pale, medial gastrocnemius(MG) and red soleus muscle of the cat. The properties of MG and soleus motor units from normal cats were examined and compared to those of MG and soleus units in steroid-treated(3-4mg triamcinolone acetonide per kg per day, 10-16 days) animals. Steroid treatment produced alterations in the strength- and speed-related properties of motor units that were more pronounced in fast-twitch than in slow-twitch units. The mean maximum tetanic tension($\overline{P_{max}}$) for types FF(fast-twitch, fatiguable) and FR(fast-twitch,fatigue-resistant) units were reduced by 63% and 71% respectively. The $\overline{P_{max}}$ for type S (slow-twitch,fatigue-resistant) units in MG was reduced by 25% but was unchanged for type S units in soleus. The mean rate of rise of tetanic tension($\overline{dP/dt}$) for FF, FR, and S units in MG were reduced by 79%, 54%,and 25% respectively following steroid treatment. The $\overline{dP/dt}$ for type S units in soleus in steroid-treated animals was increased by 73% over controls. Steroid treatment lengthened the mean twitch contraction time($\overline{CT}$) of MG type FF units and shortened the $\overline{CT}$ of type S units in both MG and soleus. The mean integrated EMG signals elicited from FF and FR units in MG were unchanged following steroid treatment but were significantly increased for type S units in both pale and red muscles. The susceptibility to fatigue of the three classes of motor units in MG and of soleus motor units was unchanged as a result of steroid administration. These findings suggest that those units most frequently activated in muscular contractions(type S units) are the least susceptible to steroid-induced changes in their contractile properties. In contrast, those units activated only occasionally in muscular contractions (FF and FR units) appear to undergo preferential changes in their strength- and speed-related contractile properties. Since the overall frequency of activation of motor units correlates well with the size of their motoneuron cell bodies, these results imply that the Size Principle can be extended as a general rule to not only account for the recruitment order and overall degree of use of motor units in muscular contractions but also to account for the patterns of motor unit involvement seen in steroid-induced myopathy. 222.10 A COMBINED EXPERIMENTAL AND COMPUTATIONAL METHOD FOR THE REMOVAL OF CROSS TALK FROM AN ELECTROPHYSIOLOGICAL SIGNAL. P.L. Weiss,* I.W. Hunter and R.E. Kearney. (SPON: L. Wolfe). Biomedical Engineering Unit, McGill University, Montreal, Canada, H3G 1Y6

Surface electrodes are commonly used to record electrophysiological signals since they can be rapidly applied and can monitor potentials emanating from a broad section of tissue. However, these electrodes also pickup other adjacent signals, which tend to contaminate the waveform of interest. EEG is often marred by noise from eye movement potentials and the ECG often impinges on respiratory muscle EMG. Since the spectra of the signals being studied (EEG and EMG in the examples above) and the unwanted, contaminating signals (EOG and ECG, respectively) overlap considerably, the use of selective filters is impractical.

One traditional approach that could be used to solve this problem would be to simply subtract the unwanted component, monitored on its own channel, from the required signal. However, this would only be possible if the separately recorded noise signal does not differ from the noise component of the physiological signal of interest. That is, it must be recorded with no time delay, no difference in scaling, and not be filtered.

We have developed an experimental method which enables the removal of unwanted waveforms using system identification techniques (Kearney & Hunter, 1981) and does not require that the two waveforms be similar. The approach has been implemented for a specific problem and consists of the following procedures: (1) The impulse response between the Input Signal (ECG_1 from electrodes placed on the chest) and the Output Signal (EMG plus ECG_2 from electrodes placed over a respiratory muscle) is identified. (2) The impulse response is convolved with the Input Signal to create the Predicted Output. (3) The Residual Output (respiratory EMG-ECG) emerges when the Predicted Output is subtracted from the Output Signal.

The Residual Output is thus an EMG signal which is only minimally marred by ECG. Data collected and analyzed in this manner are shown below; Figure 1a is the original Output Signal including both EMG and ECG and Figure 1b is the modified output signal (= Residual Output) showing negligible ECG. The original ECG (Fig. 1c) is included for comparison.

222.11 CHRONIC EXPOSURE TO 60-HZ ELECTRIC FIELD ENHANCES RECOVERY FROM FATIGUE IN MAMMALIAN SLOW-TWITCH MUSCLE. R. A. Jaffe, B. L. Laszewski* and D. B. Carr*. Biology and Energy Systems Depts., Battelle Memorial Institute, Pacific Northwest Laboratory, Richland, WA 99352.

Reports in the literature have suggested that mammalian and avian nervous systems can be affected by exposure to extremely low frequency (ELF) electromagnetic radiation. In a study of electrical substation workers (Sazonova), strength-duration curves for the adductor pollicis muscle appeared to show a significant increase in excitability following a working day exposure to high-voltage ELF fields. Experiments in the present study were designed to detect possible effects of chronic exposure (30 days) to 60-Hz electric fields (100 kV/m; unperturbed field strength) on neuromuscular function in the rat.

The exposure system is capable of simultaneously exposing 144 rats, housed in individual plastic (lexan) cages, to uniform vertical, 60-Hz electric fields. Extensive tests have been made, and document that the exposure system is free of corona discharge and ozone formation and that the animals do not receive spark discharges or other shocks in the housing system during exposure to electric fields. The system is free of significant levels of harmonic distortion and vibration. Electric field measurements showed that the electric field strength within a cage varies by about 7%, due to the effects of the lexan cage material, and that the differences among fields in different cages are less than 3%. The effective field strength was about 65 kV/m, a reduction caused by mutual interaction (shielding) among adjacent animals during exposure.

Isometric force transducers were attached to the tendons of the plantaris (predominantly fast-twitch) and soleus (predominantly slow-twitch) muscles in the urethan-anesthetized rat. Square-wave stimuli were delivered to the distal stump of the transected sciatic nerve. Several measurements were used to characterize neuromuscular function, including: twitch characteristics, chronaxie, tetanic and post-tetanic potentiation, and fatigue and recovery. The results from three independent series of experiments are reported. Only recovery from fatigue in slow-twitch muscles was consistently and significantly affected (enhanced) by electric-field exposure. This effect does not appear to be mediated by field-induced changes in either neuromuscular transmission or in the contractile mechanism itself. It is suggested that the effect may be mediated secondary to an effect on mechanisms regulating muscle blood flow or metabolism.

222.12 ARCHITECTURE OF CAT HINDLIMB MUSCLE: IMPLICATIONS FOR FUNCTIONAL SIGNIFICANCE. R.D. Sacks* and R.R. Roy* (SPON: A. Herrera). Neuromuscular Research Lab., Dept. of Kinesiology, UCLA, L.A., CA 90024

Since it is known that a muscle's architecture dictates to a major degree the force and velocity properties of that muscle, this aspect of 24 major cat hindlimb muscles was determined. Muscle wet weights, muscle lengths, fiber lengths, and angle of pinnation were used to calculate physiological cross-sectional area (PCA). Average sarcomere lengths were obtained for selected flexor, extensor and adductor muscles. Within a given muscle, the fiber length to muscle length ratio was essentially the same in all regions for almost all muscles. The calculated PCA of the knee extensors was similar to that of flexors (16.43 cm^2 vs 16.83 cm^2) whereas for the ankle extensor muscles it was more than two times greater than the major flexors (15.61 cm^2 vs 7.61 cm^2). Ratios of wet wt./predicted maximal tetanic tension for each muscle was calculated using the value 2.3kg/cm^2 for specific tension. This ratio provided a convenient means to compare the priority of muscle force vs muscle length-velocity for a give mass of muscle. For example, the mean value of this ratio for FDL was 0.96 vs 0.39 for its synergist FHL. Therefore, although these two muscles serve the same function, it appears that the FDL is designed for force production whereas the FHL is designed for velocity. The adductor femoris is unique in that it has a wide range of fiber lengths but they are in proportion to the length of that portion of the muscle from which they are obtained. Assuming the entire muscle to be biochemically homogeneous, the fibers at the distal end, which are three times longer than at the proximal end, must contract three times faster in order for all fibers to participate in maximum force production. This difference is resolved by considering the architectural features: the fibers at the distal end have 3 times as many sarcomeres in series and consequently contract 3 times faster. Therefore, it is evident that the architectural features can affect the speed of shortening of a muscle as much as its intrinsic biochemical properties. These results suggest that the complementary nature of the biochemical and morphologic features of muscles and muscle groups seem to minimize the complexity of the neural control required to produce effective movements.

222.13 MYOFIBRILLAR GEOMETRY OF SINGLE MUSCLE FIBERS AS REVEALED BY LASER DIFFRACTION STUDIES. A.F. Leung*, Y.M. Cheung* and J.C. Hwang. Dept. of Physics, The Chinese University of Hong Kong and Dept. of Physiology, Faculty of Medicine, University of Hong Kong, Sassoon Rd., Hong Kong.

Analysis was made on the intensity minima and maxima of the diffraction patterns of isolated single skeletal muscle fibers of frog. As the intensity distributions along the zero- and first order diffraction lines follow the Bessel function, a cylindrical shape for the myofibril was indicated. Myofibrillar diameters could then be predicted from studies of the intensity minima and maxima. Such calculated values of the myofibrillar diameters are in general agreement with those obtained from electron microscopic studies. When the sarcomere length was set at 2.9 μm, the calculated myofibrillar diameter increased when the muscle fiber was transferred to hypotonic solutions and decreased in hypertonic solutions. Experiments were then performed in which the sarcomere length (S) was varied by passive stretch. The changes in myofibrillar diameters at different sarcomere lengths were again in general agreement with the prediction when the volume of the myofibril (V) was assumed to be constant, (V=A). However a slight departure of the myofibrillar diameters (D) or volumes (V) from the predicted values could also be observed. The volume (V) then becomes a function of (A+BS) where B is a second constant and BS describes the departure from a constant volume. Such slight departure could be readily explained by a model in which the myofibril is assumed to be a ribbed cylinder with the ridges occurring at the Z lines. (supported in part by the Research Grants Committee, University of Hong Kong).

222.14 INTRACELLULAR LOCALIZATION OF CONCONAVALIN A (CON A) RECEPTORS IN DE-EPONIZED SECTIONS OF NORMAL AND DISEASED HUMAN MUSCLE. W. F. Odenwald*, V. Askanas, and W. K. Engel. Dept. of Neurology, Univ. of S. Calif. School of Medicine, Los Angeles, Calif. 90033

Intracellular localization of Con A receptors in glutaraldehyde-fixed muscle blocks is difficult due to the poor penetration of lectins through muscle plasmalemma. Therefore, we have developed a technique which allows direct binding of Con A to muscle cell organelles. This technique can be applied to study the binding of several different lectins to serial cross-sections of normal or diseased muscle, or other cells in order to define the profile of lectin binding to normal or pathologic subcellular organelle, and hence delinate the profile of sugar components in that organelle. One-micron-thick sections of glutaraldehyde-fixed, epon embedded human muscle were mounted on plastic cover slips, completely de-eponized with 50% saturated solution of ethanolic NaOH, rinsed with absolute ethanol and air-dried. After incubation with 0.1 M lysine-HCl in phosphate buffer, the sections were incubated in 20 and 10 ug/ml Con A in 0.1 M phosphate buffer. Then a modification of the technique of Bernhard and Avrameas (Exptl Cell Res 64, 232-236, 1971), utilizing horseradish peroxidase and DAB was applied for visualizing the sites of Con A binding. Following postfixation in 1% osmium, the sections were dehydrated, re-embedded in Epon and thin-sectioned parallel to their surface. Omitting Con A from the incubating medium, incorporating the Con A inhibitor α-methyl-d-mannoside (0.2M) in the incubation medium served as controls for the specificity of the reaction. In normal human muscle, staining was localized on the cell membrane complex (basement membrane and plasmalemma), t-tubules, sarcoplasmic reticulum, nuclear envelope and glycogen granules. Mitochondrial membranes remained unstained. In myophosphorylase deficiency, Con A binding was also strongly visualized under the muscle plasmalemma which ultrastructurally corresponded to the staining of abnormally accumulated glycogen granules, which is characteristic of this metabolic defect. In muscle fibers of familial idiopathic hypokalemic periodic paralysis, characterized by the presence of large vacuoles, which are known to be greatly dilated t-tubules, in the muscle fibers, Con A was localized on the membrane of those vacuoles and occasionally inside vacuoles bound to glycogen granules and to amorphous material. Controls were negative in all normal and diseased human muscle. Con A defines α-d-manoside (and, to lesser extent, α-d-glucoside) sugar components. This technique can now be extended to other lectins that will define other sugars to achieve at the ultrastructural level profile of sugar components in serial sections of a given organelle.

223.1 EVOKED LOCOMOTION AFTER DESTRUCTION OF DEITERS' NUCLEUS. R.M. Jell, L.M. Jordan and D.J. Ireland. Department of Physiology, University of Manitoba, Winnipeg, CANADA R3E OW3.

Recent studies have provided convincing evidence for a connection between descending vestibular outflow and the spinal stepping generator by way of direct excitatory influence on the FRA pathway to extensor motoneurons and to interneurons which mediate group IA reciprocal inhibition. The possibility that this outflow is necessary for initiation of locomotion was raised by Shik et al (Biophysics, 11:756-765, 1966) with the demonstration that some neurons in Deiters' nucleus (DN) became tonically active before the onset of locomotion evoked by electrical stimulation of the mesencephalic locomotor region (MLR), and that these neurons later became rhythmically active in synchrony with stepping. Further evidence was presented by Steeves and Jordan (Neuroscience Letters, 20:283-288, 1980) in a selective lesioning study of descending spinal tracks necessary for initiation of locomotion, showing that a region of the ventrolateral quadrant containing the lateral vestibulospinal tract (LVST) was necessary for MLR evoked locomotion. We present results which demonstrate that initiation of locomotion is not abolished by bilateral lesions of DN.

Treadmill locomotion induced in decerebrate cats by electrical stimulation of MLR was studied before and after bilateral (and, in some cats, unilateral) lesioning of DN with a hot probe using a dorsal approach. Hindlimb extensor rigidity, present before the lesion, was abolished bilaterally (or ipsilaterally) after lesioning. Hindlimb locomotion was initially abolished bilaterally (or ipsilaterally) but could be evoked with variable threshold after 2 or 3 hours. The quality of hindlimb stepping tended to be altered but ankle extensor and flexor electromyographs revealed appropriate levels and phasing of muscle activity.

These results support and extend the findings of Orlovsky (Brain Res. 40:359-371, 1972), who reported initial ipsilateral abolition of MLR evoked stepping after unilateral DN lesions, with eventual return, and strongly suggest that the reticulospinal pathways carry the descending command signals for initiation of locomotion.

223.2 EVIDENCE FOR RHYTHMIC EXCITATION AND INHIBITION OF FLEXOR AND EXTENSOR MOTONEURONS DURING FICTIVE LOCOMOTION. S.J. Shefchyk*, J.E. Menzies* and L.M. Jordan. Dept. of Physiology, Univ. of Manitoba, Faculty of Medicine, Winnipeg, CANADA R3E OW3.

Various models of the central pattern generator for locomotion have been proposed, but the details of the synaptic inputs which produce motoneuron rhythmic activity have not been determined. Previous studies have shown that the rhythmic firing of motoneurons during "fictive" locomotion is accompanied by rhythmic activity in flexor- and extensor-coupled Ia inhibitory interneurons (Feldman and Orlovsky, Brain Res. 84:181, 1975; McCrea et al. J. Neurophysiol. 44:475, 1980). This suggests that both flexor and extensor motoneurons are subject to rhythmic inhibitory input, which alone cannot account for the rhythmic activity of motoneurons (Menzies et al, Neuroscience Abst. 4, 1219, 1978). In the present study the nature of excitatory and inhibitory synaptic input to identified flexor and extensor motoneurons during fictive locomotion was examined.

Fictive locomotion was produced by stimulation of the mesencephalic locomotor region in decerebrate cats paralyzed with Flaxedil. Intracellular recordings were obtained using microelectrodes filled with 3M potassium acetate or 3M potassium chloride. Motoneurons were identified on the basis of their monosynaptic and antidromic responses to stimulation of the nerves to anterior biceps-semimembranosus, posterior biceps-semitendinosus, vastus lateralis, v. intermedius, v. medialis, sartorius, gracilis or tibialis anterior muscles. Conductance measurements obtained using a bridge circuit for injection of hyperpolarizing pulses through the recording electrode revealed the presence of synaptic input during both the depolarized and hyperpolarized phases of locomotor activity in flexor and extensor motoneurons. Intracellular chloride injection and strychnine administration (0.1 mg/kg, i.v.) revealed that these techniques could reduce or abolish the hyperpolarized phase of the locomotor cycle in all the types of motoneurons examined. The rhythmic excitatory input persisted in these experiments, and the amplitudes of excitatory postsynaptic potentials were increased. These studies establish that alternating excitatory and inhibitory synaptic input produce the depolarizing and hyperpolarizing membrane potential shifts in mammalian flexor and extensor motoneurons during fictive locomotion. The parallel effects of strychnine on the disynaptic IPSPs produced by Ia afferent stimulation and on the hyperpolarizing potentials during locomotion suggest that Ia inhibitory interneurons are the source of the rhythmic inhibition of motoneurons. It is concluded that a system of excitatory interneurons driven by or forming a part of the central pattern generator is responsible for the depolarization of motoneurons.

223.3 CAT FORELIMB MODEL PROVIDING FORCE AND EMG ACTIVITY FROM A SINGLE ELBOW EXTENSOR IN THE UNANESTHETIZED ANIMAL. D.D. ROSCOE AND M.W. KEITH*. Rehab. Eng. Cen., Case Western Reserve Univ., Cleveland, Ohio 44106.

An animal model is presented which will allow measurement of force and EMG activity of a single elbow extensor muscle in the cat forelimb to be recorded during voluntary movements in the unanesthetized animal.

Surgery was performed on the cat's forelimb using strict sterile techniques. First, the epitrochlearis muscle was completely excised. The tendons of the medial (accessory, intermediate and short portions) and long heads of the triceps muscle were then detached at their insertion on the olecranon. With these two muscle heads partially reflected proximally, the anconeus muscle was excised exposing the distal one-third of the humerus. The medial and long head tendons were reattached with sutures pulled through a small hole drilled posterior-to-anterolaterally through the humerus, just proximal to the olecranon fossa. It is critical that the tendons are reinserted into bone so that the forces generated by the medial and long heads are directed away from any adhesions formed with the lateral head during healing. The lateral head of the triceps was left intact and serves as the only extensor muscle across the elbow. Before closing the incision, the triceps were electrically stimulated and checked for activity. Only the lateral head produced elbow extension.

Two weeks post surgery, the cat was able to extend the elbow of the operated forelimb against gravity. To verify that this extension was due solely to the lateral head of triceps, the cat was anesthetized and percutaneous intramuscular electrodes were implanted in the medial and long heads. Maximal stimulation of these heads produced no elbow extension.

The animal model has been developed to evaluate a modified version of a new EMG processing technique (Hogan and Mann, IEEE Trans. Biomed. Eng. 27:382, 1980) to be used as a source of command signals in the control of powered prostheses or the control of forearm and hand movements by the quadriplegic patient using functional neuromuscular stimulation of paralyzed muscles. An electrode array will be implanted in the lateral triceps with lead wires exiting via a pyrolitic carbon transcutaneous connector located in the cat's back. Because of the surgical reconfiguration of the cat's forelimb, it will be possible to externally measure elbow extension forces produced by the unanesthetized animal during a trained task and correlate these forces to the processed EMG activity obtained from the functionally isolated elbow extensor. (Supported by NIHR grant G008005815).

223.4 COMPARTMENTALIZED ORGANIZATION OF FIBRE TYPES AND RECEPTORS IN THE TRAPEZIUS MUSCLE IN THE CAT. J. Keane* and F.J.R. Richmond (SPON: J. Milligan). Dept. of Physiology, Queen's University, Kingston, Ontario, K7L 3N6.

It is increasingly recognized that all muscles may not function as a single homogenous structure. Rather some muscles may be sub-divided into functional compartments, each with a different extrafusal fibre composition and a characteristic receptor grouping. One especially clear example of a compartmentalized muscle is the cat trapezius, a muscle with 3 distinct heads. One head, called clavotrapezius, originates from the lambdoidal crest and nuchal midline and inserts on the clavicle. The other two heads, acromiotrapezius and spinotrapezius both have a wide midline origin from cervical and thoracic vertebrae and insert on the scapula. In addition to confirming the separation of motor (spinal accessory) and sensory (C2 to T3) innervation to this muscle, examinations of the motoneurone organization, fibre histochemistry and receptor organization have demonstrated that each head of trapezius has unique characteristics.

Retrograde transport of horseradish peroxidase has shown that all trapezius motoneurones are located in the spinal accessory nucleus but that motoneurones supplying different muscle heads are grouped in different regions. Histochemical studies of extrafusal fibres showed that slow fibres accounted for less than 15% of the total fibre populations in clavotrapezius but about 30% and 50% of acromiotrapezius and spinotrapezius respectively. Muscle spindle densities were similar from one muscle head to another, and ranged from about 24 spindles per gram in acromiotrapezius and spinotrapezius, to about 34 spindles per gram in clavotrapezius. The form and arrangement of spindles differed in different heads. Spinotrapezius spindles usually existed singly and had an intrafusal fibre content with two bag fibres and 4 to 5 chain fibres. Acromiotrapezius and clavotrapezius spindles had more complex arrangements. In both acromiotrapezius and clavotrapezius there were circumscribed regions where spindles had a greater variation in their intrafusal fibre contents, and spindles with a single bag fibre were commonly seen. These same spindles were commonly linked with one another in complex spindle forms. Observations suggest that within the 3 heads of trapezius there may be further sub-compartments which differ in their receptor distribution and sensory innervation.

Supported by the MRC of Canada.

223.5 EVIDENCE FOR AUTHENTIC CHANGES IN THE GAIN OF AN AUTOGENETIC REFLEX IN THE SOLEUS MUSCLE OF THE DECEREBRATE CAT. T. R. Nichols* (SPON: H. D. Patton). Dept. of Kinesiology, Univ. of Washington, Seattle, WA 98195

A skeletal muscle with its associated reflex apparatus, together known as the motor servo, presents a mechanical stiffness which depends upon the gains of autogenetic reflex pathways and upon nonlinearities in the motor servo (Houk, J.C., Ann. Rev. Physiol., 41:99-114, 1979). The latter mechanism obtains in the case where stiffness varies with the initial or the mean force exerted by the muscle. It has been shown that, for a given central state, stiffness depends upon force but rather less upon muscle length (Feldman, A.G., Neurosci. 5:81-90, 1980). Therefore, authentic changes in reflex gain are indicated if the changes in stiffness occur independently of a change in force.

Static force-length trajectories were obtained from the soleus muscle in the decerebrate cat. In some cases, trajectories had similar thresholds but different slopes. Average stiffnesses varied over a two-fold range over the same range of forces. Transient changes in stiffness were measured during the application of ramp stretches and releases at a variety of initial forces and lengths. The stiffness of the regulated muscle varied over a three-fold range when ramps were initiated from the same initial force and length. These results indicate that the changes in stiffness were probably not due to nonlinearities associated with the motor servo. Changes due to a progressive decline in the condition of the preparation were also excluded. In addition, the static force-length trajectories could not be accounted for by the length-tension curves of a fixed population of muscle fibers contracting at a constant firing rate except at short lengths and high forces. The ramp responses could not be accounted for by the responses of unregulated muscle (no reflex action) except at very high forces.

These results indicate "spontaneous" changes in the gains of one or more autogenetic reflex pathways which probably arise from muscle spindle receptors.

223.6 ELECTROMYOGRAPHIC ACTIVITY PATTERNS OF EMBRYONIC CHICK HINDLIMB MUSCLES. M. J. O'Donovan*, M. W. Cooper* and Lynn T. Landmesser (SPON: M. Bak). Dept. of Biol., Yale Univ., New Haven CT. 06511.

We have recorded spontaneous and evoked electromyographic activity of several identified extensor and flexor muscles of the hip and knee in stage 34-36 chick embryos unilaterally in ovo, and bilaterally in an isolated spinal cord-limb preparation maintained in vitro. In ovo muscle electrical activity was recorded using flexible suction electrodes (tip diam. 100-150μ) inserted through a window in the shell after exposure of the appropriate muscles. Embryonic temperature was maintained at 35°± 2°C using an in ovo thermistor controlling a heating coil around the egg. Recordings in ovo revealed several different forms of muscle activity. Most frequently observed was a recurring, patterned sequence of bursts, in which activity alternated between antagonistic muscles. Each burst was typically 1-2 seconds long, and the whole sequence, lasting up to 30 seconds, was composed of several cycles of antagonistic activity. Occasionally, following such a period of phasic activity, both antagonistic and synergistic muscles co-contracted in a tonic discharge of variable duration, occasionally for as long as 1 minute. Other irregular and unpatterned activity was also seen. Patterned alternation of antagonistic muscles, could be evoked by tactile or electrical stimulation of the forelimb or electrical stimulation of the anterior cutaneous nerve in the thigh.

Evoked and spontaneous activity was also recorded bilaterally from the same group of muscles in an isolated cord-limb preparation (ICP), transected at the cervical cord, and maintained in oxygenated Tyrode at 30°C for several hours. In contrast to the in ovo behavior, ICP muscle activity consisted only of sequences of phasic alternation of antagonistic muscles that could occur spontaneously after several hours in the bath or be evoked earlier by a single electrical stimulus to the ventral surface of thoracic or lower cervical cord. Bilateral recordings revealed that identical muscles in both limbs were co-active during these sequences. The patterning and duration of activity between different muscles in the isolated preparation was similar to that observed for spontaneous alternating sequences in the intact embryo, suggesting operation of the same neural elements, which may represent the embryonic homologue of the intraspinal locomotor generator described in other vertebrates. (Supported by NIH Grant NS10666 to LTL, an MDA postdoctoral fellowship to MO'D and NIH Grant GM07527 to MWC).

223.7 EFFECT OF MUSCLE LENGTH ON FORCE-VELOCITY PROPERTIES OF CAT SOLEUS DURING MOVEMENT. S. A. Spector*, R. J. Gregor* and S. C. Bodine* (SPON: W. F. H. M. Mommaerts). Neuromusc. Res. Lab., UCLA, 90024.

The soleus (Sol) muscle's contribution to total force production during movement depends, in part, on its capacity to generate the required forces (F) and velocities (V) at the Achilles tendon. The in situ F-V properties of Sol suggest that this muscle's peak shortening velocity (Vmax) precludes its effective participation during movements requiring high rates of shortening (> 160mm/s; Spector et al., J. Neurophysiol., 44:951, 1980). Since Sol may shorten up to 15% of its resting muscle length (ML) during these movements (Goslow et al., J. Morphol., 141:1, 1973), the effect of ML on F-V properties and Vmax of this muscle is of interest, also.

To study the effect of ML, approximately 180 afterloaded tetanic contractions of Sol (n=5) were initiated from ML's varying from 85 to 110% of the length (Lo) at which peak tension (Po) was developed. Tendon displacements, F and V were determined for each contraction, and discrete F-V points were grouped according to the ML at which peak V of the contraction occurred. The linear form of Hill's equation, (Po-P)/V=P/b+a/b, was used to estimate Vmax for each ML.

The results show that average Vmax exhibits greater sensitivity to changes in ML than does Po. At 93% of Lo, Sol develops 94% of Po, whereas this muscle can generate only 82% of Vmax observed at Lo. Similarly, at 103% of Lo, Po is affected minimally (2%) while Vmax is reduced to 88% of the value at Lo (156mm/s).

The complete F-V plots at different ML's for one Sol are shown in Figure 1. The peak Vmax that can be developed for any given load is continually reduced as ML is decreased below Lo. These data indicate that during movements requiring rapid displacement of the Achilles tendon, the participation of the Sol is not only comprimised by its inability to generate significant amounts of force (due to its F-V characteristics), but also by its dependence on ML to develop sufficient shortening velocities.

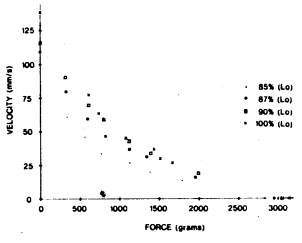

Figure 1: Force-velocity relation of Sol at different ML's.

223.8 COMPARISON OF NORMAL USE AND REFLEX RESPONSE PATTERNS OF CAT DISTAL HINDLIMB MUSCLES. L.D. Abraham, G.E. Loeb, and W.B. Marks. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205

In order to determine the function of individual muscles in the cat distal hindlimb, we compared reflex response patterns with normal patterns of muscle use in a variety of behaviors.

Chronic recording techniques were used to obtain EMG records from the following muscles: medial and lateral gastrocnemius (MG, LG), soleus (SOL), plantaris (PLT), flexor digitorum longus (FDL), flexor hallucis longus (FHL), tibialis posterior (TP), tibialis anterior (TA), extensor digitorum longus (EDL), flexor digitorum brevis (FDB), and peroneus longus (PL). Individual muscle length and tension were obtained with implanted transducers specially designed for and attached to the appropriate tendons. Stimulating electrodes were implanted on the medial plantar and sural nerves. Analog and video recordings were made during jumping, scratching, paw shaking, standing, and treadmill locomotion at different speeds. Reflex responses were recorded to brief single shocks occurring during treadmill walking at random points in the step cycle. Terminal experiments provided anatomical and mechanical data for individual muscles, as well as calibration of the implanted gauges.

In general, neither the normal use nor the reflex recruitment of these muscles could be accurately predicted from the classical anatomical dichotomy of flexors and extensors. Rather, the actual use of each muscle appeared governed by the specific requirements of the task and detailed mechanical specializations intrinsic to each muscle (e.g. fiber type and orientation) and extrinsic (e.g. insertions producing non-axial or joint-angle-dependent torques). For example, reflex responses of FDL and FHL were consistent with differences between these digit flexors in normal use (see Fleshman, Lev-Tov, and Burke, Soc. Neurosci. Abstr., 1981), and with differences in muscle fiber orientation. Thus FDL appears to be specialized for rapid digit flexions against low loads, while FHL is used for more static contractions against relatively large loads during extension. TP provided several examples of dissociation from its classical ankle extensor synergists MG, LG, and SOL. During scratching (which combines ankle flexion/ extension with inversion), extensor EMG was almost entirely from TP. TP activity at the end of stance during running (after activity in MG, LG, and SOL had ceased) reflected its increasing mechanical advantage as the ankle extends.

This type of kinesiological analysis provides a basis for relating patterns of connectivity and activity of motoneurons and detailed structural specializations of muscles with patterns of normal use.

223.9 SYNAPTIC ORGANIZATION IN FDL AND FHL MOTOR NUCLEI: A SEARCH FOR MECHANISMS UNDERLYING THE FUNCTIONAL DISPARITY IN STRICT ANATOMICAL SYNERGISTS. J. W. Fleshman, A. Lev-Tov*, and R. E. Burke. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

The flexor digitorum longus (FDL) and flexor hallucis longus (FHL) muscles of the cat are strict anatomical synergists that together flex the distal hindlimb phalanges and protrude the claws. However, previous studies (see O'Donovan et al., Soc. Neurosci. Abstr. 5:380, 1979 and 6:858, 1980) have shown that these muscles are clearly not functional synergists during locomotion. FHL behaves as a stereotyped antigravity extensor, with activity throughout the stance phase of stepping at all speeds. In contrast, FDL is a functional flexor, active primarily in the early swing phase, with little stance activity even during high speed locomotion. In addition, FDL exhibits non-stereotyped "facultative" burst behavior related to perturbations in individual step cycles and not found in FHL. We assume that functional differences reflect differences in synaptic organization in the overlapping FDL and FHL motor nuclei and we have begun to search for such differences using conventional intracellular recording and electrical stimulation methods in unanesthetized, spinal cats (anemic brain destruction). Mean amplitudes (±SD) of homonymous, heteronymous and total group Ia EPSPs were generally larger in FHL as compared to FDL motoneurons:

Motoneurons	FDL Ia EPSPs	FHL Ia EPSPs	Number
FDL	4.8 ± 2.6 mV	1.9 ± 0.9 mV	20
FHL	2.4 ± 1.2 mV	7.2 ± 2.9 mV	30

Plantaris (PL) Ia afferents produced small or negligible Ia EPSPs in most FDL and FHL motoneurons but PL cells received FDL and FHL Ia EPSPs, with FDL EPSPs > FHL in 16/17 cases. Polysynaptic PSPs were examined in motoneurons with membrane potentials >55 mV. Stimulation of the saphenous and superficial peroneal nerves produced mixed PSPs in which excitatory components were common and often predominant in FDL cells but small and often undetect- able in FHL motoneurons. Stimulation of the sural nerve and the ipsilateral hindlimb central plantar pad produced mixed PSPs with no consistent difference between FDL and FHL. Stimulation of the palmar pad or superficial radial nerve in the ipsilateral fore- limb produced polysynaptic inhibition in most FHL motoneurons but little or no hyperpolarization in FDL cells. The stronger monosynaptic Ia projection to FHL cells (implying stretch responsiveness) fits their more stereotyped antigravity role while the apparent sensitivity of FDL cells to distal skin excitation may be related to FDL's "facultative" action in perturbed steps, which is presumably attuned to other sensory feedback. The significance of forelimb input to FHL cells remains to be clarified.

223.10 RESPONSES TO CONTROLLED POSTURAL DISTURBANCES IN THE CAT. D. S. Rushmer and C. J. Russell, Neurological Sciences Institute, Portland, OR 97209.

Normal cats instrumented with chronic EMG electrodes were subjected to controlled postural disturbances during quiet standing. The disturbances consisted of anterior-posterior translations and independently controllable vertical movement of the supports under the four paws. EMG responses from shoulder and forelimb muscles and vertical forces from each of the four paws were recorded during the disturbances, and stick figures were constructed from videotape. EMG responses had "preferred" latencies of 15-20, 55-60, and 95-105 msec., times similar to those seen in the hindlimb of the dog (Mori and Brookhart, Am. J. Physiol. 215:339, 1968). The timing and amplitude variability of the response indicate that they are highly stereotyped. A major feature of the response to both forward and backward translation is stiffening of the elbow joint, so that most of the joint angle changes occur at the shoulder and digits. In backward translation, which loads the forelimbs, greater EMG activity is seen.

Drop of the support under one forelimb provokes a weight shift to the contralateral forelimb and ipsilateral hindlimb (Massion and Smith, Br. Res. 61:400, 1973), but without any concomitant placing response. When the paws on opposite sides of the body are raised and lowered in a reciprocal fashion, the action of the hindlimbs and forelimbs differs. Considerable stiffness is maintained in the elbow and wrist, so that most of the changes in forelimb position are effected by the raising or lowering of the scapula. In the hindlimbs, on the other hand, the pelvis moves very little, and most of the joint angle change occurs at the knee and ankle.

The results of more complex stimulus presentation, such as pairs of disturbances presented in sequence at various intervals, and unexpected change to a second type of stimulus after repetition of one type of stimulus for a number of trials, suggest that the response to each disturbance is organized independently over a wide range of inter-stimulus parameters.

223.11 ANKLE EXTENSOR JOINT TORQUES AND MUSCLE FORCES DURING CAT, LOCOMOTION. M. R. Zomlefer. Rehab. Eng. Res. and Dev. Cntr.(153), VA Medical Center, Palo Alto, CA 94304.

Cats (n=6) were trained to walk across a force plate which recorded vertical and horizontal contact forces during the stance phase for one hindlimb. Hindlimb trajectories were also measured using a Selspot system with an effective sampling rate of about 160 Hz. A biomechanical model for the cat hindlimb was programmed into a minicomputer (HP 21-MX), and the combined force-trajectory information served as system inputs for the model. Numerical techniques were used to estimate limb segmental velocities and accelerations, and the model then predicted the net torque about the ankle joint. Acute follow-up studies were conducted to determine parametric data (masses, moments of inertia,lengths) required by the computer algorithms.

In order to verify the model's predictions, a buckle transducer was placed over the Achilles' tendon in three animals; this transducer recorded net force produced by the principal ankle extensor muscles,i.e. soleus,medial and lateral gastrocnemius, and plantaris. The computed torque values and the known geometry of the hindlimb were then used to estimate the (minimum) net ankle force required to generate predicted torque. The computed and measured net ankle extensor forces were in good agreement, usually within 10% of one another. For the walks studied, corresponding to locomotion speeds of 0.3-0.8 ms^{-1}, the inertial terms used by the algorithm proved insignificant. Hence, for slow walks, the determination of ankle extensor torque during the stance phase requires measurement of ground contact forces and limb position.

Supported by Swedish MRC 3026 and 5402 and Jasper Fellowship at the University of Montreal. Experimental work and computer modelling were conducted at Karolinska Institute (Prof. S. Grillner).

223.12 THE EFFECT OF BIOMECHANICAL PARAMETERS ON PROGRAMMING LANDING IN CATS. P.A. Reback, J.L. Smith & R.J. Gregor*. Neuromotor Control Lab & Brain Research Institute. UCLA, L.A. CA. 90024

In our previous report (Neurosci. Abst.,1980) data were presented suggesting that forelimb EMG is predetermined centrally for voluntary landing. The onset of extensor EMG activity was shown to be constant across all jump heights for both flight and landing bursts with reference to landing and not to take-off. This study discusses the kinematic and kinetic parameters of jumping, and how they may be influenced by neural control mechanisms.

Five adult cats were trained to jump down onto a force plate from a platform placed at heights of 1.2, 1.0, 0.8, & 0.6m. Ground reactive forces (GRF) and EMG of the biceps and lateral triceps were coordinated with 16mm high speed film(100 fr/sec).

The peak GRF rises with increasing jump height and doubles as jump height changes from 0.6m (29N ± 8.28) to 1.2m (63N ± 9.59). At impact, this force brings about a quick elbow flexion (F) resulting in a rapid increase in angular velocity (ω). Although the average peak ω increases with each jump height, there is a wide distribution of values from 150-1600 °/sec at each height studied. However, the times to reach maximum ω and maximum elbow flexion post-landing are independent of jump height and remain constant at 26ms and 90ms respectively.

At landing, the cat experiences a 40ms flexion torque (T) followed by an extension T that lasts for the duration of elbow flexion. As expected, the T values vary between cats, increasing with larger moments of inertia of the forearm. In the individual cat, the T about the joint is consistent across all jump heights during the landing phase. Typical ranges for peak flexion and extension T are 18-26 kgm/kg body wt and 9-12 kgm/kg body wt respectively.

The variability of the GRF and ω at a given jump height suggests that there is considerable generality in the programming of the movement that may be compensated by the inherent properties of the muscle. An interaction between neural mechanisms and inherent muscle properties in controlling landing is implied by the temporal consistency at which maximum ω and elbow flexion occur. Finally, the independence of T values to jump height, in contrast to the GRF which parallels jump height, indicates that there is a substantial transfer of angular momentum to other parts of the body. This suggests that descending pathways may be responsible for adjusting the relative position of body segments in insure adequate transfer of angular momentum.

223.13 CHRONIC RECORDINGS OF ONGOING UNITARY ACTIVITY IN VESTIBULAR NUCLEI DURING VESTIBULAR COMPENSATION. D.W. Jensen. Dept. Otorhinolaryngology/Program in Neuroscience, Baylor College of Medicine, Houston, TX. 77030.

Guinea pigs compensate for a unilateral vestibular neurectomy relatively quickly (several days) in terms of spontaneous postural asymmetries (eye nystagmus and lateral head deviation, e.g.). However, in terms of the movement evoked directional preponderance of vestibular reflexes, the compensation is much slower (several weeks). In order to determine the time courses of long-term changes in the mean rates of ongoing discharges in central vestibular and reticular areas during these compensations, guinea pigs are being implanted with arrays of up to 10 chronically indwelling fine wire microelectrodes. Multiple and single unitary activity is biotelemetered to data acquisition equipment via a miniature FM transmitter, or by direct wire. The mean rate of ongoing discharges is monitored in the alert animal before and after a unilateral vestibular neurectomy.

Two animals have been analyzed. Ongoing activity levels in all positively identified vestibular nuclear loci recorded from thus far have remained depressed to less than half of their prelesion levels for the first 48 hours of compensation. During this time, 98% of the postural asymmetry abatement occurs.

These results and others will be discussed, especially with respect to the working hypothesis that activity levels in the vestibular nuclei are expected to be reflective of movement-evoked responses, and their compensation, and not reflective of asymmetrical postural tonus and its compensation.

223.14 RESPONSE PATTERNS OF CENTRAL VESTIBULAR NEURONS TO MODULATED OTOLITH INPUT. R. H. Schor, A. D. Miller, and V. J. Wilson. Rockefeller Univ., New York, NY 10021.

Using roll tilt, responses of single vestibular neurons and EMGs of neck and forelimb extensor muscles were obtained from 23 decebrate cats. These animals previously had all six semicircular canals rendered insensitive to angular acceleration by being plugged with bone dust. Stimulation consisted of various combinations of sinusoidal roll tilt, covering a frequency range of 0.01 - 2 Hz, providing a modulated otolith stimulus. Vestibulospinal neurons were identified by antidromic activation from the vestibulospinal tracts in the cervical cord; units were also tested with electrical stimulation of the entire labyrinth.

Below 0.1 Hz, the muscle responses are in phase with tilt, with forelimb extensors most active during side-down tilt, neck extensors during side-up; at higher frequencies of tilt, significant phase lags develop in these reflexes (Schor and Miller, J. Neurophysiol., in press). Neural responses could be classified on the basis of two criteria -- at low frequencies of tilt, maximum firing could occur during side down or side up tilt (the alpha and beta responses of Duensing and Schaefer). In addition, the behavior of the phase of the neural response over the frequency range of 0.01 to 2 Hz was usually either flat, and in phase with position, or showed a phase-lagging response similar to that observed in neck and forelimb muscles (M-like in table).

	Alpha		Beta		Other
	Flat	M-like	Flat	M-like	
All	51	1	9	38	29
Vestibulospinal	30	1	6	22	14
Monosyn. from lab.	21	0	4	14	16
Not monosynaptic	10	0	2	11	2

The two most prominent response patterns were flat alpha responses and muscle-like beta responses. The distribution of neurons shown to project to the spinal cord was similar to the entire population's. Similarly, units receiving a monosynaptic input from the labyrinth (receptor unknown) as well as those without such input are present in these classes. The phase-lagging beta responses are appropriate for contributing to the reflexes observed in the ipsilateral neck and contralateral forelimb; the role of vestibulospinal neurons with flat alpha responses awaits further study. (Supported by NASA grant NSG-2380, NIH grant NS02619, and PHS Fellowship 5-F32-NS06128).

223.15 CIRCLING INDUCED BY INJECTION OF GABA AND GABA ANTAGONIST PICROTOXINE INTO THE SUPERIOR COLLICULUS. C. Geula* and D. Asdourian. Lab. of Biopsychology, Wayne State University Department of Psychology, Detroit, MI. 48202.

Lesions of the Superior Colliculus have been shown to lead, among other things, to ipsiversive circling. Recent anatomical evidence has shown an extensive projection from Substantia Nigra Pars Reticulata to the deeper layers of the Superior Colliculus(SC), and biochemical findings suggest that GABA is the neurotransmitter involved in this projection. The aim of the present study was to investigate the role of GABA in SC-induced circling behavior. Intracranial injections of GABA, the GABA antagonist Picrotoxine or isotonic saline were made into the SC. Injections of GABA induced ipsiversive circling while injections of Picrotoxine induced contraversive circling. In both cases assymetry was also present. Saline had no effect upon circling behavior. The results suggest that GABA activity in the SC may be involved in motor assymetry.

223.16 TETRAHYDROCANNABINOL POTENTIATION OF RESERPINE-INDUCED CATALEPSY. D. E. Moss, S. N. Deyo*, J. Rogers, and S. B. McMaster*. Psychobiochem. Lab., Psychology Department, University of Texas at El Paso, El Paso, TX 79968, and A. V. Davis Center for Behav. Neurobiol., The Salk Institute, San Diego, CA 92138.

Delta-9-tetrahydrocannabinol (THC), a substance found in marihuana, potentiated reserpine-induced catalepsy in rats as measured in the "bar test" which times how long rats will stand with their forepaws on a horizontal bar 9 cm high. The rats were pretreated with 7.5 mg/kg reserpine (RES) or a placebo ip 24 hours before the tests for catalepsy in all experiments. The subjects were also pretreated with THC (1 to 10 mg/kg) or placebo by gavage 1, 2, 5, 12 or 24 hr before the bar test. THC, which produced no catalepsy by itself, produced a dramatic dose-dependent potentiation of RES-induced catalepsy with a more than 20 fold increase observed at 10 mg/kg THC ($p < .001$). The THC effect was fully developed by 1 hr after THC administration and was completed by 12 hr. The THC/RES catalepsy was slightly enhanced by the cholinesterase inhibitor physostigmine salicyclate (0.5 mg/kg) ($p < .05$), slightly but not significantly reduced by the anticholinergic scopolamine HBr (2 mg/kg), but almost completely blocked by ethopropazine (30 mg/kg), an anticholinergic antiparkinsonian drug ($p < .01$). THC/RES catalepsy was completely unaffected by naloxone (1 mg/kg).

Because the new phenomenon reported here shows that THC has important motor effects in RES-induced catalepsy which is an animal model of Parkinson's disease, it may be that THC or a similar drug can be used to increase the therapeutic potency of RES in hyperkinetic motor disorders. RES was one of the first drugs used successfully in the treatment of various choreiform disorders (Kempinsky et al., Neurol. 10, 38, 1960) and has been shown to be of benefit in tardive dyskinesia (Soto et al., Dis. Nerv. Sys. 32, 680, 1971; Villenuve and Boszormenyi, Lancet 1, 353, 1970) and in the treatment of Huntington's disease (Klawans, Eur. Neurol. 4, 148, 1970). Although the mechanism by which THC produces this dramatic interaction with RES is unknown at this time, receptor binding and other pharmacological experiments are being conducted in order to elucidate this phenomenon. It is hoped that the results of these experiments can lead to increased effectiveness in drugs used for the treatment of choreiform disorders as well as provide a behavioral model that can be used to identify neurochemical actions of THC that have important functional significance.

223.17 INVOLVEMENT OF NUCLEUS INTERPOSITUS IN ACTION TREMOR. R. J. Elble, M. H. Schieber, and W. T. Thach. Depts. of Anatomy and Neurobiology and Neurology and Neurosurgery, Washington U. Sch. of Med., St. Louis, MO 63110

A rhesus monkey was trained to insert its hand, fingers extended, into a wedge-shaped manipulandum and to track a visual display by angulating the wrist. Hold-ramp-hold and rapid alternating movements were performed under various uniform torque, viscous, and inertial loads. Microelectrode recordings were obtained from cerebellar nuclei, C7 and C8 dorsal root ganglia, and forearm muscles. Prior to CNS recording, a fine 11-13 Hz action tremor was present in the wrist movements and particularly the extensor movements under extensor loading. This tremor was associated with phase-locked bursting in the extensor muscle electromyograms (EMGs). During the first thirty days of recording from the cerebellar nuclei, this tremor exhibited a five-fold increase in amplitude while its frequency dropped to 5-7 Hz. With inertial loading, the mean tremor frequency dropped as low as 2.5 Hz, and with large viscous loads, the tremor was abolished. Using auto- and cross-spectral analyses, coherency and phase (timing) relationships were computed for tremor-related activity in the EMGs, spindle afferents, and interpositus neurons. The EMG tremor bursts in flexors and extensors were 180 degrees out of phase with respect to each other, led the peak muscle stretch by approximately 66 degrees, and were so timed that the resulting muscle tension from the EMG burst would be expected to enhance the tremor. Two spindles were studied, one flexor and one extensor. Each was modulated by the tremor. Their modulations were 180 degrees out of phase with respect to each other and had phase leads of 150 degrees with respect to peak muscle stretch. Thus, the EMG bursts followed the spindle bursts by approximately 39 msec. By applying torque pulses in opposite directions, 6 of 14 tremor-related interpositus (IP) neurons could be classified as responding to stretch of either the extensor or the flexor muscles. The tremor bursts of these neurons had an average phase lead of 51 degrees with respect to peak muscle stretch; their bursts followed spindle bursts by approximately 46 msec and EMG bursts by roughly 7 msec. Post-mortem histologic examination showed only faint gliotic electrode tracks in cerebellar nuclei (some into brainstem) without larger lesions, suggesting that these may have caused the change in tremor. In sum, tremor of 15 degrees amplitude or less produced nearly simultaneous bursts of forearm EMG and IP neurons. Since the slight damage in the vicinity of these neurons must have altered the tremor, IP neurons may play a role in feedback suppression of tremor.

223.18 LINGUAL VELOCITY AND DISPLACEMENTS IN SPEECH CONTROL. D.J. Ostry*, E. Keller*, A. Parush*, and F. Côté* (SPON: P. Braun). Departments of Psychology and Linguistics, McGill University and Université du Québec à Montréal, Montreal, Quebec,

Displacement, velocity and duration of tongue movements were examined to assess constraints on speech movement control. A computerized ultrasound recording system monitored vertical tongue dorsum displacement during the production of simple speech sounds. Three normal subjects produced self-paced sequences of non-meaningful consonant-vowel pairs, involving linguo-velar constriction in the posterior portion of the upper speech tract (e.g., /kaka/ or /gaga/). The sequences were produced at two speech rates, either with alternate vowels lengthened, or with all vowels given equal length.

The data were obtained using a unidirectional pulsed echo ultrasound transducer, placed in a vertical orientation below the chin along the midline of the jaw. The transducer was held in fixed position with respect to the hard palate by a head harness. The position of the tongue dorsum and a simultaneous acoustic signal were sampled at a one-msec rate. The tongue dorsum samples were pooled, providing an effective bandwidth of 15 Hz, and B-spline functions were derived for estimations of displacement, velocity, and acceleration.

Differences in displacement, velocity and duration of movement were obtained as a function of vowel length. Values for all three measures were greater for long vowels than for short vowels. Correlational analyses examined relations on a within-subject basis between maximum velocity on tongue lowering, distance and time to reach maximum velocity from linguo-velar contact, and distance and time from maximum velocity to the point of greatest distance from the velum. Subjects produced reliable correlations between maximum lowering velocity and distance from point of closure to the point of maximum velocity ($p < .01$ in all cases). In contrast, maximum lowering velocity was not related to any measure of movement duration. Thus peak velocities were greater for longer movements, but were not systematically related to duration. In addition, distance was correlated with movement duration only for the portion of the movement beyond the point of maximum lowering velocity. Findings are interpreted in the context of a system in which duration is a consequence rather than a specification of coordinated movement control for speech.

224.1 VITAL FREEZING OF HUMAN SCHWANN CELLS (HScC) FOR A CULTURAL FUTURE. J. V. Lawrence*, V. Askanas, W. K. Engel. Dept. of Neurology, Univ. of S. Calif., Sch. of Med., Los Angeles, California 90033.

Culturing of diseased HScC provides unusual opportunities for distinguishing between dysschwannian and dysneuronal human neuropathies, for studying biochemical and ultrastructural expression of defects in primary dysschwannian neuropathies (Neurol., 31:128, 1981, Ann. Neurol. in press) and for therapeutic trials in culture. We have recently described a technique for culturing of HScC and their histochemical and ultrastructural properties (Arch. Neurol., 37:329-337, 1980). To optimally utilize the irreplaceable patient material, we have now developed a technique for vital freezing both biopsied human sural nerve and human cultured schwann cells in dimethyl sulfoxide (DMSO) that permits long-term storage in liquid nitrogen and subsequent recovery for culturing. Some other human cells can be successfully frozen in 8% DMSO and 10% fetal calf serum (FCS) and later cultured; however, freezing of HScC required substantial modification of the freezing medium because use of that standard medium resulted in no survival of human schwann cells. The new vital freezing medium that we have used successfully is composed of 6% DMSO, 30% FCS, and 10% chick embryo extract in medium F-14. Any higher concentration of DMSO or lower amount of FCS caused decreased longevity of subsequently cultured human schwann cells and induced morphologic changes. Another important factor in successful freezing of HScC (not required for fibroblasts, lymphocytes, and myocardial cells) is slow freezing, during which the temperature drops 1°C per minute (from +25 to -60). Before slow vital freezing, the biopsied sural nerve was cleaned of epineurium and other connective tissue visible under dissecting microscope and cut into $1mm^3$ pieces, which were placed in sterile ampoules containing freezing medium. Previously cultured HScC, before slow vital freezing, were trypsinized in 0.25% trypsin for 15 min., the trypsin removed, and the cells placed in ampoules containing freezing medium. After freezing, the ampoules were stored in liquid nitrogen. In schwann cell cultures established after slow vital freezing, either in the nerve or in dissociated cells, the growth characteristics, phase-contrast, histochemical, and ultrastructural appearance of HScC were identical to the schwann cells in primary cultures of the same specimens. Vital freezing of diseased sural nerve biopsies and cultured HScC makes it possible to establish a tissue bank which provides the opportunity for studying those cells at virtually any time and also makes them available for the investigators in distant laboratories, thereby providing maximum utilization of the valuable, often irreplaceable, patient material.

224.2 NEURONAL SURVIVAL IN CNS CELL CULTURES ENHANCED BY ANTIMITOTIC DRUGS. Richard W. Burry, Department of Anatomy, College of Medicine, The Ohio State University, Columbus, Ohio 43210.

Dispersed cell cultures of the CNS contain both differentiating neurons and continually dividing non-neuronal cells. The purpose of this study was to evaluate several antimitotic drugs for their effect on neuronal survival.

Using a dispersed cell culture system of the rat olfactory bulb, several antimitotic drugs were tested to determine which would enhance neuronal survival. The olfactory bulb from two day old rats were dispersed mechanically with a Pasteur pipet and plated in Hams F_{12} with 24 mM K^+ at a density of $8X10^{-5}$ cells per 35mm dish. The drugs were added at 2 days in vitro (DIV) for 5 days at the following concentrations: methotrexate (MTX) 10^{-6}M, cytosine arabinoside (Ara-C) $8X10^{-6}$M, bromodeoxyuridine (BUdR) 10^{-5}M, and flurodeoxyuridine (FUdR) 10^{-4}M. MTX and FUdR were used in medium without thymidine. Cultures were examined every 7 days with a phase microscope and micrographs were taken.

In cultures without drugs the non-neuronal cells underwent continuous proliferations while most of the neurons died by 14 DIV. BUdR greatly reduced the number of non-neuronal cells and also allowed neurons to survive in large aggregates. By 91 DIV however, there was a return of a limited non-neuronal proliferation. Ara-C made a more permanent block of the non-neuronal cell through 91 DIV, but in the large aggregates of neurons there was a more refractile cellular debris than in BUdR treated cultures. FUdR, like Ara-C greatly reduced the number of non-neuronal cells but FUdR did not allow many neurons to survive. MTX did slow some of the non-neuronal cell growth, but like FUdR killed most of the neurons.

In summary, this study showed that BUdR reduced the number of non-neuronal cells and allowed maximum survival of neurons. BUdR incorporated before mitosis acts after mitosis in the daughter cells causing incorrect transcription of DNA to RNA. Ara-C greatly reduced non-neuronal cells with minimal effect on neurons. Ara-C inhibits nucleic acid incorporation into DNA of cells preparing for mitosis. MTX and FUdR reduced the number of non-neuronal cells and were also toxic to neurons. Both MTX and FUdR inhibit the synthesis of thymidine in cells preparing to duplicate their DNA for mitosis. It is concluded that BUdR and Ara-C, because they act later in mitosis than MTX and FUdR, are the antimitotics of choice in the olfactory bulb cell culture system. (Supported by a NINCDS Grant, NS-15894).

224.3 HYALURONIC ACID AFFECTS THE BEHAVIOR OF CULTURED NEURAL CREST CELLS. L. Luckenbill-Edds and J. Carrington*. Dept. Zoology & Coll. Osteopathic Med., Ohio Univ., Athens, OH 45701.

The extracellular matrix has been implicated in the migration and differentiation of neural crest cells in vivo (LeDouarin et al., 1975, Weston et al., 1978). We have tested the influence of hyaluronic acid (HA), a component of extracellular matrices in the early embryo, on the migration and morphological differentiation of neural crest cells in vitro. We cultured neural crest cells from neural tubes of 2-day Japanese quail embryos either in the presence of HA (5 µg/ml, Sigma type IV), or in control medium (CON) without added HA. Medium included Eagle's MEM, 10% heat-inactivated horse serum, 2mM HEPES buffer. The cultures were grown on gelatin-coated Nunc dishes and covered with a cellulose dialysis membrane (M. Derby, pers. commun.). Tubes were removed 16-19 h after explantation to eliminate contamination from neural tube cells. Cellular morphology was examined with an inverted phase contrast microscope. Migration of crest cells in paired CON and HA cultures was assessed in two ways: 1. the distance the population had migrated during the first 16-19 hours after explantation was measured for 50 cultures, 2. the total area of the culture was measured daily for 40 cultures. Since the total number of cells in a sample of 7 HA and CON cultures declined between days 1 and 3, it appears that proliferation does not contribute significantly to population outgrowth. In CON cultures, cells at first appear mesenchymal-like and migrate away from the origin where the neural tube had been located. Then, the majority of cells in CON cultures aggregate into clusters of small, phase bright cells which send out processes. Some small phase bright cells do not aggregate, but remain as single cells with branching processes. On the other hand, HA cells tend to remain mesenchymal-like, and migrate significantly further than CON cells, beginning with the first 16-19 h after explantation and continuing for the life of the culture. Few aggregates of small, phase-bright cells appear in HA cultures, and when they do, their appearance is delayed compared with CON cultures. The effect of HA is reversible, for if it is removed after 3 days of culture, the mesenchymal-like cells transform into small phase bright cells with processes as in CON cultures. On the basis of these results, our working hypothesis is that HA inhibits or delays the differentiation of mesenchymal-like neural crest cells into neurons.

Supported by grants from the American Osteopathic Foundation and the Society for Sigma Xi.

224.4 TOXICITY OF ORGANOTIN COMPOUNDS ON MAMMALIAN CENTRAL NERVOUS SYSTEM CELLS IN CULTURE. D. W. Schulz*, R. L. Thomas*, A. R. Kolber and R. S. Dyer. Chemistry and Life Sciences Group, Research Triangle Institute, Division of Neurotoxicology. U. S. Environmental Protection Agency, Research Triangle Park, NC 27709.

Several of the organotin compounds are known to induce pathological conditions such as convulsions, hyperagression, and locomotor difficulties. At the cellular level, triethyltin (TET) causes edema of CNS white matter, decreases in conduction velocity, and inhibition of oxidative phosphorylation, while trimethyltin (TMT) brings about neuronal damage specific to certain brain regions, most notably the hippocampus.

In an effort to establish an in vitro model of neurotoxicity, dissociated fetal mouse CNS cells were grown in culture and exposed to different concentrations of TET or TMT for varying durations. Cadmium (Cd), a known cytotoxin, was used as a positive control. The cells were explanted at day 13-17 in utero from either spinal cord, cortex, cerebellum, or hippocampus and maintained until functional differentiation was complete. The resulting mixed cultures contained morphologically identifiable astrocytes, oligodendrocytes, and neurons. Viability of the cultures was assessed by cell growth kinetics while morphological data was obtained using light and electron microscopy. Additional parameters monitored included changes in ATPase activity and alterations in normal electrophysiological behavior.

Each of the three organometallic compounds tested had a characteristic pattern of morphological toxicity. TMT at lower doses (10^{-6}M) selectively affected neurons, with marked changes seen in the structures of both dendritic processes and somas. TET induced formation of vacuoles in both glial and neuronal populations, while Cd caused a breakdown of all cell types. These effects were dose- and time-dependent and were reversible for TMT only. Inhibition of ATPase activity was observed following incubation with TET at concentrations as low as 3×10^{-7} M. Neurophysiological changes such as decreased resting membrane potential and depressed spontaneous activity were often noted following chronic or acute exposure to both tin compounds, but these generally occurred only after some of the above morphological changes were obvious.

The results of this in vitro study correspond well with data from whole animal experiments and suggest that a tissue culture system may provide a successful short-term method for assessing the neurotoxicity of suspected agents.

224.5 DEVELOPMENT OF CILIARY AND CHOROID NEURONS IN LONG-TERM CELL CULTURES. E. Rieske*, M. C. Kitzes*, L.-H. Liaw*, G. W. Kreutzberg* and M. Berns* (SPON: R. Wuerker). Max Planck Inst. Psychiatry, Munich, F.R.G., and Dev. Cell Biol., University of California, Irvine, CA 92717.

Cell culture conditions are described which allow maturation and long-term survival of differentiated ciliary and choroid neurons of chick embryo ciliary ganglia. Dissociated cells were cultured in medium containing 9-15 day old chick embryo eye and heart extract. The cultures were kept up to 6 months in vitro.

Initially, all cells are isolated from each other. During the first week a monolayer of non-neuronal cells is developed on top of which the neurons regenerate a fiber network. Neuron somata are 5 to 10μm in size, contain eccentric nuclei, abundant mitochondria and free ribosomes but only scant rough endoplasmic reticulum (RER). They reaggregate into small groups, their fibers being arranged into fiber bundles. At this stage neither neuron somata nor fibers are enveloped by glial cells. Axo-somatic puncta adherentia and synapses with clear and dense core vesicles and post-synaptic membrane thickening appear after 2 days.

During the 2nd and 3rd week almost all neuron somata are enveloped by satellite cells, and the nerve fibers by Schwann cells. Intracellular injection of Lucifer yellow shows that the neurons are typically unipolar.

After 4 weeks populations of small and large neurons become obvious. Small neuron perikarya, presumably choroid cells, are 10-15μm in size, have centrally located nuclei and dispersed RER. Large neuron somata, presumably ciliary cells, are about 30-45μm. Their centrally located nuclei are surrounded by abundant mitochondria, Golgi complexes and lysosomes. The RER is located at the perinuclear region. Neuronal size and ultrastructure indicate that choroid and ciliary neurons persist in vitro in spite of apparent absence of target cells.

Intracellular activity and responses to long lasting pulses of depolarizing current show that, at all stages, neurons are either silent or discharge repetitively for several min. after penetration. Neurons in cultures younger than 10-15 days have resting membrane potentials between -40 mV and -52 mV and typically are unresponsive to direct stimulation. Neurons in cultures older than 10-15 days show resting membrane potentials from -40 mV to -65 mV. Whether silent or spontaneously active, the neurons fire repetitively to long lasting high intensity pulses, as do ganglion cells in situ. The number of evoked discharges may decline with repeated current pulse delivery until only a single discharge occurs at the onset of the depolarizing stimulus.

Occasional transneuronal dye transfer after intracellular injection of Lucifer yellow may be indicative of gap junctions.

224.6 IMMUNOHISTOCHEMICAL CHARACTERIZATION OF PRIMARY CULTURES OF FETAL MOUSE SPINAL CORD. D.L. Begley*, E. Serrano*, B. Ranson*, J. DeVellis, Y-Berwald Netter*, and L.F. Eng. Dept. Path. and Neurol., VA Med Cen and Stanford U. Sch. Med., Stanford CA. 94305; Dept. Anat., UCLA, Los Angeles, CA. 90024; College of France, 75005 Paris.

The immunohistochemical PAP technique of Sternberger was employed to characterize cells in primary culture. These cultures were plated from dissociated spinal cord and dorsal root ganglia from 13 and 14 day fetuses. The cultures were analyzed at 3 and 4 weeks in vitro when neurons exhibit mature electrophysiological properties. Rabbit antibodies to the following were utilized: 1) glial fibrillary acidic (GFA) protein -- specific to astrocytes (Eng et al, J. Histochem. Cytochem. 27:513, 1978); 2) tetanus toxin-specific to neurons (Dimpfel et al, Naunyn Schmiedeberg's Arch. Pharmacol. 290:329-333, 1975); and 3) glycerol phosphate dehydrogenase (GPDH) -- specific to oligodendrocytes (Leveille et al, Brain Res. 196:287-305, 1980).

Each antiserum stained a specific cell population. GFA stained cells of three morphologies: 1) large flat polygonal cells with oval nuclei (astroblasts); 2) star-shaped cells with round nuclei and multiple processes (mature astrocytes); and 3) cells with large cytoplasmic cavities (intermediate form). Tetanus toxin stained cells of conventional neuronal morphology -- round cell bodies with large nuclei relative to cytoplasm and long branching processes. GPDH stained perinuclearly cells with 2 morphologies: 1) small bipolar cells with round nuclei surrounded by rims of cytoplasm and 2) small unipolar cells also with round nuclei surrounded by rims of cytoplasm with irregular outpouchings. Cells not stained by any of the antisera were always present in the cultures.

This study demonstrates the usefulness of immunocytochemistry and cell specific antibodies in characterizing primary tissue cultures with a heterogeneous population.

224.7 THE CULTURE OF ADULT HUMAN MUSCLE FOR BIOCHEMICAL INVESTIGATION. R.B. Moore*, M. Merickel, and S.H. Appel (SPON: A. Coats) Dept. of Neurology, Baylor College of Medicine, Houston, TX 77030

We have been interested in the biochemical characterization of adult human muscle using primary cultures with the goal of studying abnormalities in muscle disease. The primary culture of dissociated cells from adult muscle has several problems which are not necessarily encountered with embryonic or neonatal muscle: 1) Inaccuracy in the determination of the initial plating density results in cultures which develop in a non-uniform manner; 2) Low yield of undifferentiated cells greatly limits the number and kind of experiments which can be designed; 3) Heterogeneity of cell types confuses the interpretation of results.

To overcome these difficulties, we have investigated the following procedures. First, cultures of uniform plating density were obtained by replating after about 10 days in culture. There is little or no debris, the cells are large and they can be enumerated with greater precision. The plating efficiency of cells following this replating procedure was calculated to be greater than 90%. Cells from different muscle specimens that were replated at a density of 2.0×10^4 cells per 35mm dish developed similarly and fusion began between day 8 and day 10 after replating. Second, the number of cells to be used for an experiment was increased by growing them in a low calcium (100 to 200 μM) medium. This medium permits cell proliferation while preventing cell fusion. Myotubes which had formed after replating or after being grown in low calcium appeared to retain their basic properties since their resting membrane potentials and action potential parameters were not significantly different from myotubes which had formed in original cultures. Third, preliminary experiments using a discontinuous gradient of Percoll have demonstrated that a 36 to 54% interface contained a fraction of cells that were free of debris and which appeared to form more multinucleate myotubes following fusion than cells which were not placed on the gradient.

We intend to use these techniques to produce sufficient quantities of uniform cultures from both normal and diseased muscle for comparative biochemical analyses. (Supported by the Kleberg Foundation and the Muscular Dystrophy Association)

224.8 CELL CULTURE OF DISSOCIATED RAT SPINAL CORD AS AN ASSAY SYSTEM FOR TROPHIC AND TOXIC SUBSTANCES. Ken Vaca* and Stanley H. Appel. Dept. of Neurology, Program in Neurosciences, Baylor College of Medicine, Houston, Texas 77030.

Substantial evidence exists from in vivo preparations for effects of peripheral target tissues on the differentiation, growth and maintenance of spinal cord (SC) neurons. Cell culture affords a methodology for assaying the molecular basis of these effects. Several variables in culture conditions may be critical to the sensitivity of such an assay system. Mechanically dissociated SC from 13-14 day rat embryos was grown in Dulbecco's Modified Eagle Medium supplemented with 10% horse serum at a plating density of 2.5×10^5 cells/cm^2. Coculture with fused rat myotubes has only marginal (0-20% increase) effects on the ability of SC cells to accumulate and acetylate ^{3}H-choline, unless the proliferative SC cells are inhibited with 10^{-5}M fluorodeoxyuridine (FUdR), in which case muscle induces a 2-3 fold increase in ^{3}H-acetylcholine (ACh) synthesis after 5-7 days coculture. Muscle-conditioned medium can cause a modest increase in neurite outgrowth in standard medium, but can prevent complete degeneration in prolonged (2 wks or more) SC cultures treated with FUdR. Dialyzed muscle extract (MX, see Smith & Appel, this volume) had no effect on ^{3}H-ACh synthesis in standard medium, but typically caused a 30-60% increase in FUdR-treated cultures. On a poly-lysine (PLYS) or poly-ornithine (PORN) substrate, MX enhanced the tendency of the cells to aggregate and extend neurites. No aggregating effect is seen on collagen (Calf skin or rat tail) where SC cells cluster spontaneously, although neurite extension is enhanced. Thus only under certain culture conditions can SC cultures be optimally used to assay for a muscle trophic substance, which may be produced or substituted for by proliferative cells endogenous to SC.

SC cells can be grown in Bottenstein & Sato's defined medium (PNAS 76: 514-517) on a collagen substrate but start to deteriorate after a few days on PLYS or PORN. Better attachment is observed if the cells are plated in standard medium prior to switching to defined medium. SC cells can also flourish in a combination of 50% defined medium and 50% human CSF. MX enhances neurite outgrowth and ACh synthesis under both conditions. Human serum can be substituted for horse serum in standard medium, although its marked proliferative effect requires careful management with FUdR. Similar culture conditions which provide a sensitive assay for trophic factors also provide a convenient assay for toxic substances of clinical relevance.

224.9 CYCLIC MORPHOLOGICAL CHANGES OF GLIAL CELLS IN CELL CULTURES OF RAT BRAINS. K. Meller* and M. Waelsch*. (SPON: H. Eckert). Arbeitsgruppe Experimentelle Cytologie, Ruhr-Universität Bochum, 4630 Bochum, Fed.Rep.Germany.

The use of allohydroxyl-l-proline or cytosine-arabinoside and uridine in primary cultivation of isolated cells of rat brain cultures allows the separation of viable glial cell populations for long periods of cultivation (in excess of a year). During this period of cultivation it was found that glial cells undergo cyclic morphological changes.

Typical astroglial cells become flattened and form an "epithelial" monolayer. Two weeks or more later dark and small cell populations of glioblast-like cells appear between the monolayer cells. These cells divide rapidly and originate new groups of astroglial cells that are dispersed in the monolayer. This newly originated astroglia has short prolongations and becomes well differentiated after one to two weeks. In freeze-etching preparation the long prolongations of astroglial cells form typical junctional contacts, that cannot be demonstrated in any other phase of the cycle. Serum free medium causes a disappearance of the epithelial phase.

It is suggested that glial cells in the culture undergo a continual renewal and that this process is similar to the glial differentiating process in the embryonic matrix of the proliferative regions of the CNS.

224.10 CLONED THYMUS CELL LINES WITH NEURONAL PROPERTIES STIMULATE T_k ACTIVITY IN THYMOCYTES. K. Bulloch[1], R. Langman* and M. Cohn*
Division of Neuroimmunology, Department of Neurology, SUNY-Stony Brook, N.Y.11794, Developmental Biology Lab, Salk Institute for Biological Studies, LaJolla, Ca. 92138.

A study was carried out to evaluate the non lymphoid cell populations in the thymus that promote T cell maturation. To accomplish this goal, clone cell lines derived from the mouse thymus were characterized, and tested for their ability to influence the expression of T_k effector function. Because of the endocrine nature of the thymus, clones were derived from embryonic glands of the A.TL mouse utilizing tissue culture methods developed for the selection of paraneuronal cells. Two approaches were used. The cells were either subjected to treatment with the ethyl mercurial compound, thimerosal, or to the slow adaptation selection procedure. The resultant clones were then characterized as to their neurosecretory and immunological properties. In order to assess neurosecretory properties, voltage dependent channels were pharmacologically evaluated using a $^{22}Na^+$ flux assay. Histological techniques were also employed to assess the neurosecretory morphology of the cell lines. To evaluate immune function thymic and non-thymic clones were irradiated and incubated with thymocytes in the presence of con A. T_k activity was then assessed by a chromium release assay. Thymus clones selected by these methods were found to express either class A or class B "neuronal" voltage dependent channels. In addition, several of the clones expressing neuronal properties were capable of stimulating T_k activity in syngeneic but not allogeneic thymocytes. The presence of neuronal properties in thymic cell population involved in immune function is consistent with the literature. Recently, direct CNS parasympathetic (Bulloch, K. and Moore, R.Y., Anat. Rec., 196:25A, 1980) as well as sympathetic (Bulloch, K. and Loy, R., Soc. Neurosci. Abstr., 6:69, 1980) projections to the murine thymus have been described. Furthermore, both cholinergic and catecholaminergic transmitters have been shown to influence immune responsiveness. The current study begins to identify the cellular elements involved in thymic immune function and works in progress to establish a role for the autonomic nervous system in its regulation.

224.11 ACTIVITY AND LOCALIZATION OF 2′,3′-CYCLIC NUCLEOTIDE 3′-PHOSPHODIESTERASE IN NERVE CELL CULTURES H.W. Müller*, P.A. Clapshaw*, and W. Seifert (SPON: V. Braitenberg). Friedrich-Miescher-Laboratory, Max-Planck-Institute, Tübingen, W.Germany.

Previously, we have isolated 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNPase, EC 3.1.4.37) from bovine brain white matter (Clapshaw, Müller, Seifert - J. Neurochem., June 1981) and characterized the enzyme as a glycoprotein consisting of two polypeptide chains with molecular weights of approx. 53,000 and 56,000 (Müller, Clapshaw,Seifert - J. Neurochem., June 1981).

In order to understand the biological function of CNPase, we have measured and localized CNPase activity in various neuronal and glial cell lines and in fibroblasts as well as in primary cell cultures of rat CNS.

CNPase occurs in every investigated nerve cell line and in fibroblasts. Changes in enzyme activity of the cell lines can be correlated with different states of the cell cycle , growth, and differentiation. CNPase is stimulated in serum starved cultures compared to cells actively proliferating in the presence of fetal calf serum. The enzyme activity of the cells can be further increased in the G_1 state of the cell cycle by serum addition which provokes the reinduction of DNA synthesis and resumption of mitotic cycling.

The subcellular distribution of CNPase was examined in neuronal B104 and in astroglial C6 cells. Direct immunofluorescence staining with FITC-conjugated rabbit anti-CNPase antibodies indicates a discrete and specific intracytoplasmic location of CNPase. The enzyme could not be detected in the cell nucleus, at intracellular fibrillar structures, or at the cell surface. During cell fractionation CNPase activity seems to be bound to endoplasmic reticulum membranes or related membranes as monitored by marker enzyme activities.

CNPase is not present in primary neurons from rat hippocampus in culture. However, the enzyme activity could be detected in mixed glial cultures from rat brain containing astrocytes and oligodendrocytes. As indicated by immunofluorescence microscopy CNPase is not present in astrocytes but seems to be located on the cell surface as well as within the cytoplasm of the oligodendrocytes.

224.12 A COMPARISON OF ACETYLCHOLINE METABOLISM IN NERVE GROWTH FACTOR-TREATED AND UNDIFFERENTIATED PC12 CELLS. W.P. Melega* and B.D. Howard (SPON: R. Ng). Dept. of Biol. Chem., UCLA Med. School, Los Angeles, CA 90024.

PC12 is a clonal line of rat pheochromocytoma. PC12 cells synthesize acetylcholine and dopamine, store each in separate granules, and secrete each by a Ca^{2+}-dependent process. Upon exposure to nerve growth factor (NGF) the cells extend neurites. The undifferentiated and NGF-treated cells are similar with respect to choline transport. Each type of cell takes up choline by a carried mediated system (Km = 12 μM) that is Na^+ independent and insensitive to hemicholinium. Both types rapidly convert much of the accumulated choline to acetylcholine and slowly load the newly synthesized acetylcholine into granules. NGF-treated cells contain 3-4 times more total acetylcholine and granule acetylcholine per mg of protein than do undifferentiated cells. Similarly, NGF-treated cells contain 3-4 times more newly synthesized acetylcholine and load 3-4 times more of the newly synthesized acetylcholine into granules; they also release a greater percentage of the newly synthesized acetylcholine upon exposure to 55 mM K^+. Both types of cells bind quinuclidinyl benzilate (QNB) with similar affinities, but NGF-treated cells have 30% more QNB binding sites per mg of cell protein. Supported by USPHS grant NS 12873.

224.13 ENUCLEATION OF PC12 CELLS. R.A. Nichols, C.E. Chandler* and E.M. Shooter. Dept. of Neurobiology, Stanford University Sch. of Med., Stanford, CA 94305.

Previous studies have shown that nuclei isolated from the rat pheochromocytoma cloned cell line, PC12, bind nerve growth factor (NGF) in a specific and saturable fashion. When PC12 cells are cultured in the presence of NGF, the number of nuclear receptors increases over a period of days. During this time the cells internalize NGF, some of which is transported to and accumulates in the nucleus, paralleling the increase in NGF binding sites. The PC12 cells also grow neurites in response to NGF. The question then arises as to what role the nucleus plays in this phenomenon.

We have been able to enucleate PC12 cells, exploiting their ability to adhere tightly to an extracellular matrix (ECM) elaborated by bovine corneal endothelial cells. The enucleation was effected using a centrifugation technique with cells on ECM-coated plastic discs in the presence of cytochalasin B (CB) in culture medium. Detachment of 40-50% of the CB-treated cells was observed following centrifugation, although no cells detached during centrifugation without CB treatment or with CB treatment but no centrifugation. Of those cells remaining after centrifugation of CB-treated cells, 80-90% were enucleated ("cytoplasts") as evaluated by staining with either Giesma or Methyl green following fixation, or with acridine orange-ethidium bromide without fixation.

PC12 cells cultured on ECM displayed little or no neurite outgrowth (0-1%) without NGF. However, in the presence of 50 ng/ml NGF, 20-40% of the cells possessed neurites after 20 hrs. If the cells were treated with CB, this figure dropped to 10-20%. When CB treated cells were centrifuged and then cultured without NGF, little or no outgrowth was seen (0-5% of cells with neurites) and cell survival was poor. Finally, in CB-treated, centrifuged cultures maintained in the presence of NGF, 5-15% of the cells possessed neurites. Within this population the proportion of cytoplasts with neurites was similar to the proportion of nucleated cells with neurites.

The present data suggest that enucleation of PC12 cells does not prevent them from developing neurites in response to NGF, at least over a short time period. On the other hand, there is evidence suggesting that the presence of NGF in the nucleus of PC12 cells parallels the transcriptionally-dependent neurite outgrowth response. These two sets of data can be reconciled by postulating that the nucleus represses the neurite outgrowth mechanism and that either the presence of NGF in the nucleus or enucleation removes this negative control.

Finally, the present data suggest that the interaction of NGF with its receptor is required for neurite outgrowth in enucleated cells.

224.14 PEPTIDERGIC NEURONS FROM DISCRETE HYPOTHALAMIC NUCLEI IN LONG TERM TISSUE CULTURE. M. Dennis*, and M. Chrétien* (SPON: J. Lund). Protein and Pituitary Hormone Laboratory, Clinical Research Institute of Montreal, Montreal H2W 1R7, Canada.

Enzymatically dissociated cells were prepared from arcuate, paraventricular and supraoptic nuclei dissected from late foetal or early postnatal rat hypothalamus and cultured separately on poly-lysine coated glass coverslips. Cell attachment required the presence of 10% fetal calf serum during the first two days of culture, but long term growth and neuronal development was achieved in a serum-free defined medium (SFM) introduced on the third day. The morphology of cells in culture was followed by light microscopy which revealed the appearence after several days of cells with typical neuronal features and their progressive maturation up to 5 weeks in vitro, the longest period investigated. Two neuron types were observed; small (10-15 µm), oval, phase-bright cells with one or two processes and large (> 20 µm) multipolar neurons. Non-neuronal cells exhibiting typical astrocyte and oligodendrocyte morphologies were also present, but the proliferation of these cells was limited in SFM. Preliminary results indicate the presence of immunoreactive material corresponding to the neuropeptides characteristic for each region, i.e. β-endorphin in arcuate nucleus cultures and possibly neurophysin in cultures from paraventricular and supraoptic nuclei. Cultures derived from all three regions incorporated tritiated phenylalanine and leucine into tissue protein and released radiolabeled products into the medium during 16 hour pulse incubations. Two dimensional gel electrophoresis and autoradiography revealed a broad size and charge distribution of the biosynthetic products. Attempts to identify specific neuropeptides among the newly synthesized proteins will be discussed. (Work supported by MRC PG-2).

224.15 Long-term growth and selection of carotid body chemoreceptor cells in culture. Anne E. Schaffner and Mark C. Fishman, Laboratory of Developmental Neurobiology, N.I.C.H.D., N.I.H., Bethesda, MD 20205.

In order to evaluate the biochemical and physiological mechanisms of sensory transduction we have developed a system for long-term maintenance of carotid body chemoreceptor cells in primary cell culture. Carotid bodies from embryonic rats were dissected from the carotid bifurcation, enzymatically dissociated with trypsin and collagenase, and plated in collagen-coated dishes. Growth medium consisted of F12 enriched with additional amino acids (F14), 10% fetal calf serum and 80 U/L insulin. Cultures were maintained in a humidified atmosphere of 5% CO_2 and 95% air. Small epithelioid cells, exhibiting the morphology of Type I chemoreceptor cells, grew in isolation and in small clusters resembling the glomerular-like structures seen in vivo. Other cell types including fibroblasts and bipolar cells (Type II cells) were also present. The glyoxylic acid fluorescence histochemical method revealed intense catcholamine fluorescence in Type I cells growing in isolation and in clusters. Fluorescence also revealed long, slender processes on some Type I cells. Dramatic enrichment of the cultures for Type I cells was achieved by omitting the essential amino acid tyrosine (TYR) from the growth medium. This medium allows survival of only those cells containing tyrosine hydroxylase, an enzyme that catalyzes the conversion of phenylalanine to tyrosine (1). Only a few nonfluorescent cells survived in the absence of TYR. Type I cells remained viable for periods up to 7 weeks in culture during which time they continued to exhibit intense catecholamine fluorescence. Sympathetic neurons from the superior cervical ganglion (SCG), which provide efferent innervation to the carotid body, could be cocultured with Type I cells in growth medium lacking TYR if nerve growth factor was added. Growth and catecholamine fluorescence of Type I cells were unaffected by a 1 week incubation in atmospheres low in O_2 (5% O_2) or higher in CO_2 (10% CO_2). Steroids (10^{-6}M dexamethasone) were not necessary for the survival of Type I cells as they are for SIF cells from the SCG (2). This system will allow analysis of primary sensory transduction mechanisms of carotid body chemoreceptors and the nature of the synaptic transmission between these receptor cells and neurons.

224.16 ORGANOTYPIC CULTURES OF DORSAL ROOT GANGLIA FROM ADULT CATS. N. R. West. Depts. of Anatomy and Pharmacology, SUNY Upstate Medical Center, Syracuse, New York 13210.

Most nerve tissue culture models employ embryonic tissue as their starting material and commonly from chick eggs or mammals with short and easily timed gestation periods such as mice and rats. In anticipation of studies requiring direct correlations with in vivo work, it was desirable to develop a culture model of sensory neurons from cats. Due to the difficulty and expense of obtaining timed fetuses in this species and in that Murray and Stout (AM. J. Anat. 80:225, 1947) and several others have demonstrated that adult nerve tissue can be successfully explanted for culturing, it was considered reasonable to attempt establishing our model from adult cats.

Ganglia in sexually mature cats of unknown age are removed from the lumbar region of animals being used for spinal cord electrophysiological experiments. The dorsal root ganglia (DRG) are transferred quickly to ice cooled minimum essential medium supplimented with 600 mg% glucose and 50 ng/ml β-NGF (courtesy of Dr. R. W. Stach) in which the ganglia are then stripped of their perineureal capsule. After digestion with collagenase and trypsin the softened DRG are transferred to a small volume of explanting medium where any residual capsule is removed. They are then placed in a petri dish containing three drops per culture of medium where the DRG are gently teased into small clumps of neurons. The resulting suspension is pipetted into collagen coated dishes and maintained (Bunge and Wood, Brain Res. 57:261, 1973) without antibiotics but with 50 ng/ml β-NGF in the medium.

For the first four days in vitro (DIV) the axon stumps appear to swell along their length indicative of unwrapping of their myelin while at the cut tips the axons per se swell to form large bulbs. On 4 DIV supporting cells begin to migrate away from the clumps. Concommitantly, a large number of neurons undergo degeneration which continues for a week or more. During this time those neurons which are going to survive retain a fairly healthy appearance. These start to send out sprouts by 7 DIV, the new growth not coming from the cut axon tips. Myelinization starts within the clumps as early as 14 DIV and gradually continues out the growing processes. Growth continues until a state analogous to confluency is reached from which point there are only gradual changes and an occassional neuron degenerating.

Beyond their ability to survive axotomy and explantation, it is significant that at least a population of adult DRG neurons seems to be responsive to if not dependent upon NGF. This dependency upon NGF, plus neuron electrophysiological parameters and immunohistochemical affinities are being characterized.

224.17 ASTROGLIA PROVIDE A TEMPLATE FOR CEREBELLAR CELL POSITIONING IN VITRO. M.E. Hatten and R. Liem*. Dept. of Pharmacology, New York University Medical Center, New York, NY 10016

Indirect immunocytochemical staining with antisera raised against purified glial filament protein was used to study cell interactions between astrocytes and neurons dissociated from developing mouse cerebellum. During the first five days in vitro more than 99% of all processes present in cerebellar cultures were glial in origin. After that time, unstained processes appeared.

Stained astroglial processes formed a network which served as a template for cerebellar neurons. The time course of association of postnatal cerebellar neurons with astroglial processes was studied by the PAP method and by time-lapse video recordings. At plating, the cells were "rounded up" and monodisperse. Astroglial processes were extended after 4-6h in vitro, and after this time phase-bright, neuronal cells rapidly associated with the glial fibers.

Neurons could be removed from the network of astroglial process by a gentle stream of air from a Pasteur pipette mounted on a micromanipulator. The characteristic morphology of cerebellar astroglia was lost in the absence of cerebellar neurons. Purified cerebellar neurons reassociated with glial processes when added back to the glial process network. Supported by NIH grants NS-15429 to MEH and NS-15182 to RL.

224.18 SPONTANEOUS AND INDUCED DIFFERENTIATION OF NEUROBLASTOMA X GLIOM HYBRID CLONE NG 108-15: EFFECTS ON GANGLIOSIDE PATTERNS. R.L. Schnaar and N.M. Dahms*. Dept. of Pharmacology and Experimental Therapeutics, The Johns Hopkins University, Baltimore, MD 21205.

Differentiation of NG 108-15 cells in culture was quantitated using choline acetyltransferase (CAT) specific activity as a biochemical marker. The cells spontaneously differentiated (in the absence of added inducers) as the cell density increased. The CAT specific activity rose from 150 to over 400 pmol/mg protein-min as the cells approached confluence. The differentiating agents dibutyryl cyclic AMP (Bt_2cAMP, 1 mM) or a combination of PGE_1 (10 μM) and theophylline (1 mM) caused morphological differentiation (increased neurite extension) and increases in the CAT specific activity to 380 or 520 pmol/ mg-mi respectively after 72 h, regardless of the cell density. The "mock" differentiating agent, sodium butyrate (1 mM) caused morphological differentiation but only modest increases in CAT specific activity (to 240 pmol/mg-min after 72 h), and inhibited the density-dependent increase found with control cells.

Gangliosides extracted from cells grown under the various conditions described above were assayed by quantitative thin layer chromatography. All cells contained four gangliosides: monosialogangliosides GM_3, GM_2, and GM_1, and the disialoganglioside GD_{1a}. As the cell density of control cells increased, the predominant ganglioside GM_3 dropped from 35.9% (of the lipid sialic acid) to less that 19%, while GM_2 increased from 11.4% t 21.4% and GD_{1a} increased from 34.5% to 44.8% (GM_1 remained relatively constant). This shift towards more complex gangliosides was even more marked in the PGE_1-theophylline treated cells: GM_3, 12.3%; GM_2, 19.1%; GM_1, 17.2%; and GD_{1a}, 51.4%. The "mock" differentiating agent sodium butyrate caused no increase in GD_{1a}, but did cause a decrease in GM_3 (to 12.7%) and a marked increase in GM_2 (to 44.8%). The ganglioside pattern of the Bt_2cAMP-treated cells was intermediate between that of the PGE_1-theophylline and sodium butyrate treated cells.

These results demonstrate that: 1) Increased cell density causes spontaneous biochemical differentiation of NG 108-15 cells. In previous studies comparing differentiated to "undifferentiated" cells consideration must be given to the cell density of the controls. 2) Biochemical differentiation (spontaneous or induced) causes a marked decrease in ganglioside GM_3, and an increase in the more complex gangliosides GM_2 and GD_{1a}. 3) Mock differentiation causes only the GM_2 to increase without the concomitant increase in GD_{1a}. The biochemical basis for these changes, and their significance to the differentiated phenotype are matters for further investigation. Supported by NIH Grant #HD 14010, and National Foundation-March of Dimes Grant #5-302. NMD is supported by NIH Training Grant #GM 07445.

224.19 PURKINJE CELL MATURATION IN TISSUE CULTURE:AN ULTRASTRUCTURAL STUDY. N.K. Blank* and F.J. Seil (SPON: W.R. Woodward). Neurology Research, V.A. Med. Ctr. and Dept. of Neurology and Pathology, Univ. of Oregon Health Sci. Ctr., Portland, OR 97201.

Mature Purkinje cells from cerebellar explants have been shown to have many ultrastructural features similar to those found in vivo. Some investigators have also described several disimilarities, including: 1) persistence of numerous Purkinje cell somatic spines 2) the lack of relatively complete astroglial envelopment 3) an increased ratio of Purkinje cell dendritic spine to parallel fiber ratio 4) the presence of many unattached Purkinje cell dendritic spines and 5) the prominence of perineuronal extracellular space. The purpose of this study was to determine if these morphological differences were characteristic of in vitro development or were related to suboptimal culture conditions.

Cerebellar explants derived from newborn Swiss Webster mice were maintained in Maximow assemblies and fed nutrient medium twice weekly. Explants from 16-24 days in vitro were fixed in mixed aldehydes and prepared for ultrastructural studies using standard methods. Cerebellar cortex was surveyed and Purkinje cells and their dendrites were identified. The somata were relatively smooth, were ensheathed by glial processes and lacked spines. Purkinje cell dendrites were also surrounded by glial processes. Only minimal numbers of unattached dendritic spines were present, while the majority of the spines contacted parallel fibers in a 1:1 relationship. Perineuronal extracellular space was minimal. In suboptimal explants, such as in granuloprival cultures resulting from exposure to cytosine arabinoside, numerous Purkinje cell dendritic spines were found to be unattached to presynaptic elements and glial ensheathment of Purkinje cells was absent. In other suboptimal cultures, multiple dendritic spines were in contact with a single axonal terminal. The results of this study suggest that cultured Purkinje cells may attain a state of development resembling their in vivo counterparts. The previously reported atypical in vitro features were evident in suboptimal culture conditions in which complete Purkinje cell maturation was not attained. (Supported by the Veterans Administration).

224.20 IN VITRO DIFFERENTIATION OF A STEM CELL LINE FROM A RAT NEUROTUMOR RT4 TO DIFFERENT CELL LINES WITH NEURONAL AND GLIAL PROPERTIES

Yasuko Tomozawa and Noboru Sueoka* Dept. of Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO 80309

Rat peripheral neurotumor RT4 was induced by injection of neurospecific carcinogen ethylnitrosourea into newborn rat. Four morphologically distinct cell types were derived from RT4: RT4-AC, RT4-B, RT4-D, and RT4-E. Further, single cell clones of RT4-AC can generate the other three cell types (RT4-B, RT4-D, and RT4-E5) (cell type conversion). Karyotype analyses show that chromosome numbers of RT4 family are close to normal rat diploid cells. Biochemical and immunological analyses of mass populations of each of these cell types in cultured cells show the following results. The stem cell (RT4-AC) and RT4-D produce glial property markers, S100 and GFA proteins, but cell types RT4-B and RT4-E do not. The stem cell also shows a small but significant neuronal-specific response to veratridine on voltage-dependent Na^+-influx. Cell types RT4-B and RT4-E show a clear response of voltage-dependent Na^+-influx to veratridine as neuronal cells. Na^+-influx of RT4-AC, RT4-B, and RT4-E are greatly stimulated by scorpion toxin. In contrast glial type RT4-D does not show any response of voltage-dependent Na^+ influx to veratridine in the presence of scorpion toxin. These results indicate that (a) a population of the stem cell expresses both neuronal and glial properties. (b) RT4-B and RT4-E express a neuronal property and (c) RT4-D express glial properties. Therefore, cell type conversion of stem cell type to RT4-B and RT4-E seems to be a differentiation towards neuronal cells, and cell type conversion of RT4-AC to RT4-D to be a differentiation towards a glial cells in culture in vitro. In the process of cell type conversion at least two glial properties are segregated and expressed together in glial type cells RT4-D but not in neuronal type cells RT4-B and RT4-E (conversion coupling). RT4-AC and glial type RT4-D are tumorigenic cells, on the other hand neuronal type RT4-B and E are not tumorigenic. Therefore, tumorigenicity is coupled with glial property.

225.1 CHARACTERIZATION OF GLUTAMATE TRANSPORT INTO CULTURED GLIOMA CELLS. Robert A. Waniewski and David L. Martin. Toxicology Institute, Div. of Labs and Research, New York State Dept. of Health, Albany, NY 12201.

The accumulation of glutamate by glial cells in the nervous system suggests the involvement of these cells in the regulation of extracellular levels of this putative neurotransmitter. We have examined the properties of ^{3}H-glutamate uptake with LRM-55 cells, a glioma cell line derived from a rat spinal cord astrocytoma (Martin and Shain, J. Biol. Chem., 254:7076, 1979). Cells were grown in 24-well Falcon tissue culture dishes and fed Ham's F12 medium supplemented with 2.5% fetal calf serum. For uptake experiments, cells were washed and switched to a HEPES-buffered Hank's solution (pH 7.3) and incubated at 37°C. Time course experiments revealed a rapid accumulation of ^{3}H-glutamate reaching a maximum at 30 minutes. This maximum was followed by a decline in intracellular ^{3}H levels indicating rapid metabolism and release of metabolites. To estimate the initial velocity and saturation kinetics of ^{3}H-glutamate uptake, experiments were performed with incubation times of 5 minutes. Glioma cells were found to accumulate ^{3}H-glutamate primarily by a high affinity component with an apparent K_m of approximately 35 μM and a V_{max} of 5.4 nmoles/mg protein/minute. A low affinity component, found not to be saturable at substrate concentrations of up to 5mM, contributed minimally to the total uptake of ^{3}H-glutamate.

The transport system was found to be very specific for glutamate. In competition studies, all tested analogs of glutamate and aspartate were required in at least 10-fold excess of glutamate to produce any inhibition of uptake. L-cysteine sulfinic acid, L-aspartic acid and L-cysteic acid were the most potent competitors, reducing ^{3}H-glutamate uptake by 50% at approximately 50 times the concentration of glutamate. L-cysteine, D,L-homocysteic acid, D-glutamate and D-aspartate were of intermediate potency as competitors. Those analogs having little or no inhibitory effect on glutamate uptake include: N-methyl-D,L-glutamate, N-methyl-D, L-aspartate, kainic acid, D,L-alpha-methylglutamate, D,L-aspartate beta-hydroxamate, 2-amino-3-phosphonopropionic acid and asparagine. Taurine, glycine and isoproterenol were tested at concentrations of up to 10mM and were found to have no effect on high affinity ^{3}H-glutamate uptake. Diazepam inhibited uptake by only 20% with a 2 hour preincubation at 0.1 mM.

225.2 GLUTAMINE SYNTHETASE INDUCTION IN C-6 GLIOMA CELLS. W.J. Nicklas and E.T. Browning, Departments of Neurology and Pharmacology, Rutgers Medical School, Piscataway, N.J. 08854.

Brain glutamine synthetase (GS) is localized primarily in glial cells and may function to inactivate neuroexcitatory glutamate and provide a non-excitatory transport form for the carbon structure of glutamate, i.e. glutamine. Past work (J. Neurochem,30, 955) reported a low concentration of GS in C-6 glioma cells. Present studies show increased GS in C-6 cells with increasing culture passage or after treatment with dibutyryl-cyclic AMP (dbcAMP). Cells obtained from the American Type Culture Collection at passage 34 express low activities of GS (0.2-0.4 umole/mg protein/hr) 8-13 passages thereafter. Between passage 13 and 24 the activity rises to approximately 1 umole/mg protein/ hr. Cellular protein/DNA ratio rose from 13 to 18 over the same culture interval suggesting that the cells increase in size with increasing culture passage. DbcAMP (1mM) increased GS at both low and at high culture passage and also increased cellular protein/DNA. The maximum enzyme activity observed was 1.5 umole/mg protein/hr, comparable to that of rat brain homogenate in the same experiment. HPLC analysis indicated that 90% of the added dbcAMP remained in the medium after 2 days in culture. 8-Bromo-cAMP also increased GS. Butyrate (0.1 mM) did not increase GS activity. Lactate dehydrogenase activity was increased 2- to 3-fold by dbcAMP but was minimally altered by culture passage. Cycloheximide inhibited the rise in GS and lactate dehydrogenase activity induced by dbcAMP. The dbcAMP effect on cells at low passage was undetectable 3 hr after drug addition, detectable at 8 hr, reached a maximum at 48 hr after which it remained essentially constant. In conclusion, GS appears to be inducible in C-6 cultures and to reach activities observed in brain tissue under certain conditions of culture passage and drug treatment. (Supported by NS 08436, Rutgers Medical School GRS Funds, and CMDNJ Fdn.)

225.3 COUPLED DESENSITIZATION OF BETA ADRENERGIC RECEPTOR ADENYLATE CYCLASE AND INCREASED GLUCOSE UPTAKE IN C6 RAT GLIOMA IN VITRO N. Shitara*, F. Hirata*, C.J. Cummings*, P. E. McKeever*, B. H. Smith, S. Schmidt* and P.L. Kornblith*.(SPON. B.Smith)Sur. Neur. Br., NINCDS and Lab. Clin. Med, NIMH, Bethesda,MD 20205

Glucose uptake by both neurons and glia in the central nervous system may involve modulation by a direct coupling of the neurotransmitter receptor system to the glucose transport system. To study this possibility in glial cells the rat C6 cells are known to have beta-adrenergic receptors which are coupled to adenylate cyclase.

When C6 glioma cells were stimulated with 10^{-6}M isoproterenol, uptake of ^{3}H-deoxyglucose decreased by 50% in the first 30 minutes and then increased by 200% up to 150 minutes (compared to unstimulated control). This increased glucose uptake appears to be mediated through β-adrenergic receptors, since the order of potency of various catecholamines is isoproterenol > epinephrine > norepinephrine. In addition, the d-isomer of isoproterenol was much less active than the l-isomer and the β-adrenergic antagonist, propranolol, but not the α-adrenergic antagonist, phenoxybenzamine, inhibited the increase in glucose uptake. The intracellular cAMP levels under constant stimulation by β-agonists were used as a standard marker of adenyl cyclase uncoupling. Uncoupling occurred at 30 minutes at the same time that the 2-deoxyglucose incorporation rate increased.

The above data give evidence for an association between glucose uptake and β-adrenergic receptor stimulation.

225.5 VIMENTIN PHOSPHORYLATION: NOREPINEPHRINE DEPENDENT PHOSPHORYLATION IN C-6 GLIOMA CELLS. E.T.Browning Dept. of Pharmacol, Rutgers Med. Sch.Piscataway, N.J. 08854.

Vimentin forms the major subunit of a cytoskeletal intermediate (10 nM) filament in cells of mesenchymal origin including astrocytes and C-6 glioma cells. Vimentin undergoes phosphorylation on a small fraction of its copies; previous work demonstrated a 2-fold increase in vimentin phosphorylation following norepinephrine(NE) treatment of intact C-6 glioma cells (Mol. Pharmacol, 18, 427; J. Cell. Biol., in press). C-6 cells were equilibrated with ^{32}Pi for 4 hr then exposed to NE for 5' and the cellular phosphoproteins resolved by 2-dimensional gel electrophoresis as in past studies. Addition of actinomycin D to incubation fluid during equilibration of cells with ^{32}Pi decreased the ^{32}P-vimentin occurring under control conditions yet increased the increment in phosphorylation produced by NE. In the presence of actinomycin D the proportional change in phosphorylation induced by NE increased to 4.4-fold. Peptide mapping was used to further study the norepinephrine dependent phosphorylation of vimentin. Surface cultures were exposed to ^{32}Pi and NE as before. Cells were extracted with 0.5% NP-40, 2 M NaCl and residues containing vimentin were sonicated and vimentin solubilized with SDS-urea-lysine-$ZnCl_2$. Vimentin was purified by slab gel electrophoresis, cut from the gel and peptide mapped with Staph. aureus strain V_8 protease in a second gel. With increasing protease concentration vimentin cleaved into major discrete ^{32}P-peptides of 25,000 then 11,000 daltons. The labeling of ^{32}P-vimentin fragments derived from control and NE treated cultures suggested the presence of more than one phosphorylation site in the protein in that proportional increases in phosphorylation of individual peptides exceeded the increases observed in the intact vimentin. Again, increases were larger if actinomycin D was present during equilibration of cells with ^{32}Pi. Present evidence indicates that NE dependent phosphorylation can produce a 4-fold increase in phosphorylation of vimentin and suggest that the NE dependent phosphorylation site is distinct from another site which is phosphorylated under control conditions in the absence of actinomycin D.(Supported by NS 08436 and CMDNJ Fdn.)

225.6 ELECTROPHYSIOLOGY OF AND SENSITIVITY TO FUROSEMIDE AND MK473 OF Cl^- TRANSPORT IN PRIMARY ASTROCYTE CULTURES. H.K. Kimelberg and H. Hirata, Div. of Neurosurgery, Albany Medical College, Albany, New York 12208.

Astrocytes growing in primary culture show normal membrane potentials of -70 to -80mV at external K^+ concentrations of 4.5 mM K^+. These cultures were prepared from the dissociated cerebral hemispheres of 3 day old rats. Changes in external K^+ concentrations produced a close to Nernstian response in the membrane potential with a slope of up to 57mV per 10-fold change in $[K^+]_o$ for values of $[K^+]_o \geq 4.5$. The extrapolated value for $[K^+]_i$ was 130mM. In contrast, complete replacement of external Cl^- by isethionate or gluconate had either no detectable effect or resulted in a depolarization of up to 3mV. As previously reported (Neurosci. Abst. 6:548, 1980) tracer studies with $^{36}Cl^-$ showed that it rapidly enters these cells, reaching a steady state level after 10-20 min which represents around 0.15µmoles Cl^-/mg protein. Based on this steady state value and estimates of cell volume of 3 to 4µl/mg protein, the internal concentration of exchangeable Cl^- is 40 to 50mM. This is about 4 to 5-fold higher than expected from equilibration with a -70mV membrane potential. Addition of the anion $Cl^-/HCO_3^-/OH^-$ exchange inhibitor SITS (4-acetamido-4'-isothiocyanostilbene-2,2'-disulfonate) inhibited the initial rate of uptake of $^{36}Cl^-$, but had little or no effect on the steady state level. In contrast, furosemide inhibited both the initial rate of uptake and the final steady state level of $^{36}Cl^-$. Furosemide also partially inhibited uptake of K^+ as measured with $^{86}Rb^+$. Addition of furosemide also resulted in cell shrinkage, presumably due to loss of KCl, and caused intracellular acidification as measured with ^{14}C dimethyloxazolidine-2,4-dione. However, furosemide had no detectable effects on the measured membrane potential. Inhibition of Cl^- steady state levels was also found after addition of an indanyloxyacetic acid derivative of ethacrynic acid, MK473 (DCPI or [6,7 dichloro 2 cyclopentyl-1-2 methyl 1-oxo-5 indanyl] oxy acetic acid) which also inhibited $^{86}Rb^+$ uptake. In contrast SITS had no effect on $^{86}Rb^+$ uptake and its inhibition of Cl^- transport was not additive with furosemide. These results suggest that active accumulation of Cl^- in astrocytes occurs and is due to an electrically neutral coupled cation-Cl^- co-transport system involving at least K^+, which is inhibited by both furosemide and indanyl derivatives of ethacrynic acid but not by SITS. The function of the SITS and furosemide-sensitive anion exchange system may thus be primarily one of the intracellular and extracellular pH control, perhaps secondary to active accumulation of Cl^-. (Supported by NINCDS grant 13042 and a grant from Merck, Sharp and Dohme, who also supplied MK473).

225.7 A MONOCLONAL ANTIBODY TO OLIGODENDROCYTES. W.W. Peng*, R. Cole* and J. de Vellis (SPON: A. Castiglioni, Jr.). UCLA School of Medicine, Los Angeles, CA 90024.

A monoclonal antibody was obtained which distinguishes oligodendrocytes from astrocytes in rat brain primary cultures. This monoclonal antibody, named O1la, is a product of the fusion of S194/5.XXO.BU.1 myeloma cells and spleen cells from a mouse which was previously immunized with pure oligodendrocytes. Primary culture of dissociated rat brain cerebral cells prepared from 0 to 1-day-old rat pups. Oliogodendrocytes were identified as phase dark cells, resting on top of a bed layer cells of astrocytes. The overlying oliogodendrocytes were separated from the bed layer cells by mechanical shaking. The remaining astrocytes and purified oliogodendrocytes were then plated and grown on microtest plates or cover slips. The cultures were used for this study within two weeks. Antibody O1la was originally detected by ^{125}I-protein A binding assay on pure oliogodendrocyte primary cultures and cloned by limiting dilution method. Immunofluorescence experiments indicated that antibody O1la does not bind to primary astrocytes, normal fibroblasts, or C6 glioma cells, but it does bind specifically to oliogodendrocytes in purified cultures as well as mixed cultures of astrocytes and oligodendrocytes.

Since glycerol-3-phosphate dehydrogenase (GPDH) is a known biochemical marker for oligodendrocytes, a double labeling experiment of O1la antibody and anti-GPDH was performed on the same primary culture using fluorescein and rhodamine coupled second antibodies. The results demonstrate that antibody O1la and anti-GPDH bind to the same population of cells. Thus, from the morphological identification and the double labeling experiment, we conclude that the monoclonal antibody O1la is specific for oligodendrocytes in rat brain primary cultures. The distribution of O1la antigen in the rat brain and its relation to brain development and myelination will be studied. (Supported by NIH and DOE)

225.8 MONOCLONAL ANTIBODY TO A RAT GLIAL CELL ANTIGEN. E. Tiffany-Castiglioni* and J. de Vellis. Lab. of Nuclear Medicine and Radiation Biology, Univ. of California, Los Angeles, CA 90024.

A monoclonal antibody was obtained by the hybridoma technique which binds to an antigen of 1-3 week old cultured rat glial cells, C6 rat glioma cells, and glial fibers in rat brain tissue. The hybrid cell line which secretes the antibody arose from the fusion of mouse myeloma cells and spleen cells from a mouse injected with human myelin basic protein. The hybrid was detected by the binding capacity of its spent culture medium to an antigenic site in 2-3 week old cultures of glutaraldehyde- or paraformaldehyde-fixed neonatal rat oligodendrocytes using a protein A binding assay. The antigen, designated G23, was also present in aldehyde-fixed C6 cells as well as bed layer cells of neonatal rat cortex cultures from which oligodendrocytes had been removed by shaking. Astrocytes make up most of the bed layer population, though stem cells capable of differentiating into either glial cell type may also be present. Anti-G23 did not bind to fixed fetal rat skin fibroblasts or to live cells. Indirect immunofluorescence studies with FITC-labeled rabbit antibody to mouse IgG showed extranuclear binding of anti-G23 to the cell bodies of fixed (paraformaldehyde 4%, 24 h) oligodendrocytes and C6 cells, though a small percentage (<10%) of these cell types did not label. Anti-G23 also labeled most phase dark cells and some bed layer cells in 10 d and 22 d old primary cultures from neonatal rat cortex fixed 24 h, and pure cultures of the bed layer cells showed patchy staining along some cell bodies. Skin fibroblasts did not bind the antibody, nor did primary cultures or bed layer cells fixed for less than 2.5 h. The pattern of immunofluorescence in fresh and fixed (4% paraformaldehyde, 5 d) cryostat sections of 2-3 week neonatal rat brain was compared with that of anti-glial fibrillary acidic (GFA) protein. In sagittal sections of cerebellum, anti-G23, like anti-GFA, labeled Bergmann glial fibers and cells in the white matter which had small cell bodies and numerous processes. The fibers labeled by anti-G23 were finer and shorter than those labeled by anti-GFA. Both antibodies labeled more strongly in fixed than fresh-frozen tissue. In fixed and fresh coronal sections of the corpus callosum, anti-GFA labeled cells of similar shape to those seen in cerebellar white matter. However, anti-G23 detected cells of this shape only in fixed tissue. We conclude that G23 is an intracellular antigen found in glia subpopulations, notably oligodendrocytes and perhaps stem cells. Anti-G23 may have arisen in response to a contaminant of the original MBP inoculum.

Supported in part by the Bank of America-Giannini Foundation.

225.9 FURTHER EVIDENCE RELATED TO A POSSIBLE MACROGLIAL CELL INVOLVEMENT IN THE TRANSFER OF ^{3}H-PROLINE-LABELED MOLECULES ALONG FIBER TRACTS IN THE CENTRAL NERVOUS SYSTEM OF THE CAT. PART II. K.J. Berkley, N. Contos and H.H. Molinari. Dept. Psychol., Fl. St. Univ., Tallahassee, FL 32306 (KJB, NC) and Dept. Anat., Albany Med. Col., Albany, N.Y. 12208 (HHM).

Results obtained previously in our laboratory demonstrating that ^{3}H-proline (^{3}H-pro) is preferentially incorporated into the macromolecules of macroglial cells suggest that macroglial cells may be involved in the transfer of ^{3}H-pro-labeled molecules along fiber tracts. The light microscopic autoradiographic work to be reported here and in an associated abstract (Part I, Contos et al., 1981) extends these investigations.

Two studies were done to characterize the nature of the ^{3}H-pro-labeled material. (1) ^{3}H-pro was injected into the dorsal column nuclei (DCN) together with puromycin, a reported blocker of protein synthesis. No labeling occurred either in DCN or in its terminal targets. (2) The ^{3}H-pro labeling pattern was compared with that of ^{3}H-hydroxyproline (^{3}H-hyp), which is an amino acid found abundantly only in fibrous proteins such as collagen. The ^{3}H-pro and ^{3}H-hyp labeling patterns in DCN and its terminal targets were identical. These results suggest that the ^{3}H-pro in these experiments has been incorporated into a macromolecule that may be related to basement membrane collagen.

Three studies were done to characterize the transfer process. (1) ^{3}H-pro was injected directly into fiber tracts (internal capsule, internal arcuate). Dense labeling occurred over glial cells extending several mm in both directions along the length of the tracts. (2) ^{3}H-pro was injected in DCN subsequent to an injection of kainic acid, a reported neurotoxin. Labeling still occurred over glial cells in DCN, but no labeling was observed over terminal targets of DCN such as the inferior olive and thalamus. (3) ^{3}H-pro was injected in DCN together with colchicine, which is reported to interfere with axonal transport associated with microtubules. Labeling occurred not only over glial cells in DCN, but also over the inferior olive. Taken together, the results of these three experiments strongly support the involvement of glial cells in the transfer of ^{3}H-pro-labeled macromolecules along fiber pathways. The results with kainic acid and colchicine, however, indicate that this transfer probably involves a complex interaction between the glial cells and their associated neurons.

Supported by NSF grant BNS 79-03424.

225.10 FURTHER EVIDENCE RELATED TO A POSSIBLE MACROGLIAL CELL INVOLVEMENT IN THE TRANSFER OF ^{3}H-PROLINE-LABELED MOLECULES ALONG FIBER TRACTS IN THE CENTRAL NERVOUS SYSTEM OF THE CAT. PART I. N. Contos, H.H. Molinari and K.J. Berkley. Dept. Psychol., Fl. St. Univ., Tallahassee, FL 32306 (NC, KJB) and Dept. Anat., Albany Med. Col., Albany, N.Y. 12208 (HHM).

Previous electron microscopic autoradiographic work in our laboratory has demonstrated that when ^{3}H-proline (^{3}H-pro) is injected into the dorsal column nuclei (DCN), it is preferentially incorporated into the macromolecules of macroglial cells not only within the vicinity of the injection site, but also along the internal arcuate fibers projecting from DCN to its terminal targets. In contrast, when ^{3}H-leucine is injected into DCN, it is incorporated by neurons as well as glial cells in DCN, and the axoplasm of the internal arcuate fibers is more densely labeled than the associated myelin and glial cells. These results suggest that macroglial cells may be involved in the transfer of ^{3}H-pro-labeled molecules along fiber tracts. The light microscopic work to be reported here and in an associated abstract (Part II, Berkley et al., 1981) extends these investigations.

In order to examine the generality of ^{3}H-pro's incorporation pattern in the nervous system, injections of ^{3}H-pro were made in different nuclei located at several levels along the neuroaxis (e.g., cerebral cortex, thalamus, cerebellar cortex, reticular formation, lateral cervical nucleus, dorsal horn of spinal cord and dorsal root ganglion). Invariably, glial cells were densely labeled at the injection site. The density of neuronal labeling was usually less than that of the glial cells, but varied with site. For example, dorsal root ganglion cells were as densely labeled as the oligodendrocytes associated with its fiber processes, but neurons in the ventrobasal complex of the thalamus were considerably less densely labeled than their associated glial cells. In the lateral cervical nucleus, the large neurons were sparsely labeled compared to the glial cells.

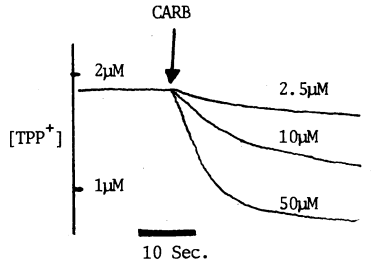
It is concluded that the dense incorporation of ^{3}H-pro into macromolecules located in macroglial cells is a generalized feature of ^{3}H-pro's incorporation pattern throughout the nervous system, whereas the neuronal incorporation of ^{3}H-pro appears to vary from site to site. The basis for this variance is not yet understood.

Supported by NSF grant BNS 79-03424.

226.1 LIGAND-INDUCED CONFORMATIONAL CHANGE OF THE CHOLINERGIC POST-SYNAPTIC MEMBRANE. S. Hestrin*, C.G. Davis*, A.S. Gordon, I. Diamond, and J.I. Korenbrot. Depts. of Neurology and Physiology, Univ. of Calif., San Francisco, CA 94143.

We have found that the cholinergic agonist carbachol induces partitioning of the hydrophobic ion TPP^+ (tetraphenylphosphonium) into AChR-enriched membranes isolated from the electroplax of Torpedo californica. The concentration of free TPP^+ in solution was measured with a TPP^+ selective electrode (which gave a Nernstian response down to 5 x 10^{-7}M TPP^+). The concentration of free TPP^+ in a Ringer's solution containing 2uM TPP^+ and AChR-enriched membranes (~10uM α-bungarotoxin binding sites) was continuously monitored. Addition of carbachol to the solution resulted in a decrease of the concentration of free TPP^+ to 1um. It was found that this response was specific for AChR since preincubation with α-bungarotoxin prevented any detectable decrease. The decrease of free TPP^+ was not the result of a change in transmembrane potential because it occurred with symmetric ionic solutions across the membrane and, in addition, was not affected by 0.1% digitonin. In the range of 1uM to 1,000uM carbachol the time constant of the initial rate of decrease was 100 seconds to 2 seconds respectively.

We conclude that binding of cholinergic ligands to the AChR induced thermodynamic changes of the post-synaptic membrane. The slow time course of the TPP^+ partitioning indicates that it is responding to events which are secondary to the conductance increase.



226.2 INFLUENCE OF PH ON THE INTERACTIONS OF DRUGS WITH THE NICOTINIC RECEPTOR-ION CHANNEL COMPLEX. Robert S. Aronstam. Department of Pharmacology, Medical College of Georgia, Augusta, GA 30912

Perhydrohistrionicotoxin (H_{12}-HTX) and phencyclidine (PCP) block neuromuscular transmission as a consequence of interactions with sites outside the nicotinic receptor (i.e., the ACh binding site) per se. While the nature of these sites is not clear, these compounds have been termed "ion channel blockers" because of their specific effects on the time course and conductances of end plate ion channels.

Specific binding of 2 nM [^{3}H]PCP to receptor-channel complexes in Torpedo membranes is negligible below pH 5.6 and is maximal between pH 6.4 and 9.2. A similar pattern is observed with the methiodide derviative of [^{3}H]PCP. In the presence of receptor agonists (acetylcholine (ACh), carbamylcholine and anatoxin-a) the extent of 2 nM [^{3}H]PCP binding is increased 5-8 fold. Under these conditions [^{3}H]PCP binding is negligible below pH 5.6, increases steadily from pH 5.6 to a maximum at pH 9.2, and decreases to about 70% of maximum by pH 11.0. While the binding of [^{3}H]H_{12}-HTX to the ion channel is also increased in the presence of receptor agonists, the binding is constant between pH 6.8 and 9.2. No specific [^{3}H]H_{12}-HTX binding could be detected below pH 5.6 and binding decreased above pH 9.2 to 60% of maximum at pH 10.0. It would appear that in the presence of receptor agonists sites or interactions are available for [^{3}H]PCP in its uncharged form (the pK_a for PCP is 9.42 at 25°, Maayani and Gross, Fedn. Proc. 39:30, 1980). In the absence of receptor agonists, [^{3}H]PCP and [^{3}H]PCP-MeI interact with a limited number of sites which are qualitatively different.

[^{3}H]ACh binding to the receptor was measured by equilibrium dialysis. Binding was totally depressed at pH 5.2 and rose to a broad peak between pH 7.6 and 9.6.

When the membranes were held at various hydrogen ion concentrations for one hour before measuring [^{3}H]ACh binding at pH 8.0, an irreversible denaturation of binding sites occurred below pH 6.4; preincubation at pH 5.2 resulted in complete inhibition. [^{3}H]PCP and [^{3}H]H_{12}-HTX binding was similarly affected by exposure to low pH. In contrast, the inhibition of all receptor and ion channel binding by previous exposure to pH levels between 9.2 and 11.0 was completely reversed upon lowering the pH. The similar senstivity to pH of ion channel and receptor binding indicates a close relationship between the sites.

Supported by NIH grant DA-02834.

226.3 ULTRAVIOLET LIGHT-INDUCED CROSSLINKING OF NONCOMPETITIVE BLOCKERS TO THE TORPEDO MARMORATA ACETYLCHOLINE RECEPTOR. R.E. Oswald and J.P. Changeux. Neurobiologie Moléculaire, Institut Pasteur, 25 rue du Dr. Roux, 75015 Paris, France.

The acetylcholine receptor (AcChR) of Torpedo electroplaque is composed of four subunits having apparent molecular weights of 40 000 (α), 50 000 (β), 60 000 (γ), and 66 000 (δ). These polypeptide chains seem to contain binding sites for AcCh, an ion channel specific for cations, and a binding site(s) for noncompetitive blockers of the response to AcCh. The AcCh sites are carried at least in part by the α subunit, and studies with the covalent blocker, 5-azido-trimethisoquin, suggest that the binding site for these compounds is carried by the δ chain (Oswald, Sobel, Waksman, Roques & Changeux, FEBS Lett., 111, 29-34, 1980; Saitoh, Oswald, Wennogle & Changeux, FEBS Lett., 116, 30-36, 1980). The portion of the molecule comprising the ion channel is unknown but may be associated with the site for noncompetitive blockers.

We have found that reversible noncompetitive blockers can be attached covalently to the AcChR by ultraviolet irradiation at 254 nm. UV irradiation of the AcChR in the presence of (^{3}H)-trimethisoquin, (^{3}H)-phencyclidine, (^{3}H)-perhydrohistrionicotoxin, (^{3}H)-chlorpromazine, or (^{3}H)-meproadifen resulted in the covalent labeling of the receptor (observed on SDS gels) in a manner consistent with the reversible binding of noncompetitive blockers. That is, the labeling was enhanced by cholinergic agonists (and some antagonists) and was inhibited by other noncompetitive blockers. Trimethisoquin, phencyclidine, and perhydrohistrionicotoxin specifically labeled the δ chain, whereas meproadifen labeled both the α and δ chains and chlorpromazine labeled all four receptor subunits. These data indicate a contribution of the δ chain to the binding site(s) for noncompetitive blockers and suggest that either other receptor subunits contribute to this binding site or that other subunits contain additional binding sites.

226.4 RELATIVE POTENCIES AND CHANNEL PROPERTIES INDUCED BY CYCLIC NICOTINIC AGONISTS. C.E. Spivak* and E.X. Albuquerque. (SPON: J.E. Warnick). Dept. of Pharmacol. & Exp. Ther., University of Maryland School of Medicine, Baltimore, MD 21201.

Several cyclic nicotinic agonists were assayed by contracture of the frog's rectus abdominis muscle and compared in terms of their receptor channel properties. The mean channel lifetime (τ) and the mean channel conductance (γ) were computed by Fast Fourier analysis of endplate current noise generated when the agonists were applied to frog sartorius endplates by iontophoresis. Natural anatoxin-a (AnTX-a) was found, by rectus abdominis assay, to be 2.5 times as potent (95% confidence interval, 2.2 to 2.9) as the synthetic, racemic mixture. Although AnTX-a is an agonist at least as potent as ACh (Spivak et al., Mol. Pharmacol. 18:384, 1980), these findings suggest that the unnatural enantiomer may be a weak inhibitor of the receptor ion channel complex. Arecoline methiodide (ArMeI), which resembles AnTX-a by its conjugated carbonyl group, induces a shorter γ than does ACh or AnTX-a. Thus at -90 mV and 22 °C, τ for ArMeI was 0.41 msec whereas τ for ACh was 1.6 msec; at -75 mV and 10 °C, τ for ArMeI was 1.4 msec whereas τ for ACh was 4.0 msec. The slopes of the plots of ln τ vs membrane potential were indistinguishable for these two compounds at both 22 °C and at 10 °C. Average γ's were also indistinguishable (~ 20 pS). The tricyclic agonist cytisine was found, by the rectus abdominis assay, to be 0.088 times as potent as racemic AnTX-a (95% confidence interval, 0.076 to 0.104). Noise analysis of endplate currents produced at 22 °C showed that mean γ induced by cytisine was about 70% of that induced by ACh when data were pooled. Paired responses (N = 6), however, to ACh and cytisine delivered succesively by a double barrelled pipet indicated no difference. On the other hand, γ induced by cytisine was significantly less ($P < 0.05$) by both types of analysis, being about 60% of that induced by ACh. (±)-muscarone, at 10 °C, induced significantly shorter τ's than did ACh at 10 °C. At -90 mV, τ for muscarone was 1.6 msec vs 4.0 msec for ACh. The voltage sensitivity of τ induced by muscarone was indistinguishable from that of the ACh-induced τ. The γ induced by muscarone was about 75 % of that induced by ACh. These cyclic agonists, which are more nearly rigid than the acyclic ones, hold more promise of discovering how parameters of structure in agonists modify fundamental responses in the receptor ion channel complex. (Supported in part by USPHS grant NS-12063 and U.S. Army Research Office grant DAAG-29-78-G-0203.)

226.5 OPEN ACETYLCHOLINE (ACh)-GATED CHANNELS BLOCKED BY CHLORISONDAMINE UNDERGO A TRANSITION TO A BLOCKED-CLOSED STATE. C. Lingle. Biology, Brandeis University, Waltham, MA 02254.

This report shows that chlorisondamine (CHLOR) blocks ACh-activated responses by a channel block mechanism. Regions of the gml muscle of the lobster, Panulirus interruptus, were voltage clamped. Synaptic currents were examined with an extracellular focal electrode placed at single synaptic sites.

Block by CHLOR of ACh currents is favored by hyperpolarization. During repetitive ACh iontophoretic responses in CHLOR, following a voltage step in the hyperpolarizing direction several pulses are required before a steady state block is obtained. Latency after voltage step prior to the first response in a series does not affect initial response magnitude. Thus, the block requires exposure to ACh. When steady-state block is reached at -140mV, intervals up to 3 min. between iontophoretic responses produce no recovery from the block. Similarly, steps in voltage from -140mV to -80mV for intervals up to 3 min. before return to -140mV do not produce recovery from the steady state blocked level. If a voltage step from -140mV to -80mV is followed by at least one ACh pulse prior to return to -140mV, the next response elicited at -140mV is unblocked.

Ejc decays are single exponentials in the presence and absence of CHLOR. $5x10^{-6}$M CHLOR shortens the ejc decay rate from 32 ms to 13 ms at -140mV and 18 to 14 ms at -80mV at 11C. In CHLOR, ACh-induced currents during voltage jumps show a slow exponential decay. Despite variations in agonist concentration between different jumps the time constant of slow decays was 2.19 ± 0.33 s at -140mV and 11C. A reaction sequence which minimally accounts for the results is:

$$A+R \underset{\alpha}{\overset{K_{12}}{<-->}} AR \underset{b^*}{\overset{\beta}{<-->}} AR^* + CHLOR \overset{f^*c}{<-->} AR^*C \overset{k_c}{<-->} ARC \overset{K_{56}}{<-->} A+RC \quad (k_o)$$

where A is agonist; R, receptor; AR^*, open channel; AR^*C, blocked-open channel; ARC, blocked-closed channel; and rate constants or equilibrium constants are as indicated. Transitions from RC to R do not seem to occur. Measured decays thus represent the rate of establishment of equilibrium among 6 states as manifested in transitions between open and closed states. The modification of ejc decay in CHLOR is interpreted to be a function of f^*c, the apparent forward blocking rate, about $10^7 M^{-1}s^{-1}$ at -140 and increased with hyperpolarization. If, during long voltage jumps, transitions between AR^* and AR^*C are assumed to be near steady-state, the slow relaxation reflects $1/k_c+k_o$, the time constant of the process establishing equilibrium between the blocked-open and blocked-closed states at a given membrane potential. Supported by a MDA postdoc, NSF BNS-78-15399, the McKnight Foundation (to E. Marder).

226.6 END-PLATE CURRENTS ARE PROLONGED AT REINNERVATING NEUROMUSCULAR JUNCTIONS. THOMAS M. ARGENTIERI* AND JOSEPH J. McARDLE. (SPON: H. SAPRU) DEPARTMENT OF PHARMACOLOGY NEW JERSEY MEDICAL SCHOOL - CMDNJ, NEWARK, NEW JERSEY.

The deep peroneal nerve was crushed approximately 1.2 cm from its entrance into the extensor digitorum longus muscle (EDL) of female Wistar rats. Under this condition, functional reinnervation begins nine days after nerve crush (McArdle and Albuquerque J. Gen. Physiol., 61:1, 1973). Animals were sacrificed 14-15 days after nerve crush and the EDL, along with a 1.5 cm length of attached nerve, was removed. The nerve-muscle preparation was then set-up for in vitro recording (20-22°C) of synaptic activity. End-plate potentials (EPP's) recorded in cut fiber preparations, were found to be prolonged at regenerating synapses. Specifically, the $T_{½}$ of EPP decay increased from a control value of 1.90±0.49 msec. to 7.00±1.87 msec. (mean ± S.E.M.). Several factors in reinnervating muscle may be responsible for this abnormality: 1) an increase in the time constant of the muscle membrane, 2) the reduction of acetylcholine esterase (AchE) activity after denervation 3) changes in the channel environment which in turn may alter channel kinetic properties, and 4) channel changes which result in altered channel life time. To exclude the influence of post synaptic cable properties, a voltage clamp technique was used to analyze the end-plate current (EPC). The $T_{½}$ decay of EPC's was also found to be prolonged during synaptogenesis from a control value of 1.52±0.18 msec. to 6.8±1.56 msec. at a holding potential of -60 mV. Experiments were also performed to study the role of AchE at regenerating synapses. EPC's were further prolonged when preparations were superfused with 1.0 μM neostigmine-bromide. This data suggests that 14-15 days following nerve crush, functional levels of AchE do exist, however, its role in regulating EPC life time remains to be quantitated. It is known that changes in membrane fluidity at the site of the acetylcholine receptor channel will alter the decay of the EPC's (Gage et al, Life Sci. 14:2277, 1974). Experiments to study the effect of denervation on membrane composition and fluidity will be discussed. (Supported by NIH Grant NS-11055-08).

226.7 REDUCTION OF CHOLESTEROL CONTENT OF MUSCLE INCREASES THE END-PLATE RESPONSE TO ACETYLCHOLINE. J.J. McARDLE AND A.J. D'ALONZO.* LABORATOIRE DE NEUROBIOLOGIE CELLULAIRE, CNRS, 91190 GIF-SUR-YVETTE, FRANCE AND DEPARTMENT OF PHARMACOLOGY, CMDNJ, NEWARK, NEW JERSEY, 07103.

Katz and Thesleff (J. Physiol. 137:267, 1957) demonstrated that the response of the muscle end-plate (EP) to acetylcholine (ACh) is directly proportional to the electrical resistance of the sarcolemma. The objective of this study was to take advantage of this relationship to increase the ACh sensitivity of the EP. To do this, animals were treated with 20,25 diazacholesterol (DC) which inhibits cholesterol synthesis. Rats received 300 mg/Kg (p.o.) of DC on days 0 and 7. Between days 20 and 25, the extensor digitorum longus muscle (EDL) was removed. Gas liquid chromatography revealed that cholesterol content of the EDL decreased from 247.5±41.1 (mean ±SEM) to 137.0±11.6 mg/g of muscle. This was associated with an increase of membrane resistance from 711±33 to 1698±163 Ω/Cm2 which was due solely to a decrease of chloride conductance from 1401 to 570 pS. Because of its anatomical advantages, the deep thoracic muscle of mice was assayed for ACh sensitivity. This muscle responds to DC similarly to the EDL. Mice were injected with 50 mg/kg (s.c.) of DC at 4 day intervals and sacrificed 4 days after the 6th injection. The EP sensitivity to ACh was increased from 2062 to 3553 mV/nCoul as a result of this treatment. This finding suggests that synaptic efficiency is increased in response to reduction of the cholesterol content of muscle. The implications of this observation for neuromuscular pathology and neurobiology in general are under investigation. (Supported by Le Fondation De L'Industrie Pharmaceutique Pour La Recherche and NIH grant NS 11055-08).

226.8 "HIDDEN" α-BUNGAROTOXIN BINDING SITES IN RAT SKELETAL MUSCLE IN VIVO. A. Pestronk, Dept of Neurology, Johns Hopkins Sch. of Med. Baltimore, MD. 21205

The distribution of acetylcholine receptors (AChR) on the surface membrane of skeletal muscle can be demonstrated by the binding of α-Bungarotoxin (α-BuTx). In innervated muscle α-BuTx binding is located mainly at neuromuscular junctions. After denervation extrajunctional α-BuTx binding increases markedly. We have found that treatment of rat skeletal muscle with saponin reveals additional "hidden" α-BuTx binding sites.

Soleus muscles from 10 wk old rats were removed, teased into longitudinal strips and fixed in 2% formaldehyde. Available surface AChR were then measured using an ^{125}I-α-BuTx binding technique. "Hidden" α-BuTx binding sites were demonstrated by incubation of muscles for 5 min in 0.5% saponin before exposure to ^{125}I-α-BuTx.

Fixed muscles showed an average of 1.5 ± 0.3 x 10^7 AChR per neuromuscular junction (NMJ). This was not different from the figure of 1.6 ± 0.3 x 10^7 AChR/NMJ found in fresh unfixed fibers from the same muscles. Treatment of fixed muscle with saponin revealed an additional 0.9 ± 0.2 x 10^7 α-BuTx binding sites localized in segments of muscle containing NMJs. Autoradiography revealed that these sites were located at and near the area of the NMJ but over a longer length of the muscle fiber. These binding sites were specific since preincubation with unlabeled α-BuTx inhibited all NMJ binding of ^{125}I-α-BuTx in control and saponin treated muscles. Blockade of surface AChR in vivo had no effect on the "hidden" α-BuTx binding sites. 5 days after injection of 5 μg of α-BuTx into the soleus muscle junctional AChR were reduced to 0.3 ± 0.2 x 10^7/NMJ while the "hidden" α-BuTx binding sites were unchanged at 0.9 ± 0.2 x 10^7/NMJ.

In NMJ-free segments of innervated muscle there were low levels of surface AChR and hidden α-BuTx sites. Extrajunctional AChR averaged 1.7 x 10^3/μm of muscle fiber compared with 1.1 x 10^3 hidden α-BuTx sites/μm. After denervation both extrajunctional AChR and "hidden" α-BuTx sites rose substantially. After 4 and 7 days of denervation there were, respectively, 16 x 10^3 and 21 x 10^3 AChR/μm of muscle fiber. In the same muscles hidden α-BuTx sites rose to 16 x 10^3 and 31 x 10^3/μm.

These results show that saponin treatment of young adult rat skeletal muscles reveals "hidden" specific α-BuTx-binding sites. The distribution of the α-BuTx sites along the length of the muscle fiber parallels that of surface AChR in both innervated and denervated muscle. It is tempting to speculate that these sites are similar to the internal AChR found in skeletal muscle in vitro (Fambrough, D.M. et al., J Cell Biol. 76:237, 1978).

226.9 α-BUNGAROTOXIN BINDS TO DEVELOPING CILIARY GANGLION NEURONS BUT NOT AT SYNAPSES. Michele H. Jacob and Darwin K. Berg. Dept. of Biology, Univ. of Calif., San Diego, La Jolla, CA 92093.

A continuing controversy exists as to whether α-bungarotoxin (Bgt 2.2) binds to neuronal acetylcholine (ACh) receptors as it does to ACh receptors in muscle and electric tissue. We and others have shown that Bgt 2.2 does bind to ciliary ganglion neurons in situ and in culture but it does not block ACh receptor function. We now report that horseradish peroxidase-labeled Bgt 2.2 (HRP-Bgt 2.2) binds specifically to membranes of functionally innervated neurons in embryonic ciliary ganglia but not at synaptic sites.

Ciliary ganglia from 14-, 16-, and 20-day old chick embryos were incubated with 10^{-7} M HRP-Bgt 2.2, reacted for HRP activity, and processed for electron microscopy. In examining the ciliary cell population, dense reaction product was observed coating the membranes of small processes which emerge from the soma in the region of preganglionic innervation. Less dense labeling was occasionally associated with the smooth membrane portions of the perikaryon. In contrast, the pre- and postsynaptic membranes of clearly identifiable synapses were not reacted even in the immediate vicinity of heavily labeled structures. Synaptic regions were characterized by a strictly parallel arrangement and thickening of the pre- and postsynaptic membranes, a widening of the cleft, an enhanced postsynaptic density, and an accumulation of clear synaptic vesicles adjacent to the presynaptic membrane. HRP labeling represented specific binding of HRP-Bgt 2.2 in that it was completely blocked by incubation of the ganglia in either 10^{-5} M Bgt 2.2 or 100 μM d-tubocurarine and 1.4 mM hexamethonium prior to and along with HRP-Bgt 2.2.

We have previously reported that another neurotoxin, Bgt 3.1, from B. multicinctus venom does block ACh receptors on ciliary ganglion neurons and that, in a separate action, Bgt 3.1 can also induce the internalization of Bgt 2.2 bound to the neuron surface. Exposure of HRP-Bgt 2.2 treated ganglia to 5×10^{-7} M Bgt 3.1 for 1 hr at 37° lead to a reduction in the amount of label associated with the ciliary cell plasmalemma and an increase in the number of reactive smooth-membraned vacuoles in the cytoplasm, suggesting that internalization of bound HRP-Bgt 2.2 had been induced.

Though the Bgt 2.2 binding site does not appear to be associated with synaptic ACh receptors at early times, it does appear to be a specific component with a restricted distribution in the neuronal membrane. It will be important to determine whether the sites do become associated with synapses at later developmental stages and whether these observations apply to choroid neurons in the ganglion as well. (Supported by NIH grant NS12601 and by the Muscular Dystrophy Association.)

226.10 INTRAMEMBRANE PARTICLES OF CULTURED EMBRYONIC MUSCLE AND THEIR RELATIONSHIP TO ACETYLCHOLINE SENSITIVITY. P. C. Bridgman*, S. Nakajima, A. S. Greenberg*, Y. Nakajima. Dept. Biol. Sci., Purdue Univ., West Lafayette, Indiana 47907.

Dissociated muscle cells derived from developing Xenopus laevis (st 15-16) somites were grown in culture for 3 hours to 3 days. Cells were tested for sensitivity to acetylcholine by quantitative iontophoresis, fixed and processed for freeze-fracture. After fracturing, the tested cells were reidentified in the platinum replicas, and an average particle size distribution was constructed.

Cells first gained sensitivity to acetylcholine within 3.5 to 10 hours of culturing. The cells during this time period would correspond to stage 19-24 in the embryo. The average level of acetylcholine sensitivity nearly tripled in the next 9 to 15 hours and then increased more slowly up until the third day of culture. Cells with sensitivity to acetylcholine had higher dispersed particle densities than cells without sensitivity, and the difference was limited to large particles with diameters between 8 to 20 nm. During the initial quick increase in acetylcholine sensitivity, the density of dispersed 8-20 nm particles also increased suggesting that at least some of these individual particles may represent acetylcholine receptors. Aggregates of large particles which are thought to represent hot spots on older cells[1] were not yet observed during this time period. Thus, in order for acetylcholine sensitivity to appear, putative acetylcholine receptor particles do not have to be in an aggregated form.

226.11 MYASTHENIC ANTIBODIES INDUCE DISPERSAL OF ACHR CLUSTERS IN CULTURED RAT MYOTUBES. S. Bursztajn, S.B. Elias*, J. McManaman* and S.H. Appel, Dept. of Neurology, Baylor College of Med., Houston, TX 77030.

Antibodies from sera of myasthenia gravis (MG) patients bind to acetylcholine receptors (AChR) and accelerate the rate of degradation of AChR in cultured myotubes. We have investigated the effect of MG antibodies (IgG) on the distribution of AChR on the surface of non-innervated rat myotubes. We have determined that AChR clusters are dispersed following incubation with MG antibodies within 6 h. of exposure. Seven day old cultures were incubated with α-bungarotoxin (α-BTX) conjugated to tetramethylrhodamine (TMR) to saturate all AChR present at time 0 (T_0). The cultures were washed to remove free α-BTX-TMR and replaced with culture media containing control IgG (5 mg/ml) or MG IgG (5 mg/ml). Sister cultures were incubated with the antibodies at 37°C for 0, 5 min., 1 h., 3h., and 6h., and then fixed in 2% formaldehyde. Clusters were visualized with a fluorescent microscope and quantitated. 92 + 6% of clusters present at T_0 remained intact after 6 h incubation with normal IgG. In cultures incubated with MG IgG, the clusters rapidly became dispersed such that after 5 min. 81 + 6%; 1 h 57 + 4% and 6 h 7 + 3% of the fluorescence present at T_0 were visualized as clusters. These effects were reversibly inhibited by incubating cultures at 4°C. To quantitate the total degradation of AChR that occurred during the incubation, sister cultures were simultaneously labeled with ^{125}I-α-BTX and treated similarly with normal IgG and MG IgG. MG IgG accelerated degradation of AChR producing a loss of approximately 50% of AChR after 6 h. However, at this time MG IgG induced the disappearance of nearly all AChR clusters. Since the loss of AChR clusters (93%) is much greater than the loss of total AChR (50%), these results suggest that: 1) AChR clusters are preferentially degraded by MG IgG, and/or 2) AChR clusters are dispersed by MG IgG. Since AChR degradation follows first order kinetics, it seems unlikely that one population of AChR is preferentially degraded over another. The appearance of small fluorescent speckles of AChR in myotubes incubated with MG IgG favors the second explanation. These microclusters have previously been seen by others and presumed to be due to cross-linking of AChR on the myotube surface. The results presented suggest that at least some of the microclusters originate in the larger clusters and that cluster formation may be the result of protein-protein interaction and not a structure fixed by the cytoskeleton (Supported by the Klieberg Foundation).

226.12 BLOCKING OF ACETYLCHOLINE INDUCED CHANNELS BY A MONOCLONAL ANTIBODY AGAINST THE BINDING SITE IN CULTURED CHICK MYOBALLS. G.Goldberg*, Y.Lass, D.Mochly-Rosen*, S.Fuchs. Dept. of Physiol. & Pharmacol. Sackler School of Medicine, Tel-Aviv University, Ramat-Aviv, Israel and Dept. of Chem. Immunol. Weizmann Inst. of Science Rehovot, Israel.

Muscle weakness in myasthenia gravis is known to be associated with an autoimmune response to muscle acetylcholine (ACh) receptor.

Studies based on the use of radioactively labelled alpha bungarotoxin have shown a reduction in the number of functional ACh receptors in myasthenia gravis.

Electrophysiological studies have shown a reduction in the miniature end plate potentials in neuromuscular junctions obtained from myasthenic patients and in experimentally induced myasthenia.

We have studied the effect of a monoclonal antibody directed against the cholinergic binding site of the ACh receptor in acute experiments, in which the antibody was applied to chick muscle cells during standard electrophysiological measurements in-vitro. We found a time and dose dependent reduction in ACh sensitivity of the muscle cells. The blocking action of the antibody could be explained by a reduction in the ACh induced channel conductance.

226.13 PURIFICATION AND SUBUNIT COMPOSITION OF A PUTATIVE ACETYLCHOLINE RECEPTOR FROM DROSOPHILA MELANOGASTER. T. Schmidt-Glenewinkel*, T.R. Venkatesh* and L.M. Hall (SPON: S.A. Cohen). Dept. of Genetics, Albert Einstein College of Medicine, Bronx, NY 10461.

A putative nicotinic acetylcholine receptor has been purified from the central nervous system of Drosophila melanogaster. The receptor was solubilized from membranes prepared from Drosophila heads using 1% Triton X-100 and 0.5 M sodium chloride. The solubilized extract was passed through an α-cobratoxin-Sepharose 4B affinity column and eluted with 0.2M carbamylcholine-1% Triton X-100 containing buffer. The eluted fraction was passed over a lentil lectin-Sepharose 4B affinity column, washed with 1M sodium chloride-1% Triton X-100 and eluted with 2% α-methylmannopyranoside in the presence of 1% Triton X-100. Subsequently this receptor fraction was applied to a small affinity column consisting of α-cobratoxin-Biogel A 15m. The column was washed with 1M sodium chloride-1% Triton X-100 containing buffer and Triton X-100 was replaced with 0.1% deoxycholate. The receptor was eluted with 1M carbamylcholine-0.1% deoxycholate. The final purification of the receptor fraction was 3700-fold with a specific activity of 2.7 μmoles ^{125}I-α-bungarotoxin binding sites/g protein. The purified receptor was labeled with ^{125}I and analyzed on sodium dodecylsulfate (SDS) - polyacrylamide gels.

Membrane-bound receptor was photolabeled in situ with the 4-methylazidobenzoimidate derivative of ^{125}-I-α-bungarotoxin and was also analyzed by SDS-polyacrylamide gel electrophoresis. From the comparison of the two gel profiles it appears that the receptor is composed of four subunits with molecular weights of 48,000, 57,000, 64,000 and 78,000 daltons. A polypeptide of 102,000 daltons, also detected on the gels, could be shown by peptide mapping to be a dimer of the 64,000 dalton subunit. A sedimentation coefficient of ~9S was found for the receptor by sucrose density gradient centrifugation. The molecular weight of the receptor as determined by gel filtration in Triton X-100 containing buffer was found to be 460,000 daltons. A second peak with a sedimentation coefficient of 13.4S and a molecular weight of 880,000 daltons was also observed and might represent a dimeric form of the receptor. (Supported by grant #1126AR1 from The Council for Tobacco Research U.S.A., Inc. and NSF grant BNS 80-41293.)

226.14 ALPHA-BUNGAROTOXIN LABELLING OF AN IDENTIFIED CENTRAL SYNAPSE. Hall,D.H., Day,J.W., Hall,L.M., Bennett,M.V.L. Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, New York 10461.

The South American hatchetfish, Gasteropelecus, has 10-14 myelinated giant axons postsynaptic to the Mauthner fibers in the medulla. In light microscopic examination of thick sections, these axo-axonic synapses appear as distinctive gaps in the heavy myelin coat investing each fiber (Model, et al., Br. Res., 45:288,1972). Previously reported data indicate that this synapse is cholinergic: 1) curare reversibly blocks transmission, and 2) acetylcholine reversibly desensitizes the synapse (Spira, et al., J. Cell Biol., 47:199a,1970).

We have found that alpha-bungarotoxin specifically binds to receptors in the hatchetfish medulla. We performed binding assays on tissue from medullas, each known to contain several dozen giant synapses. Homogenates of fresh and of formalin-fixed tissue (4%, 16 h) were tested for binding of ^{125}I-alpha-bungarotoxin, with or without high levels of d-tubocurarine. Both fixed and unfixed tissue showed a significant binding of toxin which was blocked by curare.

Autoradiography revealed that ^{125}I-bungarotoxin specifically labels giant synapses in the medulla. We used several methods to apply radiolabelled toxin: 1) in vivo pressure injection into the fourth ventricle, 2) in vivo subependymal injection and 3) 24 h soaking of formalin-fixed medullas. With each method, after incubation with toxin the tissue was washed in saline and fixed in glutaraldehyde, followed by embedding, sectioning, and autoradiography. Individual giant synapses were identified in bright field or phase contrast microscopy, and then examined in darkfield for the presence of silver grains. With darkfield illumination there is some interference from light scattered by the osmicated myelin of the Mauthner fibers and giant axons. Fixation with lower concentrations of osmium eliminated this interference, and still allowed identification of individual synapses. With each method of toxin administration we found clusters of silver grains at all identified synapses. Control experiments, done with curare and ^{125}I-toxin added simultaneously, showed no specific binding at the Mauthner fiber-giant fiber synapse. Thus we have further evidence that the hatchetfish giant synapse is cholinergic.

Supported by NRSA NS-06082 to JWD, NSF grant BNS 80-41293 to LMH, and NIH grant NS-12627 to MVLB.

226.15 FAST NICOTINIC AND SLOW MUSCARINIC POTENTIALS IN MYENTERIC NEURONS. T. Tokimasa*, K. Morita* and R.A. North. Neurophysiology Lab., Dept. of Pharmacology, Loyola Univ. Stritch Sch. of Med., Maywood, Illinois 60153.

Acetylcholine (ACh) was applied by iontophoresis onto the soma membrane of neurons in the myenteric plexus of the guinea-pig ileum. Low ejection currents (<40 nA, 5-20 ms) evoked short latency depolarizations of rapid time course closely similar to the fast excitatory postsynaptic potential (e.p.s.p.). Larger ejection currents (>40 nA, 1-2 s) evoked long latency (>500 ms) depolarizations of slow time course (total duration up to 30 s). The fast ACh potential was associated with a conductance increase, reversed its polarity at -15 mV and was abolished by hexamethonium (200 μM), and in these respects was identical to the fast e.p.s.p. The slow ACh potential was associated with a conductance decrease, reversed its polarity at -90 mV and was abolished by hyoscine (1-10 nM). A similar slow depolarization was also observed with iontophoretic application of oxotremorine. When added to the perfusion solution, oxotremorine (100 nM - 1 μM) and methacholine (300 nM - 10 μM) caused concentration dependent depolarizations which were also accompanied by a conductance decrease, and reversibly abolished by hyoscine (10 nM). At even lower concentrations, both muscarinic agonists reversibly reduced the amplitude of the fast e.p.s.p. without affecting the fast ACh potential. This action was reversed by hyoscine (1 nM). The results indicate that activation of muscarinic receptors on myenteric neurons causes both potassium channel inactivation on the soma membrane, and presynaptic inhibition of ACh release.

226.16 MUSCARINIC AUTORECEPTORS CONTROL ACETYLCHOLINE RELEASE IN SYNAPTOSOMES FROM RAT HIPPOCAMPUS. M. Marchi*, P. Paudice* and M. Raiteri (Spon: J.M. Lauder). Institute of Pharmacology and Pharmacognosy, University of Genova, Via al Capo di S. Chiara 5, Genova, Italy.

The existence of presynaptic autoreceptors modulating acetylcholine (ACh) release from central cholinergic nerve endings was investigated utilizing rat hippocampal synaptosomes in a superfusion system. The presence of exogenous acetylcholine, carbachol or oxotremorine in the superfusion medium produced a dose-dependent inhibition of the release of ^{3}H-ACh elicited by 15mM KCl in synaptosomes prelabeled with tritiated choline. Acetylcholine seems to be the most active agonist tested at the presynaptic receptors, whereas nicotine was found to be ineffective. The inhibition of ^{3}H-ACh release was antagonized by atropine or scopolamine which, as expected in superfused synaptosomes did not cause, per se, the increase of ^{3}H-ACh release found in slices or in incubated synaptosomes. Interestingly bethanechol, which is a very effective agonist at muscarinic postsynaptic receptor in the peripheral nervous system was actually inactive on the ACh autoreceptors in the central nervous system.

Our results indicate that cholinergic nerve terminals in the rat hippocampus possess autoreceptors of the muscarinic type for the control of acetylcholine release.

226.17 ACETYLCHOLINE-EVOKED CURRENT IN NEUROBLASTOMA CELLS HAS THREE COMPONENTS. Eiji Kato*, Fred N. Quandt* and Toshio Narahashi (SPON: Charles A. Berry). Dept.of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The mouse neuroblastoma cell line N1E-115 is sensitive to iontophoretic application of acetylcholine (ACh). The membrane potential response to ACh was composed of three phases: An initial fast depolarization was followed by a transient hyperpolarization which in turn was followed by a secondary slow depolarization lasting approximately 30 sec. The initial fast depolarization phase was blocked by 10 μM d-tubocurarine, but not by 0.1 μM atropine. Both the hyperpolarization and the slow depolarization were blocked by 0.1 μM atropine, but not by 10μM d-tubocurarine, and only these two phases were evoked by iontophoretic application of the muscarinic agonist methacholine.

Under voltage clamp conditions, an initial fast inward current, a transient outward current, and a secondary slow inward current were recorded in response to ACh application. These phases of current corresponded in time to the three phases of the membrane potential response. The initial fast inward current increased in amplitude by hyperpolarizing the membrane and decreased by depolarization. The mean value of reversal potential for the initial current was estimated to be -1 mV. The outward current increased in amplitude by depolarization, decreased by hyperpolarization and reversed its polarity at -67 mV (mean). This reversal potential was dependent on the potassium concentration in the external solution. When the potassium concentration was increased from 5.5 mM to 10 mM, the reversal potential was shifted in the direction of depolarization by 13 mV (mean). Decreasing the external potassium concentration from 5.5 mM to 0.5 mM caused a shift of the reversal potential in the direction of hyperpolarization by approximately 40 mV. The slow inward current increased in amplitude by hyperpolarization and decreased by depolarization. The reversal potential was approximately +20 mV.

It was concluded that the initial fast inward current is mediated by a nicotinic receptor similar to that in the endplate and postsynaptic membranes of the sympathetic ganglia. Both the outward current and the slow inward current are mediated by a muscarinic receptor. The outward current represents an increase in the membrane permeability to potassium, and the slow inward current appears to be carried by sodium and potassium. (Supported by NIH grant ES 02330).

226.18 CORRELATION BETWEEN ACETYLCHOLINE SENSITIVITY AND ALPHA-BUNGAROTOXIN BINDING AT NODOSE NEURONS IN CULTURE, E. Cooper*(SPON: K. Ruf). Dept. of Physiol., McGill Univ., Montreal, Quebec H3G 1Y6.

Dissociated neurons from newborn rat nodose ganglia (an autonomic sensory ganglion) express functional acetylcholine (ACh) receptors when grown in tissue culture. These ACh receptors are similar to nicotinic receptors of principle neurons in autonomic ganglia; the depolarizations have a fast time course (relative to muscarinic receptors), and are reversibly blocked by either hexamethonium or curare (10^{-5}M) and are unaffected by atropine (10^{-6}M). The proportion of neurons which express these nicotinic receptors depends on the culture conditions: 80-90% of neurons grown in the absence of non neuronal cells express functional ACh receptors, however only 10-30% of neurons grown in the presence of muscle (cardiac or skeletal from newborn rats) express these receptors.

Further studies on the expression and regulation of the nicotinic receptor sites in these nodose neurons would be facilitated if there were irreversible ligands for these receptors. There is some uncertainty whether alpha bungarotoxin (α-BTX), which is a useful marker for nicotinic receptors at the vertebrate neuromuscular junction, binds to neuronal ACh receptors. For example, the toxin does not appear to block ACh depolarizations of nodose neurons in culture. The question addressed in this report is whether α-BTX binding can be used as a marker for those cultured nodose neurons which express ACh sensitivity, even though the α-BTX binding site and the ACh receptors may not be identical.

The experiments consisted of combined physiological and radioautographic studies on identified neurons in culture. First the ACh sensitivity of neurons was determined by recording the membrane potential with conventional microelectrode techniques while pressure ejecting ACh (10^{-4}-10^{-3} M) onto the cell bodies; sensitive neurons depolarized 10-30 mV, insensitive neurons showed no change in membrane potential. 10-20 neurons were examined per culture and their locations were identified on photographic montages of the cultures. The cultures were subsequently incubated with I^{125} α-BTX, fixed, and processed for radioautography. The identified neurons were then examined for the presence or absence of silver grains.

The results of the preliminary experiments suggests that there is a good correlation between ACh sensitive neurons and α-BTX binding, as well as, between ACh insensitive neurons and the lack of silver grains. It appears that even though α-BTX does not block ACh depolarizations its binding may still serve as a useful marker for ACh sensitive neurons in nodose ganglion cell cultures. (Supported by MRC of Canada).

226.19 DIFFERENTIAL REGULATION OF ACETYLCHOLINE RECEPTORS IN CULTURED AVIAN RETINA. Robert G. Siman and William L. Klein. Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, Il. 60201.

Both muscarinic and nicotinic cholinergic receptors have been found in embryonic and adult chicken retina (Vogel and Nirenberg, 1976, PNAS 73, 1806-1810; Sugiyama et al., 1977, PNAS 74, 5524-5528). We present evidence obtained using retina cells grown in primary aggregate cultures that changes in cholinergic stimulation regulate muscarinic but not nicotinic receptor concentration.

Muscarinic receptor sites, monitored by the specific binding of 3H-(l)-QNB, decreased up to 76% in cultures given muscarinic agonists. Chronic agonist exposure did not alter receptor affinity for 3H-(l)-QNB. The muscarinic specific agonist oxotremorine, at 1 uM for 18 hours, induced a 67% loss of binding that was blocked by co-incubation with 10 nM atropine, a muscarinic specific antagonist. The mixed muscarinic-nicotinic cholinomimetic carbachol caused a maximum decrease of binding within 24 hours. In contrast to the large decrease found in muscarinic binding, levels of nicotinic receptors showed no change under identical conditions of stimulation. Membranes from cultures grown 48 hours in medium containing 1 mM carbachol or 100 uM nicotine bound the same amount of 125I-alpha-bungarotoxin (125I-BTX) or 3H-bromoacetylcholine (3H-BAC) as membranes from control cultures not grown in nicotinic agonist. Nicotine-displaceable 3H-BAC and 125I-BTX binding appeared to occur at related sites. Treatment of dithiothreitol-reduced membranes with 1 mM unlabelled BAC for 5 minutes, followed by extensive washing, blocked 100% of specific 125I-BTX binding. No blockade occurred in unreduced membranes. Similarly, 3H-BAC bound irreversibly to dithiothreitol-reduced membranes but not to unreduced preparations or to those reduced and then alkylated with N-ethyl-maleimide.

The rate of muscarinic receptor loss is biphasic and approximates the sum of two exponentials. For the receptor loss induced by 1 mM carbachol, the first phase had a half-time of 0.8 hours, while the second had a half-time of 3.9 hours. The first phase of the receptor loss was completely blocked by the Na-K ionophore gramicidin D. Receptor sites appeared at a calculated rate of 3.6 fmol/mg protein/hour.

Our data show that cholinergic stimulation readily alters muscarinic receptors but has little or no effect on nicotinic receptors. This differential regulation may reflect different roles played by these receptors in adaptation to altered physiological activity.

226.20 Cholinergic Agonist-Induced Down Regulation of Neuronal α-Bungarotoxin Receptors. A. Messing* (SPON: J. Q. Trojanowski). Div. of Neuropath., Univ. of Penn. Sch. of Med., Philadelphia, PA 19104.

In view of the controversy over the significance of the αBTX binding component in neuronal membranes, I sought to determine whether this receptor could be down regulated by cholinergic ligands. Dissociated monolayer cultures of chick ciliary ganglion neurons were prepared from 8-day embryos as described previously (Messing, A. and Kim, S.U., Brain Res., 208:479, 1981). Neuronal survival in these cultures typically exceeded 10,000 neurons per ganglion and cultures were used between days 4-8 in vitro. Surface binding of ^{125}I-αBTX was determined at 22°C on intact cells, and non-specific binding (in the presence of 10 μM native toxin) never exceeded 2% of the total.

^{125}I-αBTX bound to these neurons with a K_D=2.5x10^{-10} M and a Hill coefficient of n=1.01. The cholinergic ligands carbachol, nicotine and d-tubocurarine inhibited the rate of ^{125}I-αBTX binding with IC_{50}'s of 270 μM, 0.5 μM and 0.5 μM, respectively. When cultures were pre-exposed to 1 mM carbachol at 37°C, washed and then assayed for remaining αBTX sites, αBTX receptor number decreased by 25% during the first hour of agonist exposure and then remained constant through 4 hrs. of agonist exposure. Exposure for longer periods of time (1-6 days) caused an additional slower loss of receptors to a maximum of 70% below controls. The rapid loss of receptors during 60 min. of agonist exposure occurred without a change in affinity for ^{125}I-αBTX as determined by Scatchard analysis. Nicotine (3 μM), but not d-tubocurarine (100 μM), also caused a loss of 25% of the surface α-BTX receptors after 60 min. at 37°C. Both the carbachol- and nicotine-induced ^{125}I-αBTX receptor losses were prevented when the exposure took place at 4°C; receptor loss was also prevented by preincubation with 100 μM d-tubocurarine followed by coincubation with carbachol and d-tubocurarine. None of the treatments described above had any effect on neuronal number or neuronal morphology.

Cholinergic ligands clearly interact with the αBTX receptor in these neurons, and this receptor seems capable of down regulation by agonists but not by the antagonist, d-tubocurarine. These data are consistent with the hypothesis that αBTX binds to the neuronal acetylcholine receptor, despite its apparent failure to block transmission as described by others. The rapid loss of 25% of the surface αBTX receptors during the first hour of agonist exposure is in marked contrast to the results seen in muscle (Noble, M.D., Brown, T.H. and Peacock, J.H., PNAS, 75: 3488, 1978; Gardner, J.M. and Fambrough, D.M., Cell, 16:661, 1979) (supported by USPHS grants NS-05572-17 and NS-07064-01).

226.21 IBOTENIC ACID LESIONS OF THE HIPPOCAMPUS RESULT IN A LOSS OF MUSCARINIC RECEPTORS LINKED TO PHOSPHOLIPID TURNOVER. Stephen K. Fisher*, Kirk A. Frey* and Bernard W. Agranoff. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

In a previous study (Brain Res. 189, 284-288, 1980), we observed that destruction of the cholinergic afferent input (fornix/fimbria) to the hippocampus reduced neither the number of muscarinic receptors present in hippocampal nerve ending fractions, nor did it alter a functional correlate of this receptor: muscarinic-agonist stimulation of phosphatidic acid (PhA) and phosphatidylinositol (PhI) labeling from $^{32}P_i$. This result suggested that the muscarinic receptors linked to phospholipid turnover in hippocampal nerve endings are present on cholinoceptive rather than on cholinergic structures. To further investigate this possibility, we have used the neurotoxin, ibotenic acid, to selectively destroy intrinsic neurons in the hippocampus. Male guinea pigs received 3 x 10 µg ibotenic acid injections in one side of the hippocampus. Twelve days later, completeness of the unilateral injections was evaluated histologically. Following ibotenic acid lesion, the specific activity of glutamate decarboxylase in hippocampal nerve ending fractions was reduced by 30 ± 7%, and [^{3}H]quinuclidinyl benzilate binding by 42 ± 6% ($p<0.005$). While there was a loss in yield of nerve endings (23 ± 4%), activity of basal phospholipid labeling from $^{32}P_i$ computed per mg protein from lesioned hippocampus was not reduced. There was, however, a marked reduction in carbachol-stimulated labeling of PhA (91 ± 9% in the control vs. 52 ± 7% in the lesion, $p<0.005$) and in that of PhI (31 ± 5% in the control vs. 19 ± 4% in the lesion, $p<0.02$). These results, taken together with those previously obtained from the fornix lesions, confirm that hippocampal muscarinic receptors coupled to PhA and PhI turnover are located on post-synaptic cholinoceptive structures. 227.1 RESPONSE PROPERTIES OF LAYER V NEURONS TO ELECTRICAL STIMULATION OF THE CORPUS CALLOSUM IN SLICES OF CINGULATE CORTEX. B.A. Vogt and A.L.F. Gorman. Boston University School of Medicine, Boston, MA 02118.

The corpus callosum (CC) and its termination sites in areas 24 and 29 of rat cingulate cortex were isolated in vitro and the intracellular responses of layer V neurons to electrical stimulation of the CC evaluated. The distribution of synaptic contacts formed by degenerating callosal axons with pyramidal neurons in cingulate cortex were also analyzed using a combined degeneration /Golgi-EM technique.

Layer V neurons had a resting membrane potential of 60±0.68 mV (S.E. of the mean), an input resistance of 47±4.74 megohms and produced spontaneous action potentials 50±0.5 mV in amplitude. There were three types of responses to CC stimulation of increasing strengths. First, an antidromic spike followed by an EPSP with synaptic-evoked spikes and, in some instances, a longer latency IPSP. Second, an EPSP with synaptic-evoked action potentials each with discrete stimulation thresholds, but not associated with antidromic or inhibitory activity. Third, an EPSP with an all-or-none burst of action potentials. Antidromic spikes did not have an underlying EPSP, were 0.7-1.0 msec in duration and had conduction velocities of 1.3-3.0 m/s. EPSPs had a calculated reversal potential of 0 to -20 mV and were of longer duration in anterior than in posterior neurons (50±3.57 msecs vs 26±1.56 msec) and had a higher maximum amplitude in anterior neurons (20±1.0 mV vs 11±0.79 mV). At low stimulation strengths IPSPs were observed to follow EPSPs in posterior neurons, but never antidromic spikes. During CC stimulation depolarizing intracellular currents failed to uncover IPSPs in other neurons and, at higher stimulation strengths, IPSPs were suppressed by enhanced EPSP and spiking activity.

Since greater numbers of callosal axon terminals could account for enhanced EPSP activity in anteriorally located neurons, the synaptic termination of degenerating callosal axons with layer V cells was evaluated. The apical dendrites of comparably sized pyramidal neurons formed up to four times as many synaptic terminals with callosal afferents in anterior cortex as did those with posterior neurons.

Thus, it is possible to isolate responses of cortical neurons to electrical stimulation of the corpus callosum in slices of rat cingulate cortex, and differences of the neuronal responses in anterior and posterior cortices can be partially accounted for by the number of callosal afferents they receive.

227.2 INTRICACIES OF ACETYLCHOLINE-RECEPTOR INTERACTION DURING A MINIATURE ENDPLATE CURRENT; SIFTING OF MODELS BY MEANS OF COMPUTER SIMULATION. P. Pennefather* and D. M. J. Quastel. Department of Pharmacology, Faculty of Medicine, The University of British Columbia, Vancouver, B. C., Canada, V6T 1W5.

Virtually any model of transmitter-receptor interaction can be adjusted to predict, as a consequence of abrupt discharge of a quantum of transmitter into the synaptic cleft, a miniature endplate current (MEPC) with (1) rapid rise, and (2) a near exponential decay that is slowed by inhibiting acetylcholinesterase (AChE) and then accelerated by receptor blockade. Moreover, if parameters are chosen such that there is normally high capture of transmitter by receptor all models predict that the height of the MEPC should be insensitive to alteration of receptor density (Pennefather and Quastel, Neurosci. Abst. 5, 745). Nevertheless, certain aspects of the MEPC are difficult to mimic and can provide a basis for testing the validity of a particular model. The presumption of non-linear ACh-receptor interaction is compelled by the observation that MEPCs have a decay rate close to that of individual channels, together with indications that a high propertion of quantally-released transmitter is indeed captured. With non-linear systems it is necessary to integrate the appropriate differential equations (for diffusion, hydrolysis and ACh-receptor interaction) to determine how the system will behave. Our present FORTRAN program allows synthesis of theoretical MEPCs at up to 1 ms/min with as many as 10 states of the receptor, in multiple compartments; this permits testing a variety of models of ACh-receptor interaction. Aspects of real MEPCs that simulation shows to be sensitive to possible complexities in the system (e.g., cooperativity in binding, number of states, state transitions) and which are difficult to mimic quantitatively include (a) correlation of height and decay rate, (b) effects of exogenous agonist on the height and time course, and (c) effects of AChE poisoning and/or receptor blockade on the deviations from a simple exponential of the falling phase of the MEPC. We find that the simplest models that come close to predicting real MEPCs involve the existence of more than two ACh binding sites on the receptor (although channel opening requires the "cooperation" of only two ACh molecules) and a small but appreciable local desensitization of receptors during an MEPC.

Supported by the MRC and Muscular Dystrophy Association of Canada. We thank Dr. E. Puil for the use of a PDP 11/34 computer.

227.3 COMPUTER SIMULATION OF THE MAUTHNER CELL. Chris M. Wieland* and Robert C. Eaton., (SPON: A.C. Bekoff), Dept. Biol., E.P.O., Univ. of Colo., Boulder, CO 80309.

Because of its accessibility for electrophysiological analysis, the Mauthner (M-) cell of teleost fish has been utilized for a number of significant conceptual advances in synaptology. The existence of both electrical and chemical excitatory and inhibitory synapses on the cell has been helpful in elucidating detailed properties of certain synaptic interactions. Also of interest is the possibility of studying functional changes as a result of morphological development.

At present, some aspects of M-cell electrophysiology still remain inaccessible to examination with conventional techniques and another means of investigation is required. To aid in the study of synaptic interactions of the M-cell, BASIC and FORTRAN IV programs have been developed to model the electrical activity of this neuron in goldfish. Dendritic characteristics were based on the model of Furukawa (1), with biophysical characteristics of the axon hillock, initial segment, and the M-axon derived from the work of Faber and Funch (2). Mathematical representation of the dendrites and soma is based on standard cable equations while simulation of the excitable membrane is based on a four-state variable neuromime as developed by MacGregor and Oliver (3).

With these programs, biophysical and anatomical characteristics can be easily modified to simulate theoretical situations or to replicate experimental findings, such as modeling two interconnected M-cells simultaneously to simulate mutual inhibitory interactions. Since the programs are written in both BASIC and FORTRAN they can be easily adapted to most computer systems including inexpensive microcomputers.

227.4 INTERNALLY-EXPOSED POLYPEPTIDES OF THE SYNAPTIC PLASMA MEMBRANE. J.A. Babitch & D.F. Bahr*. Chemistry Department, Texas Christian University, Fort Worth, TX 76129

We previously determined the molecular weights of the major external polypeptides in the chick forebrain synaptic plasma membrane [Chiu & Babitch, J. Biol. Chem. 252 (1977) 3862-3869; Biochim. Biophys. Acta 510 (1978) 112-123]. These are membranes which have relatively low levels of carbonic anhydrase, a glial membrane marker [Parthe, J. Neurosci. Res. (1981) 119-131]. We now report the molecular weights of 4 internally-disposed synaptic membrane polypeptides.

Demonstrating that these are internally-exposed requires showing that (1) incorporation of a label occurs into polypeptides and (2) these polypeptides cannot be labeled from outside the nerve ending. To do that we incubated synaptosomes under phosphorylating conditions. Greengard and coworkers [Kreuger et al., J. Biol. Chem. 252 (1977) 2764-2773] previously suggested that the phosphopeptides they identified after such incubations might be internal synaptic components. Chick forebrain synaptosomes were incubated with histones, protein kinase and $^{32}P_i$ or γ-$^{32}P_i$-ATP either with or without apyrase. When synaptosomes were incubated with $^{32}P_i$ most of the incorporation was into soluble polypeptides. When synaptosomes were incubated with γ-$^{32}P_i$-ATP almost no labeling was observed unless protein kinase was present (when histones were labeled also) and then the bulk of the labeling was particulate. When apyrase was present, labeling from ATP dropped to levels below that of ATP alone. This indicates that protein kinase and ATP label external polypeptides (and exogenous histones), the labeling of which can be eliminated by apyrase. When synaptosomes were incubated with $^{32}P_i$ apyrase had no effect, nor did a combination of protein kinase, γ-$^{32}P_i$-ATP and apyrase.

Synaptic plasma membranes were isolated from synaptosomes incubated with $^{32}P_i$ and apyrase and plasma membrane polypeptides were separated on polyacrylamide gels. The major labeled, internally-exposed phosphopeptides have molecular weights (in thousands) of 108, 81, 69 and 55.

227.5 SPECIFIC GLYCOPROTEINS AND KAINIC ACID BINDING SITES ARE LOCALIZED AT SYNAPTIC JUNCTIONS. E. Edward Mena, Graham E. Fagg*, Alan C. Foster* & Carl W. Cotman. Dept. of Psychobiology, University of California, Irvine, CA 92717.

Synaptic glycoproteins probably play an important role in synaptic function and plasticity. The most likely glycoproteins for this function are those located specifically to the synapse. In order to identify these components synaptic junctions (SJ) were prepared from synaptic plasma membranes (SPM) by extraction with Triton X-100 and density gradient centrifugation. These SJs were enriched in the four Concanavalin A (Con A) binding glycoproteins of MWs 160,000 (I), 123,000 (II) 110,000 (III) and 95,000 (IV). We prepared crude myelin, light SPMs, SPMs, mitochondria, and microsomes and extracted them with detergent by procedures identical to those employed when preparing SJs from SPMs. Those fractions prepared from light SPMs and crude myelin contained identifiable synaptic junctions and were also highly enriched in the four Con A binding glycoproteins and the 52,000 MW postsynaptic density (PSD) protein. The SJ-like fractions from mitochondria did not contain significant levels of any of the characteristic synaptic macromolecules. However, the same fraction from microsomes, which on the basis of electron microscopy did not contain SJs, contained the 52,000 MW PSD protein to true SJs although the Con A binding glycoproteins, especially Con A-IV, were nearly absent.

The Con A binding glycoproteins of the SJ were isolated from solubilized SJs by affinity chromatography and separated by gel electrophoresis. The primary sequence of these proteins were compared by examining their two dimemsional ^{125}I-tryptic peptide maps. Con A-I, II and III had many peptides in common. The primary structure of Con A-IV was unrelated to any of the other glycoproteins. Thus, these results indicate that the Con A binding glycoproteins are markers for the SJ. Futhermore the heterogeneity that is observed among the Con A binding glycoproteins of the SJ may reside in their carbohydrate rather than protein moiety.

The SJ-like fraction prepared from crude myelin, light SPMs, and microsomes were futher analyzed for kainic acid binding sites in order to determine whether they possesed these sites and if they were distributed similiar to other transmitter binding sites. The results indicated that all SJ and SJ-like fractions contained similiar levels of binding sites for L-glu and L-asp. In contrast only those fractions that contained identifiable SJ contained high levels of KA binding sites. Thus, kainate binding sites appear more specific to synapses than L-glu or L-asp. This supports a previous suggestion that a kainate like molecule may be a neuronal modulator/transmitter.

227.6 TOPOGRAPHY AND ORGANIZATION OF SOME PROTEINS IN THE POSTSYNAPTIC DENSITY. N. Ratner* (SPON: H.R. Mahler). Dept. of Chemistry, Indiana University, Bloomington, IN 47405.

The postsynaptic density (PSD), located on the cytoplasmic side of the postsynaptic membrane of many CNS synapses, is an organelle of unknown function. Many PSD proteins have, however, been identified; among them are actin, tubulin, calmodulin and a unique "PSD protein". We have utilized a surface-specific iodination system [Markwell, M.A. and Fox, C.F. (1978) Biochemistry 17, 4807-4817] to probe the locations and accessibility of these and other PSD proteins. Actin is the major protein located on the exterior of the PSD. Other identified proteins are inaccessible to iodination unless they are first reduced with dithiothreitol. Major species that become iodinated following this treatment include PSD protein and tubulin. These results suggest that in the intact PSD these proteins may constitute a cross-linked aggregate which may be buried inside the organelle and covered by a shell of actin. These and other quantitative measurements will be used in the formulation of a model for the PSD. (Supported by research grant NS08309 from the National Institute of Neurological and Communicative Disorders and Stroke, NIH)

227.7 ANTISERUM TO TORPEDO 43K PROTEIN RECOGNIZES AN INTRACELLULAR POSTSYNAPTIC MEMBRANE PROTEIN OF THE RAT NEUROMUSCULAR JUNCTION. S.C. Froehner and V.G. Gulbrandsen*. Dept. of Biochemistry, Dartmouth Medical School, Hanover, N.H. 03755.

In addition to the acetylcholine receptor (AChR) subunits, highly-purified postsynaptic cholinergic membranes from Torpedo electric organ contain a major protein of approximately 43,000 mol. wt. (43K protein). Membrane treatments that extract peripheral membrane proteins remove the 43K protein without detectable effects on receptor function. We have shown previously by immunofluorescence on tissue sections that a rabbit antiserum directed against the 43K protein stains only the innervated membrane of Torpedo electrocytes and also recognizes a muscle antigen that is highly concentrated in the postsynaptic membrane of the rat neuromuscular junction. In these experiments, both sides of the membrane are accessible to antibodies. To determine if the 43K protein is located on the extracellular or on the cytoplasmic side of the synaptic membrane, we have examined the reactivity of anti-43K with intact muscle. Rat soleus or abductor hallucis muscles were incubated for 2 hours with either anti-AChR or anti-43K under physiological conditions. The muscles were then rinsed and cryostat sections were cut. After additional washing to remove unbound antibodies, the sections were incubated with fluorescein-labeled anti-rabbit IgG to visualize the bound antibodies and with rhodamine-αbungarotoxin to mark the endplates. Under these conditions, anti-AChR labels endplates. This finding indicates that a portion of the receptor is extracellularly exposed and also demonstrates that the synaptic region is accessible to antibodies. Little or no staining of the endplate occurs when intact muscles are incubated with anti-43K. However, if sections are reincubated with either anti-43K or anti-AChR, both antisera label the synapse. Thus, the major muscle antigen recognized by anti-43K is not exposed on the extracellular side of the postsynaptic membrane. These results are consistent with the idea that, like the Torpedo 43K protein, the muscle antigen is a peripheral membrane protein which is highly concentrated on the cytoplasmic face of the postsynaptic membrane. This work was supported by NIH grant NS 14871 and by the Muscular Dystrophy Association.

227.8 IMPULSE CONDUCTION INCREASES THE STATE OF PHOSPHORYLATION OF PROTEIN I, A NEURON-SPECIFIC PROTEIN, IN THE RABBIT SUPERIOR CERVICAL GANGLION. Eric J. Nestler* and Paul Greengard. Department of Pharmacology, Yale University School of Medicine, New Haven, CT 06511.

Protein I, a neuron-specific protein concentrated at synapses, is present in most, and possibly in all, presynaptic nerve terminals where it appears to be associated predominantly with neurotransmitter vesicles. Protein I is phosphorylated endogenously in the collagenase-insensitive region of the molecule both by a cyclic AMP-dependent and by a calcium/calmodulin-dependent protein kinase and in the collagenase-sensitive region of the molecule by a second calcium/calmodulin-dependent protein kinase. Previous studies have shown that dopamine and depolarizing agents increase the state of phosphorylation of Protein I in slices of the bovine superior cervical ganglion. These findings prompted us to determine whether stimulation of the preganglionic nerve under physiological conditions might regulate Protein I phosphorylation in the rabbit superior cervical ganglion.

The small amount of Protein I present in the rabbit ganglion (total content: 1 pmol/ganglion) necessitated the development of sensitive techniques for this study. One superior cervical ganglion from each rabbit served as the "test" ganglion and the other as the control. The preganglionic nerve supplying the test ganglion was stimulated via a suction electrode for 30 s at 10 Hz. The ganglia were then homogenized and boiled in 1% SDS; the Protein I was immunoprecipitated from the SDS extract; the precipitated Protein I was "back phosphorylated" using purified protein kinase and [γ-^{32}P]ATP; the phosphorylated samples were analyzed by polyacrylamide gel electrophoresis and scintillation spectrometry. The amount of dephospho-Protein I in stimulated ganglia was 56 $\pm$ 4% (7) [mean $\pm$ s.e.m. (N)] of that in control ganglia. In contrast, the amount of dephospho-Protein I in unstimulated ganglia was 102 $\pm$ 4% (6) of that in paired (contralateral) control ganglia. Incubating ganglia in calcium-free buffer blocked the nerve-stimulated change in Protein I phosphorylation [dephospho-Protein I in test ganglia was 103 $\pm$ 9% (4) of that in control ganglia]. The amount of dephospho-Protein I in ganglia exposed to 60 mM K^+ for 1 min was 54 $\pm$ 4% (5) of that in control ganglia. Analysis of phosphorylation sites by one dimensional peptide mapping indicated that the observed percent decreases in holodephospho-Protein I were reflected in virtually identical changes both in the collagenase-insensitive region and in the collagenase-sensitive region of the molecule.

These data demonstrate that the state of phosphorylation of Protein I is regulated by physiological activity.

227.9 CHOLINERGIC SYNAPTIC VESICLES CONTAIN AN ANTIGENIC PROTEOGLYCAN. Steven S. Carlson & Regis B. Kelly. Dept of Biochemistry & Biophysics, Univ. of California, San Francisco, Ca 94143

Antibodies raised to highly purified synaptic vesicles from fish electric organ cross-react with a cytoplasmic element of the mammalian nerve terminal, presumably the synaptic vesicle. The cross-reacting antigens are not present on the outside of a resting frog neuromuscular junction, but become exposed to the outside when the terminal undergoes exocytosis of synaptic vesicle contents (von Wedel, Carlson & Kelly (1981). PNAS 78, 1014). The antigens which are exposed on the outside of the active nerve terminal are presumably those which are inside the synaptic vesicle. We have demonstrated that electric organ synaptic vesicles contain large amounts of a material with the characteristics of a proteoglycan. It does not enter acrylamide gels. It contains protein and carbohydrate. It elutes from gel filtration columns containing SDS as a large molecular weight material between 70 and 335 kd. It binds an NP-40 detergent to wheat germ agglutinin-Sepharose 4B beads and is selectively eluted by N-acetylglucosamine. After protease digestion, a negatively charged carbohydrate is obtained with an electrophoretic mobility close to that of heparin sulfate. The proteoglycan is inside the synaptic vesicle since intact vesicles fail to bind to wheat germ agglutinin beads whereas vesicles lysed by sonication bind very effectively. The antibodies which recognize synaptic vesicles immunoprecipitate the proteoglycan. The antigens which appear during exocytosis could therefore be the proteoglycan determinants, but this has not been shown directly. The proteoglycan may play a role in packaging the contents of the synaptic vesicle. Whatever its function, the observation that synaptic vesicle proteoglycans have unique determinants suggests that their structure is functionally important.

227.10 PARTIAL PURIFICATION OF ACTIVE ZONES OF THE PRESYNAPTIC PLASMA MEMBRANE BY IMMUNOADSORPTION. George Miljanich*, Allan Brasier* & Regis B. Kelly. Dept. of Biochem.& Biophys., Univ of Calif., San Francisco, Ca 94143

A highly specific antiserum has been previously obtained against purified marine ray electric organ synaptic vesicles (anti-SV). Anti-SV also binds to the surface of electric organ synaptosomes. Thus we have been able to use anti-SV as an affinity reagent to isolate the electric organ nerve terminal presynaptic plasma membrane (PSPM). First, synaptosomes prepared by conventional means are immunoadsorbed by anti-SV to anti-antibody-coated polyacrylamide beads. This gives a 1.5-2.5 fold increase in cholineacetyltransferase specific activity (synaptoplasmic marker), a 70 fold decrease in acetylcholine receptor specific activity (innervated postsynaptic membrane marker) and a 3 fold drop in Na/K ATPase specific activity (non-innervated postsynaptic membrane marker). 5'-Nucleotidase and cholinesterase specific activities are unchanged. Electron micrographs clearly show synaptosomes bound to beads. To enrich immunoadsorbed material in PSPM, the bound synaptosomes were hypotonically lysed and sonicated. Micrographs reveal numerous small (<250 nm), irregular vesicles and less numerous membrane sheets adherent to beads. Virtually all transferase is release. About 2% of total protein and 2% of nucleotidase activity remain bead-bound. This is not unexpected since the bulk of nucleotidase activity resides in synaptic vesicles. To monitor recovery of plasma membrane, synaptosomes were surface-labeled with ^{125}I before immunoadsorption. After lysis and sonication 10-20% of radioactivity remained bead-bound, giving a 5-10 fold enrichment in bound membrane. After lysis and sonication 50-70% of anti-SV antibody remained bound indicating a 25-35 fold enrichment of surface antigens in bound membrane. Presumably anti-SV marks the active zones of the PSPM. The presence of non-vesicle components in PSPM was shown by the properties of an antiserum raised against the PSPM preparation (anti-PSPM). Anti-PSPM can mediate the immunoadsorption of synaptosomes even after pre-adsorption with disrupted synaptic vesicles to remove anti-SV antibodies. Furthermore, anti-PSPM binds to nerve terminals in frozen microtome sections of frog neuromuscular junction just as anti-SV does. However, in contrast to anti-SV, which binds to intact terminals only after stimulation, anti-PSPM binds to intact terminals without prior stimulation. In conclusion, biochemical markers, electron microscopy, anti-SV binding and immunoadsorption, and production of a specific anti-PSPM antiserum demonstrate that we have isolated a membrane preparation which is enriched in the PSPM and its active zones. (This research was supported by NIH grant NS 09878.)

227.11 ULTRASTRUCTURAL CORRELATES OF GUANIDINE STIMULATION OF TRANSMITTER RELEASE IN SYMPATHETIC GANGLIA. Joseph J. Pysh and Scott C. Ford* Dept. of Cell Biology and Anatomy, Northwestern University Medical and Dental Schools, Chicago IL 60611.

It is well known that guanidine stimulates neuromuscular transmission by increasing transmitter release, although the mechanism is unknown. It has been proposed that guanidine increases the available store of transmitter. In previous work on sympathetic ganglia we observed that in resting terminals the presynaptic grid is not fully packed with synaptic vesicles. The purpose of this study was to determine whether guanidine increases vesicle packing at the presynaptic membrane.

The 9th sympathetic ganglia of bullfrogs were used. First, we determined that guanidine enhances synaptic transmission in amphibian sympathetic ganglia. Ganglia were removed and placed in a bath of Ringer's solution. A stimulating suction electrode was placed on the sympathetic trunk and a recording electrode was positioned on the 9th ramus. In curarized ganglia (D-tubocurarine, $4x10^{-5}M$) in which the amplitude of the postganglionic compound action potential was reduced about 80%, guanidine at 5 mM produced a four-fold increase in the size of the postganglionic potential within 30 minutes whereas a 0.5 mM concentration of the drug had no effect. Paired 9th sympathetic ganglia from bullfrogs were removed; one ganglion per pair was placed in Ringer's solution as a control and the other in Ringer's containing 0.5 mM or 5 mM guanidine. After 30 minutes, each ganglion (control or drug-treated) was rapidly frozen in a Boyne freezing machine, processed by freeze-substitution and prepared for TEM. Electron micrographs of well frozen axo-somatic synapses near the ganglion surface were taken at 57,000x and enlarged to a final magnification of 155,000x. Synaptic vesicles in a zone 500 Å deep from the presynaptic membrane were counted in random coded electron micrographs. In the control synapses, measured vesicle packing at the synaptic grid was approximately 50% of the theoretical maximum. No significant difference was detected in ganglia treated with 0.5 mM guanidine. In ganglia treated with 5 mM guanidine, vesicle packing at the synaptic grid was 18% greater, however, this vesicle density was still far from the maximum.

It appears that guanidine does not act by producing gross translocations of a few vesicles to occupy empty sites at the presynaptic grid but instead might act by allowing those vesicles already in the vicinity to approach more closely the presynaptic membrane. The observed small but significant increase in vesicle packing near the junction in guanidine-treated ganglia might reflect a closer apposition by an average of 90 Å per vesicle which could potentiate calcium's role in promoting vesicle exocytosis.

227.12 EFFECTS OF NEURONAL ACTIVITY ON THE DISPOSITION OF SYNAPTIC VESICLES. Dr. L. Maler. Dept. of Anatomy, Univ. of Ottawa, Ottawa, Ont. K1N 9S9, Canada.

We have used the electroreceptor afferents of high frequency gymnotid fish to examine the reversible effects of nerve activity upon the disposition of synaptic vesicles. Electroreceptor afferents in these fish are continuously active at frequencies in excess of 100z (Hopkins, J. Comp. Physiol. 111: 172, 1976) and terminate topographically within one layer of the posterior lateral line lobe (PLLL, Carr, Maler & Sas, submitted; Maler et al., J. Comp. Neurol. 195: 87, 1981). Both electroreceptors and their afferent nerve are readily accessible for experimental manipulation. In the normal animal electroreceptor afferent terminals contain round vesicles with a bimodal distribution of diameters; the smaller vesicles are clustered against the presynaptic membrane (Maler et al., 195: 87, 1981). Nerve activity can be eliminated by sectioning the electroreceptor afferent nerve or by placing a tetrodotoxin (TTX) cuff around it. Since electroreceptors are derived from lateral line receptors they are susceptible to the action of antibiotics such as Kanamycin and Streptomycin; the cutaneous application of these antibiotics eliminates electroreceptor activity without nerve damage. All three of the above treatments cause the vesicles to disperse from their presynaptic sites. After one day the nerve sectioned animals also show degenerative changes in their electroreceptor afferent terminals, whereas the other treatments do not alter the normal cytologic appearance of terminals. After 2-4 days the TTX cuff or antibiotic treated animals have afferent terminals containing only large vesicles or extensive cisternal elements; no small vesicles at all are present near the presynaptic membrane. The electroreceptor afferent nerve was then stimulated in both TTX cuff and antibiotic treated animals; stimulation was done at the average rate expected for the afferents in question (100-250 Hz) for a period of 30 minutes or 1 hour. After 1 hour of stimulation small vesicles were once again found to be clustered adjacent to the presynaptic membrane. These experiments demonstrate that the disposition of synaptic vesicles is under the long term control of mechanisms responsive to some aspect of nerve activity; calcium influx is an obvious candidate as a presynaptic signal of nerve activity.

227.13 COLLARED PIT: A NEWLY OBSERVED STRUCTURE POSSIBLY RELATED TO VESICLE RECYCLING AT THE SYNAPSE. Toshio Kosaka* and Kazuo Ikeda, City of Hope Research Institute, Duarte, CA. 91010.

It has been shown that a reversible, temperature-dependent blockage of neuromuscular transmission occurs in the Drosophila mutant, shibire^{ts1} (shi), and that, in accord with these physiological observations at high temperature, synaptic vesicles are depleted reversibly in neuromuscular junctions (NMJ's). Furthermore, some physiological observations indicate that in shi similar kinds of temperature-induced changes occur at synapses in the central nervous system. However, no morphological studies were done on synapses other than NMJ's. We studied the fine structure of various kinds of synapses in the mutant shi and the wild-type, Oregon-R, both at low and high temperatures. For low temperature experiments, flies were dissected at 19°C, kept at that temperature for 10-20 min. and fixed at 19°C. For the high temperature experiments, flies were dissected at 19°C and kept at that temperature for 5 min., then the temperature was raised to 30°C at a rate of 1°C/min. After 5 min. exposure to 30°C, the flies were fixed.

Synapses of the thoracic ganglion, medulla, lamina, NMJ's of the coxal and dorsal longitudinal flight muscles, and NMJ's of the circular muscles in the thoracic ventricle of the alimentary tract were observed.

At high temperature the number of vesicles varied considerably, probably dependent on the kind of neuron. Some synaptic terminals had no synaptic vesicles,others had many. In addition, a preponderance of a heretofore undescribed synaptic structure was observed in a variety of synapses at high temperature. This was a particular kind of pit arising from the plasma membrane near presynaptic sites. It consisted of a spherical head portion, about 400-600 Å in diameter, with a neck portion about 150-200 Å long and about 200 Å in diameter. This neck portion was wrapped by a cytoplasmic dense material about 100 Å thick, which looked like a "collar". Many of these pits were frequently observed to be lined up along the terminal plasma membrane. This special kind of pit with a "collar", is described here for the first time, and we would like to propose to call it a "collared pit".

The important thing is that collared pits were, although very rare, also observed in control flies. Thus, the collared pits are a normal structure in the Drosophila synapse, and increase in number in shi synapses at high temperature. Although more quantitative observations are necessary to conclude the function of the collared pits, we are speculating that they are one of the structures in the pathway of membrane recycling at synapses.

227.14 UPTAKE OF HORSERADISH PEROXIDASE CORRELATED WITH SYNAPTIC ACTIVITY IN CRUSTACEAN MOTOR NERVE TERMINALS. C.S. Thompson* and H.L. Atwood. Dept. of Zoology, University of Toronto, Toronto, Ontario, Canada M5S 1A1.

Synaptic strength was correlated with uptake of the enzyme horseradish peroxidase (HRP) by different motor nerve terminals in the opener muscle of walking legs of crayfish Procambarus clarkii. Opener muscles were exposed and the excitatory axon isolated for stimulation. Preparations were soaked in a 1%-2% solution of HRP (Sigma Type VI) in crayfish saline for 40-60 min. The motor axon was then stimulated with 1.5 sec. trains of stimuli (30 Hz) delivered every 2 sec. After a period of rest, preparations were fixed in 2.5% glutaraldehyde, reacted with diaminobenzidine, and prepared for electron microscopy.

Virtually all of the HRP reaction product was found within synaptic vesicles. Confirming previous work, we found almost no HRP reaction product in terminals of unstimulated neurons. Labelled vesicles were observed with periods of stimulation as brief as 5 min. Nerve terminals were followed in serial sections to determine the distribution of labelled vesicles. They appeared scattered throughout the vesicle population and were not localized exclusively at presynaptic dense bodies (putative release sites). Synaptic vesicles were more diffusely distributed in stimulated than in unstimulated preparations. The percentage of labelled vesicles was fairly uniform along the length of the terminals. There is an apparent correlation between percentage of labelled vesicles and frequency of occurrence of presynaptic dense bodies along the terminals.

At low temperatures (2°C) stimulation produced large involutions of nerve terminal membrane. HRP reaction product was observed in synaptic vesicles, in other, much larger vesicles, and in irregularly shaped cisternae. When 3-aminopyridine was present and fixative applied immediately after stimulation a few coated vesicles were observed and the percentage of labelled vesicles increased.

From these results it appears that synaptic activity (amount of transmitter released) is correlated with uptake of marker. Synaptic vesicle membrane is probably recycled in crayfish motor nerve terminals as at frog neuromuscular junctions (Heuser,J.E. and Reese,T.S. J. Cell Biol. 57: 315-344, 1973). Labelled vesicles were not strictly associated with putative release sites (presynaptic dense bodies), and it is likely that uptake of marker is more widespread along the terminals than release of transmitter.

227.15 NEURONAL SURFACE PROTEIN RELEASE ACCOMPANIES TRANSMITTER RELEASE. K.J. Sweadner and P.H. Patterson. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Sympathetic neurons from the superior cervical ganglion of the newborn rat were maintained in dissociated cell culture in the absence of nonneuronal cells. Neurons loaded with ^{3}H-norepinephrine will release this transmitter when stimulated with 54mM K^+ + 5mM Ba^{++}, black widow spider venom (BWSV), the Ca^{++} ionophore A23187, or veratridine, or when treated with reagents which make the plasma membrane permeable to ions, such as the ionophores alamethicin and monensin, and p-chloromercuribenzene sulfonate (pCMBS). This chemically evoked transmitter release is accompanied by the release of a group of high MW (210, 180, 120K) acidic glycoproteins.

The proteins appear in the medium at the expense of cell-associated proteins of MW 230, 210, 200, and 180K, which are labeled by metabolic incorporation of ^{3}H-leucine or ^{3}H-fucose. The accessibility of the releasable proteins to enzymatic modification in intact cells indicates a cell surface location: 1) they are labeled by lactoperoxidase-catalyzed iodination at 0°C; 2) digestion with neuraminidase, which removes sialic acids, causes a basic shift in isoelectric point; and 3) low levels of trypsin degrade them and abolish subsequent evoked release of protein, indicating the lack of an intracellular pool such as in synaptic vesicles. The reduction in apparent molecular weight upon release suggests that the proteins are released from the surface by proteolysis, but the following protease inhibitors do not block the release: PMSF, aprotinin, chloroquine, leupeptin, Ep475, pepstatin, chymostatin, and pCMBS. The release process is selective, in that many other cell surface proteins are unaffected.

This evoked release of cell surface protein is dependent upon the presence of exogenous Ca^{++} (or Ba^{++}) in all conditions tested. It is possible to separate the release of norepinephrine from the release of surface protein by this Ca^{++}-dependence: norepinephrine can be released in the absence of exogenous Ca^{++} when the cells are treated with BWSV or pCMBS, while the proteins are not released under the same conditions until Ca^{++} is added. La^{+++} can also be used to separate transmitter release from protein release: 5mM La^{+++} evokes norepinephrine release but not protein release, and in fact La^{+++} blocks the release of protein evoked by BWSV. Both the presence of La^{+++} and the absence of Ca^{++} have been observed by others to block the recovery of motoneurons from heavy stimulation or from BWSV treatment. We propose that the evoked release of surface protein accompanies some event subsequent to transmitter release itself, such as the recapture of vesicle membrane fused with the plasma membrane during exocytosis.

227.16 STRUCTURAL DETAILS OF LIZARD NEUROMUSCULAR JUNCTIONS REVEALED BY CONVENTIONAL AND FAST FREEZE CRYOTECHNIQUES. J. P. Walrond and T. S. Reese. (Spon. H. deF. Webster) NINCDS, NIH, Bethesda, MD 20205

Fast freezing, freeze fracture and freeze substitution provide improved methods for preserving subcellular structural elements. Since fast freezing preserves well only those subcellular structures which lie within a few μm of the freezing surface, application of this technique to neuromuscular systems requires a preparation with superficially located synapses. The intercostal muscles of the lizard Anolis carolinensis meet this criterion, and furthermore provide a preparation amenable to examination by freeze fracture or freeze substitution. During development of the Anolis intercostal preparation several interesting aspects of its synaptic organization came to light. Zinc iodide-osmium staining for light microscopy revealed both singly and multiply innervated intercostal muscle fibers. Singly innervated muscles have en plaque type endings with tightly packed, interconnected boutons, while the axon terminals on the multiply innervated fibers, which are much less frequent and presumably tonic, appear in diffuse clusters. Ultrastructural studies of muscles stained for cholinesterase show that multiply innervated fibers also lack the deep junctional folds found in the postsynaptic membrane of singly innervated fibers. These characteristics permit singly innervated, twitch fibers to be recognized in freeze-fractured preparations. After conventional fixation and glycerination of the axon terminals, synaptic vesicle openings occur near the ends of paired double rows of P face particles. These "active zones" lie perpendicular to the axis of the synaptic ridge, another difference from the frog neuromuscular junction. Fast frozen, freeze fractured and freeze etched Anolis neuromuscular junctions show exceptional preservation of subcellular structural elements. In these preparations, the basal lamina running through the synaptic cleft appears as a delicate lattice of side arms emanating from a central denser lamina. In some instances the side arms appear to insert directly into the cell surface while at other points they seem to contact foot-like structures. In thin sections of fast frozen and freeze substituted preparations stained en bloc with lead octoate, the extrasynaptic basal lamina appeared as a thin backbone with periodic branches extending to the muscle cell surface. This technique also showed that this backbone is thicker in the synaptic cleft than on the rest of the muscle and that individual processes extend from it to the pre- and postsynaptic cell surfaces. We do not know yet the identity of these components or their specific relationships to certain intramembrane structures such as the postsynaptic receptors or components of the presynaptic active zone.

227.17 STRUCTURE AND DISTRIBUTION OF NEUROMUSCULAR JUNCTIONS ON TONIC MUSCLE FIBERS IN FROG. V. Verma*. NINCDS, LNNS, NIH, Bethesda, MD 20203 (Spon. David S. Forman)

There are two functionally distinct types of muscle fiber in the frog: tonic, which does not conduct an action potential but has a slow, sustained contraction; and twitch, which conducts an action potential and contracts more rapidly. The proportion of these two types of muscle fiber varies from muscle to muscle though tonic fibers are rare. However, the curalis leg muscle includes a pigmented bundle that is almost 50 percent tonic fibers. These fibers are known to be multiply innervated. Their synaptic clefts stained less intensely for cholinesterase than those in twitch fibers and they had on their surface 2-7 terminals which did not branch. The mean length of all terminals in a neuromuscular junctions was 236 ± 99 µm (N=10), and the length of individual terminals varied from 11 to 219 µm. The postsynaptic membrane at some places had irregular projections 0.4 to 0.6 µm in width and 0.1 to 0.5 µm in height, but it lacked synaptic folds. Like terminals on fast fibers, the sarcoplasm immediately underneath the postsynaptic membrane was characterized by electron opaque, fuzzy material which was irregularly partitioned to form small plaques located under membrane bulges. However, many areas of postsynaptic muscle lacked this specialization. The sub-synaptic region had few randomly distributed subneural filaments as compared to the organized bundles in the junctions of twitch fibers. The cytoplasmic organization of both types nerve ending was essentially the same; the only difference being that in twitch fiber terminals the active zones were arranged at regular intervals above each fold whereas there was no such precision in the terminals of tonic fibers. The structure of the Schwann cells also did not differ on tonic fibers but, in thin sections, cholinesterase staining in the nerve-muscle cleft was less intense. The tendency for neuromuscular junctions on tonic fibers to be spread out over the muscle fibers surface made it possible to identify them tentatively in a few favorable freeze-fracture replicas. Folds in the muscle surface did not extend beyond the edges of these terminals, increasing our confidence that they are terminals on tonic fibers. The P face of these terminals had double rows of large particles, that were similar to those at terminals on tonic fibers, and vesicle openings were occasionally found beside these rows. Thus, it appears that the presynaptic active zone, which is the structural basis for release of synaptic vesicles, is basically the same in terminals on tonic and twitch muscle fibers. Any differences in the functional properties of these terminals must depend on the shapes and deployment of active zones as well as special properties of the muscle membrane.

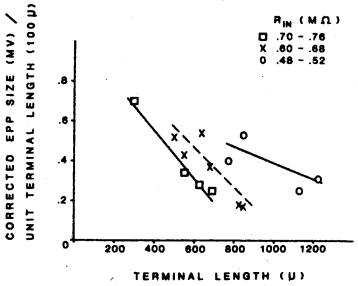
227.18 INVERSE RELATIONSHIP BETWEEN TERMINAL LENGTH AND RELEASE/UNIT LENGTH IN FROG NEUROMUSCULAR JUNCTIONS ON FIBERS OF UNIFORM INPUT RESISTANCE. B. Nudell* (SPON: A.D. Grinnell). Dept. of Biology, UCLA, Los Angeles, CA 90024.

The quantal content (m) of endplate potentials (EPPs) at frog neuromuscular junctions is known to be positively related to terminal length. However, the correlation is inexact, with wide scatter of data. We have now analyzed the EPPs of identified frog cutaneous pectoris muscle fibers, correlating release with terminal size and fiber input resistance (R_{in}). In some experiments, transmitter release was assayed by measurement of the EPPs evoked in normal Ringer and curare; in others by quantal analysis of endplate activity in low Ca^{++} Ringer. Endplates were visualized with a combined nitroblue tetrazolium (Letinsky and DeCino, 1980) and Karnovsky (1964) cholinesterase stain.

For fibers of approximately the same R_{in}, there is an inverse relationship between the level of transmitter release per unit length and total terminal length. Terminals with high levels of release/unit length tend to be shorter than do those which release relatively less transmitter/unit length. Furthermore, if the analysis is similarly restricted to fibers with nearly identical R_{in}, the total transmitter release of the largest endplates is generally no greater than that of the shorter terminals in the sample.

These findings do not contradict the overall trend of greater release and longer terminals on larger muscle fibers (with lower R_{in}). Instead, they help explain the variability in measurements of m vs. terminal length. The relationship we find is consistent with the hypothesis that, in the cutaneous pectoris, terminals are induced to grow until an adequate safety factor for transmission is achieved.

The data presented below was gathered from 14 cells of one muscle.



227.19 LONG-TERM POTENTIATION OF SYNAPTIC TRANSMISSION IN RAT SUPERIOR CERVICAL GANGLION. Donald A. McAfee and Thomas H. Brown, Div.of Neurosciences, City of Hope Research Institute,Duarte, CA 91010.

A brief period of high frequency presynaptic stimulation is known to increase postsynaptic responses to single stimuli in a number of preparations. This posttetanic increase in synaptic efficacy is transient, usually lasting for only a few seconds or minutes. However, in the hippocampus a conditioning tetanus has a long-term effect suggesting a possible role in learning and memory. We now report that long-term potentiation (LTP) also occurs in sympathetic ganglia and may be a more general property of neuronal synapses.

Isolated and desheathed ganglia were superfused with Locke solution at about 23°C. Suction electrodes were used to deliver supramaximal preganglionic stimuli to the cervical sympathetic nerve and to record the amplitude of the postganglionic compound action potential/EPSP from the internal carotid pole of the ganglion. The postsynaptic response was reduced to 50% of its maximum by curare (100 µM) in order to spare postsynaptic neurons for recruitment during increased synaptic efficacy. Atropine (2 µM) was present to block slow muscarinic responses. Postganglionic responses were elicited once a minute before and after tetanic preganglionic stimulation (20 sec at 20 Hz).

The simplest expression which describes accurately the posttetanic time course of the enhanced response consists of the sum of two exponential terms.

$$I(t) = P\exp(-t/\tau_P) + L\exp(-t/\tau_L)$$

where I(t) is a dimensionless term giving the time-dependent fractional incremental response ($I(t) = [V(t) - V_C]/V_C$, where V_C is the pretetanic control amplitude and V(t) is the posttetanic amplitude at time t). The results are summarized below. The rapid phase of this double exponential decay probably corresponds to posttetanic potentiation (PTP), since the average value of τ_P is close to the 3 minute decay time constant previously reported by Zengel, et al. (J. Gen. Physiol. 76, 213, 1980) for PTP in rabbit ganglia. By contrast, the more slowly decaying component (LTP) typically lasts for hours. (Supported by Grants BNS 79-12394 & NS 16576 and a McKnight Foundation Scholars Award).

PARAMETER	MEAN ± S.E.	RANGE	N
P	1.0 ± 0.2	0.2 - 2.0	10
τ_P	3.3 ± 0.5 min	1.2 - 5.8 min	10
L	1.2 ± 0.2	0.7 - 2.9	10
τ_L	82.2 ± 26.0 min	33.8 - 229.5 min	10

227.20 AXO-AXO-AXONIC SYNAPSES. L. E. Westrum. Depts. of Neurological Surgery and Biological Structure, Univ. of Washington, Sch. of Med., Seattle, WA 98195.

Axo-axonic synapses are typically found in CNS sensory relay nuclei and in some cases have been correlated with the phenomenon of presynaptic inhibition. In addition, vesicle-containing dendrites have been observed in synaptic glomeruli although the identification of presynaptic dendrites may be controversial in many cases. Axo-axonic synaptic contacts may involve: two axon terminals, or an axon terminal and an axon hillock, initial segment, or node (of Ranvier). I report here the unusual synaptic arrangement of three separate axonic profiles observed in the spinal trigeminal nucleus of adult cat. Profiles of axon hillocks (AH) and initial axon segments (IAS) may occasionally be seen in the neuropil. The characteristic fasicles of microtubules and cone-like emergence from a soma or large dendrite identify the AH. Membrane undercoating and fasicles of microtubules, in addition to a continuity with an AH, identify an IAS. Both AH and IAS are contacted by vesicle-containing presynaptic terminals. The most common situation is a terminal with flat synaptic vesicles (F) forming a type II, symmetrical contact with the AH or IAS. However, some of the AH and IAS profiles receive an asymmetrical, type I, contact from a terminal with round synaptic vesicles (R). In addition, a proportion of these same R terminals are postsynaptic to an F terminal, thus forming a serial synaptic complex of three separate kinds of axonic profiles: an axo-axo-axonic synapse. The F terminal lacks the usual characteristics of presynaptic dendrites. In this region the R terminal postsynaptic to an F, is usually presynaptic to a dendrite and is the primary afferent from the periphery. The origin of the F is unknown but thought to be an interneuron. Therefore, the R in the axo-axo-axonic synapse may also be a primary afferent synapsing directly on the spike generator area of the neuron and under presynaptic influence of an F synapse. The strategic position of this complex and its implications are critically relevant to the overall function of these neurons. (Supported by N.I.H. Grants No. NS 09678 and 04053. LEW is also an affiliate of the CDMRC.)

228.1 ABNORMAL β RECEPTOR FUNCTION IN BROWN ADIPOSE TISSUE OF GENETICALLY OBESE ZUCKER RATS. A. C. Sullivan*, R. O'Brien, D. Anderson*, B. E. Levin, (SPON: S. D. Cook). Dept. Pharm. II, Hoffmann-LaRoche Inc., Nutley, NJ 07110, and Dept. Neurosci., N.J. Med. School, Newark, NJ 07103.

Brown adipose tissue (BAT) accounts for up to 60% of the oxygen consumption during cold or diet-induced thermogenesis. Stimulation of this oxygen consumption in BAT is primarily under the control of the sympathetic nervous system which extensively innervates this tissue. Genetically obese Zucker rats have a decreased thermogenic capacity which does not respond to infusions of norepinephrine, suggesting receptor-effector dysfunction. Interscapular BAT of obese and lean, 4-5 mo old male Zucker rats was therefore examined to determine its role in this defect. Obese BAT pads were 4-fold heavier but had 30% less protein than lean BAT. This weight difference was due to an increased number and size of fat cells in obese BAT. Lean BAT contained $18.8 \pm 0.3 \times 10^6$ cells/pad, 77% of which were multilocular cells characteristic of BAT and 23% of which were unilocular. Obese BAT pads contained $33.4 \pm 0.7 \times 10^6$ cells, all of which were unilocular. These unilocular cells were larger in obese ($66.8 \pm 7.4\,\mu$) than lean ($48.8 \pm 2.0\,\mu$) BAT, while lean multilocular cells had the smallest diameters ($25.7 \pm 0.9\mu$). Binding of { ^{3}H } dihydroalprenalol to β adrenoreceptors of isolated BAT cell membranes produced a curvilinear Scatchard plot with a 44% increase in the apparent K_D for high affinity sites in obese (36.6 ± 4.0 nM) compared to lean (25.5 ± 1.6 nM; $p < 0.05$) BAT. The B_{max} for high affinity sites was reduced by 66% in obese$_6$ ($24.5 \pm 2.1 \times 10^{-6}$ fmol/cell) versus lean BAT ($55.4 \pm 1.8 \times 10^{-6}$ fmol/cell; $p < 0.05$), while potency for agonists in competition studies was similar between the genotypes and characteristic of the β_1 subtype. Therefore, although it is uncertain whether the morphologic abnormalities in obese BAT are the cause or effect, the reduced thermogenic capacity of obese rats can be partly attributed to a reduction of both receptor binding affinity and the number of binding sites in their BAT.

228.2 BENZODIAZEPINE RECEPTOR BINDING IN THE BRAIN OF THE SPONTANEOUSLY HYPERTENSIVE RAT. J. E. Taylor and R. M. Quock. School of Medicine, Indiana University, Evansville, IN 47732 and School of Dentistry, Marquette University, Milwaukee, WI 53233.

A number of studies have shown that neurogenic factors may be important in the initiation and development of hypertension in the spontaneously hypertensive rat (SHR). Other studies have also demonstrated that the SHR shows a marked cardiovascular hyperreactivity to anxiety and stress, which suggests that the SHR may have a functional deficiency of stress-defense mechanisms in the central nervous system (CNS). Because of the selective anxiolytic action of the benzodiazepines, it was of interest to determine whether alterations in benzodiazepine receptors were present in various brain regions of the SHR. For this purpose, ^{3}H-flunitrazepam (5 nM) binding assays were done on membrane fractions from several brain regions from the SHR and age-matched Wistar-Kyoto (WKY) normotensive controls. Specific binding was defined as that total ^{3}H-flunitrazepam bound minus that bound in the presence of 1 μM diazepam.

The binding of ^{3}H-flunitrazepam for each strain was lowest in the cerebellum and brain stem, intermediate in the thalamus/hypothalamus, midbrain, and corpus striatum, and highest in the cerebral cortex. The only region to show a significant difference in binding was the cerebral cortex, where the values were 55.3 ± 2.1 fmol/mg tissue (n=4) for the WKY and 43.4 ± 3.1 (n=4; $p < 0.02$) for the SHR cortex. Scatchard analyses of ^{3}H-flunitrazepam binding in the cerebral cortices yielded equilibrium dissociation constants of 1.76 ± 0.13 nM (n=4) for the SHR and 1.89 ± 0.12 nM (n=4) for the WKY. These data show that there is a selective decrease in the number of benzodiazepine receptor sites in the cerebral cortex of the SHR. This observation suggests that the SHR may have a diminished ability to modulate stressful and anxiety producing influences, which in turn, may contribute to the development of the hypertensive state.

228.3 CHANGES OF BRAIN SEROTONIN AND CATECHOLAMINE METABOLISM IN THE UREMIC RAT. P.J. Knott, G.O. Rankin* and K. Cressey-Veneziano*, Dept. of Pharmacology, Marshall University School of Medicine, Huntington, WV 25701

Neurological changes occur in chronic renal failure (Tyler, H.R., Am. J. Med. 44:734, 1968) suggesting changes of neurotransmission processes. Furthermore, alterations of brain serotonin (5HT) metabolism occur in experimental uremia (Siassi, F., et al, J. Nutr. 107, 840, 1977) and in advanced renal disease (Sullivan, P.A., et al., J. Neurol. Neurosurg. Psychiat. 43, 739, 1980). In the present studies, we have investigated in male Sprague-Dawley rats (350-400 g) the effects of N-(3,5-dichlorophenyl) succinimide (NDPS) a nephrotoxic agent (Rankin, G.O. Fed. Proc. 40, 675, 1981) on brain serotonin metabolism and on levels of catecholamines. Rats received NDPS (50, 100 or 200 mg/kg i.p.) or vehicle (sesame oil, 2.5 ml/kg i.p.) and brain tryptophan (TP), 5HT and 5-hydroxyindoleacetic acid (5HIAA), norepinephrine (NE), dopamine (DA) and epinephrine (EPI) levels were determined 24 and 48 h postinjection together with plasma levels of free and total TP. Plasma urea nitrogen (PUN) and plasma transaminase activity (GOT) were determined as indicators of renal and hepatic damage respectively. NDPS (200 mg/kg) increased brain TP, 5HIAA and PUN significantly. Plasma free TP was unchanged whereas plasma total TP fell and probably accounts for the elevation of brain TP and brain 5HT synthesis which only occurred in the presence or uremia. Thus, brain 5HIAA or TP correlated significantly with PUN levels ($P < 0.001$, $n = 18$) and negatively with plasma total TP ($P < 0.001$) but plasma GOT was unchanged. Further evidence that these CNS changes resulted from renal damage is shown by absence of both PUN and brain amine changes at 48 h. Brain EPI values but not NE or DA were significantly increased by NDPS at 100 mg/kg. Paradoxically within that group, brain EPI showed a strong negative correlation with PUN ($P < 0.001$). Possibly, cerebral n-methyltransferase activity is influenced directly by NDPS and indirectly by other changes occurring in uremia.

228.4 A MONOAMINE OXIDASE INHIBITOR INDUCES A TIME-DEPENDENT SUBSENSITIVITY OF DA AUTORECEPTORS. S.M. Antelman*, W.B. Orr* and L.A. Chiodo (SPON: A. Barkai). Psychobiology Program, Dept. of Psychology and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

We have recently demonstrated that repeated treatment with tricyclic antidepressants or electroconvulsive shock, two frequently used treatments against clinical depression, induce a subsensitivity of dopamine (DA) autoreceptors located on DA neurons in the zona compacta of substantia nigra (Chiodo and Antelman, Nature 287:451, 1980; Science 210:799, 1980). Moreover, the progressive induction of autoreceptor subsensitivity by these treatments appears to be a time-dependent sensitization process since repeated treatment is not required to produce this effect. The present study extends these findings by showing that phenelzine, a clinically effective monoamine oxidase inhibitor also induces a progressive subsensitivity of DA autoreceptors.

Male rats were treated with phenelzine sulfate (5 mg/kg, ip.) for either 2 or 10 days. Forty-eight hours after the last injection, extracellular single-unit activity of verified DA cells was measured as previously described (Chiodo et al., Brain Res., 189:544, 1980). DA autoreceptor sensitivity was indexed by the degree of inhibition of spontaneous activity produced by either the administration of a presynaptic dose of apomorphine (APO) (4 ug/kg, i.v.; Skirboll et al., Science, 206:80, 1979) or the microiontophoretic application of DA (0.1M, pH4.0; 2, 5, 10, 15, 20 nA ejection currents). As previously seen with all other antidepressant treatments, both 2 and 10 days of phenelzine injections significantly attenuated both APO and DA's ability to inhibit spontaneous DA activity relative to controls.

Moreover, in animals treated for 2 days and tested 10 days later, phenelzine produced a degree of DA autoreceptor subsensitivity that was identical to that seen in animals which received 10 days of the drug followed by two drug-free days.

These results extend our previous findings showing that antidepressant treatments induce subsensitivity of DA autoreceptors, and emphasize the importance of DA systems in the mechanism of action of such treatments. Since all these treatments appear to work by the induction of a time-dependent sensitization process it is interesting to speculate that such an effect underlies the known delay in their efficacy seen clinically

228.5 BENZODIAZEPINE ACTIVITY IN SEIZURE-SENSITIVE AND SEIZURE-RESISTANT MONGOLIAN GERBILS. P.J. Syapin, P.T. Duong* and L.A. Paul*. Dept. of Neurology, USC School of Medicine, Los Angeles, CA 90033 and Dept. of Anatomy, UCLA School of Medicine, Los Angeles, CA 90024.

Anticonvulsant activity of benzodiazepines (BZ) has been shown to be mediated by specific, high affinity receptor sites in the CNS. Alterations in BZ binding may therefore play a role in the etiology of epilepsy. Mongolian gerbils are animal models for epilepsy. We examined in vitro binding of flunitrazepam to brain membranes and behavioral responses to flurazepam in seizure-sensitive (SS) and seizure-resistant (SR) Mongolian gerbils. Specific binding of flunitrazepam to membranes thoroughly washed in phosphate buffer was similar to that reported for other species. However, differences in regional distribution were noted. Specific binding was enhanced 23-36% by 200 mM NaCl except in olfactory bulbs, which showed 11-14% enhancement. BZ receptors in Mongolian gerbils appear less coupled to GABA modulatory sites than in mice or rats. Comparisons between SSs and SRs revealed more binding sites in SS hippocampus, olfactory bulbs, and neocortex, and fewer sites in cerebellum. SS hippocampi were heavier than SR hippocampi. Binding in this region was enhanced less in SS than in SR by 200 mM NaCl while strain differences were absent for other regions.

Behavioral studies utilized cross-over design with drug-naive subjects with known seizure histories. Immediately following s.c. injection, animals were observed and rated in the open field for 14 minutes. Behavior noted included seizures, ataxia, aimless running, response to visual stimulus (pencil), and fecal boli. Flurazepam s.c. did not block seizures, probably due to the rapid onset of seizures after handling (<30 sec). Effects of the drug, however, included ataxia, aimless running, and failure to respond to the visual stimulus. Strain differences in these responses were noted. Counts of fecal boli were performed on all animals at four intervals during the test session. SSs and SRs had different scores on this measure of emotionality. Following drug, SSs had reduced numbers of boli in the open field, compared with their scores after saline, while SRs produced more than in the vehicle condition. Following the second administration of this antianxiety drug, the value of this variable for SRs was more than 3 times that for SSs.

The above pharmacological findings are consistent with results (Paul et al, Science, in press) indicating that the SS hippocampus may differ structurally from the SR. These results provide further evidence that BZ receptors may play an important role in seizures. (Supported by BSRG #2-S07-RR05356-20 and a grant from the Epilepsy Foundation of America).

228.6 PROTECTION AGAINST RESERPINE-INDUCED RIGIDITY BY BLOCKADE OF ALPHA-2 RECEPTORS. B.H. Wagner*, K.J. Kellar and R.J. Anderson, Depts. Pharmacol., George Washington Univ. and Georgetown Univ., Washington, DC.

The parkinson-like syndrome (tremor, bradykinesia, rigidity) induced in rats by high doses of reserpine is effectively reversed by a variety of drugs including the antipsychotics chlorpromazine and trifluoperazine. Since the alpha adrenergic blocking property of these drugs has been implicated as the mechanism, the purpose of this study was to examine the relative contribution of actions on alpha-1 and alpha-2 receptors in modifying reserpine-induced rigidity. Rats were pretreated with either clonidine (.04-1 mg/kg), yohimbine (1-5 mg/kg), methysergide (1 mg/kg), phentolamine (1 mg/kg) or SKF 7265 (36-144 mg/kg). Thirty min later the animals were given 20 mg/kg reserpine ip and evaluated by a blinded observer. Eleven categories were used to quantitate the parkinson-like and autonomic effects induced by reserpine. The severity of the reserpine effects in these rats was compared to the effects in vehicle pretreated animals. Yohimbine (an alpha-2 antagonist) was the most effective agent in protecting against the reserpine effects. Phentolamine and SKF 7265 (which block both alpha-1 and -2) were also effective; whereas clonidine (an alpha-2 agonist) and methysergide (a serotonin antagonist) were not. In all cases the alpha blocking drugs prevented the motor responses but did not alter the autonomic responses induced by reserpine. Although yohimbine and chlorpromazine are also effective dopamine blockers, the protection seems to be due to alpha adrenergic blockade since SKF 7265 (which has little affinity for dopamine receptors; Ki = 530 nM) was among the effective agents. Protection from the reserpine effects by alpha-2 blockers was achieved at doses which were not sedating whereas alpha-1 blockers such as chlorpromazine antagonize reserpine only at sedative doses. Relative adrenergic binding affinity of the test drugs was confirmed by in vitro binding assays in a separate set of experiments. Yohimbine and SKF 7265 were equipotent in displacing ^{3}H-clonidine from alpha-2 receptors in rat cerebral cortex membranes. SKF 7265 was approximately equipotent at alpha-1 and -2 receptors but was considerably less potent in displacing ^{3}H-spiperone from dopamine receptors in rat striatal tissue. The results show not only the efficacy of alpha adrenergic antagonists in protecting against reserpine rigidity but more importantly that the blockade of alpha-2 receptors may be the functionally important action. These results are consistent with the view that some descending motor pathways are controlled by an adrenergic mechanism and suggest that alpha-2 receptors are an important component.

228.7 EVIDENCE THAT THE CENTRAL NERVOUS SYSTEM OF THE SPONTANEOUSLY HYPERTENSIVE RAT (SHR) IS DEFICIENT IN β-ADRENERGIC RECEPTORS COMPARED TO WISTAR-KYOTO CONTROL RATS (WKR). Cohen, G. A.*, A. C. Black, Jr., and D. Sandquist. Dept. Anatomy, University of Iowa, Iowa City, Iowa 52242.

Intracerebroventricular (ICV) injection of epinephrine (EPI) causes a dose-related decrease in blood pressure and heart rate in rats. This hypotensive effect is blocked by β-adrenergic antagonists, but not by α-adrenergic antagonists. Thus it appears that the cardiodepressor effects of ICV EPI may act through a CNS β-receptor mechanism[1]. SHR and their appropriate control WKR were decapitated and their brains quickly removed, and frozen in isopentane chilled in liquid nitrogen until assay. They were analyzed for β-adrenergic receptor binding using ^{3}H-dihydroalprenolol by the method of Alexander et al.[2,3], using a subcellular fraction isolated between 800 x g and 32,000 x g.

Experimental Group	Dissociation Constant*	Receptor Number**
3 week old SHR	30.5 ± 5.4	0.31 ± 0.035†
10 week old SHR	31.8 ± 2.8	0.29 ± 0.03†
10 week old WKR	39.5 ± 5.4	0.53 ± 0.07

*Dissociation constant in nanomoles per liter ± standard error of the mean for at least 7 determinations.
**Number of receptors in picomoles per mg protein ± standard error of the mean for at least 7 determinations.
†Significantly different from 10 week old WKR (P<0.01: Student's "t" test).

Interpretation: The SHR CNS is relatively deficient in β-adrenergic receptors compared with WKR. The receptor number in the SHR CNS does not increase appreciably between 3 and 10 weeks. Since the dissociation constants for SHR and WKR are not significantly different, SHR may exhibit a reduced number of β-receptors rather than a change in the nature of the receptor itself. ICV EPI induces a hypotensive response mediated by β-adrenergic receptors. Since the relative deficiency of β-receptors in the SHR CNS occurs during the establishment of hypertension, the reduced number of β-receptors could play a role in the development of hypertension in SHR. 228.8 DECREASED ^{3}H-IMIPRAMINE BINDING CAPACITY IN PLATELET MEMBRANES FROM DEPRESSED MALES AND FEMALES. Kenneth B. Asarch*, Jean C. Shih, and Agnes Kulcsar*. School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

Specific high-affinity binding sites for ^{3}H-imipramine have recently been shown to exist in human brain membranes and human platelet membranes. In order to understand the clinical implications of this ^{3}H-imipramine binding, we measured the maximal binding capacity (Bmax) and the dissociation constant (Kd) for ^{3}H-imipramine in the platelet membranes from 23 untreated male and female depressives and 16 normal males and females. Ages ranged from 19 to 58 years.

Platelet membranes for binding studies were prepared from 20 ml of blood. Specific binding, defined as that ^{3}H-imipramine binding inhibited by the presence of 100 μM desimipramine, represented 75% of the total binding at 4 nM ^{3}H-imipramine. The Bmax and Kd values were determined from Scatchard plots of the specific ^{3}H-imipramine binding.

The results indicated that the male and female depressed patient groups exhibit a 20% lower Bmax than their respective normal control groups, p = .02 (Normal males, 764 fmoles/mg protein; Depressed males, 608 fmoles/mg; Normal females, 650 fmoles/mg; Depressed females, 519 fmoles/mg). Although the male subgroups displayed a Bmax about 17% higher than their respective female control groups, the effect of sex on Bmax did not quite reach statistical significance (p = .10). The effect of depression on Kd was nonsignificant, p = .69, as was the effect of sex on Kd, p = .19 (overall mean Kd = 1.9 nM). We did not observe any correlation between subject age and either Bmax or Kd in the age range studied.

Our findings extend to males an earlier finding that the ^{3}H-imipramine binding in depressed females is lower than in normal females. The decreased ^{3}H-imipramine binding may possibly represent an unsuccessful attempt to correct some biochemical abnormality in the depressed patient. Our observed trend that men have a slightly higher binding capacity for ^{3}H-imipramine than women may help to establish a basis for the clinical observation that men respond better to antidepressant therapy with imipramine than do women.

Also, we report that a small number of patients treated with tranylcypromine, amitriptyline, or nortriptyline did not exhibit any significant changes in their ^{3}H-imipramine binding parameters. 228.9 MUSCARINIC RECEPTORS IN HEART FAILURE. J.W. Wells,* H.-M. Wong* and M.J. Sole. Faculty of Pharmacy and Department of Medicine, University of Toronto, Toronto, Canada M5S 1A1.

Heart failure is accompanied by abnormalities in parasympathetic, cardiovascular regulation. To probe for effects at the muscarinic receptor, we have studied the binding of (-)-N-[^{3}H]-methylscopolamine (NMS) in cardiac tissue from the cardiomyopathic Syrian hamster, a spontaneous model of congestive heart failure. Flushed hearts from 12-25 animals were dissected into three components: left plus right atria, right ventricle, and left ventricle plus interventricular septum. Tissue was homogenised and centrifuged, and the pellets were resuspended in Krebs-Henseleit buffer. Binding was assayed at equilibrium and 30° using microcentrifugation to obtain bound [^{3}H]NMS. In younger animals (150-200 days), the specific binding of [^{3}H]NMS revealed an apparently uniform population of sites (-log K_d = 9.4) in each cardiac region of myopathic hamsters and matched controls. Capacities were 50 to 120 pmol/g protein, depending upon the region and the batch of animals. Inhibition of 1 nM [^{3}H]NMS by carbachol revealed three sites characterised by high, medium and low affinity for the agonist (-log K_d = 8.0-9.0, 6.5-7.0, 5.0-5.5). Sites of medium affinity represent 45-60% of binding in all regions. Sites of high affinity are absent from the left ventricle plus septum and constitute the minor component (12-17%) in the atria of myopathic and control animals; in the right ventricle, they constitute a greater fraction in myopathic animals (12%) than in controls (<5%). As the dystrophic animals become congestive at about 220 days, various abnormalities can arise in one or more regions. (a) There is an increase in the fraction of sites with higher affinity for carbachol. (b) Atrial and ventricular receptors lose the modulatory effects of guanylylimidodiphosphate (GMP-PNP) on the binding of carbachol. In control animals, GMP-PNP increases the Hill coefficient in a manner consistent with the interconversion of sites from high to low affinity in the atria and from medium to low affinity in the ventricles. (c) There ultimately is a disappearance of receptors from some or all of the regions studied. The data indicate that heart failure in the hamster is accompanied by profound changes in cardiac muscarinic receptors. A loss of receptors would be expected to result in parasympathetic abnormalities; changes in the binding characteristics of agonists or an absence of GTP-mediated transduction could be equally deleterious. We have observed that 10 nM carbachol arrests the spontaneous beating of isolated atria from controls but has little effect on atria from some failing animals; assays with [^{3}H]NMS showed comparable levels of specific binding in both tissues. (The MRC and Heart Foundation, Canada, and the NIH)

228.10 FURTHER STUDIES OF γ-HYDROXYBUTYRATE EFFECTS ON CEREBRAL ISCHEMIA. W. D. Rausch*, N. Merkel*, C. Maruki* and M. Spatz. Lab. of Neuropath. & Neuroanat. Sci., NIH, Bethesda, Md. 20205.

Gamma-hydroxybutyrate (GHB), the naturally occurring central nervous system depressant, was shown to be effective as a preventive and therapeutic agent in experimentally induced cerebral ischemia. The beneficial effect of GHB was manifested by amelioration of ischemic brain changes in the levels of metabolites and edema as well as by the increased survival rate of the affected animals (Spatz et al. In: Pathophysiology and Pharmacotherapy of Cerebrovascular Disorders. Baden-Baden, Verlag Gerhard Witzstrock, 1980, pp. 286-289).

To elucidate further the mechanism of GHB action in cerebral ischemia we investigated the synthesis of neurotransmitters by determining the activity of tyrosine hydroxylase which has been known to be reduced by this disease process.

Mongolian gerbils subjected to 15 minutes of bilateral common carotid artery clipping, with and without various periods of clip release served as a model for cerebral ischemia and recovery. The treatment consisted of a single intravenous injection of GHB (500 mg/kg) 2 minutes prior to occlusion.

The activity of tyrosine hydroxylase was assayed by radioisotope technique (McGeer et al., Can. J. Biochem. 45, 1557-1563, 1967) in basal ganglia of GHB pretreated and untreated animals. GHB treated and untreated sham-operated Mongolian gerbils served as controls.

The level of tyrosine hydroxylase activity was found to be 33% lower in the basal ganglia of the untreated than that of GHB pretreated animals (2.97 ± .05 nmoles/mg prot./1 hr = 100%). These findings suggest that GHB modulates the ischemic decrease of tyrosine hydroxylase activity and in this way affects the synthesis of biogenic amines. Hence, it might also prevent the decrease of monoamines observed in cerebral ischemia and subsequent secondary injury to the brain.

228.11 SELECTIVE CHEMICAL AND NEURONAL LESIONS IN HIPPOCAMPUS OF TRIMETHYLTIN TREATED RATS. J.J. Valdes, C.F. Mactutus, R.M. Santos-Anderson, R. Dawson, and Z. Annau. Dept. Environ. Hlth. Sci. Division of Toxicology, The Johns Hopkins University, Baltimore, MD. 21205

Trimethyltin(TMT), belonging to a group of toxic organotins, induces selective damage in limbic structures. TMT shows a unique and selective pattern of toxicity which may be related to the neurochemical innervation of the hippocampus and therefore the present study evaluated the effects of TMT-induced lesions on the uptake of endogenous and exogenous hippocampal neurotransmitters.

Adult male Long-Evans hooded rats received three intraperitoneal injections of 0,2,3 or 4 mg/kg TMT at weekly intervals and were killed four days after the third injection for neurochemical and neuropathological evaluation. The hippocampi were dissected and the uptake of tritiated gamma-aminobutyric acid (^{3}H-GABA) and norepinephrine (^{3}H-NE) were assessed in enriched synaptosomal preparations. KT and Vmax were computed representing, respectively, synaptosomal affinity and capacity for these transmitters. Additional rats were prepared for histology: those assessed via light microscopy were perfused with saline and neutral buffered formalin, celloidin embedded, and sectioned and stained with thionin, cresyl violet or hematoxylin and eosin; those assessed via electron microscopy were perfused with paraformaldehyde-glutaraldehyde, osmicated, plastic embedded, and thin sections were examined with an H-300 Hitachi electron microscope.

No mortality or significant weight loss occurred at 2 or 3 mg/kg, but all rats given 4mg/kg lost weight and most died. Kinetic analysis of the uptake data indicated dose-dependent effects of TMT on ^{3}H-GABA uptake with little effect on ^{3}H-NE. Rats treated with 2 mg/kg had decreased affinity and increased capacity, 3mg/kg rats reversed this trend, and the few surviving 4mg/kg rats did not differ from controls in their affinity or capacity for ^{3}H-GABA. Light microscopic evaluation revealed dose-dependent ventricular dilation, damage to neurons in CA1 and CA4, glial proliferation, and sparing of neurons in hippocampal area CA3a. Electron microscopy revealed neurons in varying stages of degeneration. Those in the early stages were filled with membrane-bound dense bodies which appeared lysosomal, those in intermediate stages contained numerous vacuoles surrounding the dense bodies, and neurons in advanced stages displayed electron-dense cytoplasm and nuclei, irregular nuclear profile, and clumped chromatin. These data suggest that loss of intrinsic hippocampal GABAergic neurons and, the subsequent disruption of intrahippocampal connections may be responsible for the expression of TMT toxicity in that structure.

228.12 DIFFERENTIAL VARIATIONS IN CENTRAL AND PERIPHERAL β-ADRENERGIC RECEPTOR SUBTYPES IN SPONTANEOUSLY HYPERTENSIVE RATS. B.B. Wolfe, P. Chatelain* and P.B. Molinoff. Dept. of Pharmacology, Univ. Colo. Hlth. Sci. Ctr., Denver, CO 80262 and Dept. of Biochem. and Nutrition, Sch. of Med., Univ. Libre de Bruxelles, Brussels, Belgium.

Differences in catecholamine levels and metabolism in various tissues obtained from spontaneously hypertensive (SH) rats compared to their normotensive controls (WKY) have previously been reported. In order to determine if there are also alterations in the β-adrenergic receptors in these rats we have measured the density and properties of the β-receptor subtypes in seven tissues obtained from SH and WKY rats. The animals were obtained from Charles Rivers and were killed at 14 weeks of age when the blood pressure of the WKY rats ranged from 98 to 115 mm Hg and that of the SH rats ranged from 140 to 170 mm Hg. Additionally, the ratio of ventricular weight to body weight was 2.79 ± 0.04 for the WKY rats and 3.36 ± 0.06 for the SH rats. There were no significant differences in the densities of β-adrenergic receptors in the atria, lung, cerebral cortex, pons-medulla or hypothalamus from these animals. However, as has been previously reported, there was a 30% ($p<.01$) decrease in the density of β-adrenergic receptors in the ventricles of the SH rats. The densities of both β_1 and β_2-receptors were also measured and this decrease was found to be exclusively confined to the β_1 subtype. In contrast to this result, the density of β-adrenergic receptors in the cerebellum of the SH rats was 70% ($p<.01$) higher than in the WKY rats. In the cerebellum of WKY rats the ratio of β_1 to β_2-receptors was approximately 5:95 and this ratio was not increased in the SH rat cerebellum indicating that most, if not all, of the increase in β-adrenergic receptor density was restricted to the β_2 subtype. Supported by the PHS (HL24353 and NS13289).

228.13 EFFECTS OF THORACIC TRANSECTION ON AMINO ACID NEUROTRANSMITTERS IN THE LUMBAR SPINAL CORD. J.D. Lane and J.E. Smith. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Following mammalian spinal cord injury in the thoracic region, the hindlimbs undergo a period of flaccid paralysis (spinal shock) after which there is a gradual evolution of muscle spasticity. These events can be explained by loss of descending excitation (or descending disinhibition on polysynaptic inhibitory pathways), followed by reactive synaptogenesis which results in the progressive exclusion of presynaptic, postsynaptic and recurrent inhibitory influences, which modulated the reflexes prior to the injury. Since this inhibition is mediated by glycine (Gly) and gamma-aminobutyric acid (GABA), the evolution of spasticity should be reflected by changes in these amino acids. Adult female cats were transected at the T5 level and maintained for varying times up to twelve weeks when the clinical signs of spasticity were paramount. On the day of sacrifice, the animals were given an intravenous injection of ^{14}C-D-glucose and killed at various times post-injection. The lumbar enlargement was removed, dissected into discrete regions, and analyzed for amino acid content and utilization; and total particulate membrane preparations were evaluated for in vitro binding of tritiated GABA, muscimol, strychnine, aspartate and glutamate in the presence or absence of specific displacing agent. The transected animals were immobilized for approximately 48 hours post-operative, after which they were ambulatory. By six weeks, the animals exhibited clonus, scissoring, involuntary walking movements, extensor spasms and contralateral reflexes to painful stimuli--these signs increased in magnitude up to twelve weeks. Compared to sham-operated controls, spastic animals showed a general decrease in utilization rates of amino acids, and the evolution of spasticity was reflected by alterations in the distribution of neurotransmitter receptors. The role of excitatory and inhibitory amino acids in descending supraspinal pathways, spinal shock and hyperreflexia will be entertained. (Supported by NINCDS Grant NS 16409).

228.14 ^{3}H-SPIPERONE BINDING IS INCREASED IN DIABETIC RATS. C.F. Saller*, D. Lozovsky* and I.J. Kopin (SPON: J.C. Eberhart). Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

Reductions in intrasynaptic dopamine (DA) lead to increases in DA receptor sensitivity. We have found that glucose administration suppresses the firing of central DA-containing neurons (Saller and Chiodo, Science, 210:1269, 1980) and presumably DA release. We now report that the binding of ^{3}H-spiperone, a DA receptor ligand, is increased in chronically hyperglycemic diabetic rats. Rats were given saline or alloxan (185 mg/kg, s.c.) to induce diabetes, and decapitated six weeks after treatment. Striata were removed and the specific binding of ^{3}H-spiperone to membranes prepared from these tissues was measured (Fields et al., Brain Res., 136:578, 1977). The maximum binding and dissociation constants were determined by regression analysis of Scatchard plots of the binding data. Alloxan treatment increased the maximum binding of ^{3}H-spiperone to striatal membranes by 30% ($P<0.01$) but did not alter the dissociation constant for spiperone. Similarly, the binding of ^{3}H-spiperone was increased by 35% ($P<0.05$) in rats made diabetic with streptozotocin (75 mg/kg, i.p.). Thus, the number of DA receptors, as measured by ^{3}H-spiperone binding, are increased in two types of experimental diabetes. Moreover, chronic insulin treatment which maintained normal body weight completely prevented or reversed increases in DA receptor number. The possible relationships between these findings and the behavioral and mood disorders sometimes associated with disturbances of carbohydrate metabolism in humans will be discussed.

228.15 CHRONIC, BUT NOT ACUTE, TREATMENT WITH AN ANTIDEPRESSANT DRUG CAUSES A DOWN REGULATION OF β-ADRENERGIC FUNCTION IN ASTROCYTES IN PRIMARY CULTURES. L. Hertz* and J.S. Richardson (SPON: P.V. Sulakhe). Depts. of Pharmacology and Psychiatry, Univ. of Saskatchewan, Saskatoon, Sask. S7N 0W0 Canada.

A recent unifying hypothesis for the mechanism of action for all classes of antidepressant drugs (monoamine uptake inhibitors, monoamine oxidase inhibitors and drugs which exert neither of these actions potently) is that chronic application of these drugs acts by leading to a down regulation of β-adrenergic activity in brain, as evidenced by a decreased binding of β-adrenergic ligands and a reduction of the isoproterenol induced accumulation of cyclic AMP (Sulser, Trends Pharm. Sci. 1, 92, 1979).

We have previously reported that normal astrocytes in primary cultures possess a large amount of binding sites for dihydroalprenolol (DHA), a β-adrenergic ligand, and that isoproterenol causes an increase in cyclic AMP accumulation in these cells, an effect which is partly inhibited in the presence of amitriptyline (Abstracts, Soc. Neurosci. 1980, 270.21) or doxepin (Can. J. Physiol. Pharmacol. 58, 1515, 1980). In the present work, we have looked at the effect of chronic administration of amitriptyline on DHA binding and cyclic AMP accumulation. The cultures were prepared from the brains of newborn mice and grown in 60 mm plastic tissue culture dishes without any drugs until the age of 2 weeks, at which time they were confluent and contained about .3 mg protein. From then and onwards, amitriptyline (1 or 5 μM) was added to some of the cultures whereas other cultures from the same batches were left untreated as controls. After 5 or 8 days of treatment no differences were observed in DHA binding. After at least 12 days there appeared to be a decline in the binding but the variability was extremely large. The accumulation of cyclic AMP in the absence of isoproterenol was not affected by pretreatment with amitriptyline but the isoproterenol induced accumulation of cyclic AMP was significantly inhibited (25-45%) in cultures which have been grown in the presence of amitriptyline for between 12 and 27 days, with little, if any, effect after 5 days of exposure. No major differences were found between the effects of 1 μM and 5 μM amitriptyline. The lower of these concentrations is comparable to that occurring in plasma of patients treated chronically with this drug. The present experiments therefore suggest that the effects of amitriptyline on astrocytes might play a crucial role in its mechanism of action. They do not exclude that neurons could be similarly affected but the difficulties in maintaining pure cultures of CNS neurons from rodents for more than a few weeks presently prevents comparable long-term drug studies with neurons. (Supported by grant MT-5957 from the MRC of Canada.)

228.16 CHRONIC FLUPHENAZINE TREATMENT INDUCES CHANGES IN GLUTAMATE CONCENTRATIONS AND GLUTAMATE HIGH AFFINITY UPTAKE IN ADULT RAT STRIATUM. M.T.Price, R. Haft*, and J.W. Olney, Dept. Psychiatry, Washington Univ. Sch. Med., St. Louis, MO.

The use of phenothiazine-type drugs in psychiatry is sometimes associated with adverse reactions, the most serious of which is tardive dyskinesia (TD). Drug-induced supersensitivity of striatal dopamine (DA) receptors provides a plausible explanation for reversible, but not irreversible symptoms of TD. Since glutamate (Glu) is known to have neurotoxic activity and is thought to be the excitatory transmitter released at cortico-striatal synapses, either reversible or irreversible TD symptoms might be attributed hypothetically to a phenothiazine-induced disturbance in Glu uptake processes, resulting in an accumulation of Glu at striatal synapses with consequent degeneration of post synaptic elements. The present study was undertaken to determine whether long-term fluphenazine (FP) treatment (1 or 2 mg/kg sc every 2 wks for 9 mos) is associated with any disturbances in Glu concentrations or Glu high affinity uptake kinetics in adult rat striatum.

The earliest detected effect of FP treatment was an increase in the Km of Glu high affinity uptake as measured in striatal synaptosomes. This first became evident after 2 mos of FP treatment and was most pronounced in rats subjected to the highest dose (2 mg/kg). When measured at subsequent treatment intervals up to 9 mos, Kms were consistently higher than age-matched controls (e.g., at 9 mos, controls = 4.05 ± 0.4 nmol/mg/3 min; FP-treated = 6.16 ± 0.3 nmol/mg/3 min). Vmax rose transiently but significantly at 5 mos and returned to control values by 7 mos. Glu concentrations in FP striata remained at control levels up to 5 mos, then increased to values ranging from 7-26% higher than corresponding controls at 7 and 9 months.

Activation of DA terminals in the striatum reportedly inhibits Glu release from cortico-striatal fibers; therefore, the blocking action of phenothiazines on DA receptors might be expected to facilitate (disinhibit) Glu release. In addition, since the earliest and most persistent change we detected was an increase in Km (↓ affinity) of the Glu uptake receptor, an FP-induced suppression of Glu uptake may have been operative. Thus, there are two possible mechanisms relevant to Glu neurotransmission (↑Glu release and ↓Glu uptake) which might be invoked to explain the elevated levels of striatal Glu in our 7-9 mos FP-treated rats. Since both mechanisms acting simultaneously would explain the elevated Glu levels better than either by itself, this is the interpretation we favor. 228.17 CEREBRAL CORTICAL NEUROTRANSMITTERS IN SENILE DEMENTIA OF ALZHEIMER TYPE. M. Rossor*, P. Emson*, C. Mountjoy*, M. Roth* and L. Iversen*. (SPON: M. Hanley). MRC Neurochemical Pharmacology Unit, Dept. Neurology, Addenbrooke's Hospital, Cambridge CB2 2QQ, U.K.

The reduction of choline acetyltransferase (ChAT) activity in cerebral cortex in senile dementia of Alzheimer type (SDAT) is presumed to reflect a loss of afferent terminals rather than of intrinsic cortical cells.

In order to assess the integrity of intrinsic neurones we have measured four putative neurotransmitters of the cerebral cortex, vasoactive intestinal polypeptide (VIP), cholecystokinin (CCK), somatostatin (SRIF) and γ aminobutyric acid (GABA), all of which appear to be confined to interneurones and are stable in human brain after death. The concentrations of these neurotransmitters and of the activity of ChAT in SDAT, were compared with age matched, histologically normal controls.

In agreement with previous studies a widespread cortical loss of ChAT activity was demonstrated in the SDAT group when compared with controls. The concentrations of immunoreactive VIP and CCK did not differ between the two groups. There were, however, significant losses of SRIF (47%) from the temporal cortex and of GABA from both the temporal cortex (26%) and the motor cortex (27%) in the SDAT cases. These findings indicate that cell losses in the cerebral cortex in SDAT are confined to specific neuronal populations.

229.1 EFFECTS OF MELATONIN AND THE PINEAL GLAND ON THYROID PHYSIOLOGY OF FEMALE HAMSTERS. Jerry Vriend* and Russel J. Reiter (SPON: Karl M. Knigge). The Neuroendocrine Unit, University of Rochester, Rochester, NY 14642 and Department of Anatomy, University of Texas Health Science Center, San Antonio, TX 78284.

Although effects of the pineal gland and effects of melatonin, one of the products of the pineal gland, have been reported in the male hamster (Vriend, Sackman and Reiter, 1977; Vriend and Reiter, 1977) effects in the female have not been documented. Blinding female hamsters (which is known to activate the pineal) resulted in a highly significant reduction of plasma thyroxin by eight weeks. Free thyroxin index, obtained by taking the product of thyroxin concentration and the percent T3 uptake of plasma (which measures the unsaturated binding sites in plasma), was also reduced in blind hamsters. Evidence for a role of the pineal was obtained by data showing that blinded hamsters that had been pinealectomized had thyroxin levels not significantly different from normal controls. In female hamsters under long photoperiod (14L/10D) daily melatonin injections (25µg daily for 8 weeks) given late in the photoperiod also resulted in a significant reduction of plasma thyroxin and free thyroxin index. The melatonin induced reduction of plasma thyroxin was also obtained in ovariectomized female hamsters receiving daily injections of melatonin late in the photoperiod. Equal doses of melatonin given in the morning, i.e. early in the photoperiod, had no significant effect. Paradoxically, the effects of melatonin injections were reversed by subcutaneous implants of melatonin (1mg) replaced bi-weekly. The results indicate a circadian sensitivity to melatonin injections. Furthermore the results indicate that chronic availability of milligram amounts of melatonin in subcutaneous depots prevents the depression of thyroxin levels obtained with single injections of 25µg near the end of the photoperiod. The results are consistent with the view that melatonin acts on a neuroendocrine control mechanism influencing thyrotrophin releasing hormone (TRH) synthesis or release.

229.2 CONTROL OF RAT PINEAL MELATONIN SYNTHESIS: EFFECT OF MONOAMINE OXIDASE INHIBITION ON SEROTONIN N-ACETYLTRANSFERASE ACTIVITY. T. S. King*, B. A. Richardson* and R. J. Reiter. (SPON: H.-C. Dung). Dept. Anat., Univ. Texas Health Sci. Ctr., San Antonio, TX 78284.

Pineal serotonin N-acetyltransferase (NAT) activity has generally been considered the rate-limiting enzyme in the biosynthesis of melatonin. Various studies have suggested that increased NAT activity following monoamine oxidase (MAO) inhibition was related to increased NAT substrate (i.e., serotonin) concentration (e.g., Bade et al., Arch. Pharmacol. 297: 143, 1977) rather than increased beta-adrenergic receptor stimulation as a result of elevated norepinephrine levels. We sought to determine the necessity of adrenergic receptor stimulation relative to changes in pineal NAT activity and melatonin content following MAO inhibition. Adult male Sprague-Dawley rats were housed in a light:dark cycle of 12:12 (lights on 0600 h). In the first experiment, rats were injected at 1200 h with 0.9% saline vehicle, 20 mg/kg pargyline or 20 mg/kg pargyline and 20 mg/kg propranolol. NAT activity and melatonin content were measured at various times from one to six hours after these injections. In the second experiment, rats were injected at 1200 h with 0.9% saline vehicle or 20 mg/kg and or 80 mg/kg harmine and pargyline: with and without conjunct injection of 20 mg/kg propranolol. NAT activity, paralleled by melatonin content, was maximal 2-4 hours after pargyline injection but comparable to saline controls 6 hours after injection. Conjunct propranolol injection nullified pargyline-induced increases in NAT activity and melatonin content at all times after paryline-injection. Higher doses of harmine and pargyline produced proportionately greater increases both in NAT activity and melatonin content. These increases were negated by conjunct propranolol injection, regardless of the dose of inhibitor used. Interestingly, no significant differences between the effects of similar doses of pargyline and harmine were noted under the conditions of this study. Higher doses of MAO inhibitors produced levels of NAT activity (15.9±3.4 nmoles pineal^{-1} hour^{-1}) and melatonin content (2089.6±267.9 pg pineal^{-1}) comparable to the normal nocturnal peak of these constituents. In summary, we suggest that beta-adrenergic receptor stimulation of pineal NAT activity, regardless of changes in NAT substrate availability, regulated melatonin production under the conditions of the present experiments. (Supported by Center for Training in Reproductive Biology Postdoctoral Grant HD 07139 and NSF Grant PCM 8003441).

229.3 EFFECTS OF AFTERNOON INJECTIONS OF LARGE DOSES OF MELATONIN ON THE NEUROENDOCRINE-REPRODUCTIVE SYSTEM OF FEMALE SYRIAN HAMSTERS. B. A. Richardson*, T. S. King*, L. J. Petterborg*, M. K. Vaughan and R. J. Reiter. Dept. of Anatomy, Univ. of Texas Health Sci. Ctr., San Antonio, TX 78284.

In the hamster the pineal mediated reproductive atrophy resulting from short day exposure can be mimicked by the afternoon administration of 25 µg of melatonin (mel). The present study was designed to determine what effects large doses (2.5 mg) of mel injected in the afternoon would have on the reproductive status of adult female hamsters maintained on either stimulatory or non-stimulatory photoperiods. Female hamsters were maintained in either a long (14L:10D; lights on 0600h) or short (10L:14D; lights on 0600 h) photoperiod. Within each photoperiodic regime the animals were injected daily with either vehicle, 25 µg of mel or 2.5 mg of mel at 1600 h. Short photoperiod resulted in an inhibitory influence on vaginal cyclicity, uterine and ovarian weights, plasma FSH and pituitary PRL. One hundred percent of both 14:10 and 10:14 female hamsters receiving 25 µg injections for 11 weeks became acyclic along with significant decreases in uterine and anterior pituitary weights and increases in ovarian weight. Plasma LH, FSH and PRL titers were significantly depressed in 14:10 animals injected with 25 µg of mel while no effect on these hormones was observed in 10:14 animals. Pituitary concentrations of LH and FSH were increased in both short day and long day exposed hamsters injected with 25 µg mel; pituitary PRL was depressed in both groups. Hypothalamic LH-RH was increased in the 10:14 animals receiving 25 µg of mel. Injections of 2.5 mg of mel failed to alter any of the parameters measured in 14:10 animals with the exception of plasma FSH which was depressed. However, in 10:14 hamsters the 2.5 mg injections appeared to inhibit most of the antigonadotrophic effects of short photoperiod. These results demonstrate that a large bolus of mel given in the afternoon when smaller doses of the indole are known to have inhibitory actions on reproduction, either fails to have any effect or appears to counter the antigonadotrophic influence of a short photoperiod. These findings may be explained by the hypothesis that mel is able to regulate the number and/or sensitivity of its own receptors. Supported by F32 ND05900-01 to B.A.R. and PCM 8003441 to R.J.R.

229.4 IN VITRO ADRENERGIC STIMULATION OF PINEAL MELATONIN PRODUCTION IN THE YOUNG AND OLD SYRIAN HAMSTER. C. M. Craft* and R. J. Reiter. (SPON: J. Hansen). Dept. of Anatomy, Univ. of Texas Health Sci. Ctr., San Antonio, TX 78284.

In vivo studies have suggested that the nocturnal peak in pineal melatonin content was depressed in old Syrian hamsters in comparison to that in young Syrian hamsters (Reiter et. al., Peptides 1, Suppl. 1:69, 1980). The purpose of this study was to examine the responsiveness of the β-adrenergic receptors within cultured pineal glands after the addition of norepinephrine (NE) or isoproterenol (ISP) by measuring and comparing melatonin content in pineals from 3-month and 20-month-old hamsters. NE in post-synaptic fibers from the superior cervical ganglia stimulate melatonin production and secretion by augmenting the activity of N-acetyl transferase (NAT). During the three weeks prior to culturing these glands, all hamsters were maintained in a photoperiod of daily 14:10 LD cycle (lights on at 0600 h). Individual pineal glands were cultured in BGJ$_b$ medium for 24 hrs and tranferred to fresh medium containing tryptophan ($5x10^{-6}$M). Half of each group also contained NE or ISP ($3x10^{-4}$M). Data were statistically analyzed using an ANOVA followed by a student t-test. NE and ISP induced significantly elevated levels of melatonin content (840±112 pg/gland/hr and 1500±90 pg/gland/hr, respectively) over control levels of melatonin content (250±70 pg/gland/hr) in cultured young hamster pineal glands. A similar increase in melatonin content was observed following NE addition to cultured old hamster pineal glands. Whether young or old, the hamster pineal gland in vitro demonstrated a 16 hour latency in melatonin production in response to the addition of adrenergic stimulants when cultures were initiated during daytime. With 3-month-old vs. 20-month-old hamster pineals, no statistically significant difference was found between these two groups. However, within each NE stimulated group, earlier incubations showed no significant differences in melatonin content until 0200 ($P<0.05$), 0400 ($p<0.01$), and 0800 ($p<0.001$). At 0400 and 0800, values were significantly different ($p<0.001$) between NE old and young unstimulated glands vs. NE old and young stimulated glands. The melatonin contents of the pineals at the end of the experiment were not significantly different. This study indicates that β-adrenergic receptors do not show impared capacity to respond to NE stimulation in aged hamsters pineals in organ culture. Therefore, we suggest that the ability of the hamster pineal gland to respond to exogenous adrenergic stimulation was undiminished in culture whether young or old. (Supported by PCM 8003441.)

229.5 EFFECTS OF BLINDING OR AFTERNOON MELATONIN INJECTION ON PARAMETERS OF THYROID FUNCTION IN THE MALE GOLDEN HAMSTER (MESOCRICETUS AURATUS). L.Y. Johnson, M.K. Vaughan and R.J. Reiter. Dept. of Anatomy, The Univ. of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

The pineal gland has been shown to have dramatic effects upon the reproductive axis of the golden hamster. Either blinding (and resultant pineal gland stimulation) or late afternoon injection of melatonin (a putative pineal hormone) cause total reproductive collapse in a matter of weeks. Additionally, blinding has been shown to result in pineal-mediated inhibition of the thyroid axis. To further explore possible extra-reproductive effects of the pineal gland, the effects of blinding or afternoon melatonin injections on parameters of thyroid function were determined in hamsters with regressed gonads.

Adult male hamsters housed in a 14L:10D lighting cycle (lights on at 0600h) were divided into three treatment groups: intact hamsters (INT), blinded hamsters (BL) and intact hamsters which received daily sc injections of 25 µg melatonin at 1700h (MEL). After 10 weeks, hamsters were sacrificed by decapitation between 0900 and 1100h; plasma was assayed for thyroid stimulating hormone (TSH), triiodothyronine (T_3) and thyroxine (T_4) concentrations. Additionally, T_3 uptake (a measure of the unsaturated binding capacity of serum proteins), the free triiodothyronine index (FT_3I) and the free thyroxine index (FT_4I) were determined.

Although plasma TSH levels were depressed in both BL and MEL hamsters, this decrease was significant only in the latter group (139.1±47.6 ng/ml (INT) vs. 53.1±11.9 ng/ml (MEL), $p<0.05$). However, plasma levels of T_3 were significantly depressed in both experimental groups (66.9±5.1 ng/dl (INT) vs. 34.6±4.3 ng/dl (BL) and 43.6±2.3 ng/dl (MEL), $p<0.001$) as were plasma levels of T_4 (3.88±0.31 µg/dl (INT) vs. 2.12±0.25 µg/dl (BL) and 2.44±0.13 µg/dl (MEL), $p<0.001$). Although T_3 uptake was unaltered by either treatment, the FT_3I and FT_4I were decreased by both blinding and melatonin injection. The FT_3I of INT hamsters (38.6±2.6) was significantly higher than that in BL (24.2±2.6) or MEL hamsters (29.4±1.7), $p<0.001$ and $p<0.02$, respectively. The FT_4I of INT hamsters (2.31±0.22) similarly was significantly elevated over that of BL (1.58±0.19) and MEL hamsters (1.71±0.11), $p<0.01$ and $p<0.05$, respectively.

It thus appears that both blinding and afternoon melatonin injections inhibit the thyroid axis of golden hamsters, suggesting a role for the pineal gland in the control of extra-reproductive endocrine function. The possible interaction of the effects of the pineal gland on reproductive and thyroid axes awaits further study. (Supported by NSF grant PCM 8003441.)

229.6 EFFECTS OF THYROID-INHIBITORY AND COUNTER-INHIBITORY AFTERNOON DOSES OF MELATONIN ON T_3 UPTAKE AND PLASMA LEVELS OF TSH, T_4 AND T_3 IN FEMALE HAMSTERS MAINTAINED UNDER LONG OR SHORT PHOTOPERIOD. M.K. Vaughan, B.A. Richardson*, L.Y. Johnson, T.S. King*, L.J. Petterborg* and R.J. Reiter. Dept. of Anatomy, The Univ. of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

Both afternoon injections of 25 µg melatonin or short photoperiodic conditions (< 12.5 hrs light/day) leads to reproductive acylicity, ovarian enlargement and an infantile uterine appearance in female Syrian hamsters (Mesocricetus auratus). Chronic availability of melatonin either as an implant or as a large dose (2.5 mg) given in the late afternoon negates the abovementioned reproductive effects of short photoperiod or low doses of melatonin by a mechanism postulated to involve the availability and/or sensitivity of melatonin receptors. Although some of the hormones involved in this reproductive response have been well characterized (LH, FSH, prolactin), other potential hormonal imbalances in these sexually-regressed hamsters have not been fully explored. The aim of the present 2 experiments was to determine the effects of a gonad-inhibitory dose (25 µg) as well as a gonad counter-inhibitory dose (2.5 mg) of melatonin on the pituitary-thyroid axis in hamsters maintained under long or short photoperiodic conditions. Thyroid hormones (T_4, T_3), T_3 uptake and plasma TSH were evaluated in 2 experiments in which adult female Syrian hamsters were maintained under short (10:14 LD) or long (14:10 LD) photoperiods (lights on 0600) and/or injected sc with either ethanolic saline, 25 µg melatonin or 2.5 mg melatonin every afternoon. In Experiment 1, hamsters in short photoperiod for 9 weeks had significantly depressed plasma TSH, T_4, T_3 and free thyroxine index (FT_4I) as compared to animals kept in long photoperiod. In Experiment 2, sc injections of 25 µg melatonin into hamsters maintained in the long photoperiod for 11 weeks had significantly depressed plasma TSH, T_4, T_3 and FT_4I; a similar injection protocol into hamsters kept in the short photoperiod depressed plasma TSH, T_3 uptake, FT_4I and FT_3I. However, large doses (2.5 mg) of the indole given every afternoon to hamsters in long photoperiod significantly augmented the plasma levels of T_4, T_3 uptake and the FT_4I; similar treatment of animals maintained in a short photoperiod had no depressive effect on plasma thyroid hormones as did the lower 25 µg dose of melatonin. In conclusion, it appears that either short photoperiod or low doses of melatonin (25 µg/day) given in the late afternoon have a depressive effect on the pituitary-thyroid axis similar to that previously described with the pituitary-gonadal axis. Supported by F32 ND05900-01 to B.A.R. and PCM 8003441 to R.J.R.

229.7 REGULATION OF HUMAN MELATONIN SECRETION BY ENVIRONMENTAL LIGHT VIA A CENTRAL PACEMAKER AND PERIPHERAL SYMPATHETIC STIMULATION. A. J. Lewy*. (SPON: R. M. Brown). Dept. of Psychiatry, Univ. of Oregon Health Sciences Ctr., Portland, OR 97201.

Melatonin secretion occurs only at night in both diurnal and nocturnal mammalian species. Melatonin secretion is acutely suppressed by light; the light/dark cycle also entrains a central pacemaker, the suprachiasmatic nuclei (SCN) of the hypothalamus. A specific neuronal pathway, the retinohypothalamic tract, which extends from the retina to the SCN, mediates the effects of light. Melatonin secretion is the result of the circadian oscillation which originates in the SCN and which stimulates the pineal's beta-adrenergic receptors via peripheral sympathetic neurons.

Human melatonin secretion (as measured by gas chromatography-negative chemical ionization mass spectrometry) appears to be regulated in the same way as other mammalian species. Propranolol (120 - 140 mg po qhs) blocks the nighttime rise in melatonin secretion, presumably by its blockade of postganglionic beta-adrenergic receptors. Clonidine (2-3 ug/kg iv qhs) also reduces nighttime melatonin secretion (Lewy, A., Siever, L., Uhde, T., et al, in preparation), presumably by stimulating presynaptic alpha-2-auto-receptors peripherally, although a central effect cannot be excluded. These findings suggest that the human pineal is innervated by peripheral sympathetic neurons, which is true of all other mammalian species.

Light acutely suppresses human melatonin secretion; healthy subjects require much brighter light (500-1500 lux) than do other species. Patients with affective disorder appear to be supersensitive to light, even in the well state; this is consistent with, and could possibly explain, phase-advanced circadian rhythms observed in these patients. Human melatonin secretion appears to be regulated by the light/dark cycle as well, since certain blind subjects have abnormally phased or "free-running" melatonin secretory rhythms. These results also suggest that blind individuals are heterogeneous in terms of their synchronization to the day/night cycle. Future endocrine research in blind subjects, which hopefully will be stimulated by these results, should take into account the heteregeneity of this population.

Human plasma melatonin appears to be a useful "marker" for adrenergic function, the central pacemaker, and the effects of light in humans. Ocularly-mediated light appears to affect human endocrine systems. Other possible endocrine and behavioral effects of light in humans are appropriate research areas. Intensity of light should be a key methodological variable in the planning of future research in this area. Appropriately intense light may also have therapeutic uses.

229.8 DISSOCIATION OF N-ACETYLSEROTONIN AND MELATONIN LEVELS IN SERUM OF RATS, L.J. Grota, G.M. Brown, & S.F. Pang*. U. of Rochester, Rochester, N.Y. and McMaster U. Health Sciences Center, Hamilton Ontario L8S 4J9.

N-acetylserotonin is frequently considered an inactive intermediate in the synthesis of melatonin (5-methoxy, N-acetyltryptamine) from serotonin. Our laboratory has developed antisera that will specifically bind melatonin and other antisera that will specifically bind N-acetylserotonin. Using these antisera, a radioimmunoassay for serum melatonin and a radioimmunoassay for serum N-acetylserotonin have been developed and validated. These two assays were used to determine N-acetylserotonin and melatonin levels in the serum of male albino rats housed 2/cage with ad libitum feeding and with the lighting, temperature, and humidity mechanically controlled. When rats are housed under 12 hours of light and dark, serum N-acetylserotonin and melatonin have 24-hour rhythms with a characteristic crest during the latter half of the dark period. Daytime N-acetylserotonin is approximately 1.2 ng/ml with the crest level reaching 2.21 ± 0.27 ng/ml (N=9). Daytime melatonin levels are about 15 pg/ml with a crest level at 40 pg/ml occurring late in the dark period. When rats are placed in a 2 hour light 22 hour dark cycle for two months, serum melatonin has the same level and pattern as those in 12 hour light-dark cycles, i.e., crest levels occur 18 hours after light onset. In contrast to these data, serum N-acetylserotonin levels of 2L:22D animals are elevated at crest to 3.54 ± 0.61 ng/ml (N=11) and the crest occurs 8 hours after light onset. In another experiment, male rats were housed in constant light for 30 days and then placed into a 12 hour cycle of dark and light. At the end of 30 days of constant light, melatonin levels were 12 pg/ml and N-acetylserotonin levels were 0.8 ng/ml. Both of these levels are similar to trough levels observed in cycling light for the respective substances. During the initial and subsequent exposure to 12 hour dark-light cycles, melatonin showed elevations during the dark periods and supression during the light periods. In contrast to these data, N-acetylserotonin levels showed no consistent relationship with dark and light periods. These two studies demonstrate that N-acetylserotonin levels in serum are approximately 50 fold higher than melatonin levels in rat serum and that the 24-hour pattern of secretion of these two substances can be dissociated suggesting that they may be discrete hormones with separate regulatory mechanisms and target sites.

229.9 CHRONIC EXPOSURE TO 60-Hz ELECTRIC FIELDS: EFFECTS ON SEROTONIN AND ITS METABOLITES IN THE RAT PINEAL

L. E. Anderson, B. W. Wilson, D. I. Hilton*
R. D. Phillips, Pacific Northwest Laboratory, Operated by Battelle Memorial Institute, P.O. Box 999, Richland, Washington 99352.

Serotonin, in addition to its function as an important brain neurotransmitter, serves as a precesor for the melatonin and 5-methoxytryptophol in the pineal. These indole hormones appear to be key factors in the adaptive response of the organism to external stimuli. Melatonin levels, which normally exhibit circadian rhythmicity with increased concentrations during the hours of darkness, have been measured as a general indicator of pineal function. The enzymes, which act upon serotonin in the initial step of it's conversion to melatonin and 5-methoxy tryptophol, are serotonin-N-acetyl transferase (SNAT) and monoamine oxidase respectively. Hydroxyindole-O-methyl transferase serves as the O-methylation enzyme which is common to both pathways.

We have recently reported that the normal nocturnal increase in pineal melatonin concentration is significantly depressed with a concommittant increase in 5-methoxy tryptophol concentration, by chronic (30 day) exposure to 60-Hz electric fields. Concurrent measurements in these same animals showed that overall SNAT activity was depressed in the exposed group relative to controls.

As an extension of these studies we have recently compared pineal serotonin levels for exposed and control rat populations at four different time points in a 24 hour period. High resolution glass capillary column gas chromatographic mass spectrometry was employed to monitor selected ions from butanol/ethyl acetate extracts of aqueous pineal sonicates to which internal standard had been added. The monitoring of several ions allowed simultaneous measurement of pineal serotonin and melatonin concentrations with high specificity.

Findings from these studies indicated that compared to control populations, pineal serotonin levels in exposed animals were perturbed. The observed effects on pineal serotonin concentration may be due to interference with normal SNAT activity induced by altered neuronal input to the pineal as a result of electric field exposure.

229.10 THE EFFECT OF PINEALECTOMY ON COLD-INDUCED CHANGES IN BROWN ADIPOSE TISSUE.

K. S. Kott* and B. A. Horwitz* (SPON: E. Sassenrath). Dept. of Animal Physiology, Univ. of California, Davis, CA 95616.

Previous work has suggested that the pineal gland may play a role in mammalian thermoregulation by influencing the thermogenic effector brown adipose tissue. In such experiments, hamsters receiving melatonin via subcutaneous implants of beeswax pellets had larger deposits of brown fat than did those receiving no exogenous melatonin regardless of the photoperiod imposed (Nature 247:224, 1974). In view of this finding plus the fact that cold exposure elicits increased brown fat deposition in a variety of species (Phys. Rev. 49:330, 1969), the present study was designed to investigate whether such cold-induced increases in brown fat weight are dependent on pineal secretions.

Nine Long-Evans hooded male rats were pinealectomized at 62 days of age; eight control rats were sham-operated. Throughout the experiment the animals were exposed to a 12 hr light/12 hr dark cycle, housed singly, and provided with food and water ad libitum. At 75 days of age, four pinealectomized and four sham-operated rats were transferred to 5°C, while five pinealectomized and four shams remained at 22°C. At 107 days of age, all 17 rats were sacrificed at 2330 hrs, five hours after "lights out." Brown adipose tissue from the cervical and interscapular regions was excised and weighed. A radioimmunoassay (modified from Res. Commun. Chem. Path. & Pharm. 10:693, 1975) was used to determine melatonin levels in the pineal.

After 32 days in the cold, the control (sham) rats had significantly larger amounts of brown adipose tissue (interscapular plus cervical) than did control rats maintained at 22°C, there being an increase of approximately 95% in the interscapular regions and 60% in the cervical regions of the cold-exposed controls. In contrast, pineal levels of melatonin in these cold-exposed rats (2.82 ± .75 ng/pineal, $\bar{X}$ ± S.E.) did not significantly differ from those living at 22°C (1.75 ± .38 ng/pineal). Increased brown fat weights were also observed in the cold-exposed pinealectomized rats, the magnitude of these increases being comparable to those seen in the cold-exposed controls. In rats housed at 22°C, pinealectomy did not significantly alter brown fat weights.

These results are interpreted as indicating that the pineal gland is not essential for the increased weight of brown adipose tissue induced by cold exposure. (This study was supported by NSF grant PCM 77-22706.)

229.11 KINETICS OF PHASE SHIFTS INDUCED BY PROTEIN SYNTHESIS INHIBITORS IN THE CIRCADIAN RHYTHM OF NEURONAL ACTIVITY FROM THE EYE OF APLYSIA,

D. P. Lotshaw* and J. W. Jacklet. Dept. of Biology, SUNYA, Albany, N.Y. 12222.

The isolated eye of Aplysia exhibits a circadian oscillation in the rate of spontaneous compound action potentials (CAP) recorded from the optic nerve. Phases of the oscillation are designated in H of circadian time (CT) 0 to 24. CT 0 is the phase when CAP rate has increased to 1/2 maximum. Protein synthesis inhibitors, puromycin (PURO) (Rothman and Strumwasser, J. Gen. Physiol. 68, 359) and anisomycin (ANISO) (Jacklet, Science 198, 69) induce phase dependent phase shifts of the oscillation. We re-evaluated the phase response curves (PRC) for PURO and ANISO using 6 H pulses of 265 µM PURO or 0.5 µM ANISO; lowest concentrations that induced maximal phase shifts. ANISO induced an all delay PRC with maximum 6 H delays for pulses applied between CT 18 and CT 1. PURO induced maximum phase delays of 8-9 H between CT 21 and CT 0 and phase advances of 4-5 H between CT 1 and CT 3. The ANSO and PURO PRCs differ only in the magnitude of the maximum phase delays and the PURO induced phase advances. The concentrations of ANISO and PURO used inhibit protein synthesis by 95% for ANISO and 44% for PURO, as measured by ^{3}H-leu incorporation into TCA insoluble material. Inhibition is maximal within 1 H and recovery of protein synthesis is equally rapid. To investigate the differences in phase delays produced by ANISO and PURO the effect of pulse duration was measured. For ANISO applied at CT 21, the size of the phase delay approximately equals the pulse duration up to 9 H, slope = 1, but for PURO the slope of the pulse duration vs phase delay size approximately equals 1.5. The dose of PURO needed to induce a significant phase shift during the delay or advance phases was measured. Higher doses were needed for advances (150 µM) than for delays (50 µM). However, the PURO dose needed to get maximal advances or delays is similar (265 µM). These data suggest that PURO treatments have an additional dose dependent effect that lengthens phase delays and produces phase advances. Since protein synthesis recovers equally well from ANISO or PURO after a pulse, prolonged inhibition cannot account for the difference. PURO effects may be related to accumulation of PURO containing nonsense peptides. These data also are evidence for a continual protein synthesis requirement in the circadian oscillation between CT 18 and CT 1 and suggest that the inhibition of protein synthesis phase shifts the circadian clock by stopping the oscillation during the protein synthetic phase.

229.12 A GOLGI STUDY OF THE HAMSTER SUPRACHIASMATIC NUCLEUS.

Kenneth J. Mack, William T. Greenough, and Carol Sue Carter. Neural and Behavioral Biology Program, and Department of Psychology, Univ. of Illinois, Champaign, IL, 61820.

The hypothalamic suprachiasmatic nucleus (SCN) was studied using Nissl stains and Golgi-Cox impregnations in young adult male and female hamsters. Nissl studies located the nucleus immediately superior to the posterior third of the optic chiasm. An area of the SCN, 400um long, 500um wide, and 400um high was studied in Golgi-Cox coronal sections. Three types of neurons were found, classified according to the number of primary dendritic branches. These types were unipolar (25%), bipolar (50%), and multipolar (25%). The average SCN neuron studied (across classes) had two primary branches and a total dendritic length of 145um. Less than half of the neurons studied had second order branches, and uncommonly a neuron would possess up to fifth order branching. Dendritic density distribution plots, calculated as in prior work (Greenough et al, Brain Res. 126:63,1977), revealed that the highest dendritic density appeared in the central and lateral aspects of the nucleus. Statistically significant differences in dendritic density were seen between males and females, although these differences are not obvious to casual visual inspection. An analysis of dendritic fields revealed that individual SCN neurons tend more frequently to send dendrites in dorsal and lateral orientations. Females' neurons tend to send their dendritic processes out dorsally, while males' neurons send dendrites dorsomedially and ventrolaterally. Also, ventrally located cells were found to send their dendritic processes dorsally, while dorsal cells would send processes both ventrolaterally and dorsally. Finally, some SCN neurons were found to send their dendrites up to 40um across the midline into the contralateral SCN. This was primarily seen in the posterior portion of the SCN, between 60-190um above the optic chiasm. Approximately one out of every six cells within 70um of the midline would send dendritic processes into the contralateral SCN.

229.13 THE SUPRACHIASMATIC NUCLEUS OF THE RAT: A MORPHOMETRIC ANALYSIS OF SYNAPTIC ORGANIZATION. M.F. Bernstein*, J.P. Card and R.Y. Moore. Department of Neurology, SUNY at Stony Brook, N.Y. 11794

Several investigations have demonstrated that the suprachiasmatic nuclei (SCN) of the rat are composed of a heterogeneous population of neurons and axon terminals which are both morphologically and chemically distinct. Afferents to the rat SCN are known to form terminal fields within clearly circumscribed subfields of the nucleus. However, with the exception of retinal afferents, little is known of the fine structural organization and termination of SCN afferents. In this study we present preliminary findings of a systematic morphometric ultrastructural analysis of the rat SCN neuropil. Five adult female Sprague-Dawley rats were perfused intracardially with buffered aldehyde solutions and brains processed for transmission electron microscopic analysis of the SCN. In order to standardize the analysis among animals and to ensure systematic sampling of all regions of the SCN, the analysis was conducted at four levels throughout the rostrocaudal axis of the SCN. These included coronal planes through the most rostral and caudal poles of the nucleus as well as two intermediate levels. Within the two intermediate levels, analysis of the neuropil was divided among four subdivisions of the nucleus; dorsomedial, dorsolateral, ventral (ventral third) spanning the mediolateral extent of the SCN/optic chiasm interface, and a small area at the ventrolateral extent of the SCN. Previous studies indicate that this method of subdivision would be effective in sampling the neuropil of the SCN in that the divisions separate areas known to be distinguishable cytoarchitectonically and immunohistochemically. In addition, this parcellation reflects divisions evident in the differential distribution of the afferent innervation of the nucleus. Axon terminals within the SCN can be separated into at least ten categories on the basis of vesicle size and shape, the prevalence of large granular vesicles, the density of the axoplasm, and in some instances, on the basis of mitochondrial fine structure. Many of the boutons establish synaptic contacts with dendrites; axosomatic synaptic contacts are rare. A number of dendro-dendritic synapses are evident within the nucleus as well as occasional synaptic contacts between vesicle-filled boutons. Preliminary evidence indicates that some of the morphologically distinct categories of axon terminals are located preferentially within specific subfields of the nucleus. Further morphometric analysis of bouton distribution within the SCN of both normal and experimental animals is currently being conducted to determine if any of the bouton categories can be correlated with any specific system of afferents. Supported by USPNS Grants NS-06247 and NS-16304.

229.14 LONG-TERM AND SHORT-TERM EFFECTS OF CLORGYLINE (A MONOAMINE OXIDASE TYPE A INHIBITOR) ON LOCOMOTOR ACTIVITY AND ON PINEAL MELATONIN IN THE HAMSTER. C. Craig*, L. Tamarkin*, N. Garrick*, and T. Wehr* (SPON: J. C. Gillin). CPB and CNB, NIMH and IRP, NICHD, NIH, Bethesda, MD 20205.

In a previous study we observed that the irreversible MAO-A inhibitor clorgyline lengthened the free-running period of the activity-rest cycle in Syrian hamsters housed in constant darkness. We now report effects of clorgyline on locomotor activity and on the pineal melatonin circadian rhythm in hamsters entrained to light:dark schedules.

Male hamsters (N=27) housed with running wheels were entrained to a light:dark schedule of LD 14:10 (lights-off 1500h to 0100h). After 4 weeks' baseline recording, time of lights-off was advanced 4 hours (LD 10:14) and 15 animals were implanted subcutaneously with osmotic mini-pumps that released clorgyline at 2 mg/kg/day. After 6 weeks of treatment in LD 10:14, all of the treated animals failed to advance the time of activity-onset to the same extent as controls. Total activity was also reduced in the treated animals. Pineal melatonin (pg/pineal) of control vs. clorgyline-treated animals was 601 ± 10 vs. 862 ± 25 at 2000h, 829 ± 14 vs. 1011 ± 6 at 2300h, 61 ± 6 vs. 496 ± 18 at 0130h, and 42 ± 4 vs. 241 ± 10 at 0300h. Mean MAO-A activity (with 5-HT as substrate) was 56 nmol/mg protein/h in control animals and 4 nmol/mg protein/h in clorgyline-treated animals. From the beginning to the end of an 8-week treatment period, clorgyline-treated male hamsters (N=5) maintained in LD 14:10 showed a 1-hour delay in the onset of activity, compared with controls. In a third study, animals in LD 14:10 were given ip injections of saline or clorgyline at 1000h on the day of sacrifice. One group was injected for 3 consecutive days. Pineal melatonin levels during exposure to light at night and total brain MAO-A activity were measured.

CLORGYLINE (mg/kg)	MELATONIN (pg/pineal)			% MAO-A
	2230h	2300h*	2400h**	Inhibition
0.0	956±15	38± 4	36± 5	0
2.0	430±17	101±11	139±14	92
4.0	854±15	545±20	500±21	91
8.0	765± 7	990±25	863±12	92
2.0 (X 3 days)	945±20	925±17	1056±19	94

*lights on 30 minutes, **lights on 90 minutes.

These data demonstrate that clorgyline treatment 1) slows re-entrainment to an advance of the lighting schedule 2) delays activity-onset relative to a fixed lighting schedule 3) reduces locomotor activity 4) inhibits MAO-A activity > 90% and 5) blocks light suppression of pineal melatonin.

229.15 POTENTIATING EFFECTS OF LESIONS OF THE INTERPEDUNCULAR NUCLEUS ON MELATONIN-INDUCED REPRODUCTIVE HYPOTROPHY IN UNDERFED MALE RATS. C. A. Stockmeier* and D. E. Blask* (SPON: J. B. Angevine). Dept. of Anatomy, Coll. of Med., Univ. of Arizona, Tucson, AZ 85724.

Melatonin (Mel) injections cause a marked decrease in weights of testes and accessory sex organs in underfed male rats. The antigonadotrophic effect of Mel, a putative pineal hormone, may be mediated by the serotonin system of the midbrain raphe. We wished to see if partial interruption of neural input to the raphe would modify this effect in underfed rats. Six groups of Sprague-Dawley male rats (40 days old) were maintained on a 14hL: 10hD light:dark cycle (lights on 0600-2000). Unoperated groups were of three kinds: fed intact (FI), underfed Mel-injected (UMel) and underfed saline-injected (US). The three operated groups were: underfed Mel-injected habenula-lesioned (UMelHb), underfed Mel-injected interpeduncular nucleus-lesioned (UMelIPN) and underfed sham interpeduncular nucleus-lesioned (UMelSham). Underfed rats received one-half the normal daily food intake of FI rats, while Mel-treated rats received daily injections (s.c.) of Mel (50 µg) between 1650-1750. Hb and IPN lesions (2mA, 30s) were placed stereotaxically in Innovar^{R}-anesthetized animals. In the sham-operated rats, the electrode was lowered to a point just above the IPN and then removed. After 35 days of Mel injections and underfeeding, the rats were weighed and decapitated; weights of testes, seminal vesicles, ventral prostates and pituitaries were recorded. The UMel group showed reduced ($p<0.05$) gonadal, accessory sex organ and pituitary weights compared to US controls. In the UMelIPN group, testicular and accessory sex organ weights were further depressed ($p<0.05$) compared to UMel controls. The ventral prostates and seminal vesicles, but not the testes, of this UMelIPN group were also lighter ($p<0.05$) than in UMelShams. Gonadal and accessory sex organ weights of UMelHb rats did not differ from UMel controls. It seems that IPN lesions potentiate Mel antigonadotrophic effects in underfed male rats. Since the reproductive organ weights of UMelSham rats fell between those of the UMel and UMelIPN animals, sham IPN lesions also appear to potentiate Mel effects, although less so than electrolytic IPN lesions. Therefore, lesions in or near the interpeduncular nucleus might interrupt inhibitory input to melatonin receptors possibly present on raphe neurons. Disinhibition of such Mel receptors might further potentiate the antigonadotrophic effect of melatonin in undernourished male rats.

229.16 PRIMATE CIRCADIAN RHYTHMS IN HYPOTHALAMIC AND BODY TEMPERATURES. Charles A. Fuller. Division of Biomedical Sciences, University of California, Riverside, CA 92521

Preoptic hypothalamic temperature in mammals has long been known to play a key role in the short-term regulation of deep body temperature. Superimposed upon this steady-state regulation of body temperature is a 24-hour circadian rhythm. We have shown in the squirrel monkey (Saimiri sciureus) that this oscillation is precisely regulated in that it is highly reproducible. However, the role of preoptic temperature in regulating this rhythm is not known. A first step in assessing this role has been to examine the relationship between preoptic and colonic temperature rhythms in the squirrel monkey.

Three chair-acclimatized squirrel monkeys, previously prepared with preoptic hypothalamic re-entrant tubes were used in this study. Chaired animals were exposed to each of three ambient temperatures (20°, 26°, 32°C) for one to three days, while measuring colonic and hypothalamic temperatures. In all cases, the animals were synchronized to a light-dark cycle, with lights on at 08:00 and lights off at 20:00 hours (LD 12:12).

The results indicate that the hypothalamic and colonic temperature rhythms are very similar in waveform, amplitude and phase at all three ambient temperatures. In all cases, the hypothalamic temperature was higher than colonic temperature. This difference was minimal (0.4°C) at the thermoneutral temperature of 26°C. At 32°C this difference was slightly higher (0.6°C) while at 20°C the temperature difference was maximal (0.9°C). The amplitude of the hypothalamic and colonic temperature rhythms was similar at all three ambient temperatures. The amplitudes, however, were maximal at the coolest temperature (2.5°C) and minimal at the thermoneutral temperature (1.9°C). This effect on amplitude was a result not only of ambient temperature influence on the steady state level of body temperature during the day, but also on the rate of fall of body temperature in the early night. The phase relationships of both rhythms at all three temperatures showed the same similarities in that the maximum body temperature was reached late during the lights on period, and the minimum temperature was reached during the latter half of the lights off period. It thus appears, that the rhythms in hypothalamic temperature and colonic temperature are very similar although the temperature difference between them is variable. This suggests other neural centers are involved in the regulation of these rhythms. (Supported by NSF Grant BNS-792441 and PHS Grant BRD-RR09070.)

230 SYMPOSIUM

NEURAL MECHANISMS OF ATTENTION. J. C. Lynch (Chairman; Univ. of Mississippi), M. I. Posner* (Univ. of Oregon), M.-M. Mesulam (Harvard Univ.), K. M. Heilman (Univ. of Florida), V. B. Mountcastle (Johns Hopkins Univ.).

Our peripheral sensory systems are continuously processing millions of bits of incoming information. However, the higher neural function of selective attention permits only a very small portion of this information to reach consciousness. Current evidence indicates that the neural systems which participate in the control of attention are distributed widely in the central nervous system, with processing nodes located in several brainstem, midbrain, thalamic, and cortical structures. The purpose of this symposium is to present recent experimental findings which relate to the anatomical organization and connectivity of these areas, to describe recent studies of the effects of damage to one or more of these processing nodes in humans and in subhuman primates, and to present the results of studies of neural processing at the single cell level related to attention at one of these nodes.

Dr. Posner will discuss three distinct components of visual attention, their separate time courses, and their dissociation in certain neurological disorders. Dr. Mesulam will describe the regions of the CNS in which lesions produce contralateral neglect or inattention, will analyze the connectivity of these regions, and will propose a model of cortical organization which could play a major role in the overall modulation of directed visual attention. Dr. Lynch will describe the effects of posterior parietal and prefrontal cortical lesions on visual attention and extinction tasks in monkeys. Dr. Heilman will describe experiments relating neglect and akinesia in brain damaged patients, and discuss the neural basis for the observation that neglect is more common after right hemisphere lesions than after left hemisphere lesions. Dr. Mountcastle will describe the influence of different states of directed visual attention upon the excitability of single light-sensitive neurons in the posterior parietal cortex of monkeys. He will relate the activation properties of these cells to their possible roles in the direction of visual attention, in spatial perception, and in the constancy of perception of the visual surround during locomotion and head movement.

231 WORKSHOP

ALTERED AXONS: IS COMPULSIVE CONDUCTION REPLACED BY SPONTANEOUS SPIKING?

W. H. Calvin (Chairman), S. G. Waxman, M. Rasminsky, J. W. Moore, J. L. Ochoa

Regenerating axons, and even "normal" axons with altered myelination or microenvironment, initiate impulses ectopicly: chemo- and mechanosensitivity, afterdischarge following a priming train, sometimes even spontaneous firing or a susceptibility to cross-talk. Alterations in conduction following demyelination will be compared to normal functional architecture, to ask: How does a trigger zone arise?

William H. Calvin, Chairman (Univ. of Washington, Neurological Surgery): "ECTOPIC SPIKING FROM REGENERATING AND DEMYELINATED AXONS."
Introduction: Neuromas and regenerating axons; focal demyelination; DRG and theory for safety factor compensation. Spontaneous spiking and afterdischarge following conduction.

Stephen G. Waxman (Stanford University, Neurology): "FUNCTIONAL ARCHITECTURE OF MYELINATED AND DEMYELINATED AXONS."
Segregation of sodium channels to nodes, potassium channels beneath myelin. Demyelination changes the channel distribition, continuous conduction properties.

Michael Rasminsky (McGill University and Montreal General Hospital, Neurology): "CONDUCTION AND ECTOPIC SPIKING IN SPINAL ROOT AXONS OF DYSTROPHIC MICE."
Saltatory and continuous conduction in dysmyelinated axons. Abnormal excitation manifested by spontaneous ectopic excitation, ephaptic excitation, autoexcitation or afterdischarge.

Single sensory unit recordings in man during both pathological and experimentally induced ectopic spiking, and their subjective sensory correlates.

232.1 NUCLEAR PROGESTIN RECEPTORS IN THE RAT BRAIN. T.C. Rainbow, M.Y. McGinnis*, L.C. Krey*, and B.S. McEwen, The Rockefeller University, New York, NY 10021.

We used an in vitro exchange assay to demonstrate that translocation of cytosol progestin receptors to nuclear fractions occurs in rat brain after administration of progesterone (P), and to relate nuclear translocation to proceptive sexual behavior produced by P. Our assay procedure was similar to that of Blaustein and Feder (Endocr. 106:1061, 1980), and utilized ^{3}H-R5020, a synthetic progestin, as a specific ligand to measure progestin receptors. As 2h after s.c. administration of 1 mg P to ovariectomized (OVX) rats primed with 20µg estradiol benzoate (EB), the amount of nuclear progestin receptor in fractions from preoptic area (POA) and medial basal hypothalamus (MBH) increased from 27 ± 8 fm/mg DNA in the absence of exogenous P to 128 ± 12 fm/mg DNA (n=10). There was also an increase in the amount of nuclear receptor in intact rats during the proestrus release of P. Nuclear receptor levels were 35 ± 5 fm/mg DNA at 1200 on proestrus before the preovulatory rise in serum P had occurred, but were 75 ± 8 fm/mg DNA at 1630 after serum P levels were elevated (n=8).

The nuclear receptors in EB-primed rats in the absence of P probably consisted mostly of unoccupied receptors because their levels were not decreased by adrenalectomy, which eliminated adrenal progesterone. Furthermore, unlike the translocated receptors, these receptors could be removed from nuclear fractions with low ionic strength buffer. We also observed that P administration resulted in low levels of nuclear translocation in MBH-POA fractions from OVX rats not given EB, and in fractions from cerebral cortex, which unlike the MBH-POA, has no estrogen-inducible progestin receptors. This indicates that both estrogen-induced and non-induced progestin receptors will translocate to cell nuclei.

In behavioral studies, the amount of receptor in MBH-POA nuclear fractions from EB-treated rats varied with the dose of P given, and was directly related to the amount of proceptive sexual behavior (quality of lordosis posture, presence or absence of solicitation), produced by 3 different doses of P (0.25, 1 and 4 mg). Our results establish that progestin receptors in rat brain will translocate to cell nuclei after administration of P, and are consistent with the notion that P influences sexual behavior by genomic activation.

Supported by NS07080, HD10168, an institutional grant RF70095 from the Rockefeller Foundation for research in reproductive biology, and postdoctoral fellowships from the NIH.

232.2 EFFECTS OF A MINIMAL ESTRADIOL STIMULUS ON SEXUAL RECEPTIVITY AND PROGESTIN RECEPTOR INDUCTION FOLLOWING OLFACTORY BULB REMOVAL. M.Y.McGinnis*, A.R.Lumia* and B.S.McEwen (SPON: B.G. Lindsey). The Rockefeller University, New York, NY 10021 and Skidmore College, Saratoga Springs, NY 12866.

In female rats primed with estrogen and progesterone (P), olfactory bulb removal potentiates feminine sexual behavior relative to sham-operated (Sham) controls. We investigated a) whether bilaterally olfactory bulbectomized (BOB) rats would show increased behavioral sensitivity to estradiol (E_2) under conditions of minimal E_2 dose and exposure times, and b) whether the facilitation of lordosis seen in BOB rats could be attributed to changes in progestin receptor (PR) induction by E_2.

In the first study, 5 mm long Silastic capsules containing 5% E_2 (diluted with cholesterol) were implanted sc for 2 days. At 24 and 48 h rats received 200 ug P in propylene glycol sc and were tested for lordosis 4-6 h later. Sham animals showed low levels of lordosis when tested at 24 h, but achieved high levels of responding by 48 h. In contrast, BOB rats displayed high levels of lordosis at both 24 and 48 h, and were significantly higher than Shams on both tests. In the second study, BOB and Sham rats received a brief, 6 h exposure to 100% E_2 in Silastic capsules (5 mm). At 24 h, 200,500,750 or 1000 ug P was administered sc and rats were tested for lordosis 4-6 h later. Mean lordosis quotients in both groups were low with 200 ug P, and rose in a dose-response manner with increasing P doses. In BOB rats, lordosis was significantly higher than in Shams after 200, 750 and 1000 ug P. Another group of rats was tested for lordosis after 4 h E_2 exposure. This dose of E_2 followed by 1 mg P was sufficient to facilitate lordosis in BOB rats, but not in Shams. Because the 4 h E_2 exposure resulted in a clear differentiation between responding (BOB) and non-responding (Sham) animals, we used this 4 h E_2 exposure to examine PR induction in pre-optic area (POA), hypothalamus (HYPO) and pituitary (PIT). Rats were sacrificed at 24 h, and PR binding measured using the synthetic progestin ^{3}HR5020 as ligand. Following this brief E_2 exposure, there was no PR induction in POA, HYPO or PIT of either BOB or Sham rats. Our behavioral results indicate that BOB rats are behaviorally more sensitive to a minimal E_2 stimulus, and display lordosis after E_2 doses and exposure times insufficient to facilitate behavior in Sham rats. The apparent dissociation between lordosis and PR induction suggests that the potentiation of lordosis following olfactory bulb removal may not be related directly to increased PR binding.

232.3 ESTRADIOL AND PROGESTERONE CHANGE SENSITIVITY TO PROGESTERONE IN GUINEA PIGS VIA MODULATION OF THE HYPOTHALAMIC PROGESTIN RECEPTOR SYSTEM. Jeffrey D. Blaustein. Dept. of Zoology, Iowa State University, Ames, IA 50011.

In order to delineate further the role of progestin receptors in the hypothalamus-preoptic area (HP) in the regulation of lordosis in female guinea pigs, we injected estradiol benzoate (E_2B) and progesterone (P) in various regimens that result in responsiveness to, refractoriness to, or restoration of responsiveness to P-facilitation of lordosis. We attempted to correlate the effectiveness of P to facilitate lordosis with the effectiveness of P to cause accumulation of nuclear progestin receptors (NPR) in HP measured by an in vitro (^{3}H)R 5020 binding assay.

A P injection (.5 mg) 40 h after an E_2B injection (2µg) in ovariectomized guinea pigs resulted in lordosis in 83% of the guinea pigs and caused 30% depletion of cytoplasmic progestin receptors (CPR) and 200% increase in the concentration of NPR 4 h after injection compared with controls. By 24 h after injection, after heat had terminated, the concentration of NPR was no longer elevated, but the concentration of CPR remained depressed 55% lower than that of controls. This depression was seen with both untreated cytosol and with cytosol that had been pretreated by gel filtration to remove unbound steroids. These P-injected guinea pigs were refractory to P-facilitation of lordosis, and a second P injection 24 h after the first (64 h) resulted in a 70% lower concentration of NPR than in oil-injected controls. This decrease in the concentration of NPR appears to be due to the 55% lower level of CPR available at the time of the second P injection compared with controls.

E_2B (10µg) injected concurrently with the first P injection (40 h) restored behavioral sensitivity to the second P injection (64 h) and caused 160% higher concentration of NPR compared with guinea pigs that had received only P at 40 h. The increased concentration of NPR in E_2B-injected animals appears to be due to increased availability of CPR. E_2B injection at 40 h increased the concentration of CPR by 40% within 12 h, and guinea pigs that received E_2B concurrently with the P had a 50% higher concentration of CPR 24 h later compared with animals that had received only progesterone.

It seems that estradiol increases and P decreases the concentration of CPR in HP such that a subsequent P injection results in a high or low concentration of NPR, and perhaps consequently, to presence or absence of lordosis responses. The presence of sufficient NPR may be a requirement in the process by which P facilitates lordosis in estradiol-primed rodents.

232.4 IN SITU LOCALIZATION OF R5020 AND PROGESTERONE IN THE VASCULARLY SEPARATED AND ISOLATED RHESUS MONKEY HYPOTHALAMUS: LOCALIZATION OF A PROGESTERONE-CONCENTRATING LOCUS. D.R. Garris*, R.B. Billiar*, Y. Takaoka*, R.J. White* and B. Little*. (Spon: G.R. Athey) Dept. Anatomy, East Carolina Univ., Greenville, NC 27834, Dept. Reproductive Biology, Case Western Reserve Univ. and Brain Research Lab., Cleveland Metropolitan General Hospital, Cleveland, OH 44106.

Previous studies, utilizing a neurosurgical procedure for in situ hypothalamic isolation, documented that differences exist in the localization of various ovarian steroid concentrating cells in the primate hypothalamus (Neuroendocr. 32:124, 1981). The present study was designed to elucidate the location, density and pattern of progestin (R5020) and progesterone (P) concentrating neurons within the vascularly isolated and separated hypothalamus of the ovariectomized, estradiol-treated rhesus monkey. Radiolabeled steroids (80 µCi ^{3}H-R5020 or ^{3}H-P) were directly perfused in a dextran-blood solution into one-half of the isolated hypothalamus. The contralateral half of the hypothalamus was perfused in an identical manner with a mixture of radioinert and radiolabeled R5020 or P. Both sides were then perfused with radioinert microspheres for analysis of vascular patency. Brains were subsequently prepared for autoradiography. The distribution of ^{3}H-R5020 and ^{3}H-P was limited to the hypothalamus-thalamus area in all preparations and exhibited a cross-circulation of less than 10% between sides. ^{3}H-R5020 and ^{3}H-P labeling of hypothalamic neurons was markedly reduced on the side treated with the radioinert competitor. Large numbers of ^{3}H-R5020 and ^{3}H-P concentrating neurons were localized in the medial preoptic area, ventromedial (VMH), periventricular (PERI) and infundibular nuclei. Fewer labeled cells were localized in the suprachiasmatic, supraoptic and medial mammillary nuclei. Other hypothalamic areas were essentially devoid of R5020 or P concentrating cells. The localized distribution of the labeled cells was not affected by vascular perfusion since microspheres were observed in all nuclear regions regardless of whether or not labeled cells were present. A specific P-concentrating locus of cells was found in all the preparations. The locus was not confined to a specific, anatomically distinct nucleus but included the ventral PERI and medial one-third of the VMH near the mid- point of the VMH nucleus. The results of these studies demonstrate the existence and distribution of distinct R5020 and P-concentrating cells within the hypothalamus of the rhesus monkey. It is suggested that the medial-basal hypothalamic nuclei serve as a functional feedback site for P in the regulation of the hypothalamic-pituitary axis in the primate. (Supported by NICHHD Grants HD05691, HD07120 and HD07640).

232.5 SEX DIFFERENCES IN 3H-ESTRADIOL UPTAKE IN BRAIN AND PITUITARY OF THE RAT AFTER BROMOCRIPTINE TREATMENT. D. W. Gietzen,* D. E. Woolley* and M. A. Thompson* (SPON: R. Dagirmanjian). Dept. of Animal Physiology, Univ. of California, Davis, CA 95616.

Increases in 3H-estradiol ($3H-E_2$) uptake in brain and pituitary after treatment with dopaminergic agonists in the female have been reported previously by us. This study confirms these observations and extends them by measuring $3H-E_2$ uptake after bromocriptine in the male as well.

In vivo total, specific and nonspecific nuclear, supernatant and total tissue binding of $3H-E_2$ was measured 1 hr after injection (1 µg/kg $3H-E_2$ iv) in gonadectomized-adrenalectomized adult male and female rats. The dopaminergic agonist bromocriptine (5 mg/kg ip) or the vehicle was injected 1 hr prior to $3H-E_2$ administration. Specific binding was defined as diethylstilbestrol (DES) blockable radioactivity.

In the female rat bromocriptine significantly increased specific binding in the nuclear fractions of the basal hypothalamus (BH) and anterior pituitary (AP). In addition, bromocriptine increased total binding in nuclear fractions of dorsal hypothalamus (DH) and septum (SEP) and in supernatant fractions of AP, anterior hypothalamus, DH, amygdala, SEP and cortex. When values for nuclear and supernatant fractions were summed, significant increases were noted in the uptake of all tissues. Plasma levels of radioactivity were not affected by bromocriptine.

By contrast, bromocriptine pretreatment did not change $3H-E_2$ uptake in any tissue in male rats. Furthermore, $3H-E_2$ uptake did not differ in brain or AP between control male and female rats. The lack of a sex difference in the rat brain with regard to $3H-E_2$ uptake in the absence of other treatment has been noted previously in this laboratory and by others. The present report describes a sex difference in $3H-E_2$ uptake after bromocriptine treatment in AP and several brain areas of the rat known to contain E_2 receptors. Sex differences in response to apomorphine (another dopaminergic agonist), in prolactin and LH regulation, in tuberoinfundibular dopaminergic neuronal activity and in monoamine oxidase activity have been noted by others.

The fact that specific binding of $3H-E_2$ was increased in the female, but not in the male, rat in the BH and AP after treatment with a dopaminergic agonist could have important implications with regard to the sex differences in feedback effects of E_2 and in catecholamine-E_2 interactions. The observation that total tissue uptake was increased in all brain areas after dopaminergic treatment implies a general interaction between E_2 and dopamine throughout the brain in the female, but not in the male. (Supported by NIH grant HD12385.)

232.6 ESTROGEN AND PROGESTIN RECEPTOR BINDING IN BRAIN AND PITUITARY AFTER RETROCHIASMATIC KNIFE CUTS. C.P. Phelps, M.Y. McGinnis, D.M. Nance and B.S. McEwen. University of South Florida, Tampa, FL; Rockefeller University, NY, NY and Dalhousie University, Halifax, Nova Scotia, Canada.

Surgical interruption of retrochiasmatic anterior and lateral connections of the hypothalamus (HYPO) is known to interfere with LH release by the pituitary (PIT) and ovarian steroid-sensitive sexual receptivity. In this study we have examined estrogen and progestin receptor binding in the preoptic area (POA), HYPO and PIT of female rats after retrochiasmatic frontolateral cuts (FLC) or sham surgery (SHAM) made with a Halász-type knife. The behavioral effects of FLC were evaluated using pre- and post-surgical testing of lordosis quotients (LQ) after either estradiol benzoate (EB, 2µg/rat x 2d) or pure estradiol implants (E_2 in Silastic capsules x 2d), plus progesterone (P, 0.5mg/rat) injected 4-6hr before tests with experienced males. Nuclear estrogen-receptor complexes in brain and PIT were quantified using an exchange assay developed by Roy and McEwen (1977). Cytosol progestin receptor binding was determined according to the method of MacLusky and McEwen (1980) using the synthetic progestin ^{3}HR5020 as ligand. Two weeks after the final behavior test, the rats were sacrificed by decapitation 2 days after implantation of E_2 capsules and the POA and HYPO were dissected from the remainder of the brain on ice. The PIT of each animal was also removed and placed on ice. Tissue from 2 rats was pooled for each sample receptor determination. Analysis of variance revealed highly significant ($p<0.001$) effects of FLC on post- versus pre-FLC LQ's. As expected, post-hoc tests indicated that the mean LQ of the post-FLC test was significantly lower than pre-FLC LQ's and both pre- and post-SHAM LQ's. In addition, nuclear E_2-receptor binding in the HYPO of FLC rats was significantly decreased relative to corresponding SHAMS. E_2-receptor binding in POA and PIT were not affected by FLC. Cytosol progestin receptor binding values in all tissues were also not changed by FLC. This was unexpected in view of the behavioral deficit after E_2 plus P treatment. The biochemical and behavioral results of this study support the contention that there is a proportional linkage between the number of E_2-nuclear receptors in the hypothalamus and the capacity to display lordosis after E_2 plus P following surgical disconnections of anterolateral hypothalamic efferents and afferents. Supported in part by USPHS HD11345 and NS06156.

232.7 TREATMENT OF NEONATAL RATS WITH MSG ALTERS NEUROENDOCRINE FUNCTION BY DECREASING CYTOSOL ESTROGEN RECEPTORS. J.F. Rodriguez-Sierra, J.D. Blaustein, C.A. Blake, R.W. Clough and K.A. Elias*, Dept. of Anatomy, Univ. Nebraska Med. Ctr., Omaha, NE 68105 and Dept. of Zoology, Iowa State Univ., Ames, IA 50011.

We have previously reported that treatment of neonatal female rats with monosodium glutamate (MSG) interferes with normal reproductive function: delayed puberty, abnormal estrous cycles, suppression of ovulation and sexual behavior, and lack of compensatory ovarian hypertrophy (Rodriguez-Sierra et al., NEUROENDOCRINOLOGY 31:228, 1980). We ascribed neuroendocrine deficits to the neurotoxic effects of MSG on neurons in the mediobasal hypothalamus (MBH). We have now tested whether the neurotoxicity of MSG may occur in estrogen-sensitive cells to disrupt ovarian-hypothalamic-pituitary gland feedback mechanisms. Sprague-Dawley female rats were treated with MSG (4 mg/g BW, sc) on days 1,3,5,7, and 9 of age. Littermate controls were either injected with saline or remained untreated. At approximately 70 days of age, all rats were bilaterally ovariectomized. Ovaries were blotted and weighed. Two weeks after ovariectomy, rats were decapitated, trunk blood was collected, and serum was frozen until radioimmunoassays of prolactin and luteinizing hormone (LH) were performed. The pituitary gland was removed and weighed. The brain was dissected over an ice-cold glass slide, and the MBH and preoptic area (POA) were separated and weighed. The pituitary gland and both brain regions were homogenized and centrifuged, and the cytosol fractions were used for determination of estradiol receptors. The data was expressed in terms of fentomoles of ^{3}H-estradiol/mg protein. The MSG treated rats had significantly lower body weights than control rats throughout the experiment. Ovary and pituitary gland weights were 50% lower in the MSG-treated rats than in controls. Serum prolactin levels were elevated in the MSG-treated rats (255 vs. 130 ng/ml). Serum LH levels increased in both groups, but the differences were not statistically different. Nevertheless, 6 of 10 MSG-treated rats had serum LH levels below 300 ng/ml, while only 1 of 7 control rats had levels this low. The cytosol estradiol receptors were reduced significantly in the MBH and inthe POA of the MSG-treated rats. Pituitary gland cytosol estradiol receptors were virtually identical in both groups. The results support our hypothesis that neonatal MSG treatment exerts neurotoxic effects on estrogen-sensitive neurons. A reduced ability of the brain to monitor serum estradiol levels could explain some of the endocrinopathies of the MSG-treated rat. It is surprising that the pituitary gland is drastically reduced in size and yet maintains a normal complement of estradiol receptors. We are in the process of determining the specific hypothamic nuclei affected by the MSG treatment. (Supported by grants from the Univ. Nebr. Med. Center, NIH (HD11011) and BNS-8013050.

232.8 A REGIONAL ANALYSIS OF NEURAL CHANGES RELATED TO MASCULINIZATION AND DEFEMINIZATION. E. J. Nordeen* and P. Yahr. Dept. of Psychobiology, Univ. of Calif., Irvine, Irvine, CA 92717

Gonadal steroids act perinatally to masculinize and to defeminize adult sexual responsiveness. These processes can occur independently. In rats, masculinization refers to an increase in the likelihood of male sexual behavior in response to either androgenic or estrogenic stimulation in adulthood. This masculinization can be induced by exposing the developing anterior hypothalamus-preoptic area (AH-POA) to hormones such as estradiol (E_2). Defeminized animals are less likely to show either female sexual behavior (i.e., lordosis) or surges of luteinizing hormone (LH) in response to E_2 stimulation in adulthood. This defeminization occurs following hormonal stimulation of the developing medial basal hypothalamus (MBH). Sex differences in both neuroanatomy and steroid hormone binding exist in both the AH-POA and MBH. These differences develop in response to the same hormonal treatments that produce defeminization and masculinization. However, neither masculinization nor defeminization has been specifically linked to any neural change. Since masculinization and defeminization involve separate brain regions and produce opposite changes in E_2 sensitivity, sex differences in hormone binding may be regionally specific. We examined cell nuclear binding of ^{3}[H]-E_2 in the AH-POA, MBH, amygdala (AMY) and cortex (CX) of adult male and female rats. Females bound more ^{3}[H]E_2 than males in cell nuclei of both the AH-POA and MBH 60 min after an IV injection of 40 µCi [2,4,6,7-^{3}H]-E_2. Neither AMY nor CX showed a sex difference in E_2 binding. These data argue against a quantitative relationship between regional E_2 binding and E_2 sensitivity. In order to better define the relationship between steroid binding and masculinization, we are now assessing nuclear E_2 uptake in females that were masculinized by E_2 implants into the developing AH-POA.

The sexually dimorphic nucleus (SDN) of the POA provides an example of a sex difference in neuroanatomy. This nucleus is larger in males than females and its size is influenced by neonatal hormonal stimulation. However, the relationship between the size of the SDN and either masculinization or defeminization is unknown. We examined the SDN of females that were masculinized neonatally by unilateral intrahypothalamic E_2 implants. As adults these females show more mounts and intromission patterns than control females when injected daily with 2 µg estradiol benzoate + 200 µg dihydrotestosterone propionate. However, they show neither reduced female sexual behavior nor impaired LH secretion. Presently, it appears that there is no difference in the size of the SDN between these masculinized females and controls. Thus the relationship between the SDN and sexually dimorphic behavior remains unclear.

232.9 GLUCOCORTICOID BINDING IN THE BRAIN IS SEX DEPENDENT. B. B. Turner and D. A. Weaver. Depts. of Biology & Psych., Virginia Polytechnic Institute & State University, Blacksburg, VA 24061.

Sex-related neuroanatomical and neurochemical differences have been found in rodents and birds in those brain areas responsible for the control of sexual behaviors. In examining possible sex-related differences in cytosol binding of corticosterone, we chose the hippocampus (HC), which is known to have the largest number of glucocorticoid receptors, and the hypothalamic-preoptic area (HYP) which is known to be involved in the control of sexual behavior.

In a series of ten experiments, male and female Sprague-Dawley rats (70-90 days of age) were adrenalectomized 12 hrs before sacrifice. Rats were anesthetized with Metofane anesthesia and thoroughly perfused with cold dextran-saline. Tissues from 3 rats of the same sex were pooled for each experiment. Tissues were homogenized in Tris-EDTA buffer containing 10% glycerol and centrifuged at 105,000 g for 60 min. Aliquots of supernatant were then incubated with 6 concentrations of ^{3}H-corticosterone (2-30 x 10^{-9}M). Incubation in 100 fold excess unlabeled steroid was used to determine non-specific binding. The steroid bound to receptor protein was separated from free steroid by passage through LH-20 columns. Analysis of the double reciprocal plots obtained showed that ^{3}H-corticosterone binding was significantly greater in the HC in females (B_{max}=148±1 fmoles/mg protein) than in males (B_{max}=121±5 fmoles/mg protein), $p<.001$. In contrast, binding in the HYP was markedly reduced ($p<<.001$)in females (B_{max}=75±2 fmoles/mg protein) as compared to males (B_{max}=105±1 fmoles/mg protein). In HC the binding affinity was the same for males (K_d=4.16 x 10^{-9}M) and females (K_d=4.41 x 10^{-9}M). In HYP binding affinity was significantly lower ($p<<.001$) for females (K_d=7.17 x 10^{-9}M) than males (K_d=4.60 x 10^{-9}M).

This study demonstrates significant sex-dependent differences in the cytosol binding of corticosterone in HC and HYP of rats. Our results suggest that the HC of the female rat, due to its larger number of receptors, may be subject to greater modulatory control by glucocorticoids than the male. Learning, memory, and spatial orientation are functions thought to be under the control of the HC. Glucocorticoids are believed to have a modulatory role in the regulation of these functions. The sex-dependent receptor differences reported here suggest a possible explanation of the sex related differences reported to exist with respect to spatial ability. The significant decrease in receptor number and apparent affinity in the female HYP may serve a protective function with respect to reproductive capacity during episodes of stress. (Supported by an NIH BRSG grant from VPI & SU).

233.1 DIVERSE ACTIONS OF HEMICHOLINIUM-3 CONGENERS ON THE ACETYLCHOLINE ACTIVATED RECEPTOR-IONIC CHANNEL. E.G. Henderson, K.A. Alkadhi*, R.L. Volle, L.S. Reynolds*, J.J. Lambert*, and M. Ashford*. Dept. of Pharmacology, Univ. of Conn. Health Ctr., Farmington, CT 06032, and Dept. of Zool., Univ. of Nottingham, Nottingham, U.K.

The effects of hemicholinium-3 (HC-3), hemicholinium-15 (HC-15) and terphenyl-hemicholinium-3 (TPHC-3) on endplate currents (e.p.c.s) in transected frog cutaneous pectoris muscles were examined. At holding potentials (Vm) more negative than -90mV, HC-3 (50-100μM) caused a monotonic increase in the rate of e.p.c. decay (α) (Henderson et al., Fed. Proc. 1981: 40, 263). E.p.c. decay was biphasic at less negative Vm's, the initial phase being faster and the final phase slower than control. At Vm=-30mV, the relative amplitude of the terminal phase equaled that of the initial fast phase. At +30mV, a single slow exponential decay was observed (Vm=+30; α=1.75, control; α=.336 $msec^{-1}$, HC-3). Over the range Vm=-70 to -10mV, α_{slow}=.3 $msec^{-1}$ and α_{fast}=1.7 $msec^{-1}$, were independent of Vm. Peak e.p.c. amplitude (Ip) was depressed at all Vm's, but more depressed at negative Vm's. Similar results were obtained using Mg^{++} depressed intact muscles. In patch clamped chick skeletal muscles, HC-3 (50μM) decreased measured mean channel open time of ACh (5x 10^{-7}M) activated channels from 6.03±1.18 msec to 1.55±.02 msec at Em's -30 to -40mV. In the presence of HC-3, single channel events occurred in bursts. Such behavior would be expected if the blocked interval was long compared to the open time.

HC-15 (50-200μM), a mono-quaternary analog of HC-3 , caused a monotonic slowing of e.p.c. decay at all Vm's, with no effect on Ip. HC-15 (100μM) increased voltage dependence (H) of α from -144 to -118 mV. All effects of HC-3 and HC-15 were rapidly reversible. TPHC-3 (5-100μM) caused a time and concentration dependent decrease in Ip and an increase of α. While α was increased in 5μM TPHC-3, H was unchanged. TPHC-3 ≥ 10μM increased α and reduced voltage dependence. The effects of TPHC-3 on e.p.c. parameters were slowly reversible with recovery of α faster than Ip. These findings suggest that simple chemical modification of these molecules will lead to further insight into the kinetics of ACh activated ionic channels. (Supported by grants NIH NS-07540 and the U. Conn. Res. Foundation.)

233.2 MULTIPLE ACTIONS OF DMAE ON ACETYLCHOLINE-ACTIVATED IONIC CHANNELS IN THE FROG NEUROMUSCULAR JUNCTION. K.A. Alkadhi*, L.S. Reynolds*, E.G. Henderson and R.L. Volle. Dept. of Pharmacology, Univ. of Connecticut Health Center, Farmington, CT 06032.

The effect of α,α'bis(dimethylammonium acetylaldehyde diethylacetal)-p-p'-diacetylbiphenyl dibromide (DMAE), an analogue of hemicholinium-3, was investigated on neurally evoked endplate currents (e.p.c.s) in the transected cutaneous pectoris muscle of the frog. Within one minute of perfusion of DMAE (50 or 100μM), a marked initial prolongation of e.p.c. decay was observed at all holding potentials. At -90mV holding potential the prolongation of e.p.c. decay was immediately followed by marked shortening. However, at +30mV the initial prolongation of the decay persisted and no shortening was seen. Similar results were obtained in intact Mg^{++}-depressed muscles. The normal relationship between decay and holding potential was reversed by DMAE (H: control=-145mV; DMAE=+344.8mV) but the single exponential nature of the decay was unchanged at all holding potentials. DMAE depressed the peak e.p.c. and the current-voltage relationship became non-linear at hyperpolarized potentials with no change in the reversal potential. Pretreatment of the muscle with neostigmine (5μM) to inactivate acetylcholinesterase partially antagonized the initial prolongation of the e.p.c. decay but had no effect on the subsequent shortening of the decay phase or the depression of the peak e.p.c. amplitude. Washout of DMAE resulted in marked prolongation of the decay phase of e.p.c.s. This prolongation of the decay as well as the depression of the e.p.c. peak amplitude were not readily reversed by continued perfusion of drug-free Ringer solution (α=rate constant of decay, Ip=e.p.c. peak current at -90mV: control, α=0.752, Ip=319nA; 100μM DMAE, α=1.492, Ip=96nA; 25 min washout, α=0.495, Ip=110nA). Smaller concentrations (5μM) of DMAE produced only long-lasting prolongation of the decay phase and a small increase of peak e.p.c. amplitude. These results suggest that DMAE action involves more than one site at the acetylcholine-activated ionic channel. (Supported by NIH NS07540 and the Univ. of Conn. Res. Found.)

233.3 TWO PHASE DECAY OF MPSPS AT HATCHETFISH GIANT SYNAPSE. Day,J.W., Huse,W.D., Bennett,M.V.L. Dept. of Neurosci., Albert Einstein College of Medicine, Bronx, New York 10461.

In the medulla of the South American hatchetfish, Gasteropelecus, the Mauthner fibers are presynaptic to 10-14 myelinated giant fibers. The axo-axonic synapses formed by these fibers appear to be nicotinic cholinergic (see Hall,D.H. et al., this meeting). The input resistance of the giant fiber is 1 MΩ, its time constant is less than 100 μs, and it has a space constant of 3 mm.

Under voltage clamp the postsynaptic current (PSC) reverses at -15 mv, has a rise time of 80 μs, and decays in two phases (Huse, W.D., Bennett, M.V.L., J. Biophys. 33:14a, 1981). The early, fast falling phase shows little voltage dependence and has a decay constant of 300 μs. The late, slowly falling phase is voltage dependent and is slower at hyperpolarized membrane potentials, similar to the PSC of the frog neuromuscular junction. Its decay constant is 750 μs at the resting potential of -90 mv. Miniature postsynaptic currents (MPSCs) have a rise time of 50-100 μs when clamped at the resting potential, but falling phases were difficult to characterize because of noise.

Because of the fast time constant of the membrane the decay phase could be studied in unclamped voltage records. Miniature postsynaptic potentials (MPSPs), which averaged 1 mv in amplitude, were recorded on an FM tape recorder. A computer was used to digitize records and select MPSPs on the basis of rapid rise, slow fall, and amplitude within a given range. 300-500 MPSPs were averaged together, aligning the points of greatest rate of rise. The rise time of the averaged MPSP was 75-80 μs. The similarity of the rise time for the MPSP and MPSC shows that the high frequency components of the current are reflected in the voltage records, and are not appreciably filtered by the membrane or recording apparatus. The decay of the averaged MPSP is similar to that of the PSC and has two phases. The decay constant of the faster phase is 350 μs, and that of the slower phase is 700-800 μs. These data complement the voltage clamp findings and show that the two decay phases of the PSC reflect mechanisms operating at the level of the quantal event. The presence of a rapid phase followed by a slower phase in the decay of the PSC cannot be described, with any combination of rate constants, by the three-state model that Katz and Miledi used for the frog neuromuscular junction. More complicated schemes with two open states, multiple transmitter binding, or a blocking action of acetylcholine like that seen with some local anesthetics are possible explanations that require further study.

Supported by NRSA NS-06082 to JWD, and NIH grant NS-12627 to MVLB.

233.4 CALMODULIN STIMULATES PHOSPHORYLATION OF THE ACETYLCHOLINE RECEPTOR, H. Smilowitz, R.A. Hadjian*, J. Dwyer* & M.B. Feinstein* Dept. Pharmacol., U. Conn. Hlth. Ctr., Farmington, CT 06032

Acetylcholine receptor (AChR) enriched membranes were prepared from frozen electric organ of Torpedo, C. by differential and density gradient centrifugation. Membranes from various fractions along the gradient were used to assay endogenous phosphorylation in the absence and presence of Ca^{++} and calmodulin (CDR). Each of the AChR enriched membrane fractions exhibited a 3-5 fold stimulation of endog. phosphorylation by Ca^{++} and CDR. Both Ca^{++} and CDR are needed for maximal stimulation although Ca^{++} alone affords a small but reproducible stimulation of endog. phosphorylation. The stimulation of endog. phosphorylation of the Torpedo membranes by Ca^{++} and CDR is completely inhibited by 25μM trifluoperazine (TFP). TFP at 50μM inhibits basal phosphorylation by 60% suggesting that most or all of the basal phosphorylation may be due to endogenous CDR. In fact, heat resistant material which stimulates CDR dependent phosphodiesterase activity is present in our membrane preparation.

SDS polyacrylamide gel electrophoresis shows that the major phosphorylated species (both in the presence and absence of Ca^{++} and CDR) are Mr 65K, 58K, 41K, and 39K polypeptides. A Mr 50K polypeptide is also phosphorylated to a lesser extent. The Mr 65K, 58K and 50K phosphorylated polypeptides correspond to components of the purified AChR from Torpedo, C. The identity of the Mr 41K polypeptide is still unresolved. The 39K polypeptide is not a component of the AChR. Polypeptides of 43K and high molecular weight are not appreciably phosphorylated.

Fluoride (5mM), Vanadate (100μM) and ouabain (1 mM) inhibit ATPase activity present in our membranes and further stimulate AChR phosphorylation. Ouabain stimulates less well than Vanadate or fluoride which inhibit all ATPase activity in our membranes. The anti-ATPase activity of fluoride can, therefore, account for most but not all of the stimulatory effect of fluoride in the phosphorylation assay; fluoride stimulation is 1.5 fold greater than vanadate in the presence of high levels of CDR. The mechanism is not yet known.

This phosphorylation system has been further characterized. The concentration of CDR which affects half maximal stimulation is 55nM. The apparent Km of the kinase for ATP is about 80μM. The phosphorylation reaction stimulated by potassium and inhibited by sodium. Under our optimal assay conditions including 100μM ATP, 100μM Vanadate, 0.4μM CDR, 50μM free Ca^{++} and 100 mM KCl, maximal phosphorylation is achieved in 30-45 min at 20°C and represents about 1 nM phosphate per mg of membrane protein of which, 10-15% is the AChR. (Supported by the Muscular Dystrophy Association.)

233.5 AUTAPTIC EXCITATION IN TURTLE OLFACTORY BULB IN VITRO. R.A. Nicoll and C.E. Jahr, Depts. of Pharmacology and Physiology, UCSF, San Francisco, CA 94143.

Excitation of olfactory bulb mitral cells is followed by an inhibitory postsynaptic potential (IPSP) which is mediated predominantly by activation of dendrodendritic reciprocal synapses located between the mitral (excitatory) and granule (inhibitory) cells (C.E. Jahr and R.A. Nicoll, Science 207:1473, 1980). When the inhibitory half of the reciprocal synapse is blocked by the GABA antagonists, bicuculline or picrotoxin, mitral cell activation is followed by an excitatory depolarizing potential instead of an IPSP. This depolarizing after-potential (DAP) can be sufficiently intense to elicit prolonged repetitive firing.

We first considered the possibility that the DAP was produced by a slowly inactivating, tetrodotoxin (TTX) sensitive, sodium conductance as is seen in cerebellar Purkinje cells (R. Llinás and M. Sugimori, J. Physiol. 305:171, 1980). TTX blocks directly evoked fast spikes in mitral cells revealing calcium spikes. However, TTX did not block the DAP.

The DAP is calcium-dependent since it was blocked by the calcium antagonists, cadmium and cobalt. This finding suggested that the DAP might represent a slow voltage-dependent calcium conductance or, alternatively, a feedback of excitatory transmitter released from the same mitral cell. If the DAP were due to a voltage-dependent calcium conductance, it should be blocked by injecting a hyperpolarizing current pulse, as has been shown in other cells. Such a pulse did not abort the mitral cell DAP. Furthermore, barium, which readily passes through calcium channels but does not support synaptic transmission, blocked the DAP while actually increasing the size of the TTX-resistant spike. This suggests that the DAP is transmitter mediated. Iontophoresis of either glutamate or aspartate (putative transmitters for the mitral cell) in the presence of bicuculline or picrotoxin, depolarized mitral cells. Addition of α-amino adipate, which antagonizes aspartate responses in other systems, reversibly blocked the DAP with no effect on the calcium spike. Since TTX did not block the DAP, a pathway dependent on propagated action potentials is excluded. We suggest that mitral cell activation causes the dendritic release of an excitatory transmitter, possibly aspartate, which feeds back directly onto the same mitral cell.

Supported by NIH grants NS 16485 and RCDA NS 00287 to R.A.N.

233.6 DL-MUSCARINE DECREASES A POTASSIUM CONDUCTANCE TO DEPOLARIZE MAMMALIAN SPINAL CORD NEURONS IN CELL CULTURE. L.M. Nowak and R.L. Macdonald. Dept. of Neurology, The University of Michigan, Ann Arbor, MI 48109.

We have investigated the postsynaptic actions of dl-muscarine (MUS) on multipolar spinal cord neurons in primary dissociated cell culture and report that MUS evoked atropine-sensitive, slow membrane depolarizations associated with a decrease in a membrane potassium conductance (g_K).

Spinal cords and attached dorsal root ganglia were dissected from 12-13.5 day old fetal mice, and grown in culture at 35° for 4-10 weeks prior to electrophysiological investigations. Intracellular recordings of voltage and current responses were made from neurons bathed in buffered saline on the modified, heated (30°-35°), stage of an inverted phase-contrast microscope. High impedance (30-45 MΩ) 4M potassium acetate-(KAc) or 3M potassium chloride-filled (KCl) micropipettes were used for conventional intracellular recording with the bridge technique. Low impedance (10-20 MΩ) KCl-filled micropipettes, shielded with conductive paint (within 1-2 mm of tips), were used for single electrode voltage-clamp recordings (3KHz switching frequency; a 50% duty cycle). MUS and 10 μM GABA were applied to the neuronal surface by pressure pulses (1-2 sec at .25-3.0 psi) from blunt (2-10 μm tips) glass micropipettes.

MUS evoked dose-dependent (1-10 μM), slow (4-6 sec to peak at 30°C), reversible depolarizations accompanied by decreased membrane conductance during recordings with KAc-filled and KCl-filled micropipettes. Responses to 10 μM MUS were eliminated by <2 μM atropine. GABA evoked rapid (2 sec to peak) depolarizing responses and increased membrane conductance during intracellular recording with KCl-filled micropipettes. Both MUS and GABA evoked inward currents from the same neuron at resting membrane potential (RMP). GABA current responses decreased as membrane potential was voltage-clamped at increasingly depolarized potentials and response polarity reversed between -20 and -10mV. MUS-evoked inward currents increased with depolarization, decreased with hyperpolarization and had extrapolated reversal potentials (RP_es) 15-30 mV below RMP, suggesting that MUS decreased a g_K. Potassium-dependence of MUS-responses was confirmed by a shift of RP_es and RMPs to more depolarized potentials when bath potassium concentration was changed from 5 to 25mM.

MUS-currents, in contrast to GABA-currents, did not vary linearly with membrane potential at hyperpolarized potentials suggesting that MUS may decrease a voltage-dependent g_K in mammalian CNS neurons as has been described in frog sympathetic ganglion neurons (Brown & Adams, 1980).

233.7 NOREPINEPHRINE (NE) AND ISOPROTERENOL (IP) DO NOT CONSISTENTLY HYPERPOLARIZE CA1 PYRAMIDAL NEURONS (PNs) OF THE RAT HIPPOCAMPUS SLICE IN VITRO. G.R. Siggins and D.L. Gruol. A.V. Davis Center, The Salk Institute, P.O. Box 85800, San Diego, CA 92138.

Many past extracellular studies show that iontophoretically applied NE inhibits hippocampal PNs in vivo. Although two recent studies on the hippocampal slice preparation (Langmoen et al., Brain Res. 208: 349, 1981; Segal, Brain Res. 206: 107, 1981) have described weak hyperpolarizing actions of NE applied to CA1 PNs by a micro-drop method, the precise mechanism of this inhibition is still equivocal. We have tested on PNs of the rat hippocampal slice (120-160 gm rats, 350-400 μm slices) the effects of NE or IP applied by superfusion or by pressure from pipettes (10 μm tips) containing 10 mM IP or NE in HEPES buffered CSF (pH 7.4). In both cases perfusion of the slice with artificial CSF (pH 7.4; temperature held at 33,34, or 35°) was continuously maintained at 1-2 ml/min over all surfaces of the slice, to prevent artifactual environmental changes with drug application. In the 12 PN's chosen for study, resting membrane potentials were steady for 1-5 hours at -55 to -75 mV, spikes were 80-100 mV and input resistance was 20-40 Mohms. NE was applied to 6 cells, in 8 complete tests by perfusion (20 μM to 1 mM) and in 10 tests by pressure (40 psi); IP was tested on 6 PNs, 15 times by perfusion (50 μM to 2 mM) and 3 times by pressure (40 psi). NE or IP slowed spontaneous activity in 44% of tests, speeded in 33% and had no effect in 23%. However, membrane potentials generally were not effected (NE, 48% of tests; IP, 61%) or slightly depolarized (NE, 29%; IP, 28%), rather than hyperpolarized (NE, 23%; IP, 11%). Potential changes for any one cell were inconsistent and small: 0.5-4 mV (1.36 ± 0.91 mV, mean ± S.D.). These changes in firing rate and membrane potential usually occurred without change in input resistance. Occasionally, paroxysmal depolarization shifts developed with NE or IP, or on washout. Lack of hyperpolarization was seen whether KCl or K acetate recording electrodes were used. Perfusion of NE in CSF with 10 mM $MgCl_2$ (to block synaptic activity) did not reveal hyperpolarizations. NE or IP were ineffective even in cells which displayed hyperpolarizations to adenosine and somatostatin and depolarizations to glutamate. We conclude either that NE and IP, even in high concentrations, inhibit PN's in CA1 by some mechanism other than hyperpolarization of the PN soma, or that the present hippocampal slice preparation is not adequate for analysis of mechanisms of adrenergic responses seen in vivo.

233.8 PATCH CLAMP ANALYSIS OF GLUTAMATE RECEPTORS. K.A.F. Gration*, J.J. Lambert*, R.R. Ramsey* and P.N.R. Usherwood* (SPON: S.J. Potashner). Dept. of Zool., Univ. Nottingham, Nottingham NG7 2RD, U.K.

The extracellular patch clamp technique has been used to record currents passing through single glutamate D-receptor channels in the extrajunctional membrane of locust muscle. This preparation is particularly well suited to the patch clamp technique for the following reasons:-

1) The conductance of the glutamate channels is sufficiently large (~120 pS) to enable information to be gained on channel life-times <1 ms.

2) Pretreatment with Concanavalin A inhibits receptor desensitization enabling the effects of relatively high concentrations of glutamate (10^{-4}M - 10^{-2}M) on channel activity to be studied. For relatively low concentrations of L-glutamate (10^{-6}M - 5 x 10^{-5}M) mean channel life-time does not change significantly with glutamate concentration. Within this concentration range frequency distribution of channel life-times constructed with 50 μs bin widths are not exponential but exhibit a peak. The distributions can be described by two exponentials as follows $A\,(e^{-t/\tau_2} - e^{-t/\tau_1})$ where for glutamate $\tau_1 < \tau_2$. This suggests that the life-time of the glutamate channel involves two time-dependent processes. The process characterized by τ_1 has the effect of delaying the observed event of channel closure which is characterized by τ_2. At glutamate concentrations > 5 x 10^{-5}M the mean life-time of the channel appears to increase with increasing glutamate concentration. With 10^{-3}M glutamate, the channel remains mainly in the open state with only transient closings. Relatively long open times have been observed in the absence of Con A suggesting that this phenomenon is a natural property of the glutamate channel.

We have extended these studies to other glutamate agonists (quisqualate a more potent agonist than glutamate and cysteine sulphinate a weaker agonist than glutamate) in an attempt to discover the nature of the different potencies of agonists. Our results suggest that the agonists gate channels of similar conductance and that the relative potency of an agonist is determined mainly by channel life-time and the probability of receptor activation. (Supported by a grant from the British Science Research Council to P.N.R. Usherwood.)

233.9 Low agonist concentrations reveal complex kinetic behavior of GABA-induced membrane channels in tissue cultured mouse spinal neurons. David A Mathers* and Jeffery L. Barker. Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, Md. 20205

Standard noise analysis procedures were used to study the influence of agonist concentration on the power spectral density of membrane current fluctuations induced by γ-aminobutyric acid (GABA) in tissue cultured mouse spinal cord (SC) neurons.

When GABA concentrations above 25μM were used, we obtained power spectra which were well described by a single time constant (Lorentzian) spectrum of the form $S(f) = S(0)/[1 + (f/f_c)^2]$, where fc is the half-power frequency of the spectrum. This observation is consistant with the view that, at high agonist concentrations, GABA spectra largely reflect the activity of a single population of two-state ionic channels. The lifetimes of these channels are then inferred to be exponentially distributed with mean value $\tau_{GABA} = 1/(2\pi f_c)$. At 23°C, τ_{GABA} = 30 ± 2.2 msec (mean ± S.D.) was calculated. Muscimol, an isoxazole believed to interact with vertebrate GABA receptors, also produced single time constant spectra when applied at concentrations above 25μM. In this case, however τ_{musc} = 76 ± 14.9 msec at 23°C was found.

When low agonist concentrations (1-10μM) were used, GABA spectra frequently deviated from the single Lorentzian form. These spectra were adequately described by the sum of two Lorentzian terms $S(f) = S(0)_s/[1 + (f/f_{cs})^2] + S(0)_f/[1 + (f/f_{cf})^2]$. The corresponding time constants calculated from such two component GABA spectra were $\tau_s = 1/(2\pi f_{cs})$ = 46 ± 8.9 msec and $\tau_f = 1/(2\pi f_{cf})$ = 9 ± 1.6 msec at 20°C (n = 5 cells). Qualitatively similar double Lorentzian spectra were also obtained using muscimol as agonist at concentrations in the range 1-10μM. In this case τ_s = 85 ± 19.6 msec and τ_f = 13 ± 6.4 msec at 20°C were calculated. In the case of both agonists, τ_s and τ_f were not appreciably influenced by membrane potential or by the mean amplitude of the agonist induced current, μ_I. For both agonists, however, the spectral ratio $S(0)_s/S(0)_f$ was found to increase at more positive membrane potentials and with increasing values of μ_I.

The results show that, at low agonist concentration and at negative membrane potentials, an additional fast kinetic process can be detected in the response of the SC cell membrane to GABA and muscimol. It is not yet clear whether this additional process, which is also seen in extracellular patch clamp records (Biophys. J., 33: 14a, 1981), reflects the presence of more than one type of GABA-operated ion channel in the SC cell membrane.

233.10 AN INCREASE IN K^+ CONDUCTANCE PRODUCES THE SLOW IPSP IN BULLFROG SYMPATHETIC GANGLIA. J.P. Horn and J. Dodd*. Dept. of Neurobiology, Harvard Medical School, Boston, MA. 02115.

In the 9th and 10th paravertebral sympathetic ganglia of the bullfrog, the slow IPSP is produced by cholinergic activation of muscarinic receptors on C-type neurons(Dodd & Horn, this volume). We have investigated the ionic mechanism of this synaptic potential by determining the IPSP's dependence upon membrane potential and ion concentration gradients. Conventional balanced bridge recordings were made with a single intracellular microelectrode.

At membrane potentials greater than -65mV, IPSP amplitude varies as a linear function of membrane potential, with a reversal potential near -100mV. However, the IPSP diminishes in amplitude as membrane potential is depolarized from -65mV. This complex behavior appears to be produced by the non-linear I-V relation of C cells. The decrease in IPSP amplitude with depolarization below -65mV always corresponds to a sharp drop in cell input resistance. This suggests that the IPSP is shunted by the non-synaptic membrane when the cell is depolarized beyond -65mV. The synaptic conductance increase implicit in these results was also investigated by passing 0.5 second constant current pulses before and during the IPSP. As expected, there was always a decrease in membrane resistance during the IPSP.

The IPSP reversal potential implies an increase in membrane conductance to K^+ and/or Cl^-. Since use of KCl filled microelectrodes and substitution of extracellular Cl^- by methylsulfate had no detectable effect on the IPSP reversal potential, Cl^- appears not to be involved. When extracellular K^+ was varied, the IPSP reversal potential changed in close agreement with values predicted by the Nernst equation. In summary, our results indicate that the muscarinic IPSP in bullfrog sympathetic neurons is produced by an increase in membrane K^+ conductance. (Supported by NIH grants NS13288 and NS07112 and a Harkness Fellowship to J.D.).

233.11 MONOSYNAPTIC MEDIATION OF THE MUSCARINIC SLOW IPSP IN SYMPATHETIC GANGLIA OF THE BULLFROG: INTRACELLULAR EVIDENCE. J. Dodd* and J.P. Horn (SPON: E. Furshpan). Dept. of Neurobiology, Harvard Medical School, Boston, MA. 02115.

In sympathetic ganglia of many species preganglionic nerve stimulation produces a fast suprathreshold nicotinic EPSP followed by a slow muscarinic IPSP. In the bullfrog there are conflicting hypotheses, based on extracellular recordings, as to the cellular location of the muscarinic receptors responsible for the IPSP. Libet and his coworkers[1] have proposed that the IPSP is produced by muscarinic excitation of catecholamine-releasing interneurons. They suggest that chromaffin-like SIF (small intensely fluorescent) cells are the interneurons. On the other hand, Weight and his colleagues[2] have made observations to the contrary and proposed that acetylcholine activates inhibitory muscarinic receptors located directly on sympathetic neurons. We sought to resolve this issue with intracellular recording.

In the 9th and 10th paravertebral ganglia of the bullfrog there are two types of principle neurons which are identifiable based on the latency and origin of their fast nicotinic inputs. The IPSP occurs only in long latency C-type neurons which are innervated by spinal nerves 7 and 8. Our experiments were done on C cells visualized with Nomarski optics. In confirmation of intracellular studies by others[3], we found that the IPSP was clearly present in normal drug-free preparations. In curare, totally atropine-sensitive IPSPs, of up to 35mV amplitude, were obtained and could be closely mimicked by iontophoresis of acetylcholine onto C cells. The best mimicry was achieved when the iontophoretic pipette was very close to the impaled cell. More important, when synaptic transmission was blocked in low Ca^{++}/high Mg^{++}, the acetylcholine response remained undiminished. These results demonstrate the presence of inhibitory muscarinic receptors on C neurons and indicate that the slow IPSP is monosynaptic. In light of these findings, it would be interesting to do similar experiments on mammalian sympathetic ganglia where the situation remains unclear. (Supported by NIH grants NS13288 and NS07112 and a Harkness Fellowship to J.D.).

233.12 INTEGRATION OF PEPTIDERGIC AND MUSCARINIC SYNAPTIC TRANSMISSION IN AMPHIBIAN SYMPATHETIC GANGLION NEURONS. T. J. Sejnowski and S. W. Kuffler†. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Intracellular recording from paravertebral sympathetic ganglia of the bullfrog has established that in the large B neurons two slow excitatory postsynaptic potentials are produced by stimulating two different nerves: a muscarinic response lasting up to 1 min, which is mediated by acetylcholine, and a noncholinergic response lasting up to 10 min, which is mediated by a peptide resembling luteinizing hormone-releasing hormone (LHRH) (Jan, Jan & Kuffler, Proc. Nat. Acad. Sci. 76: 1501, 1979; 77: 5008, 1980).

Using a single-electrode voltage clamp, we have confirmed previous reports that a conductance decrease occurs in most ganglion cells near the resting potential during the peptidergic response to nerve stimulation or external application of LHRH. However, when a cell was clamped at hyperpolarized potentials, conductance increases often occurred during the response; in these ganglion cells the peak amplitude of the peptidergic current increased with hyperpolarization. Among the cells in which only a decrease in conductance occurred, it was possible in a few cases to reverse the polarity of the peptidergic current at a hyperpolarized potential. More than one mechanism may contribute to the generation of the peptidergic response.

Conductance decreases and conductance increases also occurred during the slow muscarinic responses. In the same cell the muscarinic and peptidergic responses had the same voltage dependence and were accompanied by the same conductance changes.

The similarity between the muscarinic and peptidergic responses, despite their different time courses, suggests that they are produced by similar mechanisms. Their interaction was examined to test whether the mechanisms are shared. When evoked together, their combined currents were generally less than the sum of the individual currents. Furthermore, during a prolonged saturating response to bethanechol, a muscarinic agonist, the response of a cell to LHRH was completely blocked, and conversely, a saturating response to LHRH completely blocked the effect of bethanechol. Since the muscarinic and peptidergic receptors are independently blocked by pharmacological agents, the interaction between the two responses occurs at a stage beyond activation of the receptors.

233.13 VERAPAMIL, A CARDIAC "CALCIUM CHANNEL BLOCKER" PROMOTES DESENSITIZATION OF ACETYLCHOLINE RECEPTORS. ANGELES B. RIBERA* AND WILLIAM L. NASTUK, DEPT. OF PHYSIOL., COLUMBIA U., N.Y.C., 10032

Calcium ion (Ca^{++}) influx increases across the agonist-depolarized post-junctional membrane (PJM). Nastuk and Parsons (J Gen Physiol 56:218, 1970) postulated that desensitization (DS) of the acetylcholine receptor (AChR) at the frog neuromuscular junction involves the intracellular accumulation of Ca^{++}. Thus, blockage of Ca^{++} influx would be expected to inhibit DS. On this basis, we examined the effects of Verapamil (Ver), an antagonist of Ca^{++} channels in cardiac muscle, on DS of the AChR.

DS was assayed by measuring the decline in depolarization of the PJM produced during the repetitive ionophoretic application of carbachol (carb). The standard test was a 1 Hz 45 sec train of 10 msec duration carb pulses. In preliminary investigations with 10 mM Ca^{++} Hepes-Ringer bathing a frog sartorius muscle preparation a 25% DS level was achieved. Contrary to expectations, the addition of 10 µM Ver to the bathing medium increased the DS level substantially. With the Ca^{++} concentration reduced to 1.8 mM the carb train did not produce measurable DS. Under these conditions, following the addition of 10 µM Ver the DS amounted to 40-50% with a $t_{1/2}$ of 2-3 sec. Recovery from DS was 90% completed in 5 sec. 10^{-4} µM Ver did not decrease the mepp amplitude, block nerve evoked neuromuscular transmission or decrease PJM sensitivity as measured by single iontophoretic carb pulses. Apparently AChR activation is necessary for 10 µM Ver to manifest its effects. The $t_{1/2}$ and DS level were not altered by an increase in the iontophoretic current amplitude, but an increase in the current duration to 50 msec led to a decrease in the $t_{1/2}$ to less than 1 sec and an increase in the DS level to 80%. In the range of 1-50 µM Ver these effects were concentration dependent.

Our paradoxical results with Ver can be understood if one assumes that Ver binds to sites exposed during AChR activation and thereby decreases single channel ionic conductances.

234.1 LIGHT-INDUCED VOLTAGE FLUCTUATIONS IN BARNACLE PHOTORECEPTORS, Ehud Kaplan*, A. Mauro* and S. Poitry* (SPON: Frank Brink). The Rockefeller University, N.Y., N.Y. 10021.

In dim light, the membrane potential of many photoreceptors exhibit discrete waves (quantal bumps). These waves are believed to result from single photon absorptions, and summation of them produces the receptor potential. In bright light the mean frequency of the discrete waves increases, but the mean amplitude decreases, thus providing a mechanism for light adaptation.

We studied the lateral eye photoreceptors of the barnacle, Balanus Eburneus, to find out whether they, too, show discrete waves. They did not. Even when the eye was fully dark adapted, we never saw discrete waves. This result confirms the reports by previous investigators (S.R. Shaw, J. Physiol. (1972), 220, 145; A.J. Hudspeth and A.E. Stuart, J. Physiol. (1977), 272, 1; A. Fein, personal communication). However, dim light induced small (<1 mV) fluctuations, which increased with light intensity up to moderate levels. Voltage clamp studies are under way to obtain light-induced current fluctuations, which should yield a spectral analysis uncompromised by the appreciable membrane time constant (≈250 ms.). Meanwhile a spectral analysis of the light-induced voltage fluctuations was made as a first approximation and showed that the frequency components were predominately below 10 Hz. The power spectrum of the fluctuations did not match the frequency response deduced by a Fourier transform analysis of the response to dim flashes, namely, the responses were too slow to account for the spectral density of the voltage noise. This suggests that more than one process is involved in generating the light-induced voltage fluctuations.

234.2 VOLTAGE-ACTIVATED AND CALCIUM-ACTIVATED CURRENTS STUDIED IN SOLITARY ROD INNER-SEGMENTS FROM THE SALAMANDER RETINA. C. R. Bader, D. Bertrand* and E. A. Schwartz*. Dept. de Physiologie, Ecole de Médecine, 1211 Geneve 4, Switzerland and Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637, U.S.A.

Solitary inner-segments of rod-photoreceptors were obtained by the enzymatic dissociation of tiger salamander (Ambystoma tigrinum) retina. Their voltage-dependent currents were studied using the voltage-clamp technique (Bader, MacLeish and Schwartz, 1979, J. Physiol. 296:1-26). These solitary inner-segments were continuously superfused with a medium to which combinations of drugs could be added to selectively isolate individual currents. Five currents were identified: 1) a voltage-dependent K+ current, blocked by tetraethylammonium, with a reversal potential at -72 mV; 2) a current responsible for inward rectification, blocked by extracellular caesium and carried by Na+ and K+, with a reversal potential at -32 mV; 3) a regenerative calcium current, blocked by cobalt, with a null potential at +45 mV; 4) a calcium-activated potassium current, blocked by intracellular EGTA or intracellular caesium; 5) a calcium-activated anionic current, carried in part by chloride, blocked by intracellular EGTA, with a reversal potential at -17 mV. These currents can all be activated in the physiological range of voltage in which vertebrate photoreceptors function.

234.3 VOLTAGE- AND TIME-DEPENDENT SUPPRESSION OF THE LIGHT RESPONSE IN VERTEBRATE RODS. Stuart A. Lipton* (SPON: D.D. Potter). Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Solitary rods from the tiger salamander were dissociated with papain, maintained in culture for several days, and retained their light sensitive properties. Responses in voltage and voltage-clamp were studied prior to and following a hyperpolarizing step that ranged from 50 to 95 mV from the resting potential. Immediately after the step, the light response to a saturating flash was decreased in amplitude but recovered with time. The extent of the decrease seemed to depend on the size of the hyperpolarization and fit the Boltzmann relation; for the largest step, there was no detectable response to light for 0-2 secs. Generally, 30-40 secs were needed for complete recovery of the original response. No decrement of the light response was observed with hyperpolarizations of less than 50 mV from rest or with depolarizing pulses. Concurrent with the depression of the light response after a hyperpolarizing step, most voltage records showed a depolarizing overshoot. In voltage-clamp this was manifest as a depolarizing tail current. This tail current was of similar duration to the decrease in light response and was eliminated by a bright flash.

To decide whether the tail current and the decrease in response amplitude were related to a voltage-sensitive current involved in the light response or to another conductance which was sequentially triggered after photostimulation, TEA, Co, and Cs were used to suppress the voltage-dependent currents of the inner segment (Bader, Bertrand & Schwartz, 1981, Neurosci. absts). Under these conditions and in low Ca^{2+} (MacLeish, Schwartz & Tachibana, 1981, Neurosci. absts), the tail current was blocked by illumination and had a reversal potential between 0 and 10 mV. If the only effect of a hyperpolarizing step were the increased conductance and the tail current, one might see no change or even an increase in the amplitude of the light response during this period (since more channels may be available for blockade). Instead, as described above, smaller light responses were observed. The mechanism for this is unclear; there may be a voltage-dependent desensitization of the channels to blocking particles or a decrease in availability of blocking particles. Because Ca^{2+} has been proposed as the blocking particle, it was of interest to examine its role in these phenomena. When impaled with EGTA-filled electrodes, rods in both normal Ringer's and low Ca^{2+}, TEA, Co, Cs cocktail exhibit little or no tail current or inhibition of the light response following hyperpolarization. Since voltage-dependent suppression does not occur with EGTA, and analysis by the Boltzmann relation predicts that a valency of 2 is associated with the decrement in the light response after hyperpolarization, the data might suggest that Ca^{2+} interacts with the channels responsible for the light response.

234.4 VOLTAGE AND TIME DEPENDENCE OF THE GENERATOR CURRENT IN SOLITARY RODS FROM THE SALAMANDER RETINA. P. R. MacLeish, E. A. Schwartz* and M. Tachibana. Dept. of Neurobiology, Harvard Medical School, Boston MA 02115 and Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago IL 60637.

Solitary rod photoreceptors were obtained by enzymatic dissociation of the tiger salamander (Ambystoma tigrinum) retina. Voltage and time dependent currents that normally flow through the inner segment were suppressed by a mixture of pharmacological agents (Bader, Bertrand and Schwartz, 1981, Neurosci. Abstr.). The current entering the outer segment and controlled by light, the generator current, was studied with the voltage-clamp technique (Bader, MacLeish and Schwartz, 1979, J. Physio. 296, 1-26). When the concentration of extracellular calcium was greater than 2 mM, the generator current was voltage dependent but showed little time dependence as previously reported (Bader, MacLeish and Schwartz, 1979, J. Physiol. 296, 1-26). When, however, the concentration of extracellular calcium was less than 0.1 mM, the generator current was both voltage- and time-dependent. The magnitude of the time-dependent part depended on the holding potential and was greater at -70 mV than at -30 mV for small voltage steps. The current-voltage curve, measured 100 msec after the voltage was stepped from -70 mV to a new value within the physiological range, had a shallow negative resistance region. The entire current reversed polarity between 0 and +5 mV.

In the absence of the above pharmacological agents and in the presence of a concentration of 3 mM external calcium, the time course of the voltage response to a flash differed from that of the current observed in voltage clamp. The difference was attributed to voltage- and time-dependent currents that were not controlled by light (Bader, MacLeish and Schwartz, 1979, J. Physiol. 296:1-26). In the presence of the pharmacological agents that block these voltage- and time-dependent currents and with a concentration of external calcium of 0.1 mM, the time course of the voltage response to a flash also differed from that of the current observed in voltage clamp. In this case, the difference is attributed to the voltage- and time-dependent properties of the generator current that are increased in size when external calcium is lowered in concentration.

234.5 EFFECTS OF D.C. MAGNETIC FIELDS ON VERTEBRATE PHOTORECEPTION
M.S. Raybourn. Rad. Biophy.Grp./L.B.L., Univ. of Calif.,Berkeley, Berkeley, CA. 94720

Recent work has shown that rhodopsin has a finite diamagnetic anisotropy that results in physical orientation of isolated rod outer segments by external d.c. magnetic fields of 1-2 Kgauss. Since bleaching reduces this effect, the summed anisotropy of oriented rhodopsin molecules is a postulated mechanism. The physiological significance of these effects is unknown.

We are using d.c. electromagnetic fields (up to 10K gauss) to study this question electrophysiologically. Extracellular recordings from the in vitro turtle eyecup during exposure to magnetic fields are being used to quantitate any effects. In brief, we are substituting d.c. magnetic fields for background illumination and monitoring the changes in retinal responses and sensitivity in the ERG a-and b-wave intensity-response functions. Both rod-cone (Chelydra) and all-cone (Pseudemys)retinas are being used in order to study any photoreceptor cell differences in magnetic field susceptibility.

Our results so far indicate:(1) external d.c. magnetic fields have a large suppressive effect (25-75%) on the response amplitude of both photoreceptor types to light flashes during exposure; (2) this response compression is not manifest in any subsequent reduction of retinal sensitivity;(3) the phase relationship between the time of exposure and the diurnal light:dark(L:D) cycle is the most important, and surprising, factor in these results; and (4) while our earlier data showed clear response compression at 2.5K gauss and higher, more recent data suffest that this effect is seen as low as 25-50 gauss and saturates around 100 gauss.

These results indicate that external d.c. magnetic fields have a significant effect on vertebrate phototransduction and that very low field strength exposures act, in some unknown way, as if they are shunting the transmembrane current fluxes due to photoisomerization. The central importance of the diurnal L:D cycle implicates a metabolic aspect hitherto unsuspected. Coupled with the low field strength effects and the fact that both rod and cone photoreceptors are affected, this suggest that the diamagnetic anisotropy of rhodopsin is not crucial for these effects. (Supported by the Department of Energy).

234.6 TRACKING VARIABLE WAVEFORM AND AMPLITUDE ACTION POTENTIALS WITH A MICROCOMPUTER SYSTEM BASED UPON A NOVEL ARCHITECTURE.
Robert C. Gesteland and Dennis L. Director*. Northwestern University Evanston, IL 60201.

Extracellularly recorded action potentials from single neurons often have large variations in amplitude and waveform. These variations are prominent in cells with small axon diameters such as olfactory receptors. In such cells the locus of spike origin varies with firing rate and the stimulus often drives the cell to depolarization block. Activity of one cell cannot be separated from that of neighbors with the usual techniques of amplitude selection and derivative analysis (counting phases of the field potential). However, the waveform of the field potential from any particular cell does change in a regular way for successive spikes. Activity of the cell can be tracked if a faithful representation of the waveform is recorded. Film is adequate to the task. However the quantity required and the analysis effort are prodigious. Digital recording of the waveforms of the delayed signal initiated by triggers from an amplitude selector operating on the real time signal is much more efficient. Attempts to use commonly available laboratory computers for this recording task are frustrated by inability to acquire data rapidly enough or by failure to store the data as rapidly as it is acquired. Even a fast machine dedicated to data acquisition may not suffice because transferring acquired data to disc cannot occur while the bus is dedicated to acquisition. Specialized machines can be constructed using dual-ported memory as the acquisition buffer. Not only is this memory expensive, it also must be rigidly tied to the acquisition device. The solution to this problem lies in an innovative architecture. An inexpensive laboratory computer with a dual bus can be used to acquire and store real time data from one or more sources at high sampling rates. We use the DEC LSI-11 microcomputer. The Q bus used for intersystem communication is split into a processor bus and an acquisition bus. An arbiter connected to both decides when to allow information transfer between the two. The A/D converter runs at full speed, the processor runs independently of data acquisition, and the system disc can store the data from the acquisition buffer as quickly as if it were in the system main memory. All commercially available LSI-11 peripherals can be used without modification. The computer configured in this way remains as a general purpose machine in the laboratory and can be used for data analysis, document preparation and other standard computing tasks. This architecture improves throughput by about a decimal order of magnitude.

This work was supported by NSF Grant No. BNS-17479 and NIH Grant No. 5-R01-NS14663.

234.7 SURFACES OF ROD PHOTORECEPTOR DISC MEMBRANES.
Dorothy Roof, Juan Korenbrot, and John Heuser*. Dept. of Biochemistry, University of California, San Francisco, and Dept. of Physiology, Washington University, St. Louis, MO.

The surfaces of disc membranes in rod photoreceptor cells from the toad, Bufo marinus, were exposed by quick freezing, followed by freeze fracture and deep etching. The luminal surface of the disc membrane exhibits a rough texture which appears to be composed of 6 nm. particles tightly packed at a density of about 30,000/um^2. These dimensions suggest that the texture arises from protrusions of the integral membrane protein, rhodopsin, into the intradisc space. The cytoplasmic surface of the disc membrane exhibits a collection of much larger bumps (8-12 nm.) present at about 1/15 the concentration of rhodopsin. These large particles can be removed by washing the membranes in the dark with 0.1 iso-osmotic medium plus EDTA; biochemically this treatment depletes the membranes of GTP binding protein (GBP) leaving cGMP phosphodiesterase (PDE) intact. The large particles can be partially returned to stripped membranes after reconstitution with a GBP-enriched supernatant. In contrast, the density of large particles does not correlate with the presence or absence of PDE. Thus, the large particles probably represent GTP binding protein, one of the major peripheral proteins known to associate with the cytoplasmic surface of discs. In addition, the large particles are missing within a narrow 30 nm. band around the disc rim, and the rims are connected by wisp-like filaments stretching from disc to disc, across disc incisures, and from discs to plasma membrane.

235.1 MOLECULAR MECHANISM OF SWEET TASTE: EVIDENCE FOR THE IMPORTANCE OF HYDROGEN BONDING. S.S. Schiffman. Dept. of Psychiatry, Duke University Medical Center. Durham, N.C. 27710, U.S.A.

Two lines of evidence point to the importance of units capable of intermolecular hydrogen bonding (i.e. AH-B systems) for the sweet taste. First, application of the psychophysical method of cross adaptation revealed that more than one type of receptor site mediates the perception of sweetness. Fourteen stimuli, seven artificial sweeteners varying widely in chemical structure as well as seven sugars, were cross adapted with one another. The best mutual cross-adaptation occurred for stimuli with identical AH-B site types, i.e. acetosulfam and sodium saccharin. In addition, taste detection thresholds for 11 sweeteners varying widely in chemical structure were determined for young and elderly subjects. For both groups, sweeteners with the lowest detection thresholds tended to have the greatest number of units (AH-B systems) capable of intermolecular hydrogen bonding. Use of the method of magnitude estimation with 10 sweeteners revealed that the elderly perceived less growth in intensity with increasing concentration than young subjects. The slopes of the psychophysical functions relating concentration and perceived intensity were flatter in all cases for elderly subjects; the mean ratio, slope(young)/slope(elderly), was 2.06. The largest relative decline in slope was found for those stimuli with the greatest number of possible AH-B types, suggesting that the possibilities for concerted intermolecular hydrogen bonding may decline with age.

235.2 ELECTRO-CHEMICAL STIMULATION OF TASTE. T.C. Pritchard and C. Pfaffmann. Rockefeller Univ., New York, NY 10021

Electrical polarization of the tongue elicits gustatory activity, but its mechanism has been in dispute. On the basis of multi and single unit experiments, Pfaffmann and Pritchard (Olfaction and Taste VII, 1980, 175-178) have proposed that electric taste is the product of an iontophoretic process. Thus, electric taste would be expected to have many properties in common with fluid stimulation of the tongue. The present investigation compares chorda tympani (CT) single unit responses evoked by chemical and electrical stimulation of the tongue.

Single units of the CT were isolated by microdissection in nembutalized golden hamsters. The anterior half of the tongue was drawn into a special flow chamber which permitted either chemical (i.e. fluid) or electrical stimulation. The electrical polarizing current was passed through a .001 M Na saccharin solution which bathed the tongue thereby allowing either Na^+ cations or the saccharin anion to be iontophoresed depending upon the polarity of the current.

The results support the hypothesis that electric taste is a special form of chemical stimulation of the tongue at the current levels employed. Single units which were sensitive only to electrolytes (NaCl or HCl) responded to stimulation by the anode (passing Na^+) but not to that of the cathode (passing saccharin). Other single units exclusively sensitive to sucrose responded to cathodal but not anodal stimulation. Units which responded to both electrolytes and sucrose responded to anode and cathode. Somatosensory units isolated from the lingual nerve unresponsive to gustatory stimulation could not be driven with this electric taste paradigm.

The threshold for cathodal stimulation (.25 $\mu A/cm^2$) is about ten times higher than that observed for the anode. Response latencies for anodal and NaCl stimulation approach 30 ms whereas for cathodal and sucrose stimulation the latencies consistently exceed 300 ms. In general single units which responded to low intensity electrical polarization also responded to fluid stimulation at very weak concentrations. The converse was true for higher threshold fibers.

The striking similarity of electrically and chemically induced gustatory neural activity has already enabled its use as a probe during CNS exploration. Further research will assess the potential of electric taste for studies of neural coding, receptor biophysics and clinical diagnostics.

235.3 THE DISTRIBUTION OF GUSTATORY NERVES WITHIN THE NUCLEUS OF THE SOLITARY TRACT IN RAT. R.B. Hamilton and R. Norgren. The Rockefeller University, 1230 York Avenue, New York, NY 10021.

Gustatory receptors occur in five concentrations in the oral cavity. Fungiform papillae on the anterior tongue are innervated by the chorda tympani nerve (CT). Foliate and circumvallate papillae on the posterior tongue receive gustatory afferent axons via the lingual branch of the glossopharyngeal nerve (LIX). The taste buds on the palate and larynx are innervated by the greater superficial petrosal (GSP) and superior laryngeal nerves (SLX), respectively. These nerves primarily terminate in the nucleus of the solitary tract (NST), however, the relationship of the terminal distributions to one another is not well described. We applied crystals of horseradish peroxidase (HRP) to the cut central end of CT, GSP, LIX, and SLX, as well as to the otic ganglion (OG), the lingual nerve (LV) and the cervical vagus (X). After 60-72 hours survival, the tissue was processed using modified tetramethyl benzidine procedures for visualizing transganglionic anterograde transport of HRP (Kalia & Mesulam, 1980). The distribution of anterior HRP reaction product was as follows. CT terminals first appear just dorsal to the spinal trigeminal nucleus oralis at the level of the genu of the facial nerve, become heaviest in lateral NST 400u caudally, and finally end 1400u after their first appearance. GSP label begins at the level of heaviest CT labeling, becomes most extensive in NST 800u further caudally and finally ends in dorsolateral NST 1600u after it begins. Afferent axons that travel through OG overlap the densest areas of both CT and GSP termination. LIX terminals first appear in lateral NST just rostral to the densest CT label, but fill lateral NST approximately 1000u further caudally. Caudal to this level LIX terminals in lateral NST diminish rapidly, but small neurons clustered within the tract and in the dorsal third of medial NST remain heavily labeled. SLX terminates sparsely in lateral NST at levels where LIX label is heaviest. SLX label only becomes heavy, however, over the densely packed neurons situated within the caudal solitary tract. Label from X axons appears very sparsely in the caudal half of lateral NST, but becomes very dense in the medial division just rostral to the obex, filling the commissural nucleus on both sides. Axons from LV terminate in nucleus oralis just lateral to the CT distribution in NST and hugs its lateral edge until the roots of X reach the nucleus. At this level many LV axons invade lateral NST and terminate extensively just rostral to obex. A few terminals reach the dorsal third of medial NST in the same area innervated by LIX axons. Axons innervating gustatory receptors in the anterior tongue (CT) and palate (GSP) overlap considerably in rostral NST. Those innervating the posterior tongue (LIX) and larynx (SLX) terminate caudally and do not overlap substantially.Supported by NSF BNS80-06444/NIH NS01050

235.4 EARLY EVENTS IN THE FORMATION OF OLFACTORY AXONS. Albert I. Farbman, Richard E. Heller and Diane Scholz.* Department of Anatomy, Northwestern University, Chicago, Illinois 60611.

During differentiation of olfactory receptor cells, the proximal cellular processes which become the axons must penetrate the barrier of the epithelial basement lamina as they grow toward the presumptive olfactory bulb. This morphological study, using Golgi impregnation and transmission electron microscopy, considered the following questions: 1) which cells are involved in enabling the growing receptor cell axons to penetrate the basement lamina? 2) what is the origin of olfactory nerve Schwann cells? Olfactory mucosa from fetal rats on days E15, E16 and E17 (E1 = day when mother is sperm positive) were studied. Golgi material reveals that before the receptor cell's proximal process leaves the epithelial compartment, it forms a triangular, foot-like extension, the base of which lies on the basement lamina and the apex is directed toward the perikaryon. Electron micrographs of these foot processes show that in their early stage they contain abundant free ribosomes and a moderate amount of dense filamentous substance. Later, the number of ribosomes is significantly diminished and an increased amount of filamentous material imparts an electron density to the cytoplasm. Those proximal processes which have penetrated the basement lamina are uniformly narrow (0.1 - 0.3 μm in diameter), contain axially oriented microtubules and significantly less filamentous substance than the foot processes. Golgi preparations show these axons to be narrow with few varicosities. Axons first reach the ventral aspect of the presumptive bulb on day E15. Islands of cartilage, the precursor of the cribriform plate, first appear between bundles of axons on day E16. Schwann cell processes accompanying olfactory axons have been seen as continuous cytoplasmic strands crossing from the epithelial compartment into the lamina propria. Pericytes and endothelial cells of blood vessels in the region of the basement lamina send cytoplasmic processes into the epithelial compartment. It is tentatively concluded that 1) both epithelial and connective tissue elements contribute to the alteration of the basement lamina, thus enabling the olfactory axon to exit from the epithelial compartment; 2) Schwann cells originate in the olfactory epithelium and accompany the growing axons as they leave the epithelium.

235.5 CONNECTIONS OF THE MAIN OLFACTORY BULB (MOB) IN MICE. G.D. Adamek & M.T. Shipley. Graduate Program in Neuroscience, Northwestern University, Evanston, IL 60201 and Department of Cell Biology & Anatomy, Northwestern Univ. Medical School, Chicago, IL 60611.

The odor of a strange conspecific male causes pregnant mice to abort. Although this effect depends upon the olfactory system, the central connections of the mouse olfactory bulb have never been systematically studied. Thus it is unclear whether this salient, odor-dependent reaction is reflected in this species' neural circuitry. We have determined the connections of the MOB using antero- and retrograde labeling with 1-2% wheat germ agglutinin-HRP injections confined to the MOB in BALB-C mice.

Efferents: The MOB projects ipsilaterally to the accessory olfactory nucleus (AON), the ventral and dorsal portion of the hippocampal rudiment (V and DHR), the entire extent of the piriform cortex (PC) and olfactory tubercle (OT), the anterior cortical (ACo) and posterolateral cortical (PLCo) amygdaloid nuclei, parts of the lateral entorhinal cortex (LEC) and the nucleus of the lateral olfactory tract (nLOT). The projection to the PC extends dorsally into the insular cortex. A projection to the contralateral AON was observed. Afferents: Neurons projecting to the MOB were found ipsilaterally in all divisions of the AON except the external, the VHR, all the PC, part of LEC, nLOT, vertical and horizontal limbs of the diagonal band, preoptic area, several sub- and hypothalamic areas, 3 raphe nuclei and the locus coeruleus (LC). A few labeled cells were seen in the hippocampal formation. All divisions of the contralateral AON project to the MOB.

The pattern of MOB connections in the mouse is similar to that of several other species but the hypothalamic, LC and raphe inputs to the mouse MOB appear to be more prominent than in the rat (de Olmos et al, J.C.N. 1978) and hamster (Davis et al, Br. Res. Bull. 1979); subthalamic inputs to the bulb have not been described in any species. The connections of MOB in the rat and mouse are more extensive than those reported for the hamster (Davis et al, op cit). These may represent species differences or the fact that relatively large MOB injections are needed to demonstrate certain circuits. Injections in AON rule out large MOB injections that may lead to ambiguity in the MOB connections reported here.

Studies of the accessory olfactory bulb and the AON are underway to determine if the mouse's central olfactory pathways differ from those species that do not exhibit odor-dependent abortion. Potential differences between male and female mice will also be examined to see if the pregnancy blocking effect has a demonstrable anatomical basis.

235.6 ARE THE OLFACTORY BULB EFFERENT AXONS TOPOGRAPHICALLY ORGANIZED? William S. Seibly*, George Maeda*, and T. J. Willey. Dept. of Physiology, Loma Linda Univ., Loma Linda, CA 92350.

Olfactory bulb efferents in the cat pass caudally over the prepyriform cortex in a broad fiber sheet called the Lateral Olfactory Tract (LOT). The LOT can be visually traced to the periamygdaloid cortex where the bundle of fibers becomes narrow and compact. Near the bulb the LOT circumferentially bounds the olfactory peduncle. A multielectrode monitoring array with equi-spaced probes at one mm intervals was constructed. The array was built to conform to the curved surface and geometry of the prepyriform cortex including the surface projecting pathway of the LOT. Stimulating electrodes were positioned in the olfactory bulb to straddle the mitral cell layer and to activate dorsal, lateral, ventral and medial bulbar aspects. Action potentials were recorded from the array as they propagated past each electrode and computer processed by averaging. Surface contour maps and potential profiles were developed to test the hypothesis for topographical representation of mitral cell projections in the LOT. The potentials were spatially represented for each sampling interval (35 μ sec) for the entire conducted action potentials. Antidromic conduction conditions were achieved by stimulating on the multi-electrode matrix and recording from a fixed electrode across the mitral cell dipole in the olfactory bulb. Conduction velocities and spatial and temporal dispersions were also computed from these data.

The velocity of nerve impulses decreased by 50% between the rostral to caudal aspects of the LOT. Velocities ranged from 20 m/sec at the peduncle to about 10 m/sec at the posterior cortex. Computed "hot-line" trajectories for the axis of bulbar projection reveal orderly topographic relationships at the peduncle. By mid cortex or about 5 mm posteriorly this projection is diffuse. These findings support the anatomical data of Price and Sprich (1975) and Devor (1976) showing the LOT as a flattened representation of the bulb with considerable intermingling of the axons originating in the dorsal and ventral. Sensory template analysis disputes the need for neural images from bulb to cortex to be precisely topographically organized in contrast to other sensory systems.

235.7 GUSTATORY SPECIFICITY OF PREABSORPTIVE INSULIN SECRETION. Kent Berridge* and Harvey J. Grill (SPON: L. Hurvich). Dept. Psychol. and Inst. Neurol. Sci., U. Pennsylvania, Phila., Pa. 19104.

Preabsorptive insulin release (PIR) occurs prior to enteric absorption when palatable nutrients are taken or infused into the mouth. While both the palatability and the caloric significance of tastes have been shown to be important in the elicitation of this neuroendocrine reflex, the characteristics of the adequate stimulus for the PIR remains unknown. This study examined the ability of a wide variety of novel palatable nutrients and nonnutritive substances to elicit a PIR. Nine sugars and sugar alcohols (glucose, fructose, sucrose, maltose, galactose, mannose, sorbitol and glycerol: all .8 M; lactose: .5 M), 6 amino acids (L-phenylalanine, L-arginine, L-leucine, L-lysine, L-proline, L-tyrosine: .05 M), two oils (sunflower and mineral), a complex nutrient (fresh rat milk), and Na saccharin (.007 M) were tested. In addition, the sensitivity of the PIR to taste concentration was examined in a study of 4 concentrations of glucose (.17, .125, .55, 2.76 M). Each experiment tested the PIRs of 5 rats to 4 novel tastes. One taste was always .8 M glucose, which served as a comparison standard. Each rat received one taste presentation per day, and received all 4 tastes in counterbalanced order. No rat was used in more than 1 experiment, and each experiment was replicated 1-3 times. Procedure: 5 male rats were implanted with oral and jugular cannulae 1 day prior to testing. Test: 4 h food-deprived rats were habituated to the test chamber and a 200 ul jugular blood sample was taken. One ml of a novel taste solution was infused into the mouth over 1 min, and consummatory responses and quantity ingested were recorded. Blood samples were taken each min for the first 5 min, and every other min for the next 4 (Berridge, Grill, & Norgren, 1981). Blood samples were centrifuged, and the plasma radioimmunoassayed for insulin and assayed for glucose. We found that: a) sugars and sugar alcohols were far stronger PIR elicitors than the other tested substances, b) the ability of sugars and sugar alcohols to elicit a PIR was unequal (equimolar glucose, maltose, & glycerol elicited high amplitude PIRs (.7 - 1 ng/ml), sucrose & sorbitol elicited intermediate responses (.4 - .6 ng/ml), and fructose, mannose, lactose, & galactose produced little or no PIR), and c) the PIR magnitude was correlated with stimulus concentration. These differences occurred in spite of the very similar consummatory responses evoked by the different tastes. These and earlier data suggest that neither the palatability nor actual nutrient value of a taste stimulus predicts PIR magnitude. Rather, some complex and as yet unspecified property of gustatory afferent stimulation determines the amplitude of the PIR. 236.1 VISUAL ACUITY DEFICITS IN GOLDFISH WITH COMPRESSED RETINOTECTAL PROJECTION: COMPARISON OF HORIZONTAL AND VERTICAL GRATINGS. Dean Yager and Martha Romeskie. State University of New York, College of Optometry, New York, New York 10010.

Visual acuity for vertical and horizontal square-wave gratings was measured by a technique of conditioned suppression of respiration. Normal baselines were established for the two eyes separately; acuity was better for vertical gratings than for horizontal gratings. Next, one optic nerve was crushed in the orbit, and the contralateral caudal half-tectum was ablated. Sensitivity to light in the operated eye-tectum pair returned within 3-4 weeks following surgery. Acuity was less than 0.5 cycle per degree until about three months later, at which time there was a rapid increase in acuity.

Acuity for vertical gratings did not return to normal values; there was a permanent deficit, confirming results which have been reported earlier. For horizontal gratings, acuity for the operated eye-tectum pair also failed to return to normal. These results are consistent with the notion that compression of the retinotectal projection in the rostro-caudal tectal axis produces receptive fields of post-sysnaptic tectal cells that are expanded in both the temporal-nasal and superior-inferior directions of the visual field. In addition, post-synaptic tectal recording should reveal a greater sensitivity to vertically-oriented stimuli than to horizontally-oriented stimuli in normal as well as in compressed-projection fish.

236.2 GRADIENTS OF SYNAPTOGENESIS AND CELLULAR MATURATION IN THE PRIMATE SUPERIOR COLLICULUS DO NOT CORRESPOND TO GRADIENTS OF NEURONAL GENERATION. M.L. Cooper and P. Rakic, Sect. Neuroanatomy, Yale University School of Medicine, New Haven, Ct. 06510

The timing of cell origin and order of neuronal settling have been frequently suggested as determinants of the sequence of cell maturation and of neuronal connectivity. To test this hypothesis in the rhesus monkey, we analyzed spatial gradients of cellular maturation, including synaptogenesis, in the superficial grey layer (SGS) of the superior colliculus (SC) at various embryonic (E) ages. At E47, most neurons destined for the developing superficial layers have been generated and have attained their final relative positions (Cooper & Rakic, Neurosci. Abstr., '80). These cells are contained in a uniform band of small, darkly Nissl-stained neurons situated at the outer edge of the SC. By E54, the superficial band is no longer uniform in appearance across its mediolateral (ML) or anteroposterior extents.Rather, superficial cells in the middle of the rostral pole of the SC are considerably larger and stain paler than the more medially or laterally located cells.This sharp middle-peripheral difference in cell staining becomes progressively less pronounced at more caudal levels of the SC. Such dissimilarities in Nissl-staining characteristics are also evident at E61, but have largely disappeared by midgestation (E83). The presence of regional differences in the tempo of SGS maturation was confirmed and amplified by quantitative EM analysis in E54 and E61 specimens. We made probes consisting of overlapping electron micrographs through the outer 200μ (the approximate thickness of the SGS at these ages) of the medial, middle, and lateral regions of the SC at each of three coronal levels. Point-counting of EM montages through the medial and lateral portions of the anterior SC revealed consistently greater amounts of extracellular space than were present in the middle region. The amount of neuropil (the cross-sectional area excluding extracellular space, somata, radial glia and blood vessels) was smaller medially and laterally than in the middle, as were the densities of synapses, both in terms of synapses/μ^2 of total cross-sectional area and synapses/μ^2 of neuropil alone. (The synaptic density is fairly constant across the ML extent of the adult anterior SGS.) These differences in synaptic density and neuropil development were no longer evident at the most posterior coronal level. Thus, although our previous ^{3}H-thymidine studies (Cooper & Rakic, '80) showed no significant ML variation in the time of neuron origin in the superficial SC, the middle region begins to mature much earlier than the more medial or lateral areas. This finding demonstrates that in the primate, SC gradients of neuronal maturation (as defined by synaptogenesis,development of neuropil and light microscopic appearance) do not correspond to those of cellular proliferation. (Supported by EY-02593).

236.3 ALTERED INDIVIDUAL TERMINAL ARBORS IN COMPRESSED PROJECTIONS TO THE SUPERIOR COLLICULUS. George M. Sachs* and Gerald E. Schneider (SPON: R. Held), Dept. Psychology, M.I.T., Cambridge, MA 02139.

After ablation of a caudal portion of the superior colliculus (SC) in newborn hamsters, projections from the contralateral retina compress onto the remaining portion of the SC (Jhaveri and Schneider,'74, Anat. Rec., 178,383; Finlay,et al.,'79,Nature, 280,153). By visualizing single axons in these compressed projections, we investigated alterations in their terminal arborizations.

Small amounts of HRP were injected into the optic tract of normal adult hamsters and hamsters that had undergone caudal tectum ablations at birth. Parasagittal sections were reacted with a DAB procedure. Individual HRP-filled axons were traced into the SC and their arborizations were charted with the aid of a drawing tube. We focused our analysis on a type of axon which forms dense arbors in the upper portion of the stratum griseum superficiale. Previous work has indicated that such axons originate in the contralateral retina. In normal animals, fibers of this type show terminal arbors of consistent dimensions, extending 90-150 μm in the rostrocaudal axis. After the early caudal tectum lesions, arbors of such axons showed significant reduction in their rostrocaudal extent. Occasionally, axons in early lesioned animals showed bizarre trajectories. Some fibers extended caudally into the SC only to loop back in an abrupt 180°turn and course rostrally, leaving the SC through the optic tract. Their ultimate termination could not be traced because of dark reaction product from the injection site. In the SC, these looping fibers sent out a thin collateral which distributed a small number of terminals in either stratum griseum superficiale or stratum opticum.

Udin and Schneider (Exp. Br. Res., in press) have found a reduction in the number of retinal ganglion cells participating in compressed retinotectal projections. The results of the present study show that compression also involves a reduction in the extent of individual terminal arbors, for at least some retinotectal axons. It is likely that removal of tectal tissue increases competition for terminal space, and that this heightened interaxonal competition serves to decrease the size of arborizations. Fibers with drastically reduced terminal arbors may be sustained by abnormal terminations in the diencephalon.

(Supported by NIH grant EY 00126)

236.4 WIDESPREAD BRANCHING OF RETINOTECTAL AXONS: TRANSIENT IN NORMAL DEVELOPMENT AND ANOMALOUS IN ADULTS WITH NEONATAL LESIONS. G.E. Schneider, L. Rava*, G.M. Sachs*, and S. Jhaveri*[1], Dept. of Psychology, M.I.T., Cambridge, MA 02139.

Brains of Syrian hamsters, aged 0-21 days postnatal, were prepared with Rapid Golgi methods and cut sagittally. Immature axons of the optic fiber layer of the superior colliculus (SC) were found to pass through a stage of multiple, widespread branching before the several types of single, dense terminal arbors characteristic of the adult (Sachs and Schneider, Soc. Neurosci. abstracts, 1980) became recognizable. Axons with widespread branching patterns first became prominent in 3-day-old animals.

Single axons in adult animals which had been subjected to partial tectal lesions on the first or second postnatal day were visualized by an HRP-filling technique (Ibid.). In cases of rostral- or mid-tectal damage, examples of axons with two distinct, widely separated end-arbors were found. Each of these arbors was smaller than most arbors found in similar studies of normal adult hamsters. In cases of early unilateral lesions of superficial tectal layers with simultaneous early removal of the ipsilateral eye, individual axons entering the damaged SC were followed across the midline to the intact superficial gray layer. A series of examples of such axons revealed multiple branching patterns with distinct, abnormally small end-arbors.

The single-axon descriptions fit studies of retinotectal topography in similar cases with early tectal lesions. In these studies, small retinal lesions were made in the adult to elicit anterograde degeneration, which was traced with the Fink-Heimer technique. Results showed that axons from single regions of the retina, if deflected from their normal trajectories, often terminated in one or more small patches in addition to a larger patch in the tectal region expected from electrophysiological mapping studies (Finlay et al.'79: JCN 183,721; Nature 280,153).

We conclude that during normal development, multiple widespread branches of single optic-tract axons within the superficial tectal layers progressively lose all branches except those forming a single terminal cluster. This process can be disrupted by neonatal lesions so that more than one cluster of terminals can persist into adulthood. The normal narrowing of the end-arbor may be influenced by competitive interactions which are altered after the early lesions. However, when multiple end-arbors form, the total number of terminals does not appear to be appreciably expanded; thus, each end-arbor is abnormally small.

236.5 RELATIONSHIP BETWEEN DEVELOPING OPTIC AXONS AND THEIR TARGET CELLS IN THE SUPERFICIAL SUPERIOR COLLICULUS OF THE MOUSE. M.A. Edwards,G.E.Schneider, and V.S. Caviness, Jr. MIT, Cambridge, MA and E.K. Shriver Center, Waltham, MA (Sponsor:Roger Williams)

The earliest afferent axons from the retina to the superior colliculus of the rodent are largely concentrated at the surface (rat: Lund and Bunt,1976; hamster:Frost,So and Schneider,1978). In the adult animal optic fibers travel primarily within the stratum opticum (SO),deep to the surface,and arborize among their target cells in the overlying suficial gray stratum (SGS). We examined this developmental change in the mouse by determining:(1) the time of origin and migration of superficial collicular neurons with H^3-thymidine autoradiography,(2) their state of differentiation with Golgi impregnations, and (3) the time of arrival and distribution of retinal afferents with anterograde HRP labelling after eye injection in utero and silver impregnation of normal fibers.

Most cells of the colliculus become postmitotic on embryonic days E11 through E13. Although the cells generated on these days overlap in their final distribution within the upper collicular layers, cells labelled on E11 predominate near the surface of SGS.Relative positions of these two cohorts become set by E15, suggesting that the majority of the E11 and E13 cohorts have completed their migrations by this time.Golgi impregnations of neurons within the outer 100 μm of the colliculus at E15-17 reveal a rapid growth and differentiation of dendrites and axons which is consistent with the autoradiographic findings.Within the same period the early retinal projection is composed of axon fascicles concentrated at the collicular surface, although more widespread fiber bundles course through the subjacent cell populations to a depth of 80-100μm.From E17 to birth(P-0=E19) the rostrocaudally coursing bundles of optic fibers become more evenly distributed through a depth of 120 um,without a surface concentration.Thereafter the superficial gray layer appears as a fiber-sparse zone above the longitudinal fiber fascicles, progressively widening to a nearly adult thickness by the time of eye opening(P-13).

The observed sequence of events suggests that the earliest optic fiber fascicles concentrated at the collicular surface are lost by degeneration and/or dispersion in the course of neuropil development in the perinatal period.The lower level of the band of optic fiber fascicles present from E15 to PO presumably marks the level at which the definitive stratum opticum develops by continued ingress of optic fibers, while cells above this level,although largely fixed in their post-migratory positions,form the SGS by a protracted period of expansion by differentiation. *NEI Postdoctoral Fellowship

236.6 OPTOKINETIC NYSTAGMUS IN LONG-TERM MONOCULARLY DEPRIVED CATS. R. Malach*, N.P. Strong* and R.C. Van Sluyters. School of Optometry, University of California, Berkeley, CA 94720.

Prolonged monocular deprivation (MD) is known to cause substantial functional disconnection of cortical visual pathways, but whether it also exerts a direct effect on subcortical visual function remains unclear. We feel the optokinetic nystagmus (OKN) system of the cat can serve as a behavioral model for studying the relative effects of MD on cortical and subcortical pathways, since both are involved in mediating this reflex in the cat.

Cats were monocularly deprived from eye opening to about one year of age and then the deprived eye was opened for OKN testing. OKN was elicited by rotating a large patterned drum around the cat at various velocities while monitoring eye movements with the search coil technique.

The gain of the monocular OKN reflex was severely reduced when stimuli were presented through the deprived eye. This deficit was most pronounced at higher drum velocities. While some OKN response remained when the stimulus to the deprived eye moved in a nasalward direction (N-OKN), the reflex was almost totally abolished for stimuli moved in a temporalward direction (T-OKN), where occasionally even a reverse-OKN was elicited. OKN through the non-deprived eye was strikingly more vigorous (with gains close to one at low velocities), although here too the gain of the T-OKN response was usually lower than that of the N-OKN.

The results of this study, and others in normal and lesioned cats, will be discussed in terms of the effects of MD on the subcortical pathways mediating OKN in the cat.

237.1 AUTORADIOGRAPHIC, HRP AND BEHAVIORAL DATA SUGGEST THAT N.R. MAGNOCELLULARIS MODULATES PAIN WHILE N.R. GIGANTOCELLULARIS CONTROLS POSTURE AND LOCOMOTION. Lee-Ming Kow, Donald W. Pfaff and Frank P. Zemlan. The Rockefeller University, N.Y., N.Y. 10021 and Department of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

HRP application to unilaterally transected lateral or ventral column fibers at C_2 or T_{10} in the rat indicated that an extensive group of N.r. magnocellularis (nmc) neurons projected primarily through the lateral columns to caudal spinal levels. After microiortophoretic deposit of ^{3}H-amino acids (aa's) to nmc, labeled fibers were observed to project to the lateral reticular nucleus, hypoglosal nucleus, dorsal motor nucleus of the vagus, and raphe pallidus. The majority of labeled fibers coursed caudally through the lateral columns to the dorsal aspect of the dorsal horn, the lateral aspect of laminae V, VI and VII, and X through lumbar levels.

A large bilateral group of HRP labeled cells was observed in n.r. gigantocellularis (ngc) after transection and enzyme application to the ventral columns at C_2. After microiontophoretic deposit of ^{3}H-aa's in the rostral aspect of ngc, labeled fibers were observed to project laterally to the lrn, the facial nucleus, and contralateral ngc. Caudally, labeled fibers formed facicles in the MLF, ultimately joined the spinal ventral columns to project to laminae VII, VIII and X, through cervical levels.

Bilateral electrolytic lesions were placed at the caudal extent of nmc. Significant analgesia was observed during the first 2 postoperative weeks as indicated by increased response latencies to thermal stimulation and increased pressure thresholds for eliciting vocalization. Bilateral electrolytic lesions were also placed in ngc + nmc. In addition to the analgesic effect observed after nmc only lesions, a time dependent motor syndrome was observed postoperatively. Initially, posture and locomotion were characterized by limb hyperextension followed by a second phase where locomation was characterized by alternate hyperextension and hyperflexion of the limbs. The rapid balistic movements indicated that the effect of the lesion may have been due to altered gamma-loop activiy in both extensor and flexor muscle groups.

The anatomical and functional data taken together suggest that spinal lateral column fibers (nmc) are concerned with the modulation of sensory activity, particularly nociception; while ventral column projections (ngc) are more concerned with motor function.

237.2 THE EXTENT AND NUMBER OF MEDIAL MEDULLARY NEURONS SUFFICIENT TO INHIBIT TAIL-FLICK IN RATS. I.D. Hentall, G. Zorman and H.L. Fields. Depts. Neurol., Neurosurg., Univ. Calif., San Francisco, San Francisco, CA 94143

We showed previously that 8 μA, 200 μsec, 50 Hz, monopolar stimuli in the rat's nucleus raphe magnus (NRM) will inhibit tail flick to noxious heat. The average radius of suprathreshold current spread and the number of excited neurons is estimated here.

Microelectrodes placed in the medial medulla for concurrent extracellular stimulation and recording of single cells consisted of Pt-plated stainless steel. Their impedances were about 500 kΩ at 1KHz. With the amplifier input AC-coupled, artefact from the 0-10 μA, 200 μsec pulses subsided in 1.5 msec. Cell excitation was detected by collision with an antidromic spike, which was activated by electrodes on the dorsolateral funiculus; thus all tested neurons were medullospinal in their projections. A prolonged ability to "follow" at 100 Hz was used to indicate direct excitation; indirect excitation rarely appeared. For each cell, thresholds (I_t) and peak-to-peak spike heights (V) were found at different depths. Ferric ions were deposited by current for anatomical localization.

All 29 cells fitted $I_t=K_2r^2$ ($P<0.05$), with the radial distance to the initiation zone (r) and constant K_2 determined by 2nd order regression. The equation $I_t=K_1r$ fitted a few cells better, but most far worse. The analogous constant of spike spread ($1/V=C_2r^2$) increased with K_2, suggesting extracellular conductance affects these constants. Also, conduction velocity and K_2 appeared inversely related, implying a role for cell size. The successful square law must approximate a more complicated equation; the soma's extracellular current flow vector being constant at threshold under this law is probably irrelevant. A more complicated relationship, involving integration of voltage in the somato-dendritic region, was explored with some success; lack of space here prevents its description.

NRM cell density found by standard nuclei-counting was 4560 per mm^3. Applying the square law, for the average cell the suprathreshold current spread with an 8 μA stimulus is 126 microns. This is well within the NRM, whose smallest dimension is 1 mm. Assuming like-distributed sample and population K_2 values, the number of stimulated cells is 61. Available anatomical evidence suggests only 5% of these are the behaviorally relevant ones which contain serotonin or enkephalin and project to lumbar cord. Hence only 3 medullospinal neurons at most are required to prime analgesia circuitry. Neuronal redundancy or, more likely, multifunctional overlap, must be high, since all NRM sites suppress tail-flick equally well.

237.3 CROSS TOLERANCE BETWEEN TWO BRAINSTEM SITES SUPPORTING, STIMULATION-PRODUCED ANALGESIA. B.E. Thorn-Gray, R.M. Ashbrook* and M.H. Johnson* Dept. of Psychology, The Ohio State University, Columbus, Ohio 43210.

Electrical stimulation of the periaqueductal gray (PAG) produces inhibition of pain response to a number of noxious stimuli with a variety of species. Research investigating the neural/chemical substrate of stimulation-produced analgesia (SPA) has raised questions as to whether SPA is mediated by the endogenous opiate system (at least part of which purported to the pain inhibitory in function).

As a preliminary step in investigating the neural substrate of SPA, our lab has been interested in whether cross-tolerance can be demonstrated between neural areas supporting SPA. If the effect is more electrode-locus-specific, rather than anatomical-system-specific, we would not expect cross-tolerance between areas.

Thirty rats were implanted with two bipolar stimulating electrodes (either two PAG loci or one PAG and one dorsal raphe magnus-DRM). Stimulation consisted of biphasic rectangular wave pulse pairs of 1 msec. with 100 μsec. pauses in between pairs. Stimulation intensity ranged between 40 μA - 250 μA depending upon site and variability within the animal. Sites of initial stimulation were counterbalanced. Tail flick latencies were taken both during and immediately after stimulation. After one week recovery, stimulation was given in the second area (method identical to the first). After an additional week recovery, animals were given repeated stimulations (between 10-20 series) until tolerance to the analgesia had occurred. Immediately following demonstration of SPA tolerance in the area given repeated stimulation, animals were stimulated in the second site and observed for TF latencies to determine whether tolerance spreads across areas or remains localized in the area of stimulation.

When compared to implanted sham-stimulated controls, and when compared to their own pre-stimulation baseline (baseline $\bar{x}$ = 3.1 sec.) animals with two PAG implants showed significant analgesia in both sites, both during and immediately after stimulation (Site 1 $\bar{x}$ on = 5.7 sec; $\bar{x}$ off = 6.0 sec; Site 2 $\bar{x}$ on = 6.8 sec; $\bar{x}$ off = 4.7 sec). On test day three, significant cross tolerance was achieved between sites 1 and 2 ($\bar{x}$ baseline = 3.3; pre-tolerance analgesia: $\bar{x}$ on = 7.9, $\bar{x}$ off = 5.4; tolerance (site 1): $\bar{x}$ on = 2.7, $\bar{x}$ off = 1.8; $\bar{x}$ tolerance (site 2): $\bar{x}$ on = 4.4, $\bar{x}$ off = 3.4). Preliminary evidence indicates that cross tolerance is also demonstrable between PAG and DRM sites. The above evidence suggests a neuroanatomical system mediation of stimulation produced analgesia.

237.4 MEDIAL THALAMIC LESIONS REDUCE THE AVERSION-GATING ACTION BUT NOT THE REWARD OF LATERAL HYPOTHALAMIC STIMULATION. K. D. CARR, K. A. BONNET* and E. J. SIMON. Depts. of Psychiatry and Pharmacology, New York Univ. Med. Ctr., New York 10016.

As reported previously (Carr and Coons, Brain Research, in press) lateral hypothalamic stimulation has an aversion-gating action which is correlated with, but dissociable from, self-stimulation reward elicited through the same electrodes. Rats that lever-press to escape electrical stimulation of medullary nucleus reticularis gigantocellularis (NGC) respond less when sub-reward-threshold pulses to the lateral hypothalamus (LH) are paired with those to NGC. If NGC stimulation is made inescapable, these rats lever-press at high rates to obtain trains of LH pulses of the same amplitude as had inhibited escape. This lever-pressing behavior (for low intensity LH trains during aversive NGC stimulation) is not inhibited by gastric loading although classical self-stimulation (for higher intensity LH trains in the absence of NGC stimulation) is inhibited.

To investigate further the aversion-gating phenomenon and its relationship to self-stimulation reward, rats were implanted with monopolar stimulating electrodes in both the LH and NGC. In addition, electrodes to be used for making electrolytic lesions were implanted bilaterally in the medial/intralaminar thalamus. During each daily test session, threshold currents were determined for: (i) elicitation of a criterion rate of 12 (or more) lever-presses per minute to obtain 2-sec 25 pps trains of LH stimulation, (ii) elicitation of a criterion rate of 12 (or more) lever-presses per minute to obtain 2-sec escapes from 25 pps stimulation of NGC, and (iii) experimenter-delivered LH pulses which when paired with pulses in the NGC train would reduce escape lever-pressing from the former criterion rate of 12 (or more) to 8 (or less). Following a period of training and threshold stabilization, data were collected over four consecutive daily sessions. All animals were then anesthetized but only some received bilateral thalamic lesions. The next four consecutive days of testing revealed that the ability of LH stimulation to inhibit NGC-escape is impaired (i.e. thresholds in test (iii) increase) by medial/intralaminar thalamic lesions although self-stimulation reward (through the same LH electrodes) is unaltered. These results indicate that the aversion-gating triggered by stimulation of an appetitive behavioral system in the LH is indeed a separate function from appetitive reward and is mediated, at least in part, by a medial/intralaminar thalamic integrator.

237.5 ROLE OF THE ADRENAL MEDULLA IN OPIOID STRESS ANALGESIA. J. W. Lewis, M. G. Tordoff, J. E. Sherman* and J. C. Liebeskind. Dept. of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

The analgesic response to prolonged footshock stress appears to be mediated by opioid peptides, whereas that following brief footshock stress is nonopioid (Lewis et al., 1980). Hypophysectomy attenuates the opioid but not the nonopioid form of stress analgesia. While suggesting a role for pituitary opioids, these results may also be due to secondary changes in hormone deprived target glands. Therefore, we investigated the role of the adrenal in both forms of stress analgesia.

Two weeks after either adrenalectomy (ADX), adrenal demedullation (MDX), adrenal medullary denervation by celiac ganglionectomy (CGX), or sham surgery, rats were tested for baseline pain sensitivity and for analgesia to either prolonged (2.5 mA, 1 sec shock/5 sec, for 20 min) or brief (2.5 mA, continuously for 3 min) stress using the tail-flick test. All rats received both stresses in counterbalanced fashion.

ADX, MDX, and CGX antagonized opioid ($p < .01$, compared to shams), but not nonopioid, stress analgesia. MDX and CGX were as effective as ADX. None of these manipulations affected baseline response latencies. RIA indicated that ADX, but not MDX or sham surgery, reduced serum corticosterone. Thus, MDX appeared not to impair adrenocortical function. These results suggest an important role for the adrenal medulla, but not adrenal cortex, in opioid stress analgesia.

Stimulation of adrenal medulla releases both catecholamines and enkephalin-like peptides. To determine which of these may be critical to stress analgesia, rats were tested for analgesia to prolonged stress 24 hr after the last of two daily injections of reserpine (2 mg/kg). This drug regime is known to deplete catecholamine and increase enkephalin-like peptide concentrations in the adrenal (Viveros et al., 1980). Reserpine treated animals displayed significantly enhanced analgesia ($p < .01$, compared to saline controls). This enhancement appears to be mediated by opioids since naltrexone (3 mg/kg) blocked opioid stress analgesia as profoundly in reserpine treated as in saline treated animals.

While not precluding the participation of opioids of brain and pituitary origin, these findings strongly suggest that enkephalin-like peptides, released from the adrenal medulla, are critically involved in certain forms of stress analgesia. (Supported by NIH grant #NS07628 and MHTP grant #MH15345.)

237.6 NOCICEPTIVE RESPONSES OF SPONTANEOUSLY HYPERTENSIVE AND WISTAR-KYOTO NORMOTENSIVE RATS. A. Randich* (SPON: L. Mitchell) Dept. of Psychology, The Univ. of Iowa, Iowa City, IA 52242

Nociceptive responses of spontaneously hypertensive rats (SHRs) and age-matched Wistar-Kyoto normotensive rats (WKYs) were assessed with the hot-plate assay, flinch-jump assay, and conditioned suppression paradigm. SHRs showed significantly longer latencies to either paw-lick or jump than WKYs in the hot-plate assay ($55^{o}C \pm 0.05^{o}C$). In contrast, SHRs showed significantly lower response thresholds to both flinch and jump than WKYs to an electric grid shock stimulus in the flinch-jump assay. In accord with the latter findings, SHRs acquired conditioned suppression of instrumental responding at a significantly faster rate than WKYs to a 3-min white noise stimulus repeatedly paired with a 1.0-mA, 0.8-sec electric grid shock stimulus.

These findings demonstrate a fundamental dissociation of nociceptive responses to different aversive stimuli in SHRs, and support the view that blood pressure and pain regulatory systems are physiologically linked. It is suggested that hypoalgetic behavior in the hot-plate assay may involve compensation for cardiopulmonary baroreceptor resetting and enhanced activation of endogenous opioid pain-inhibition systems, whereas hyperalgetic behaviors in the flinch-jump assay and conditioned suppression paradigm may involve sino-aortic baroreceptor resetting and reduced activation of endogenous pain-inhibition systems.

238.1 A BEHAVIORAL ANALYSIS OF CHRONIC PHENYLETHYLAMINE ADMINISTRATION IN RATS. K. Mueller. Dept. of Pediatrics, Univ. of Calif. - San Diego, La Jolla, CA 92093*

Altered phenylethylamine (PEA) levels have been reported in metabolic (PKU) and behavioral disorders (depression, aggression, schizophrenia) in humans. Exogenous PEA has been reported to produce abnormal behavior in rats which under certain conditions is similar to that produced by amphetamine. In fact, endogenous PEA has been suggested to mediate the central effects of amphetamine. The "PEA hypothesis" of behavioral disorders invites a more careful examination of the behavioral effects of chronic PEA.

Long Evans hooded rats (n=24) were administered 60 or 100 mg/kg PEA intraperitoneally (IP) or subcutaneously (SC) for 21 days (SC injections were terminated after 13 days due to multiple cutaneous lesions). The animals were observed in their home cages every 4th day for 40 (60 mg/kg) or 70 (100 mg/kg) min. An additional 6 chronic saline injected animals were also observed.

After a few days of PEA the animals exhibited amphetamine-like behavior but with important differences. In general, IP animals exhibited increasingly long periods of immobility which were not necessarily accompanied by the stereotyped sniffing characteristic of amphetamine. On the other hand, SC animals exhibited increasing locomotion, which by day 13 assumed the 3 phase pattern characteristic of amphetamine. Paradoxically, however, obviously stereotyped head movements (SHM) were often accompanied by locomotion equal to or greater than that exhibited by saline controls. Thus, like amphetamine, the route of administration markedly influenced the behavioral response. There was a significant change in SHM over time only in the 60 mg/kg SC group. These animals exhibited an increase in SHM from days 1 to 9 but a decrease from days 9 to 13. In the saline controls, rearing and locomotion were highly correlated with rears generally slightly exceeding locomotions. In SC PEA aniamals rearing and locomotion were poorly correlated with locomotions generally exceeding rears. Piloerection and copious salivation were common in all PEA rats. Other behaviors such as Straub tail, hindlimb abduction, tremor, and treading were occasionally observed. Thus although chronic PEA produced stereotyped behavior similar to that produced by amphetamine it also produced a dissociation of the various components of the amphetamine response, supporting the hypothesis that these components may be subserved by different mechanisms.

*This research was performed in the laboratory of W. L. Nyhan.

238.2 BARREL ROTATION IN RATS INDUCED BY INTRAVENTRICULAR CHLORPROMAZINE METHIODIDE: AN ANTIMUSCARINIC EFFECT. R.E. Burke*, H. R. Wagner, and S. Fahn. (SPON: T. Pedley), Dept. Neurology, Columbia Univ. College of P & S, New York, NY 10032.

Barrel rotation is a unique motor phenomenon in rats in which sustained twisting develops along the animal's long axis, resulting in repetitive lateral rolling. It was first reported with intraventricular injection of somatostatin (SRIF) (Cohn & Cohn, Brain Res. 96: 138, 1975), and subsequently with intraventricular injection of substance P and vasopressin. Barrel rotation has recently been reported folowing intraventricular injection of chlorpromazine methiodide (CPZMI), a quaternary ammonium derivative, and suggested as an animal model of torsion dystonia (Rotrosin et al., Neurology 30: 878, 1980). Unlike chlorpromazine, CPZMI is not a dopmaine antagonist, because it has no effect on CNS dopamine metabolism even when injected intraventricularly.

We have studied the specificity and pharmacologic basis of CPZMI barrel rotation. In a series of 31 control injections, including CNS depressants, excitants, and agonists and antagonists of putative neurotransmitters, (dopamine, ACh, GABA, NE, serotonin, glutamate, glycine), only antimuscarinic agents induced barrel rotation. Six antimuscarinics, representing different chemical classes, induced the effect. Simultaneous intraventricular injection of the muscarinic agonist carbachol inhibited CPZMI barrel rotation; whereas atropine, a muscarinic antagonist, enhanced it.

CPZMI is a weak inhibitor for the binding of ^{3}H-spiroperidol, a dopamine receptor ligand (K_i=6 μM). In contrast, CPZMI is a potent inhibitor for the binding of ^{3}H-quinuclidynl benzyilate, a muscarinic receptor ligand (K_i=11 nM).

We conclude that CPZMI-induced barrel rotation is an antimuscarinic effect. The similarity of CPZMI barrel rotation to that induced by SRIF suggests a role for SRIF in modulating cholinergic function. The relevance of barrel rotation to clinical movement disorders remains to be determined.

238.3 PREVENTION OF THE SEROTONIN SYNDROME IN RATS BY REPEATED ADMINISTRATION OF MONOAMINE OXIDASE INHIBITORS. I. Lucki and A. Frazer. Depts. of Psychiat. and Pharmacol., Univ., of Penna. and Vet. Adm. Hospital, Phila., Penna. 19104.

The binding of ^{3}H-serotonin in brain is decreased by repeated treatment of rats with monoamine oxidase inhibitors (MAOIs) but not by treatment with tricyclic antidepressants (TCAs). In the present study, we examined whether drug-induced decreases in serotonin receptors would inhibit a behavioral response due to the activation of such receptors. The response studied was the "serotonin syndrome", which is characterized by repetitive forepaw treading, hindlimb abduction, body rigidity, tremor, lateral head weaving, and Straub tail. In one experiment, repeated (40mg/kg twice daily for 7 days) but not acute treatment of rats with nialamide blocked completely the development of the serotonin syndrome induced by either 5-methoxy-N,N-dimethyltryptamine (5MeDMT; 9mg/kg) or d-lysergic acid diethylamide (LSD; 4mg/kg). In rats treated repeatedly with nialamide, even a supramaximal dose of 5MeDMT (27mg/kg) failed to produce the serotonin syndrome. By contrast, neither acute nor repeated treatment of rats with amitriptyline altered the appearance of the behavioral syndorme caused by either serotonin agonist.

In addition, treatment of rats for 7 days with other MAOIs like pargyline (25mg/kg) or phenelzine (10mg/kg) reduced significantly the ability of 5MeDMT (3mg/kg) to cause the serotonin syndrome. 5MeDMT did produce a robust syndrome in rats treated repeatedly with either desmethylimipramine, chorimipramine, or iprindole. If rats were pretreated with parachlorophenylalanine, then repeated administration of nialamide no longer blocked the serotonin syndrome induced by 5MeDMT.

The relationship between the ability of MAOIs to reduce ^{3}H-serotonin binding sites and to block the ability of serotonin agonists to cause the serotonin syndrome indicate that these neurochemical and behavioral effects are related. Furthermore, our results suggest that the serotonin syndrome is produced by activation of serotonin$_1$ rather than the recently described serotonin$_2$ receptors, as it has been shown by others (Science, 210:88-90, 1980) that repeated treatment of rats with either MAOIs, TCAs, or iprindole decrease serotonin$_2$ binding sites in the central nervous system. (Supported the Vet. Admin., MH 29094 and MH 14654).

238.4 LOFEXIDINE BLOCKS ACUTE OPIATE WITHDRAWAL. M.S.Gold, A.L.C. Pottash, W.J. Annitto,* I.Extein, H.D.Kleber. Fair Oaks Hospital and Psychiatric Diagnostic Laboratories of America, Summit, N.J. 07901, and Yale Univ. School of Medicine, New Haven, CT 06510.

We have described potent antiwithdrawal effects for clonidine the alpha-2 adrenergic agonist (1,2) which reduces brain noradrenergic activity. On the basis of clonidine's efficacy in human opiate withdrawal(1,2) and preclinical rodent and primate studies (3) we have postulated noradrenergic hyperactivity in opiate withdrawal and suggested that new nonopiate medications with central anti-norepinephrine (NE) activity might be found which are equipotent to clonidine in antiwithdrawal efficacy but without clonidine's marked sedative and hypotensive effects. More recently, we have suggested that lofexidine, an imidazoline derivative which is a structurally related analogue of clonidine, may be the ideal non-opiate antiwithdrawal agent.

We have recent data from 9 male chronic methadone addicts which demonstrates potent antiwithdrawal activity for lofexidine and offers additional support for the NE hyperactivity hypothesis of opiate withdrawal.

Following procedures reported previously (1,2) lofexidine (3 ug/kg) was administered, the withdrawal score fell rapidly and significantly ($p < 0.01$) from 30.3.3 ± 8.6 to 8.2 ± 5.5 at 120 minutes after lofexidine. Systolic and distolic blood pressure were not significantly decreased and remained in the normal range. All patients were successfully detoxified from chronic methadone addiction and switched to long acting opiate antagonist naltrexone in this inpatient study. Our data with lofexidine suggest that antiwithdrawal effects can be separated from antihypertensive and sedating effects.

238.5 ASPECTS OF THE PHARMACOLOGY OF LIMB FLICKING AND YAWNING IN CATS. J.L. Marini* & M.H. Sheard. Dept. of Psychiatry, Yale Univ. Sch. of Med., 34 Park Street, New Haven, CT 06508

Relative to their occurrence after saline, high frequencies of limb flicking (LF) and yawning (YA) are seen in cats after i.p. doses of d-lysergic acid diethylamide (LSD) and other hallucinogens with serotonergic properties, and LF plays a central role in a behavior model for such drugs (Jacobs et al., Commun. Psychopharm. 1:243, 1977). Although it has recently been shown that LF is not specific for hallucinogens (e.g., Marini et al., Neurosci. Abst. 6:700, 1980), the elicitation of LF and YA by such drugs, and their susceptibility to tolerance after single doses, makes them useful in the behavioral pharmacology of hallucinogens and related substances.

Adult, home-cage-acclimated male and female mongrel cats in good health were used in these studies. Results are rates of occurrence for the 90 min following i.p. doses of drugs or saline (control).

The muscarinic agonist pilocarpine (PILO, 0.125-1.0 mg/kg as HCl salt, n=4-6) did not elicit YA, but gave a dose-dependent increase in LF that was maximal at 0.5 mg/kg (26 $\pm$ 5.8; control, 0.3 $\pm$ 0.2, $P < .01$). This confirms that LF is elicitable by non-hallucinogens. The effects of PILO (0.5 mg/kg, n=4) were antagonized by pretreatment (15 min) with 0.5 mg/kg of the peripherally-acting antimuscarinic agent, N-methylscopolamine bromide (MESCO), showing that a peripheral mechanism can elicit LF.

LSD (0.01, .025 & .05 mg/kg as bitartrate, n=6-9) produced increased rates of LF (40-50 per 90 min, $P < .03$) and YA (6-8 per 90 min, $P < .03$). The related ergolene, lisuride (LIS, as hydrogen maleate, .025 & .05 mg/kg, n=8-9), elicited LF (19-33 per 90 min, $P < .05$) but not YA. Pretreatment with MESCO (0.5 mg/kg) 15 min before LSD (.01 mg/kg, n=6) or LIS (.05 mg/kg, n=6) had no effect on LF or YA. Pretreatment with methysergide was reported to antagonize LSD-elicited LF and YA and LIS-elicited LF, results consistent with a serotonergic mechanism for LSD- and LIS-elicited LF and YA (Marini & Sheard, Europ. J. Pharmac., in press, 1981).

Combining LSD and LIS (.025 mg/kg each, n=4) resulted in an additive effect on LF compared to either drug alone, but in a reduced rate of YA. Apomorphine (APO, .05 or 1.0 mg/kg as HCl salt) given 15 min before either .01 or .025 mg/kg of LSD did not affect LF relative to LSD alone, but the higher APO dose antagonized YA (n=5-6, $P < .05$). These results suggest that a dopamine (DA) mechanism inhibits serotonin (5HT)-mediated YA in the cat. Drug-induced YA may be useful in studying concomitant DA and 5HT effects of drugs (e.g., LIS).

238.6 BEHAVIOURAL EVIDENCE FOR NEUROCHEMICAL PATHOLOGY AFTER TREATMENT OF NEWLY HATCHED CHICKS WITH CYCLOHEXIMIDE OR GLUTAMATE. Paul R. Sanberg and Richard F. Mark*. Department of Behavioural Biology, Research School of Biological Sciences, Australian National University, Canberra, A.C.T., 2600, Australia.

Previous studies have demonstrated profound behavioural alterations in older chickens which received forebrain injections of cycloheximide (CXM) or glutamate (GLU) when newly hatched. The acquisition, attentional and emotional deficits found in these birds have not been related to any brain pathology[1]. CXM has been shown to increase the concentration in the brain of GLU in neonatal chicks. It has been suggested that an accumulation of this amino acid may underlie the behavioural deficits induced by CXM[2]. In order to assess possible pathology in these birds, we have studied the integrity of the dopaminergic and cholinergic neurotransmitter systems in the paleostriatum using drug-induced motor activity.

Compared to saline-injected controls, bilateral forebrain injections of CXM (20 µg in 25 µl saline) or GLU (210 µg in 25 µl buffered saline) in 2-day-old chicks resulted in significantly less activity in response to intraperitoneal injections of the dopaminergic agonist, apomorphine (2 mg/kg) or the cholinergic antagonist, scopolamine (2 mg/kg) when tested in BRS activity platforms four weeks later (Fig. 1). In addition, these birds were found to be much more susceptable than controls to convulsions induced by pentylenetetrazol (50, 100 and 200 mg/kg).

The results suggest that CXM or GLU injections in neonatal chicks cause damage to neurotransmitter mechanisms localized on intrinsic and/or efferent neurons in the paleostriatal complex (basal ganglia), the nuclei responsible for motor behaviour in birds.

238.7 DOPAMINE-NOREPINEPHRINE ANTAGONISM IN ATTENTION DEFICIT DISORDER WITH HYPERACTIVITY IN CHILDREN. W. O. Shekim, J. Javaid, H. Dekirmenjian, D. B. Bylund, J. M. Davis. Children and Youth Center and the Clinical Research Center, University of Missouri Health Sciences Center, Columbia, MO 65201.

None of the biochemical studies in attention disorder with hyperactivity in children consider the possibility that hyperactivity may result from an imbalance or abnormal interaction between dopamine (DA) and noradrenergic (NE) systems. To test the hypothesis of possible abnormal interaction between DA and NE, the authors examined the relationship between the excretion of 3-methoxy-4-hydroxy-phenylglycol (MHPG), the main metabolite of central nervous system NE, and homovanillic acid (HVA), the main metabolite of DA in 16 hyperactive boys and 12 controls. They further examined the effect of d-amphetamine (0.5 mg/kg body weight daily for two weeks) has on that relationship. The hyperactive children were admitted to a Clinical Research Center after meeting certain exclusionary and inclusionary criteria. Twenty-four hour urine samples were collected on ice in bottles containing 0.5 gm sodium meta bisulfite/liter of urine. MHPG was analyzed according to the method of Dekirmenjian and Maas (1970) and HVA according to a modification by Dekirmenjian and Dziedzic et al, 1972.

The correlation co-efficients r between MHPG and HVA excretion were significantly negative in hyperactive boys when the rational effects of age, body surface, and 24-hour urinary creatinine were removed. (Partial r with age removed: - 0.542, df = 14, $p < 0.05$, partial r with body surface removed - 0.559, df = 14, $p < 0.05$, partial r with 24-hour urinary creatinine removed - 0.544, df = 14, p = ns). Furthermore, the correlation co-efficient r on the Pearson Product Correlation Co-efficient Test in hyperactive boys and in responders at baseline differed significantly from the correlation co-efficients in post-treatment and in controls. The correlation co-efficient post-treatment did not differ from controls. The administration of d-amphetamine to hyperactive boys changed the negative correlation that existed in the excretion of MHPG and HVA to a positive one similar to that in controls, i.e., pre-treatment r - 0.537 vs post-treatment 0.544 $p < 0.01$, controls r: 0.328.

The evidence presented in this paper indicates the involvement of an altered relationship between NE and DA in the etiology of hyperactivity and d-amphetamine may correct such a relationship.

239.1 SPECIFIC HIGH AFFINITY ^{3}H-Ro5-4864 BENZODIAZEPINE BINDING SITES IN RAT BRAIN AND PERIPHERAL TISSUES. Hans Schoemaker*, Marla Bliss*, Susan H. Yamamura* and Henry I. Yamamura (SPON: Paul F. Consroe). Dept. Pharmacology, Univ. Arizona Hlth. Sci. Ctr., Tucson, Arizona 85724.

Benzodiazepines bind with high affinity to specific receptors in the mammalian brain and various peripheral tissues, e.g. the kidney. The benzodiazepine receptors present in the brain and peripheral tissues can be distinguished by both clonazepam and the chloro-diazepam analog Ro5-4864. Thus, whereas clonazepam has high affinity for the central benzodiazepine receptor, it has only very low affinity for the peripheral receptor. The reverse is true for Ro5-4864. Recently, ^{3}H-Ro5-4864 has become available and the specific binding of this new ligand to rat brain and peripheral tissues was studied. After decapitation, the brain and peripheral tissues were dissected and homogenized in 50 mM Na/K phosphate buffered saline (pH 7.4). Aliquots were incubated with ^{3}H-Ro5-4864 (NEN) in the presence or absence of various drugs. After 120 min incubation at 0-4^{0}C, membranes were harvested by filtration over Whatman GF/B filters and washed with 3x5 ml cold buffer. Binding in the presence of 1μM unlabelled Ro5-4864 was defined as nonspecific. Equilibrium binding experiments indicate that ^{3}H-Ro5-4864 binds with high affinity (Kd= 1.3nM) to rat kidney membranes. The pharmacological profile of this receptor is similar to that already described for the peripheral receptor labelled by ^{3}H-flunitrazepam. Diazepam, flunitrazepam and Ro5-4864 potently displace ^{3}H-Ro5-4864 binding in low nanomolar concentrations whereas clonazepam shows only a weak inhibition at 1μM. A high affinity ^{3}H-Ro5-4864 binding site could also be demonstrated in several brain areas. ^{3}H-Ro5-4864 binds with high affinity (Kd=1.2nM; Bmax=220fmol/mg protein) to membranes of the cerebral cortex, the pharmacological profile of this site being comparable to that of the peripheral ^{3}H-Ro5-4864 receptor. In addition a second ^{3}H-Ro5-4864 binding site may be present in this tissue. Binding is not or only slightly affected by several non-benzodiazepine anxiolytics, sedatives/anticonvulsants, stimulants /convulsants, or alkyl-β-carboline-3-carboxylate derivatives. The pyrazolopyridine derivative tracazolate, which enhances ^{3}H-flunitrazepam binding to cerebral cortical membranes, inhibits ^{3}H-Ro5-4864 binding in this tissue. ^{3}H-Ro5-4864 binding shows a regional distribution, binding being highest in the brainstem and cerebellum, and lowest in the striatum. The cellular localization in the brain, i.e. neuronal or non-neuronal (e.g. glial) is currently being investigated as well as the subcellular localization. This study was supported in part by USPHS grants and a RSDA to H.I.Y.

239.2 γ-AMINOBUTYRIC ACID AND BENZODIAZEPINE RECEPTORS: COPURIFICATION AND CHARACTERIZATION. Moshe Gavish* and Solomon H. Snyder+. *Israel Institute of Technology, Dept. of Pharmacology, Haifa, Israel and +Johns Hopkins University, School of Medicine, Depts. of Neuroscience, Pharmacology and Psychiatry, Baltimore, Maryland 21205

γ-Aminobutyric acid (GABA) and benzodiazepine receptors have been solubilized and purified by procedures such as gel filtration, ion-exchange, lectin, and affinity chromatographies. All of these procedures enhance the specific activity of each receptor to a similar extent. The drug specificities of [^{3}H]muscimol and [^{3}H]flunitrazepam binding sites are the same after extensive purification by affinity chromatography compared to the membrane bound and initially solubilized receptors. GABA and chloride stimulation of benzodiazepine binding is retained in pure receptors. Two bands are covalently labeled with [^{3}H]flunitrazepam after ultraviolet irradiation of the purified receptor. The persistent association of GABA, benzodiazepine, and chloride recognition sites after extensive purification suggests that they may be part of a single macromolecular complex. Further purification in attempts to isolate homogeneous receptors has clarified the benzodiazepine-GABA linkage.

239.3 BRAIN REGIONAL VARIATION IN BENZODIAZEPINE AND GABA RECEPTOR ASSOCIATION. Fredrik Leeb-Lundberg* and Richard W. Olsen (SPON. M.A. Baker). Division of Biomedical Sciences, University of California, Riverside, CA 92521.

Anesthetic barbiturates (pentobarb.) enhanced the binding of both [^{3}H]benzodiazepines (BZ) (Leeb-Lundberg, Snowman and Olsen, PNAS 77, 7468-7472 (1980) and [^{3}H] γ-aminobutyric acid (GABA) (Olsen, Snowman, and Leeb-Lundberg, Fed. Proc. 40, 309 (1981)) to receptor sites in rat brain membranes. Only part of these GABA and benzodiazepine receptor sites seem to be coupled as indicated by interactions with barbiturates and the GABA receptor antagonist bicuculline. BZ receptor binding in fresh, well-disrupted and washed rat brain membranes was assayed by filtration, using 0.5 nM [^{3}H]diazepam in 20 mM KPO_4, 0.2 M KCl, pH 7.5 at 0^{0}C. GABA receptor binding in frozen-thawed and well washed rat brain membranes was assayed by centrifugation, using 2 nM [^{3}H]GABA in the same buffer at 0^{0}C. Pentobarb enhancement of BZ binding was due to a change in K_D, while enhancement of GABA binding was due to a change in B_{max}, apparently by converting GABA receptor sites of immeasurably low affinity to higher affinity. Both effects, mediated by barbiturate/picrotoxinin receptors, were saturable (EC_{50} 100-200 μM), competitively blocked by picrotoxinin (μM), dependent on Cl^- or other anions able to penetrate GABA ionophores, and correlated very well with anesthetic potency and enhancement of GABAergic postsynaptic responses by a series of barbiturates. Bicuculline only blocked a fraction of the pentobarb-enhanced BZ binding; this fraction varied with brain region, from 10-70%. The maximal percent enhancement of BZ and GABA binding by pentobarb also varied with brain region, from 20-180%. While pentobarb enhancement of GABA binding in various brain regions did not correlate with total pentobarb-enhanced BZ binding, it agreed very well with regional variation in bicuculline-sensitive pentobarb-enhanced BZ binding, with cortex > hippocampus ≥ thalamus ≥ striatum ≥ pons-medulla = cerebellum. The bicuculline-insensitive fraction of pentobarb-enhanced BZ binding sites appears to be associated with higher affinity β-carboline binding sites. These results suggest that barbiturates affect multiple BZ receptor sites, only part of them being coupled to GABA/bicuculline receptors.

Supported by NSF Grant BNS 80-19722.

239.4 BENZODIAZEPINE "TYPE 1" RECEPTORS: A BIOCHEMICAL STUDY. D.L. Niehoff, J.M. Palacios, M.J. Kuhar, †R. O'Brien and †D. Horst. Dept. of Neuroscience, Johns Hopkins Univ., Sch. of Med., Balto., MD 21205; †Hoffman-La Roche, Nutley, NJ.

A variety of pharmacological, biochemical, behavioral and anatomical methods have confirmed the existence of a heterogeneous population of benzodiazepine (BZ) receptors in rat brain. The triazolopyridizine (TPZ) drugs, exemplified by CL218,872 (CL) are a class of compounds which can discriminate between two subpopulations of BZ receptors: Type 1 has a high affinity for TPZ's and Type II has a low affinity. We have used ^{3}H-CL to label and characterize BZ receptors in the rat cerebellum, which contains primarily Type 1 receptors (Young et al., J. Pharmacol. Exp. Ther., 216:825, 1981).

Synaptosomal membrane preparations (P_2) of rat cerebellum, suspended to 10 mg/ml in 50 mM Tris citrate (pH 7.1) were used in most of these experiments. When investigating the effects of GABA, chloride ion, and pyrazolopyridines on ^{3}H-CL binding, the pellet was resuspended and washed in 50 mM Tris citrate 3 times to remove endogenous GABA. ^{3}H-CL (2.5 nM), displacing drugs, and membranes (1 ml. final volume) were incubated on ice for 60 min. prior to termination by centrifugation. Blank values were determined in the presence of 1 uM clonazepam.

^{3}H-CL binding was saturable and had highest densities in the cerebellum, followed by cerebral cortex and hippocampus. Scatchard analysis revealed a K_D = 23 nM and B_{max} = 32.9 fmol/mg tissue. The use of higher concentrations of ^{3}H-CL suggested the presence of an additional lower affinity site. The binding of ^{3}H-CL was inhibited more potently by (+)-B10 than by (-)-B10 (IC_{50} values = 1 nM and 50 nM respectively), and by clonazepam and methyl-beta-carboline carboxylate in the 1-10 nM range. In multiply-washed membranes, 1-100 uM GABA potentiated ^{3}H-CL binding. However, 25-500 mM NaCl failed to potentiate ^{3}H-CL binding, while enhancing ^{3}H-flunitrazepam binding in the same membranes. Similarly, cartzolate (1 μM) (SQ 65396), potentiated ^{3}H-flunitrazepam binding in the presence of 150 mM NaCl, while failing to potentiate ^{3}H-CL binding in the same membrane preparation.

In summary, ^{3}H-CL binding has many, but not all, of the same characteristics as ^{3}H-BZ binding. ^{3}H-CL binding is not potentiated by chloride ion, even in the presence of cartazolate. Thus, the Type 1 site appears coupled to the GABA site, but may not be closely associated with the chloride conductance channel.

Supported by grants, DA00266, MH00053, TW02583 and a NSF Predoc. Fellowship Award.

239.5 ADDITIONAL EVIDENCE FOR SEVERAL BENZODIAZEPINE/ANION/GABA RECEPTOR COMPLEXES IN RAT CEREBELLUM AND FOREBRAIN. R. F. Squires. Rockland Research Institute, Orangeburg, NY 10962.

NaCl protects dialysed benzodiazepine (BZ) receptors (from rat forebrain or cerebellum) against heat inactivation (30 min, 60°C) in a concentration dependent way with complete protection above 500 mM. GABA and several GABA mimetics are without protective effect alone but reduce the concentration of NaCl required for 50% protection (from 280 mM without GABA to 30 mM in the presence of 1 mM GABA). LiCl, KCl, CsCl and NaCl yield similar protection patterns while sodium or potassium phosphate yield a different pattern. In the presence of NaCl (20-100 mM) GABA enhances protection in a saturable, concentration dependent way, with Hill numbers (α) near 0.7 and "Kd" values ranging from 10 µM (at 100 mM NaCl to 75 µM (at 20 mM). Picrotoxin potentiates the protective effect of high ($\geq$ 200 mM), but not low, NaCl concentration. Other GABA mimetics, including imidazoleacetate (ImAA), piperidine-4-sulfonate (P4S) and isoguvacine (IGV) also protect in saturable, concentration dependent ways, but provide less maximum protection than GABA. Time courses of heat inactivation at 60°C in 50 mM NaCl using saturating concentrations of several GABA mimetics show that P4S or IGV selectively protect a small (30-40%) sub-population of BZ receptor complexes in both cerebellum and forebrain while ImAA protects a larger subpopulation (44 and 56%, respectively, in cerebellum and forebrain). GABA, 3-amino propane sulfonate (APSA) and, beta-guanidinopropionate provide the greatest protection (62-69% in cerebellum, 70-80% in forebrain). These results indicate the existence of at least four receptor complexes in both cerebellum and forebrain which differ with respect to their constituent GABA and anion recognition sites. All GABA mimetics tested, protected less in cerebellum than in forebrain. APSA and ImAA showed the greatest differences in their effects on cerebellum and forebrain, respectively. Evidence from other laboratories suggest that brain BZ receptors exist at tetramers of MW near 200,000 containing (at least) two subunits with MW's near 50,000. The lactate dehydrogenase model for BZ receptor multiplicity is one interesting possibility which may account for several of the above findings (α_4, $\beta_1\alpha_3$,$\beta_2\alpha_2$, $\beta_3\alpha_1$,β_4). Several substances partially inhibit ^{3}H-FLU binding ("plateau" inhibition). These include strychnine (Imax 64%, "Kd" 135 µM, α = 0.66), cyproheptadine (63%, 62 µM, 0.92), 4-guanidinobenzoate (27%, 56 µM, 0.87) and tabernanthine (82%, 38 µM, 1.1). These substances appear to uniformly affect all BZ receptors by allosterically decreasing Bmax and/or increasing the Kd for flunitrazepam.

239.6 PHYSICOCHEMICAL PROPERTIES OF THE GABA AND BENZODIAZEPINE RECEPTOR PROTEINS FROM MAMMALIAN BRAIN. F.A. Stephenson,* A.E. Watkins,* R. King,* D. Gusman,* D.V. Greenlee* and R.W. Olsen. University of California, Riverside, CA 92521

Detergent-solubilized GABA receptor (GABA-R) and benzodiazepine receptor (BZ-R) were both found to co-migrate on gel filtration chromatography and sucrose gradient centrifugation with a molecular weight of 355,000. Soluble binding of [^{3}H]muscimol (GABA-R) and [^{3}H]flunitrazepam (BZ-R) was assayed by polyethylene-glycol precipitation and centrifugation, determining nondisplaceable background with 10 µ M muscimol or flunitrazepam respectively. Triton X-100 (0.5%) solubilized 55% (5.3/10.3 pmol/g bovine cortex tissue) of BZ-R but only 5% (2.5/64 pmol/g tissue) of GABA-R. However, deoxycholate (0.5%) solubilized 63% of BZ-R and 31% of GABA-R and both these values could be further improved by including protease inhibitors. Deoxycholate extracts were unstable at 0°, so were exchanged by gel filtration column chromatography into 0.5% Triton X-100, in which both binding activities were more stable at -20° and 4°C. Scatchard plots of soluble GABA-R gave K_D values for [^{3}H] muscimol and [^{3}H] GABA of 12 nM and 50 nM respectively; both gave a B_{max} of 1.55 pmol/mg protein; soluble [^{3}H] flunitrazepam binding gave a K_D of 8 nM and B_{max} of 0.8 pmol/mg (4 expts.). Solubilized BZ-R binding was enhanced $\geq$ 20% by both GABA (10 µ M) and pentobarbital (0.5 mM). Both GABA-R and BZ-R comigrated on Sepharose 6B columns, with a Stokes radius of 6.81 nm. Fractionated BZ-R binding was still enhanced by GABA but not pentobarbital. GABA-R and BZ-R also co-migrated on centrifugation in sucrose gradients in H_2O and D_2O (+0.5% Triton X-100), with $s^0_{20,w}$ = 12.5 and $\bar{v}$ = 0.73 ml/g, indicating very little bound detergent. The frictional coefficient was 1.46 and the calculated molecular weight of both proteins was 355,000. Thus at least a portion of GABA-R and BZ-R in brain membranes seem to be associated with a large multisubunit protein complex which can be solubilized under certain conditions and is consistent with both in vivo and in vitro interactions between benzodiazepines and GABA receptors. This complex may also contain the GABA-regulated chloride ion channels and the modulatory sites for barbiturates and related depressant drugs and picrotoxinin-like convulsants.

240.1 REFLEXIVE AND ACQUIRED CONTROL OF A HUMAN LIMB MUSCLE. M. C. Wetzel and J. W. Davis*. Psych. Dept., Univ. of Arizona, Tucson, AZ 85721.

Classical conditioning procedures extended work to distinguish reflexive from conditioned movements. Previous findings showed that the pretouchdown EMG burst in quadriceps (biceps or rectus) femoris could be produced or eliminated by discriminative stimulus (operant conditioning) control during both cat (Wetzel, M. C., 1981a, b, Am. J. Phys. Med., in press) and human (Wetzel, M. C., 1981c, J. Human Movement Stud., in press) treadmill locomotion. The present experiments examined some conditions that influenced the effectiveness of 1) an eliciting stimulus, tap to the patellar tendon, over the subsequent reflexive extensor EMG and 2) several events that preceded the tap and therefore might acquire conditioned reflex or discriminative stimulus control over the same quadriceps muscle.

Results for 6 Ss accorded with previous findings in several respects. The reflexive EMGs were larger when the fists were clenched in response to a click discriminative stimulus (heard when the tape recorder switched on) than when there was no clench; most responses were ipsilateral; and EMG amplitude varied appreciably within daily sessions of 60 - 200 trials, during which reinforcement contingencies were invariant.

Conditioned responses were highly dependent upon conditions and Ss. When present, however, differential control was seen by the recorder click that occurred about 500 msec before the tap, the clench discriminated by that click, a tone that began 300 msec before the tap, and/or a touch to the skin covering the patellar tendon. The touch was not established as an effective conditioned stimulus when its onset coincided closely with the tap.

Bilateral acquired responses were rare, but the ipsilateral EMGs comprised several bursts distinguished by amplitudes and latencies that varied with the controlling stimuli. There was little "temporal" conditioning.

It was concluded that early reports of knee jerk conditioning must be repeated and reinterpreted (e.g., Twitmyer, 1902, reprinted in 1974, J. Exp. Psychol., 103, 1047-1066). In most previous studies of motor control in intact animals or humans, multiple sources of stimulation have been present but confounded. Differential reinforcement procedures are recommended to identify specific eliciting (reflexive), conditioned, and discriminative stimuli. In this way the relative strength of the three control sources can be disclosed.

240.2 CHARACTERISTICS OF HUMAN ARM TRAJECTORIES. W. K. Abend*, E. Bizzi and P. Morasso*. Dept. of Psychology, M.I.T., Cambridge, MA 02139.

In order to investigate the strategies used to plan and control arm trajectories, we have recorded two-joint arm movements performed by normal adult humans. Subjects grasped the vertical handle of a lightweight hand-position transducer and briskly moved the handle to each of a series of visual targets. The arm was restricted to move in a horizontal plane and the wrist was braced, so that only the shoulder and elbow joints were active. Signals from the transducer allowed the computation of the position and speed of the hand and joints during the movement.

When subjects were asked simply to move the handle from one target to another, they generated a roughly straight trajectory. The speed profile of these straight trajectories was bell-shaped. When the subjects were asked to produce curved hand trajectories, three unexpected results were obtained. First, the trajectory curvature profile usually displayed one or more peaks, so that the trajectory had a segmented appearance, as if the subjects were trying to approximate the curve with low curvature segments. Occasionally, curved movements without any clear discontinuity were produced. Second, at the time of peaks in the curvature of the trajectory, the hand slowed briefly. Therefore, while the speed profile for a straight hand movement was bell-shaped, the profile for curved movements was multipeaked. Third, the average duration of the curved trajectories was significantly greater than that of straight movements having the same path length. These three findings were obtained in all parts of the work space and even when the subject traced constant curvature guide paths without visual feedback.

The results are surprising because there is no a priori reason why the curved trajectory should so frequently appear segmented, or why the velocity and duration characteristics of curved and straight hand trajectories should differ. These characteristics may reflect central mechanisms involved in trajectory planning and control, but other explanations can be advanced. The Coriolis and reaction forces may be more significant during curved movements and affect the trajectory and velocity. Another possibility is that muscles which span two joints (e.g., biceps) may allow the implementation of straight hand paths without the need for central trajectory planning (Hogan, N., Proc. Joint Automatic Controls Conf., 1:TA10-B, 1980). If these muscles actually impose a tendency toward straight trajectories, this could result in the segmented appearance of curved movements and the associated velocity irregularities. (Research supported by NIH grants NS09343, NS06416 and AM26710.)

240.3 SEPARATE CORTICAL CELL SYSTEMS FOR THE CONTROL OF JOINT MOVEMENT AND OF JOINT STIFFNESS. D.R. Humphrey and D.J. Reed*, Lab. of Neurophysiol., Emory Univ. Sch. Med., Atlanta, GA 30322.

With simple, voluntary movements about a joint, agonist and antagonist muscles are activated reciprocally. Such movements are accompanied often, however, by a co-contraction of antagonistic muscles at joints which must be stiffened, in order to provide postural stabilization for the moving part. To date, little is known about the central systems which control such co-contraction, though there is ample evidence to suggest that such systems may malfunction in various motor disorders.

To study further this basic form of motor control, we have recorded from wrist flexor-extensor (F-E) motor units (N=128) and from motor cortex cells (N=108) in monkeys that have been trained to control the position of the wrist in the presence of imposed forces which attempt alternately to flex and then to extend the wrist. As the frequency of such perturbation increases, the animal shifts from a mode of joint position control by graded, reciprocal activation of wrist F-E muscles toward one in which the wrist is stiffened tonically by a sustained co-contraction of these muscles. At the level of the spinal cord, the convergence of these two, apparently distinct control signals is detectable in the discharge patterns of single motor units. At the level of the motor cortex, however, the two signals appear to originate in part from separate neuronal populations, both of which contain pyramidal tract and other, identified output cells. Cells which lie within the center of the low-threshold, microstimulation-defined, wrist F or E zones tend to fire in a graded, reciprocal manner; these cells are also highly responsive to cutaneous inputs from the palm, or from joint receptors in the fingers and/or wrist. In contrast, units which lie in an adjacent, slightly anterior zone tend to fire in a manner which correlates highly with the degree of agonist-antagonist co-contraction. These cells are essentially unresponsive to somatosensory input from the arm and hand. Moreover, microstimulation within this zone tends to evoke F-E co-contraction.

We propose, therefore, that, at the level of the motor cortex, these two fundamentally different modes of muscle control are mediated in part by separate neuronal systems. By virtue of these separate systems, the motor cortex appears to be capable of controlling independently (1) reciprocal activation of antagonistic muscles, and hence joint movement, and (2) co-activation of these muscles, and hence the stability or mechanical stiffness of the joint. (Supported by NIH Grant NS 10183).

240.4 MOTOR UNIT CONTROL IN SKILLED PERFORMERS. A. P. Xenakis*, R. S. LeFever*, C. J. De Luca. (SPON: T.F. Weiss) NeuroMuscular Research Lab., Children's Hospital Medical Center, Harvard Medical School, Boston, MA 02115.

Multiple channel myoelectric (ME) signals were recorded from an indwelling bipolar needle electrode during both constant-force and force-varying isometric contractions of the First Dorsal Interosseous (FDI) and the deltoid at levels up to 80% of maximal voluntary contraction (MVC). The data was obtained from three groups of highly skilled individuals: three 1500 meter freestyle swimmers, three powerlifters and three concert pianists. These subjects ranked among the best in the world (including Olympic and World Champions). A computer assisted visual procedure was used on the ME signal to reliably detect the firings of concurrently active motor units (up to 8) throughout the contraction [R.S. LeFever and C.J. De Luca, Abstracts of the Soc. for Neuroscience, 1978].

Utilization of this methodology on 209 motor units demonstrated that the firing rate behaviour was different for the deltoid and the FDI. This difference in behaviour was noted in: the firing rate at recruitment(8.41 $\pm$ 1.99 pps for the FDI and 12.84 $\pm$ 2.55 pps for the deltoid), the near maximal firing rate (43.0 $\pm$ 5.19 pps for the FDI and 33.0 $\pm$ 3.54 pps for the deltoid), the firing rate at decruitment(7.86 $\pm$ 2.33 pps for the FDI and 8.61 $\pm$ 2.57 pps for the deltoid). Also, the firing rate of the FDI was linearly related (r=0.65) to the force, whereas the deltoid motor units demonstrated a preferred level for the firing rates. This behaviour was significantly (typically $p<0.23$) invariant with subject groups (training) and force rate of the contraction. Furthermore, these findings are in direct support of data reported on unskilled subjects by previous authors [R.S. LeFever and C.J. De Luca, Abstracts of the Soc. for Neuroscience, 1979].

The results show that the effects of training appear to have no demonstrable affect on the CNS control of the firing rate properties of motor units. According to other investigators, the training effects primarily impose themselves on the properties of the end organ itself ("use hypertrophy of the muscle). (Supported in part by NIAMDD Grant AM 19665, the Insurance Institute for Highway Safety and Liberty Mutual Insurance Company).

240.5 CHANGES IN FIRING OF PALLIDAL NEURONS DURING ARM REACHING MOVEMENTS IN A REACTION TIME TASK. M.E. Anderson and F.B. Horak. Depts of Physiology and Biophysics and Rehabilitation Medicine and Regional Primate Research Center, University of Wash., Seattle WA 98195.

The firing of many neurons in the globus pallidus changes in a manner that is temporally correlated with the repetitive trained movements used in most testing situations. The timing of these changes has been reported by some to precede the movement, and the suggestion has been made that their activity might be involved in the initiation of or preparation for the movement.

We have reported earlier (Horak and Anderson, 1980) that stimulation in the globus pallidus of monkeys making rapid arm reaching movements in a forced reaction time task changes the movement time but does not change the reaction time, which is terminated by the onset of the movement. The time at which stimuli must be applied is critical. For example, stimuli that cause the movement to be slowed must be applied within a period about 50 to 150 msec preceding movement initiation. Earlier stimulation does not change either movement time or reaction time.

We now report the firing patterns of pallidal neurons studied in the same tracks in which stimuli subsequently were applied. Changes in activity of neurons with movement-correlated discharge usually were initiated in a period of time 50 to 150 msec prior to the onset of the movement, the same time period during which stimulation caused a change in movement time. EMG activity was recorded from wrist, elbow, shoulder, and thoracic back muscles during the same trials, and in most cases, changes in unit activity occurred following, instead of preceding the onset of EMG activity. Current data seem to indicate that exceptions are units in most rostral portions of GP,

We would hypothesize that pallidal neurons associated with movement, at least those in posterior portions of GP, play a role in scaling the buildup of EMG activity during a movement, and, thus, in determining the speed of movement initiated or gated by other mechanisms.

240.6 FEEDBACK IN FOREARM MOVEMENTS AND ABSOLUTE POSITION SENSE: AN INFORMATION THEORY ANALYSIS, Barbara Sakitt, Massachusetts Institute of Technology, E10, Cambridge, Mass. 02139, U.S.A.

Experiments were conducted to study the role of feedback in achieving precision in human visually triggered forearm movements. The conditions used were: (1) Deliberate smooth movements without corrections: These are characterized by a single peak in the velocity trace, intermediate values of velocity, and attainment of the final average EMG activities of biceps and triceps before the movement is completed. (2) Correcting movements: The subject keeps moving until he thinks that his arm is pointed at the target. These trials are characterized by a series of step-like movements, with the EMGs changing at each step. The velocity trace has many peaks and varies in an irregular fashion. (3) Passive movement-passive posture: The subject keeps his arm limp while it is passively moved in a zigzag trajectory, and then maintained at final position by external forces. The subject then estimates the elbow joint angle. (4) Passive movement-active posture: After the arm is moved passively, the subject tenses his arm so as to actively maintain final posture. He then estimates his joint angle. For all conditions, the subject does not see his arm during the movement, but after each trial, receives visual feedback.

The data were examined by both Information Theory and a conventional error analysis. The results were: (1) Absolute position sense for passive movements followed by either active or passive posture was considerably worse than the precision attained by both the deliberate smooth and the correcting movements; i.e., the subject could move more precisely to a target than he could estimate by absolute position sense. (2) Correcting movements were slightly more precise than the deliberate smooth ones. The small amount of improvement of the correcting versus smooth deliberate movements is quantitatively accounted for by the conscious position sense results. This suggests that the difference in precision between movements and position sense is not due to the former having access to better position feedback than that available to consciousness.

How can one move consciously to a target more precisely than one knows where one's arm is? Corollary discharge and proprioceptive feedback by themselves are not precise enough to explain the precision of voluntary movements. This paradox might be explained by the hypothesis that the system has a more precise way to compare "motor" information, i.e. corollary discharge and proprioceptive feedback, with visual feedback after each trial than it can judge "motor" information on an absolute basis. This more precise comparative information is then used to increase the accuracy of future movements.

240.7 DYNAMIC INTERACTIONS BETWEEN LIMB SEGMENTS DURING PLANAR ARM MOVEMENT. T. Flash* and J. M. Hollerbach* (SPON: T. Zeffiro). Dept. of Psychology, M.I.T., Cambridge, MA 02139.

Movement of multiple segment limbs requires generation of appropriate joint torques which include contributing terms arising from dynamic interactions among the moving segments. These interactions, arising from reaction, centripetal, and Coriolis forces, are not present for single joint movements. This work is an assessment of the significance of the interaction forces relative to single joint movements for planar two degree of freedom arm movement.

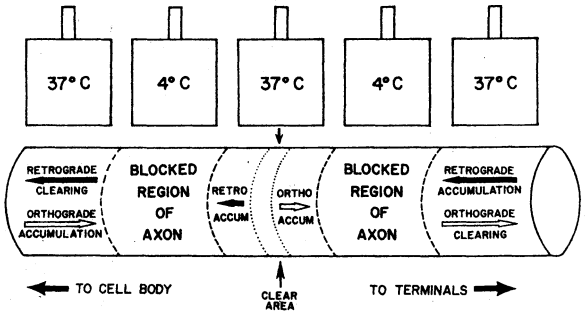
Measurements of human arm movement between two targets, involving the shoulder and elbow joints, were made to yield a time sequence of joint angles and, after differentiation, the joint velocities and accelerations. A general purpose simulation program for arbitrary open loop kinematic chains was developed and used to solve for the interaction forces given the experimental kinematic data. Segmental parameters such as principal inertias, lengths, masses, and internal axes were obtained from a computational model by Hatze (C.S.I.R. Tech. Report, TWISK 79, Pretoria, 1979).

The results indicate that the dynamic interaction terms are significant, even for slow movements. Consequently, models of movement which simplify the motor control dynamics by exclusing some interaction terms, usually the velocity terms, can lead to major errors in the computed magnitudes of the joint torques. This study stresses the fact that motor control programs must devise means for compensating for joint interactions during multiple joint movement. These interactions cannot be overlooked when physiological studies of trajectory formation by multiple segment limbs are conducted. (Research supported by NIH grant AM26710.)

241.1 THE MEMBRANOUS RETICULUM WITHIN MYELINATED AXONS IS NOT RAPIDLY TRANSPORTED. Mark H. Ellisman and James D. Lindsey, Department of Neurosciences, University of California, San Diego, School of Medicine, La Jolla, CA 92093.

The axoplasmic reticulum has been described for myelinated axons in many reports as an anastomosing network of tubules. We have used a focal chilling method to block axonal transport in two places (see diagram below). After 4 hrs. all axoplasmic materials transported faster than 25 mm/day should clear from this central warm area. Whatever formed elements that remain in this central region would not have been rapidly transported. These double blockade experiments were conducted on mouse saphenous nerve. In these studies we have found that: 1) the axonal reticulum does not accumulate against a block designed to trap orthogradely moving vectors; 2) there is no evidence of continuity between the axonal reticulum and the orthogradely moving vectors; 3) the axonal reticulum remains in the region between two cold blocks were only non-motile elements should be found; 4) the axonal reticulum does not accumulate against a dam designed to trap retrogradely moving elements; 5) although retrogradely moving elements appear to associate with the axonal reticulum they do not fuse with it and are not contained in it.

We conclude that the axoplasmic reticulum represents a separate membrane system from either orthogradely or retrogradely moving rapid transport vectors and that this cisternal system is not rapidly transported. Supported by grants to MHE from MDAA, MS, and NIH NS14718.



241.2 AXONAL TRANSPORT OF NA-K-ATPASE IN HAMSTER OPTIC NERVE. Susan C. Specht, Teresa Candelas* and Roberto Ocasio-Rivera*. Dept. of Pharmacol., Univ. P. R. Sch. Med., San Juan, P. R. 00936.

The NaK-ATPase, a major membrane-bound enzyme of neural tissue, is responsible for maintaining transmembrane NaK-gradients. Nerve endings are particularly enriched in this enzymatic activity. The mammalian enzyme consists of two subunits, a catalytic subunit and a smaller glycoprotein of unknown function. Enzymatic activity in rodent brain increases markedly during the first two weeks of life. To obtain a better understanding of factors involved in the development of nerve ending membrane, we have examined the axonal transport and enzymatic activity of NaK-ATPase of adult and immature (12 days-old) hamster brain.

The NaK-ATPase of hamster brain was partially purified by NaI and glycerol treatments. The catalytic subunit was identified by phosphorylation with ^{32}P-ATP in the presence of 100 mM NaCl or KCl. Its approximate molecular weight on SDS-PAGE was 96,000. Associated proteins found in most preparations had molecular weights of approximately 47,000 and 51,000. Staining by the periodic acid-Schiff's reaction indicated that both are glycoproteins.

To examine the axonal transport of the enzyme and associated glycoproteins, hamsters were injected intraocularly with ^{35}S-methionine or ^{3}H-fucose (250 μCi per preparation) and sacrificed 24 h later. The enzyme was isolated, run on SDS-PAGE and counted. The data demonstrate that both the catalytic subunit (labeled with ^{35}S-methionine) and the associated glycoproteins (labeled with ^{3}H-fucose) are transported rapidly to the optic nerve ending.

Kinetic parameters were determined for enzyme from both adult and immature hamsters. The pH optimum for both was pH 7.6. The optimal Na/K ratio was 90/60 mM for adult and 140/10 mM for enzyme from 12 day-old hamsters. Activity of the adult enzyme was 96-100% sodium dependent, whereas that from the 12 day-olds was only 88% sodium dependent.

These preliminary studies suggest that investigation into the axonal transport of NaK-ATPase will provide insight into the maturation of nerve ending membrane.

Supported in part by NIH-PHS grant EY 02334 from the National Eye Institute.

241.3 AXONAL TRANSPORT OF $NA^{+}K^{+}$ATPASE AND PROTEIN I IN RETINAL GANGLION CELLS. C. Baitinger* and M. Willard* (SPON: D. Gottlieb). Dept. Anat. and Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

In order to compare the axonal transport of proteins destined for two different membranous organelles, we identified among the radiolabeled axonally transported proteins NaKATPase (the sodium pump, specifically associated with the axolemma) and Protein I, a synaptic vesicle- and postsynaptic density-associated substrate for cAMP-dependent protein kinase (Bloom, F.E. et al., PNAS 76: 5982,1979). Proteins synthesized in rabbit retinal ganglion cells were labeled by an intravitreal injection of ^{35}S-methionine, and the radioactive axonally transported proteins were recovered in the optic tract and superior colliculus. ATPase and Protein I were separated from other labeled proteins by two-dimensional gel electrophoresis, and identified by comparison with standards identified by their characteristic phosphorylations with γ-^{32}P-ATP (K^{+}-sensitive in the case of the two catalytic subunits of ATPase (α, MW=100K and α+, MW=105K); cAMP-dependent in the case of the two components of Protein I (Ia, MW=85K, Ib, MW=80K). The contribution of local protein synthesis to labeled ATPase and Protein I present in the tract and colliculus was assessed by direct injection of ^{35}S-methionine into these structures; labeled ATPase and Protein I were at most minor components of proteins labeled in this manner.

Both of the catalytic subunits of ATPase were labeled in the optic tract and superior colliculus by 3 hours, indicating that they are transported down the axons at a velocity of at least 240 mm/day, the velocity of the most rapidly transported proteins (Group I). ATPase remained labeled in both the optic tract and superior colliculus for at least 16 days, consistent with the interpretation that it turns over slowly at its destination in the axolemma. Labeling of Protein I was first detected in the optic tract at 6 hr, increased until 4 days, and was barely detectable at 8 days; on the other hand, Protein I remained heavily labeled in the colliculus until at least 16 days. This behavior is consistent with the interpretation that Protein I passes through the axons and accumulates in the synaptic terminals, as expected for a synaptic vesicle-associated protein.

These results provide the first assignment of a function to an electrophoretically identified Group I protein, the NaKATPase, supporting the hypothesis (Lorenz & Willard, PNAS 75:505, 1978) that Group I serves in whole or in part to supply proteins to the plasma membrane. The delayed labeling of Protein I is a characteristic of Group II proteins; the reported association of Protein I with synaptic vesicles is consistent with the possibility that Group II (which includes mitochondria) serves to supply cytoplasmic membrane-bounded organelles.

241.4 VELOCITY AND METABOLISM OF AXONALLY TRANSPORTED LABELED CATECHOLAMINES IN BULLFROG SYMPATHETIC NERVE. W. J. Litchy*, S. Brimijoin, and C. Reiter*. Depts. Neurology and Pharmacology, Mayo Fdn., Rochester, MN 55905.

Values for transport velocity of endogenous norepinephrine have previously been reported in mammals, amphibians, and teleosts. However, direct, full scale studies of the transport of exogenous, radiolabelled catecholamines have never been carried out. We now report on the metabolism and axonal transport of ^{3}H-labeled catecholamines in adrenergic axons of the sciatic nerve of the bullfrog (Rana catesbeiana). After injection of ^{3}H-norepinephrine (sp. act. 46.5 Ci/mmole) into the capsule surrounding a sympathetic ganglion (S_G) the sciatic nerve was incubated for 4, 8, and 12 hours at 20°C in a frog Ringer's solution. After incubation the nerve was cut into 3-mm sections, which were homogenized in 0.4 N $HClO_4$ with 10 mM EDTA, and centrifuged at 1000 g for 10 minutes. Radioactivity in portions of the supernatant fractions was determined by liquid scintillation spectroscopy. A profile of labeled material was observed that migrated rapidly in a distal direction. From the displacement of the front of this profile, a maximum transport velocity of 5.3 mm/hour was calculated. This is similar to the velocity determined by stop-flow techniques for endogenous catecholamines, when corrected for temperature. Regression analysis of this data indicated that the lag time for transport was less than 20 minutes as compared to 90 minutes for proteins labeled with ^{35}S-methionine.

To determine the nature of the catecholamines that were transported, the material that accumulated at a ligature was analyzed by reverse-phase high performance liquid chromatography (HPLC) using electrochemical detection. It was found that 8 hours after injection greater than 95% of the radioactivity that accumulated at the ligature had an elution time similar to that of an epinephrine standard. On the other hand, only about 50% of the radioactivity remaining in the ganglia had an elution time similar to epinephrine. The remainder eluted with the norepinephrine standard. We conclude that the synthesis and processing of transported catecholamines in this species is largely completed in the nerve cell body. (Supported by Mayo Foundation and NIH Grant NS 11855.)

241.5 BLOCK OF FAST AXONAL TRANSPORT CAUSED BY MICRO-INJECTION OF THE ACTIN DEPOLYMERIZER, DNase I, INTO THE AXON OF AN IDENTIFIED NEURON. Daniel J. Goldberg, Dept. Pharmacol. and Center for Neurobiol. & Behav., Columbia U. Coll. P&S, New York, N.Y. 10032

It has often been suggested that actin participates in generating the force for fast axonal transport. Until recently there has been scant experimental support for this idea, one difficulty having been the lack of specific actin inhibitors that could easily permeate the axolemma to gain access to the transport apparatus. Within the past year, this difficulty has been surmounted by micro-injecting inhibitors directly into the cell bodies of giant identified invertebrate neurons. Deoxyribonuclease I (DNase I), which, in addition to its enzymatic activity, specifically depolymerizes actin filaments, decreased the transport of serotonin in the giant cerebral neuron of Aplysia (Goldberg et al., Proc. Nat. Acad. Sci., U.S.A., 77:7448, 1980) and of protein in the leech Retzius cell (Isenberg et al., Brain Res., 194:588, 1980). Because the inhibitors were injected into the cell bodies, however, it could not be concluded that they blocked the actual movement of material along the axon rather than the assembly of organelles in the cell body or the export of the organelles into the axon.

In the experiments reported here, DNase I has been unequivocally shown to block fast axonal transport by injecting it directly into the axon. In initial experiments, DNase I was injected into the cell body of the Aplysia cell R2 prior to intrasomatic injection of ^{3}H-fucose to label glycoprotein for transport. During a 4 hour period after ^{3}H-fucose injection, much less ^{3}H-glycoprotein exited the ganglion in the axon of R2 (measured as a percentage of total ^{3}H-glycoprotein in the cell) than in the absence of DNase I. The amount of ^{3}H-fucose incorporated into glycoprotein in the cell body was also greatly reduced, indicating that DNase I injected into the cell body can inhibit stages in the processing of material for transport.

In subsequent experiments, DNase I was injected into the axon of R2 rather than the cell body. It was found that essentially no ^{3}H-glycoprotein progressed past the site of DNase I injection and, in fact, a very large accumulation of radioactivity was observed just proximal to that site.

In addition to demonstrating that an actin depolymerizer blocks fast transport of materials along the axon, these experiments establish a protocol to assess unambiguously the effects of large, hitherto unusable, probes, such as enzymes and antibodies, on transport within the axon.

241.6 CHANGES IN THE AXONAL TRANSPORT OF THE CYTOSKELETON DURING DEVELOPMENT, AGING, AND REGENERATION. P.N. Hoffman, J.W. Griffin* and D.L. Price*. Depts. of Ophthalmology, Neurology, and Pathology, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

In order to test the hypothesis that the pattern of slow axonal transport in regenerating neurons resembles the developing state, we have examined the effects of development/aging on the axonal transport of the principal cytoskeletal proteins (actin, tubulin, and the neurofilament triplet polypeptides) and compared these results with studies of the transport of these proteins in regenerating neurons.

Axonal transport of the cytoskeletal proteins was examined in the motor neurons of male Sprague-Dawley rats at 3 and 8 weeks and one year of age. The transport velocities of each of the principal cytoskeletal proteins declined with age. At 3 and 8 weeks and one year of age, the leading edge of the actin wave moved at average rates of 5.2, 3.9, and 2.1 mm/d, respectively, while tubulin was transported at average rates of 3.8, 2.8, and 1.8 mm/d, respectively. The average velocity of the neurofilament triplet proteins also declined.

Hoffman and Lasek [Brain Res. 202:317-333, 1980] have shown that the transport of actin and tubulin is increased during axon regeneration. The present study indicates that this increase is maximal at two weeks postaxotomy; transport returns to normal by six weeks. In eight-week old animals two weeks postaxotomy, the leading edge of the actin and tubulin waves moved at average rates of 7.0 and 6.1 mm/d, respectively, as compared to 3.9 and 2.8 mm/d in controls. The total level of radioactivity in both of these proteins was significantly increased during regeneration (120-150% of control values). In contrast, at two weeks postaxotomy, the level of radioactivity in the neurofilament triplet was reduced to 50% of control values.

The transport velocities of actin and tubulin fell more than twofold between three weeks and one year of age. This trend was dramatically reversed during regeneration during which the velocities of these proteins exceeded those of the three-week old animals. In terms of transport velocity, this pattern resembles the profiles occurring in developing nerve cells. In addition, the level of radioactivity in the neurofilament triplet proteins was reduced by half during regeneration at the same time that the labeling of both actin and tubulin was significantly increased. Since the embryonic motor axon is characterized by an abundance of microtubules and fewer neurofilaments, this change leads to a pattern similar to that seen during development.

242.1 LOCAL SPIKING INTERNEURONES AND THE CONTROL OF LEG MOVEMENTS IN THE LOCUST. M.Burrows and M.V.S. Siegler*. Department of Zoology, University of Cambridge, Cambridge CB2 3EJ, U.K.

The local neurones involved in the control of limb movements, and described so far in the thoracic ganglia of insects, have proved to be unusual in that they do not produce action potentials. They synapse upon the motor neurones, which they control by the graded release of transmitter. These interneurones form a population diverse in their morphology, and in their physiological effects.

We now describe a population of local interneurones in the meso- and metathoracic ganglia of the locust that normally do produce action potentials. Anatomically, they are a diverse, and probably large population, as revealed by intracellular staining. They have extensive dendrite arborizations in both the ventral neuropile, to which sensory neurones predominantly project, and in the dorsal neuropile, where motor neurones have the majority of their branches. Their cell bodies form two ventral groups; one close to the midline of the ganglion, the other lateral and close to the emergence of the first lateral nerve. No neurone that has been stained has a process that can be readily described as an axon. At a gross level, the spiking local neurones are not easily distinguishable from the non-spiking ones. Each local spiking interneurone can be activated either by specific movements of one hind leg, but no other legs, or by stimulation of specific sense organs in that leg. For example, an interneurone may respond only to extension of the femoral-tibial joint, or only to stimulation of a few hairs on the femur. By contrast, non-spiking interneurones each respond to diverse sensory inputs. Anatomical evidence suggests that there are several spiking local interneurones that respond to each of the different sensory stimuli. The interneurones spike readily when depolarized with injected current, but there is no apparent motor effect, measured either from extracellular myograms, or from simultaneous intracellular recordings in motor neurones. This is in contrast to the results of stimulating the non-spiking interneurones, where small currents produce obvious motor effects. It is possible that only the summed activity of several spiking local interneurones, which are normally activated together, is sufficient to produce a motor effect.

Local spiking interneurones represent yet another population of small neurones that must be taken into account when explaining the neural control of locomotion. Could they be responsible for the primary integration of information supplied by the massive numbers of sensory neurones?

242.2 PROPRIOCEPTIVE DEPENDENT INHIBITORY PATHWAYS TO HINDLEG FLEXOR MOTORNEURONS IN THE LOCUST. J. D. Steeves and K. G. Pearson. Dept. of Zoology, UBC , Vancouver, B.C. , V6T 2A9 , and Dept. of Physiology, Univ. of Alberta, Edmonton, Alberta , T6G 2H7.

A distinctive behavior of many animals is a ballistic movement to avoid capture. One ballistic escape response is the jump of the locust which is produced by a stereotyped motor pattern (Heitler and Burrows, J. Exp. Biol., 66: 203-220, 1977). Initially there is a complete flexion of both hindleg tibiae, followed by a period of coactivation of flexor and extensor motorneurons (MNs). The jump arises from the sudden inhibition of the flexor tibiae MNs. This allows the isometrically contracted extensor tibiae muscles to rapidly shorten, thereby extending the tibiae, launching the animal into the air.

Recently a pair of interneurons (M-neurons) have been identified in the metathoracic ganglion (one for each hindleg) whose properties suggest they are the trigger neurons for the jump (Pearson et al., J. Neurophysiol., 43: 257-278, 1980). These M-neurons monosynaptically inhibit flexor tibiae MNs, have a high threshold for activation, and receive strong excitatory input from several sensory modalities (visual, auditory, tactile, and proprioceptive). Due to the high threshold for spike initiation in the M-neurons, the external sensory inputs alone (eg. movement within the visual field) rarely activate the M-neurons. However during the coactivation of the flexor and extensor tibiae MNs, preceeding the jump, proprioceptive feedback depolarizes the M-neurons thereby decreasing their threshold for activation. It has been suggested that only during this period could external sensory stimuli activate the M-neurons and trigger a jump (Pearson et al., 1980).

In order to test this hypothesis, intracellular recordings were obtained from metathoracic flexor MNs and the M-neurons according to previously described methods (Pearson et al., 1980). Inhibitory postsynaptic potentials (IPSPs) in flexor MNs, in response to movements within the visual field or to auditory stimuli, were only seen in the presence of proprioceptive feedback from the hindleg. Furthermore, the M-neurons were activated under the same experimental conditions. An external stimulus alone, in the absence of proprioceptive feedback, rarely produced a burst of activity in the M-neurons or IPSPs in the hindleg flexor MNs. We propose that this proprioceptive "gating" of inhibitory pathways to flexor MNs occurs at the postsynaptic membrane of the M-neuron. Proprioceptive "gating" would ensure the development of suffcient isometric tension in the extensor tibiae muscles before a successful jump is triggered in response to external stimuli. (Supported by the MRC and NSERC of Canada)

242.3 SITES OF LEECH MOTONEURON CONNECTIONS SUGGESTED BY INTRACELLULAR STAINING OF PAIRS OF NEURONS USING HORSERADISH PEROXIDASE AND LUCIFER YELLOW SIMULTANEOUSLY. B. Granzow and W. B. Kristan, Jr., Dept. of Biology, UCSD, La Jolla, CA. 92093.

We are currently employing a double intracellular staining technique in the leech Hirudo medicinalis to investigate the spatial relationships between pairs of identified swim motoneurons. One cell in a ganglion is filled with the enzyme horseradish peroxidase and another in the same gangion is filled with Lucifer Yellow. The ganglion is processed according to the method of Macagno et al., (Brain Res., in press, 1981). Using a combination of uv epi-illumination and transmitted green light, the two cells can be observed simultaneously in whole mounts, and the processes of the individual cells can be distinguished from one another even in areas where they may overlap. In this way, potential sites of synaptic contact are revealed.

We have found, for example, that one motoneuron, cell 1, which inhibits the excitor motoneuron, cell 3, appears to make direct contact with cell 3. Likewise, cell 2, also an inhibitor motoneuron, appears to make direct contact with cell 4, another excitor motoneuron. The sites of electrotonic coupling between bilateral homologues are also suggested using this technique. That these are areas of synaptic contact will require confirmation by electron microscopy.

Our anatomical results support the hypothesis that the inhibitor and excitor motoneurons are monosynaptically connected. The usual physiological tests for monosynaptic connections have been inconclusive in these cases, since the connetions are mediated by transmitter release which is influenced by D.C. changes in pre-synaptic membrane potential without requiring action potentials. In addition, the spike initiation zones of motoneurons are distant from the cell bodies so that current injected into the pre-synaptic cell body in order to drive an action potential, itself causes a post-synaptic response which masks the effect of the action potential. This precludes tests based on a one-to-one relationship between driven pre-synaptic action potentials and IPSPs.

There are two morphologically distinct areas of contact between cell 1 and cell 3. We are extending these experiments to determine whether one or both areas might be involved in synaptic transmission between the two cells: by making selective kills of each of the areas using the cell-kill method of Miller and Selverston (Science 206:702, 1979) and by investigating the ultrastructure of these areas using electron microscopy.

242.4 LOCAL CIRCUIT INTERNEURONS AND MOTOR NEURONS IN THE RESPIRATORY SYSTEM OF THE CRAB. R. A. DiCaprio and C. R. Fourtner. Dept. Biological Sciences, SUNY/Buffalo, Buffalo, NY 14260.

The respiratory system in the crab, Carcinus meanas, has been described by Young (1975; J. comp. Physiol. 101: 1-37). The motor pattern consists of reciprocal activity in at least five levator and five depressor motor neurons. Simmers and Bush (1980; Brain Res. 197: 247-252) have recently described physiologically three interneurons which are either active during the respiratory rhythm or can control the frequency of the rhythm. We have extended their studies using Lucifer-yellow (Stewart, 1978; Cell 14: 741-759) filled electrodes to record from and identify motor neurons and interneurons. Of particular interest in our studies thus far are two local circuit interneurons. The first interneuron produces non-spiking oscillations, of approximately 8 mv, which are in phase with the respiratory rhythm; the depolarizing phase occurring during the levator burst and the hyperpolarizing during the depressor burst. Application of steady hyperpolarizing current slowed the rhythm by increasing the duration of both the levator and the depressor bursts. Depolarizing pulses applied at any time during the cycle could reset the rhythm. Cleared whole mounts following Lucifer-yellow injection revealed a local circuit neuron with its soma on the lateral edge of the ganglion and anterior to a highly branching dendritic field, located in an extremely lateral position in the neuropile. The second interneuron produced low amplitude, approximately 1.0 mv, hyperpolarizations which were coincident with depressor activity. During periods of no respiratory rhythm, depolarization of this interneuron started the rhythm and an increase in the depolarization increased the frequency of the rhythm; subsequent hyperpolarization stopped the rhythm. This particular interneuron had two separate dendritic areas: one similar to that of the first interneuron and the second dendritic area in a medial region of the neuropile. The cell body was anterior to the dendritic fields and mid-way between the lateral edge and the mid-line of the ganglion. Our physiological and morphological studies clearly demonstrate that local circuit, non-spiking interneurons are an integral part of the central pattern generator producing the respiratory rhythm in the crab. (Supported by grants IF32NS06277 to R.A.D.; K04NS00141 and UB H079 to C.R.F.).

242.5 REPETITIVE AND SPONTANEOUS DRIVER POTENTIALS IN CRUSTACEAN CARDIAC GANGLION NEURONS. A. Berlind. Bekesy Laboratory of Neurobiology, 1993 East-West Rd., Honolulu, HI 96822 and Biology Department, Wesleyan University, Middletown, CT 06457.

In crustacean cardiac ganglion neurons a slow depolarization, the driver potential (DP), underlies each burst of spikes. DPs can be isolated by treatment with tetrodotoxin; they have been shown by Tazaki and Cooke to involve Ca^{++} influx and to be terminated by a V-dependent K^+ current and possibly a Ca^{++}-activated K^+ current. DPs were recorded from large cells (motorneurons) in ganglia of the crabs Podophthalmus vigil and Portunus sanguinolentus. In contrast to previous results in Portunus, where a brief (20-100 msec) depolarizing stimulus is required to elicit each DP, a large percentage of Podophthalmus ganglia in TTX exhibit periodic, long-lasting (1-5 min) spontaneous trains of DPs. In ganglia that do not show spontaneous DPs, long-lasting trains can usually be elicited by a strong 3-sec depolarizing current pulse, by a rapid series of brief pulses, or by treatment with dopamine. The Podophthalmus ganglia can also be driven by 3 sec depolarizing current pulses to fire repetitive DPs, the frequency of which increases with increasing current strength. This contrasts strongly with Portunus, where long depolarizing current of any suprathreshold intensity evokes only a single DP. In Portunus, neither suppression of the V-dependent K^+-current by tetraethylammonium (50 mM), nor suppression of a fast K^+-current by 4-aminopyridine (2 mM) allows repetitive DPs in response to a long current pulse; treatment with procaine (5 mM) allows repetitive DPs. Evoked DPs in Podophthalmus and Portunus also exhibit distinct differences in form and ion dependency. The Podophthalmus DP rises much more rapidly and is of shorter duration, is less effectively suppressed by the addition of Mn^{++} to the medium, and is not increased in amplitude by raising the external Ca^{++} concentration or lowering Na^+. The results 1) show that DP mechanisms may show distinct differences in detail even in closely related species; 2) suggest that endogenous properties of individual neurons might play a considerably more important role in the generation of rhythmic output by this system than has previously been assumed.

242.6 INTRACELLULAR RECORDINGS FROM IDENTIFIED MOTORNEURONS IN THE NEMATODE ASCARIS. R. E. Davis* and A. O. W. Stretton. Neurosciences Program and Department of Zoology, University of Wisconsin, Madison, Wisconsin 53706.

We have been investigating the motornervous system of the large parasitic nematode, Ascaris (Stretton, A. O. W. et al., PNAS 75:3493, 1978). The dorsal and ventral nerve cords of Ascaris are connected by a repeating pattern of single identified motorneuron processes, called commissures. A mat of muscle cells overlies the commissures. After removing a portion of this muscle with fine forceps single commissures can be visualized and penetrated with a microelectrode. The large diameter of the commissural process (10-20 μ) facilitates these electrophysiological recordings.

The dye, Lucifer Yellow (Stewart, W. W., Cell, 14:741, 1978) has been injected into motorneurons through intracellular microelectrodes and the neurons identified by subsequent fluorescence microscopy. Utilizing high resistance 3M KCl-filled microelectrodes (60-100 MΩ) we have obtained intracellular recordings from representatives of each commissural motorneuron type. Resting membrane potentials vary between -25 and -40 mV depending on the motorneuron type being investigated. Excitatory motorneurons tend to have higher resting potentials than inhibitory motorneurons.

Two excitatory motorneuron types (DE1, DE3) show rhythmic spontaneous inhibitory post-synaptic potentials (IPSPs); one excitatory motorneuron type (DE2) exhibits patterned excitatory post-synaptic potentials (EPSPs), probably from two different sources. The inhibitory motorneuron types (DI, VI) display membrane potential oscillations. Current research is being directed at the following questions: (1) the membrane properties of the motorneurons, (2) the ionic bases of their signals and (3) the physiology of the synaptic interactions known anatomically to exist between motorneurons.

243.1 EVIDENCE FOR A PASSIVE INFLUENCE ON NEURAL CREST CELL DISTRIBUTION IN THE TRUNK OF THE AVIAN EMBRYO. M. Bronner-Fraser* (SPON: R. Eckert). Dept. of Physiol. and Biophys., Univ. of Calif., Irvine, CA 92717.

Neural crest cells migrate along two pathways in the trunk of avian embryos: a dorsolateral route just under the ectoderm; and a ventral route between the neural tube and the somite. The mechanisms causing crest migration to defined loci are not understood. The evidence presented here suggest a role for passive environmental influences, independent of cell motility.

Previous experiments have used an injection technique to introduce neural crest and other cell types to the ventral neural crest pathway (Bronner-Fraser and Cohen, Devel. Biol., 77:130, 1980). These studies demonstrated that neural crest-derived pigment cells are capable of migrating ventrally even after differentiation; however, somite cells and skin fibroblasts do not migrate along the ventral route.

In the present study, retinal pigment epithelium cells (RPE) were injected onto a neural crest pathway by the same injection method. These cells are the only pigmented cells in the body which are not of neural crest origin. Like crest-derived pigment cells, these RPE cells distribute along the ventral neural crest pathway. Unlike neural crest pigment cells which extend processes after injection and look morphologically like migratory cells, the RPE cells remain rounded and do not appear to be actively moving. This observation raises the possibility that factors other than active migration may affect localization of the injected RPE cells (and perhaps endogenous crest cells as well). To test this possibility, monodispersed latex polystyrene beads were injected onto the ventral pathway as an inert probe of the environment. These beads are of approximately the same size as neural crest cells. The latex particles distribute along the neural crest pathway with a time course similar to that of endogenous crest cells. In the majority of cases, the beads localize near the sympathetic ganglia or adjacent to the dorsal aorta, in close proximity to endogenous crest cells. It is unlikely that the latex particles are adhering to migrating neural crest cells; in tissue culture, only a small percentage (on the order of 1%) of neural crest cells nonspecifically bind latex beads. The results suggest that there exists a passive component which influences the distribution of neural crest cells as well as non-motile substances along the ventral crest pathway. The fact that other cell types (somites and fibroblasts) do not migrate along this pathway may indicate that certain cells have intrinsic or cell surface characteristics which override the passive environmental effects.

243.2 NUCLEUS LOCUS COERULEUS: A MORPHOMETRIC GOLGI STUDY IN RATS OF THREE AGE GROUPS. S. Diaz-Cintra*, L. Cintra*, T. Kemper* and P. J. Morgane. (SPON: W. Stern). Worcester Foundation for Expt. Biology, Shrewsbury, MA 01545.

Using Rapid Golgi and Nissl techniques, three major cell types were identified in the nucleus locus coeruleus of male rats at 30, 90 and 220 days of age: fusiform, multipolar and ovoid. One hundred neurons per age group, encompassing all three cell types from all parts of the nucleus, were selected for quantitative study. The following measures were made on all cells in the three age groups: major and minor axes of the cell body, number of somatic spines, number of primary and secondary dendrites, diameter of primary and secondary dendrites, linear extent of primary and secondary dendrites and the number of dendritic spines on primary and secondary dendrites (the latter measured along a 50 micron segment near the midpoint of the dendritic length). The most striking age-related changes were that all three cell types showed significant decreases in spine density on both primary and secondary dendrites between 30 and 90 days of age with the most marked decreases seen in the ovoid cells. On the other hand, between 90 and 220 days all three cell types showed significant increases in primary and secondary dendritic spine densities. The most marked increase in dendritic spine density was seen in the ovoid cells. Perisomatic spine counts were also significantly decreased in all three cell types between 30 and 90 days with the greatest decrease (52%) seen in the multipolar cells. Only the ovoid cells showed a significant increase in perisomatic spines between 90 and 220 days of age (35%). Special neuro-vascular relations of dendrites of locus coeruleus neurons to blood vessels, such as we previously observed in the nucleus raphe dorsalis, were not seen. Relative to dendritic branching, the cells of the locus coeruleus show a typical reticular type organization with prominent dendritic fields extending widely outside the "nucleus." These dendrites extend into the central gray and dorsal nucleus of Gudden as well as into the trigeminal nucleus laterally. In the dorsal nucleus of Gudden there is considerable overlap with dendrites of neurons of the nucleus raphe dorsalis. It is of interest that the dendritic spine densities of the 3 types of locus coeruleus cells show exactly opposite developmental tendencies from those we previously described in the nucleus raphe dorsalis (Brain Res. 207: 1-16, 1981). In the nucleus raphe dorsalis each cell type showed significant increases in dendritic spine density between 30 and 90 days followed by significant decreases in dendritic spine density between 90 and 220 days of age. (Supported by NSF grant 79-22507 and NICHD grant HD-06364).

243.3 THREE DIFFERENT AND POSSIBLY COORDINATED PATTERNS OF HISTOGENESIS IN THE RABBIT'S TELENCEPHALON : AUTORADIOGRAPHIC EVIDENCE. Victor Fernández* and Rodrigo O. Kuljis (SPON: A. L. de Blas). Dept. of Physiology and Biophysics, University of Chile and Dept. of Neurobiology and Behavior, S.U.N.Y. at Stony Brook, New York 11794.

Autoradiographic studies of CNS development have consistently shown that cell migration and deposit sequences (histogenic gradients) depend on the topographic location of the structures under formation, rather than on their functional role in the adult (Fernández et al., Brain Behav. Evol. 16:113-128, 1979). Here we analyze the histogenic gradients of three functionally different areas that, being telencephalic derivatives, share a close topographic relationship in embryogenesis.

Fifty-four rabbit embryos ranging from the 15th day of gestation up to the newborn stage received a single pulse of ^{3}H-thymidine, via maternal intraperitoneal injection (5mCi/Kg). After different survival periods, development of the septal, neostriatal and neocortical areas was studied autoradiographically.

The septal area develops between the 15th and at least the 25th embryonic days (nucleus accumbens continues further), following a medial to lateral gradient. Thus, cells are laid progressively closer to the neuroepithelial layer from which they originated. The neocortical area develops between the 15th and 22nd embryonic days according to a ventro-lateral to dorso-medial gradient. In this case cells are laid progressively farther from their original matrix layer. The neostriatal area develops between the 15th and 18th embryonic days along a medio-ventral to latero-dorsal gradient. In this instance cells are laid in isochronic columns roughly perpendicular to their germinal layer, such that cells originating at the same time are laid at different distances from this layer, and they are deposited in an orderly fashion according to their time of birth (Fernández et al, loc.cit.).

Although these gradients seem to be quite different when considered individually, it is possible to view them as forming part of a common topographic-but not temporal-gradient involving the whole telencephalon. A topographical sequence can be imagined, in fact, which would start at the medial portion of the septal region, involving progressively more lateral structures. After passing through the neostriatal area, this gradient would reach the basal area of the neocortical primordium, sliding along the lateral wall of the lateral ventricle, and fanning out across the entire extent of the cortical plate. We hypothesize that this situation could be due to the modification of the simple deposit sequence (such as that seen in the septal area) by factors operating as mechanical guides along the path of cell migration and deposit at the neostriatal and neocortical levels(Kuljis and Fernández, in preparation). 243.4 ADJUSTMENT OF CONNECTIVITY IN RATS DEPRIVED OF LAYERS II-IV OF CEREBRAL CORTEX BY PRENATAL DESTRUCTION OF PRECURSOR CELLS. L. Yurkewicz, E.G. Jones, K.L. Valentino, and J.W. Fleshman, Jr. Dept. of Anatomy & Neurobiology and McDonnell Center for the Study of Higher Brain Functions, Washington University, School of Medicine, St. Louis, Missouri 63110.

Injection of the cytotoxic drugs methylazoxymethanol acetate or 5-azacytidine to pregnant rats at 15-17 days gestation leads to the birth of infants that grow to maturity lacking layers II-IV of the cerebral cortex but with earlier and later developing parts of the brain intact. In the affected animals, at maturity, we studied the structure of the sensory-motor regions with Nissl and Golgi methods, their input-output connections with anterograde and retrograde tracing methods and the receptive field properties of neurons in the cortex and ventroposterior thalamic nucleus, with electrophysiological methods.

The remaining layers V and VI are structured and subdivided as in normal rats but layer V is surmounted by a molecular layer. Pyramidal and non-pyramidal neurons are visible. Pyramidal neurons are normal except in the superficial half of layer V where many have widely divaricated apical dendritic trees and a high proportion are inverted. Layer VI cells project only to the thalamus; layer V cells, including the inverted and atypical pyramids, project into the pyramidal tract. A number of islands of aberrant cells whose migration may have been arrested, occur in the external capsule. These cells though abnormally oriented, have many of the characteristics of pyramidal neurons and project axons through the corpus callosum which is much reduced in size.

Thalamic afferents terminate in a bistratified manner; (abnormally) just superficial to the somata of the deeper layer V pyramids and (normally) at the junction of layers V and VI. Mapping of unit responses in the cortex and in the structurally normal thalamus indicates that body somatotopy is preserved and that receptive field sizes are unchanged from normal.

These findings show that the destruction of target cells in the cortex prior to the arrival of thalamic afferents does not prevent the afferents from colonizing the cortex and establishing a normal somatotopically organized pattern of connections, partly in an abnormal position. This is associated with changes in the morphogenesis of pyramidal cells though these still appear to send their axons to appropriate targets.

243.5 QUANTITATIVE ANALYSIS OF NEURONAL MORPHOMETRY: ORDER AND ANGULAR STUDIES OF HIPPOCAMPAL PYRAMIDS FROM NORMAL AND ABERRANT HUMAN BRAIN. Albert M. Paldino. Dept. of Neuroscience, Rose F. Kennedy Center for Research in Mental Retardation and Human Development, Albert Einstein Coll. of Med. of Yeshiva Univ., Bronx, New York 10461.

Morphometric analyses have been carried out on hippocampal pyramidal neurons from six human infants. Five of these infants were preterm, with gestational periods ranging from 22-to-30 weeks; all had normally developed brains as assessed by routine gross and microscopic examinations. The sixth infant was born at 36 weeks and survived for three weeks; chromosomal studies performed on this infant confirmed the clinical impression of TRISOMY 18.

Small blocks of tissue obtained at autopsy were fixed with formalin and subjected to the Rapid Golgi process. Three dimensional coordinate data representing individual neuronal structures were obtained with a computer microscope and mathematical analyses were performed on these data by computer programs written in FORTRAN.

Preliminary branch ordering studies have been performed on these neurons by the centrifugal (somatofugal) method. Initial segments projecting from the soma were assigned order 1; mother segments of order N gave rise to daughter segments of order N+1. These studies included the calculation of the average number of segments/order/cell, total length/order/cell, and average segment length/order/cell for both apical and basilar dendritic systems. The results from normally developed cortex suggest the following: The average dendritic segment length/order/cell is small during the early stages of gestation (18-to-26 weeks) and subsequently increases during the latter stages of gestational development (26-to-30 weeks); the average number of basilar segments/order/cell systematically increases throughout the gestational period. For the infant of 36 weeks gestational age (g.a.) with TRISOMY 18, the average dendritic segment length/order/cell for both apical and basilar dendritic systems suggests a staggered level of development.

Our previous studies in normally developed human cortex demonstrated that dendritic branch and fission angles could be reliable indices of maturation. Preliminary investigations of these angular parameters in the 36 weeks g.a. infant with TRISOMY 18 and three weeks of extrauterine survival suggest that this infant attained a level of cortical development comparable with that of a normally developed infant of 26-to-30 weeks g.a. These quantitative assessments of a developmental lag in cortical neurons of an infant with confirmed TRISOMY 18 may facilitate an understanding of the neuronal basis of mental retardation.

243.6 DEVELOPMENTAL CHANGES OF THE SUBPLATE LAYER IN THE FRONTAL CORTEX OF HUMAN FETUS. I. Kostović, Dept. of Anatomy, Med. Faculty, 41001 Zagreb, Yugoslavia.

In a previous study /Kostović and Molliver,Anat.Rec.,178: 395,1974/ we have demonstrated the presence of prominent synaptic lamina /subplate layer, s.l./ below the cortical plate in the neocortex of human fetuses. Experimental studies in primates suggested that s.l. may serve as a"waiting" compartment for incoming cortico-cortical fibres during critical period of fissural development and that subplate neurons participate in the morphological rearrangements after prenatal cortical injury /Goldman-Rakic,Pregr. Brain Res., 53:3,1980/. To examine developmental changes of the subplate layer and their relation to fibre growth and gyral development, orbito-lateral frontal cortex of human fetuses ranging between 15 and 38 weeks of gestation /w.g./ was analyzed by means of Nissl, Gless silver, Golgi and acetylcholinesterase / AChE/ methods.

Several features characterize neuronal organization of the subplate layer /situated below the cortical plate and above the fetal "white" matter/: a/ presence of loose axonal network with numerous growth cones,b/ the multiplicity of neuronal types with random distribution, c/ permanent shifts in AChE reactivity. The following developmental changes were observed: a/ Gradual increase in the thickness between 15-32 w.g. /up to 10 mm/, thereafter,during rapid development of secondary gyri, there is a gradual decrease of s.l.This change starts in the orbital-inferior frontal gyrus while in the middle-superior frontal gyrus prominent s.l. was found through 31-36 w.g.,b/ AChE reactivity appears at 16 w, transient strong staining was observed at 22 e.g., later there is gradual decrease in AChE reactiviy, c/after 32 w.g. reduction of axonal network was found and many subplate neurons become incorporated into approaching fascicles of gyral "white" matter. This change begins in the orbital cortex and proceeds towards lateral frontal gyri.

In conclusion, subplate layer reaches its greatest prominence during a period /22-34 w.g./ of intensive growth of cortical fibres and formation of primary gyri in the human frontal lobe. Several weeks before birth, concomitantly with the reduction of axonal network below cortical plate and formation of secondary gyri, s.l. become less conspicuous. We suggest that s.l. is reduced by growth of its axons into cortical plate and by incorporation of subplate neurons in the gyral white matter./Support: SIZ V and RSIZ Spec.obraz./

244.1 TRIMETHYLTIN INDUCED HYPERACTIVITY: TIME COURSE AND PATTERN. P. H. Ruppert, T. J. Walsh, L. W. Reiter and R. S. Dyer. Neurotoxicology Division, Health Effects Research Laboratory, US Environmental Protection Agency, Research Triangle Park, NC 27711.

Trimethyltin (TMT), a neurotoxic organotin compound, produces structural damage primarily in the hippocampus, but also in the pyriform cortex, amygdaloid nucleus and neocortex. Limited neuropathological changes are evident as early as 2 days following a single dose of TMT. Maximal damage is seen 21 days following dosing and persists for at least 70 days post-treatment (Brown et al., Am. J. Path. 97:57-82, 1979). Swartzwelder et al. (Neurotoxicol., submitted) have reported that TMT rats were hyperactive in a 2 min open field test 40 days after dosing. The purpose of the present experiment was to determine the time course, dose dependence and circadian pattern of hyperactivity produced by acute exposure to TMT.

Adult male Long-Evans hooded rats (N=10/group) were intubated with either 0, 5, 6, or 7 mg/kg trimethyltin chloride as the base given in a volume of 1.0 ml/kg. Motor activity was automatically measured in a figure-eight maze consisting of 10x10 cm alleys that converge on a central arena (Reiter et al., Environ. Health Perspect. 12:119-123, 1975). Animals were tested for 1 hr starting 2 hr after dosing on Day 0, and again on Days 4, 8, 16 and 32. On Days 49-51, activity was measured over a 23 hr period. There were no differences in body weight between groups at any time following dosing. Animals treated with 7 mg/kg TMT exhibited hyperreactivity and spontaneous seizures which were most evident 5-10 days after dosing and disappeared by Day 16 following treatment. There were no differences in activity on the day of dosing, but on all subsequent days the 7 mg/kg TMT animals were hyperactive in comparison to all other groups. The time course for development of hyperactivity which was apparent by Day 4 and asymptoted on Day 16, parallels the time course of neuropathological changes, which first appear 2 days after dosing and are maximal within 3 wks (Brown et al., 1979). In addition to increasing the total amount of activity, TMT also changed the spatial pattern of activity; activity was increased in the "figure-eight" portion of the maze but not in the blind alleys. Activity of the 7 mg/kg TMT animals was also increased during all periods in the 23 hr test. These results demonstrate that structural damage produced by acute exposure to TMT is associated with long lasting hyperactivity.

244.2 TRIMETHYLTIN TOXICITY IN GRASSHOPPER MICE (ONYCHOMYS TORRIDUS). K.L. Hulebak*, Z. Annau. Dept. Environ. Hlth. Sci., Div. Toxicology, The Johns Hopkins Univ., Baltimore, MD 21205

Trimethyltin (TMT) is an organometallic neurotoxin which produces specific neuronal lesions in discrete brain regions. Damaged areas include the hippocampus, pyriform cortex, septal nucleus and amygdala. These lesions have been shown in the rat to be accompanied by hyperirritability and possibly increased agonistic behaviors.

The present study determined the acute toxicity (LD-50) of trimethyltin chloride in two species of mice, Mus musculus (CFW) and Onychomys torridus, and assessed the effects of chronic TMT exposure on the social behavior of Onychomys. These carnivorous rodents not only display a diverse repertoire of social behaviors, but also show predatory behavior towards prey such as crickets.

The LD-50 was determined by intubating groups of 8 mice (both CFW and Onychomys) with 0, 1.0, 2.0, 2.25, 2.5, 2.75, and 3.0 mg/kg TMT in saline. Animals were observed for a period of 14 days post-intubation. At 2.75 mg/kg, all animals died 7 days post-intubation. At 2.25 mg/kg, half the animals died three days post-intubation. Survivors showed whole-body tremors with severity dependent on dose. The tremors disappeared in the survivors by five days post-intubation.

Same-sex pairs of male and female grasshopper mice were exposed (p.o.) to 0, 0.5, and 1.0 mg/kg TMT weekly, for 3 weeks. Their performance on a variety of behavioral tasks and situations was monitored on a weekly basis during exposure, and at one month post-exposure, and compared with their pre-exposure performance. Behavioral tasks included auditory startle reflex, a test of predatory aggression (cricket-killing), and undisturbed social behavior of each pair. The latter category consisted of general maintenance behavior, agonistic behavior, and mutual social behaviors. Results indicate sex-, dose-, and time-dependent depression of the auditory startle reflex, and concomitant disruptions of social, agonistic and general activity behaviors of the mice.

244.3 NEURONAL RESPONSES TO AN ENVIRONMENTAL POLLUTANT IN AN INTACT MARINE ANIMAL. J. E. KANZ, M. D. DUVALL. Marine Biology Dept. Texas A&M University at Galveston, Galveston Tx. 77553

Drilling fluids are heavy mixtures which include barite ($BaSO_4$), lignosulfonates, fungicides, bacteriocides and even pesticides and are used to facilitate several off-shore oil platform drilling related functions, e.g., removal of drill cutting and lubrication of drilling bits. After use, drilling fluids are usually discharged into the environment around the platform where they have been shown to adversely effect a wide range of marine fauna.

A recently developed in vivo extracellular recording technique coupled with new computer procedures for analysis of the extracellular neuronal data have been applied to determine the effects of drilling fluid on the nervous system of the marine gastropod Aplysia. Therefore, utilizing a freely behaving animal it is possible to monitor subtle changes in neuronal activity which over short-term (1-4 days) have no detectable behavioral correlates. Two types of Aplysia siphon nerve activity were studied and compared before and after cannulation of drilling fluid into the body cavity: 1) spontaneous background activity and 2) the frequency and pattern of activity making up a spontaneous burst of activity from a network of cells in the abdominal ganglion (Interneuron II). 244.4 AN EXAMINATION OF THE PROGRESSION OF BEHAVIORAL AND PATHOLOGICAL EFFECTS IN MICE EXPOSED TO THE PARASITE TOXOCARA CANIS. Z.S. Dolinsky, R.G. Burright‡ and P.J. Donovick, Dept. of Psychology and Center for Neurobehavioral Sciences, SUNY Binghamton, Binghamton, N.Y. 13901, and B. Summers* and R.H. Cypess‡ Dept. of Preventive Medicine, Cornell Univ., Ithaca, N.Y. 14850.

Toxocara Canis a parasitic roundworm commonly infects dogs. The eggs of the parasite are excreted in the animal's feces and may be ingested by children. The larval stage of this parasite is known to migrate through various organs in the human including liver, lung, muscle, and CNS. The long term viability of the eggs in the environment, and the difficulty in diagnosis and treatment of this parasitic infection make it a potential health problem.

We examined the time course of behavioral and pathological changes, over a period of 86 days, in mice intubated with 1000 embryonated decorticated eggs of Toxocara Canis. A battery of behavioral tests (Home cage observation, Open field, Swimming, Shock sensitivity, Balance) was administered at each of 3 post intubation periods (Period 1 -- 8-10 days post intubation, Period 2 -- 49-51 days, Period 3 -- 84-86 days). All animals were intubated on the same day, however each post intubation period was comprised of an independent group of animals. At each post intubation period animals were sacrificed at the end of behavioral testing and liver, lung, muscle, and brain were examined for histopathology.

Toxocara treated animals showed depressed levels of activity relative to controls on a select number of measures during the first test period. However, the scope and severity of behavioral changes became more severe on the subsequent two periods.

Peripheral organs showed marked pathology during the first post intubation period, followed by a decrease in severity on subsequent test periods. While larvae were present in the brain, only mild inflammatory changes were observed during the first period. However, a progressive Wallerian Type degeneration of major fiber pathways was observed on subsequent post intubation periods.

These results suggest that pathological changes in both peripheral organs and brain which are associated with Toxocara Canis infection may have behavioral consequences in mice. However, the time course of the behavioral changes, with respect to relative CNS and peripheral tissue pathology, suggest the critical involvement of the CNS in the behavioral effects associated with Toxocara Canis infection.

These results may have important implications in the etiology of behavioral disorders for children who have a known history of pica for dirt. (Supported by NSF (DAR7911233) grant to PJD & RGB)

244.5 TOXOCARA CANIS AND LEAD ALTER SENSORY REACTIVITY OF MICE. P. J. Donovick, Z. S. Dolinsky, V. P. Perdue, and R. G. Burright*, Dept. of Psychology and Center for Neurobehavioral Sciences, SUNY Binghamton, Binghamton, N.Y. 13901, and R. H. Cypess*, Dept. of Preventive Medicine, Cornell Univ., Ithaca, N.Y. 14850.

The common parasite roundworm of dogs, Toxocara canis, presents a health problem to humans. The eggs of the parasite are excreted in the dog's feces. The long-term viability of these eggs makes them a health hazard, particularly to children who may play in areas frequented by dogs. Thus, in urban settings individuals may be exposed both to parasites and other toxic elements, such as lead, as well. Previously, we found that several measures of motoric behavior were dramatically altered in mice infected with Toxocara canis. In that report we noted that combined ingestion of parasite plus lead often resulted in a less severe syndrome than when the parasite was administered alone.

In the present research we examined the effects of Toxocara canis and lead toxicity in mice on behaviors less dependent on fine motor coordination than those previously employed. Sensory reactivity as reflected in ingestion of saccharin and quinine solutions was measured in adult mice which had been administered Toxocara canis alone or in combination with lead. In addition, seizure susceptibility to ECS was assessed. Measures of taste reactivity indicated that in mice, lead or Toxocara may alter the mode of interaction with the environment. Thus lead increased sensitivity to alterations in palatability of fluid while administration of the parasite alone diminished such reactivity. The combined lead and Toxocara group fell between these extremes. While the two agents did not have an additive effect in the case of taste reactivity, the combined group exhibited the least severe electroconvulsive shock seizures. It is, however, interesting to note that the combined group did not exhibit more neuropathology than the parasite alone group.

These results suggest that Toxocara canis alone or in combination with lead can alter behaviors which have strong sensory components. They may have important health implications for urban children with known history of pica for dirt.

This research was supported in part by a grant to P. J. Donovick and R. G. Burright from NSF (DAR7911233).

244.6 SCRAPIE VIRUS AND ALTERED PUP GROWTH: EVIDENCE FOR ALTERED MATERNAL BEHAVIOR? R.F. Seegal and J.E. Hotchin. Div. Labs. & Research, New York State Dept. Health, Albany, New York 12201.

Scrapie is a fatal degenerative neural disease of sheep thought to be caused by a viroid-like agent capable of relication although it induces no antibody response in the host. It has been transferred from sheep to the mouse, hamster and primate. This agent, a member of the spongioform encephalopathies, gains in experimental and clinical importance because of its close relationship to the human disorders Kuru and Creutzfeldt-Jakob disease.

The earliest signs of infection are often behavioral and include changes in locomotor and open-field activity, sucrose-water consumption and Y-maze performance (Heitzman and Corps, 1968; Outram, 1972; McFarland and Hotchin, 1980). However, little effort has been devoted to a study of reproductive behaviors in spite of the fact that Parry and Livett (1976, 1977) noted changes in neurophysin levels in hypothalamic and infundibular regions of scrapie infected sheep brain-areas intimately involved in neuroendocrine control.

Nulliparous Nylar:nya mice were injected intra-cerebrally (IC) with either a 10^{-2} dilution of infected mouse brain containing approximately 10^{6} mouse LD_{50s} of the Chandler strain of scrapie /gram of brain tissue or a 10^{-2} dilution of normal mouse brain (NMB). These animals were mated so parturition would occur on about Day 50 post-infection. When pregnant the animals were individually housed with wood shavings provided for nest construction. Dams were inspected daily for births. All litters were culled to eight pups with cross-fostering within treatment employed to equalize litter size. No attempt was made at matching the sexual composition of the litter and only litters with 7,8 or 9 pups were included in the analysis.

No differences in sex ratio, initial number of pups born or mean weight of the pups at birth were noted. However, by two weeks post-parturition there were significant differences in the mean weight of the pups (offspring of scrapie mothers weighed significantly less than offspring of NMB inoculated mothers). These effects became more pronounced in the final week before weaning. No difference in mortality or quality of nest construction were noted between the experimental and control animals.

These results are among the earliest recorded following scrapie infection and suggest that the differences in pup body weight are a function of post-parturitional changes in behavior and/or physiology of the mother rather than in-utero changes in development of the offspring induced by the virus infection.

245.1 CONDITIONED RESPIRATORY BEHAVIOR IN RABBITS CORRELATES WITH CHANGES IN SPATIO-TEMPORAL ACTIVITY IN THE OLFACTORY BULB. G.W. Davis, W.J. Freeman, T. Whitney.* Dept. Phys.-Anat., Univ. of Calif., Berkeley, CA 94720.

The techniques of classical conditioning and multi-channel recording of neural activity have been applied to assess changes in sensory processing during conditioning of respiratory respones.

Rabbits were trained through classical aversive conditioning to give a respiratory response (sniffing) when a conditioning stimulus (CS) (amyl acetate 1/2000, or butyric acid 1/2500; dillution olfactometer) was presented followed after 2.5 sec. with shock. The instantaneous rate of respiration was monitored by a circumabdomenal pneumograph, and conditioned responses(CRs) were detected through statistical criteria executed by an Interdata 7/16 minicomputer. The neural activity of the olfactory bulb(OB) was recorded through an array of 64 electrodes implanted over the dural surface of the left OB. Six seconds of data from the array was recorded (2.5 ms digitization interval/channel) for each trial presentation of the CS or blank trials with no CS. Individual damped sinusoidal bursts of bulbar activity (35-80 Hz, 50-100 ms in duration) were selected before and after presentation of the CS. Twenty to thirty trials per session were accumulated, and as many as 30 sessions made up the total data base. Burst amplitudes (64 channels, 75 ms time series/channel) were averaged across trials according to temporal relationship to the CS: pre-CS, and post-CS bursts.

The results show that 1) the automated detection of statistical flucuations in respiration rate is an effective method for monitoring olfactory conditioning 2) approximately 300 ms after the arrival of CS, a marked decrease in burst amplitude occurs, and 3) statistically significant differences in spatial structure are detected.

The results raise several questions regarding the processing of olfactory information in the presence of behaviorally relevant stimuli. For example, does the arrival of behaviorally important odors cause the OB to alter its activity, or does the 300 ms delay between arrival of the CS and the initiation of changes in the bursts indicate that centrifugal impulses to the OB are suppressing the processing of further, possibly distracting, information.

245.2 VISUAL EVOKED POTENTIALS DURING CLASSICAL EYEBLINK CONDITIONING. M. Serdaru*, J. Rohrbaugh, K. Syndulko and D.B. Lindsley. Dept. Psychology, Univ. Calif., Los Angeles, CA 90024.

Visual evoked potentials (VEPs) to a conditioned stimulus (CS) were evaluated during preconditioning, conditioning, and extinction phases of a classical eyeblink conditioning procedure. VEPs were recorded from scalp sites overlying central (Cz) and occipital (O1) areas. Two experimental groups, with 7 subjects each, participated in 2 sessions - the first a preconditioning session, and the second session comprising conditioning and extinction trials. For one group of subjects, the CS was presented foveally, whereas for the second group the CS was presented 20° in the temporal field. For both groups, green light-emitting diodes served as the light sources, and viewing was with the right eye. The unconditioned stimulus (UCS) was an airpuff delivered to the cornea 850 msec after light onset. The reinforcement ratio during conditioning was 100%.

The VEPs to peripheral stimuli were substantially smaller than to foveal stimuli, in accord with previous findings. Both foveal and peripheral VEPs, however, showed changes during the 30 conditioning trials. These changes were centered about a negative component at about 200 msec (N200) and, to a lesser extent, a late positive component at 300 msec or later (P300), both of which were larger during the conditioning trials. Relative to preconditioning values, the VEP enhancement persisted also through the 25 extinction trials. These changes were observed both at Cz and O1, and were more pronounced on trials eliciting a conditioned blink than on trials for which no conditioned blink was obtained. A comparison of the average VEP obtained during the first 15 conditioning trials with the VEP from the last 15 trials yielded no major differences in N200, suggesting that the acquisition of the VEP changes was fairly rapid, and that they were resistant to habituation. The VEPs for voluntary responders (i.e., those subjects with short latency responses) did not differ appreciably from the VEPs of conditioned responders. No effects, either in the frequency or latency of the conditioned blink, or in the responsiveness of the VEP to the conditioning procedures, were associated with the variable of foveal versus peripheral stimulation.

245.3 RAPID CONDITIONING OF EYEBLINK REFLEX: RESPONSE TOPOGRAPHY. N.E. Berthier,* B. Betts* and C.D. Woody (Spon: B.E. Swartz) Depts. of Anatomy and Psychiatry, UCLA Med. Center, Los Angeles, CA 90024

Classical conditioning was studied in a mammalian preparation in which a discriminative response with multiple latency components could be rapidly acquired. During training, the CS (a 75 db click) was followed 340 ms later by a mechanical tap of the glabella (US) which elicited a bilateral eye blink (UR). Electrical stimulation of the lateral hypothalamus (HS) was delivered unilaterally 580 ms after the CS. A discriminative stimulus (DS; 75 db hiss) was delivered 4.4 s after the CS. Seven cats were run through series of conditioning and extinction sessions (US and HS omitted) with 10 s intertrial intervals. The orbicularis oculi EMG was rectified, filtered (Tc=5ms), and digitized with a PDP 11/44 computer to produce post-stimulus histograms with 2 ms bins. EMG deviations larger than 3 sd above the mean of the spontaneous activity in the 400 ms prior to CS delivery were defined as responses. During training, the CR increased with trials reaching asymptote (74% CRs) within 9 trials. Several response peaks could be distinguished. The most prominent of these (i.e. 5 sd above mean spontaneous activity) were classified into four windows (0-80 ms, 120-200 ms, 220-260 ms, 280-300 ms) based on their latency following CS or DS delivery. Analysis of variance indicated that cats made a comparable number of responses to the CS and DS in the shortest window (0-80 ms), but more responses to the CS than DS in the last three windows ($p \leq .006$). Responses to the CS during the last three windows increased with training. During extinction the cats initially made more responses to the CS than to the DS ($p \leq .001$), but by the 9th trial of extinction there was little responding to either the CS or DS.

This model of conditioning lends itself to electrophysiological investigation due to the speed of acquisition and the ability to characterize the rapid acquisition objectively by computer analysis of the orbicularis oculi EMG. The conditioned response was acquired rapidly within 9 trials, was discriminative for the CS, and extinguished within 9 trials when the CS was presented without US or HS. The response did not develop when the order of CS-US-HS presentations was reversed (backward conditioning), nor did a response develop within 100 pairings of CS-US or CS-HS alone. The latency of the conditioned response to the CS decreased during training, but this did not seem to represent simply a shortening of response latency. Instead, additional responses of a shorter latency were acquired while longer latency responses were maintained. Responses within the first 80 ms after CS or DS presentation seemed primarily to reflect sensitized responding to the stimulus, responses of $\geq$120 ms latency representing the discriminatively performed CRs. (Sup.by BNS78-24146&AFOSR81-0179)

245.4 NEURONAL ACTIVITY RECORDED FROM THE AMYGDALA CENTRAL NUCLEUS DURING AVERSIVE PAVLOVIAN HEART RATE CONDITIONING IN THE RABBIT. Craig D. Applegate*, Robert C. Frysinger*, Bruce S. Kapp & Michela Gallagher. Dept. of Psychology, University of Vermont, Burlington, Vermont, 05405.

Evidence in the rabbit demonstrating that (1) lesions or pharmacological manipulations of the amygdala central nucleus (ACE) attenuate vagally-mediated, aversively conditioned bradycardia (Kapp et al, Physiol. Behav., 1979; Gallagher et al., Pharmac. Biochem. Behav., 1980), (2) the ACE projects monosynaptically to dorsal medullary cardioregulatory nuclei (Schwaber et al., Neuro. Lett., 1980), and (3) electrical stimulation of the ACE produces bradycardia and depressor responses (Kapp et al., submitted) suggests that the ACE may contribute to the expression of conditioned bradycardia in this species. Based on these data, it was hypothesized that changes in ACE neuronal activity should develop to a conditioned stimulus (CS) and correlate with the bradycardia elicited to that CS during aversive Pavlovian conditioning.

To test this hypothesis multiple unit activity was recorded from 34 ACE sites in 26 New Zealand rabbits during the acquisition of a conditioned bradycardia response using an aversive Pavlovian conditioning procedure. The procedure consisted of an orienting phase in which a 1 Khz, 5.0 sec., 85 db tone (CS) was presented alone, a conditioning phase in which CS offset was coincident with a 500 msec, 2.0 mA eyelid shock (UCS), and an extinction phase in which the CS was again presented alone.

In support of the hypothesis, the neuronal activity at twelve ACE sites showed increases to the CS which emerged during the conditioning phase of the procedure, and the increased activity from two of these sites was significantly correlated with the bradycardia response. The activity from these latter placements was characterized by (1) low levels of spontaneous, pre-CS activity, (2) short latency (< 50 msec) increases in activity to the CS which were sustained for the duration of the CS and (3) a pattern of development to the CS over trials of the conditioning phase parallel to the pattern of development of the conditioned bradycardia response to the CS. Activity recorded from the remaining sites showed either no obvious changes to the CS or complex changes to the CS over the course of the procedure

The results are consistent with the hypothesis that the ACE contributes to the expression of conditioned bradycardia in the rabbit, but also suggest that neural elements of the ACE do not respond in a unitary fashion under the conditions of the Pavlovian procedure employed. (Supported by USPHS Grants RO1 MH31811 and KO2 MH00118 to BSK).

245.5 ANTERIOR LIMBIC UNIT ACTIVITY DURING DELAYED RESPONSE IN CATS. S.A. Stwertka, T.I. Lidsky, J.S. Stamm, F.C.T. Chang and S.C. Linares* SUNY at Stony Brook, NY

The anterior limbic cortex (ALC) has been reported to be involved in sequential behaviors, response suppression and attention. We investigated single unit activity of this area during the cat's performance of a task requiring some of these behaviors. Animals prepared for chronic recording performed visually cued delayed response (DR) with head immobolized, sitting in a restraint box, facing a response panel consisting of two levers each with a small light centered above them. A trial began when flickering illumination of one of the lights for 1 sec. indicated the side to be responded to after a delay of 3-5 secs. Illumination of both lights after the delay signaled that a lever press was to be made to the cued side. Correct responding delivered water to the liquid deprived cats.

Of 340 units sampled, 42% were related to aspects of DR performance. In percentages of task related cells, 56% responded with the same sign of activity (increase or decrease in rate) both to the cue and choice lights, 19% had a response to the cue which persisted throughout the delay until time of lever pressing, 8% responded during the delay only and 16% had a response to the cue which was followed by activity opposite in sign during the delay, then returning back to cue characteristic activity again to the choice lights. For all unit types both increases or decreases in activity were seen, although suppression of activity was more frequent. Differential effects for left and right trials were seen in a proportion of all unit types during their responsive phase. Latencies to on responses in cue and choice light related cells varied between 50 and 75 msec. In control tests, visual stimulation delivered with the panel lights and analysis of eye movements recorded during some sessions revealed contributions to DR task relatedness both from sensory, visually driven cells and units associated with eye movements, with activity both preceding and occurring during the movement.

These preliminary results indicate relations between the activity of ALC neurons and components of DR performance.

245.6 EFFECTS OF ANTERIOR THALAMIC LESIONS ON DISCRIMINATIVE AVOIDANCE BEHAVIOR AND NEURONAL ACTIVITY IN THE CINGULATE CORTEX. M. Gabriel, Edward Orona, Kent Foster* and Richard W. Lambert*. Dept. Psych., Univ. Texas, Austin, TX 78712.

Past studies have demonstrated the development of discriminative multiple-unit activity in the cingulate cortex and in the anteroventral (AV) nucleus of the thalamus, in response to the positive and negative conditional stimuli (CS+ and CS-) during differential conditioning of locomotory avoidance behavior in rabbits (Gabriel, M., Foster, K., Orona, E., Science, 208:1050, 1980). The discriminative neuronal responsiveness developed in the deep laminae (V-VI) of cingulate cortex in an early stage of behavioral acquisition, but discriminative responsiveness in the superficial laminae (I-IV) and in the AV nucleus did not develop until a late stage of acquisition, after the development of significant discriminative behavior. These results suggested that the deep laminae subserve neural encoding relevant to original acquisition but that the late-formed code produced by the AV nucleus may contribute to behavioral retention. The late-formed code in the superficial laminae may reflect feedback from the AV nucleus informing cortex that the code is being produced in thalamus.

To test these ideas male albino rabbits (N=8) with chronically indwelling unit recording electrodes in the superficial laminae, and with lesioning electrodes in the AV nucleus, received training to a criterion on the discriminative avoidance task, followed by bilateral electrolytic lesions (1.5 ma. for 45 sec) of the AV nucleus. Controls (N=7) had lesioning electrodes implanted but they did not receive lesions. Eight days after training each rabbit was tested for retention using an extinction procedure, followed by reacquisition and reversal training. The behavioral expression of the original habit was significantly attentuated in the lesioned subjects, relative to controls in all of the test phases. Excitatory, discriminative neuronal activity occurred in the superficial laminae of the control subjects during reacquisition, and reversal of the discriminative response occurred during reversal training. However, the neuronal activity of the lesioned subjects manifested only inhibitory ("off") responses to the CSs, and no significant discriminative effects during the test phases. These results are compatible with the original hypotheses. In addition, they suggest that neurons of the AV nucleus normally produce excitatory effects in the cingulate cortex. Removal of the excitatory influence results in a predominance of inhibitory drive upon the cingulate neurons.

WITHDRAWN

245.8 MODULATION OF LONG-TERM POTENTIATION (LTP) BY AMPHETAMINE. R. L. Delanoy, D. L. Tucci* and P. E. Gold. Dept. of Psychol., Univ. of Virginia, Charlottesville, VA 22901.

The effects of amphetamine (AMPH) on the response of dentate granule cells to low frequency angular bundle stimulation before and after LTP were examined in pentobarbital anesthetized rats. Recording and stimulating electrodes were implanted in the dentate granule cell layer and the angular bundle, respectively. Test stimuli (40 V, 100 μsec) were delivered at a rate of 0.5 Hz. The baseline latencies and amplitudes of the three extremes of the waveform (1st EPSP, population spike, 2nd EPSP) were averaged from 20 consecutive traces. Saline or AMPH (0.3 or 1.0 mg/kg, IP) was then injected. The waveform was again charted 12 min later and compared with the preinjection waveform. At 15 min after injection, rats received a stimulation train (20 V, 65 μsec, 100 Hz, 1 sec) which resulted in half-maximal LTP. At 23 min after injection, rats received a second high frequency train (40 V) which produced maximal potentiation. The potentiated waveforms were charted 3 min after each high frequency train and were compared to the post-injection waveform.

In general, AMPH reduced the latencies of the unpotentiated evoked response peaks with the higher dose being more effective. AMPH did not alter the amplitude of the evoked response. LTP was characterized by decreased latencies and increased amplitudes of the evoked response peaks. Those animals which had received the lower dose, but not the higher dose, of AMPH showed enhanced potentiation on several measures. As compared to the evoked responses seen in saline-injected rats following LTP, the low-dose AMPH animals showed significantly larger decreases in the latencies of the 1st EPSP and population spikes and a larger increase in the amplitude of the 2nd EPSP. These latter AMPH effects appear to be the result of a drug effect on LTP itself because: any effects of AMPH on the evoked response prior to potentiation were subtracted prior to analysis of the waveform; the dose-related effects of AMPH on changes in latency differed in potentiated and unpotentiated evoked responses; AMPH resulted in an increase in the 2nd EPSP amplitude of potentiated but not unpotentiated responses. These results suggest that the mechanisms underlying potentiation of a monosynaptic pathway may be modulated by the concurrent activity of other neuronal systems, possibly including biogenic amines. In this regard, it may be interesting to note that the inverted-U dose-response relationship of AMPH to LTP is analogous to reported effects of pre- and post-training AMPH injections on behaviorally-assessed memory.

245.9 LONG-TERM POTENTIATION FACILITATES THE ACQUISITION OF PERFORANT PATH STIMULATION AS A DISCRIMINATIVE STIMULUS. R.W. Skelton, A.G. Phillips, and J.J. Miller, Depts. of Psych. and Physiol., Univ. of Brit. Columbia, Vancouver, B.C., Canada V6T 1W5.

Electrophysiological investigations of long-term potentiation (LTP) have shown that brief activation of hippocampal afferent pathways can result in an enduring increase in synaptic efficacy. (Bliss, 1979). Although LTP satisfies many of the theoretical requirements of a neural mechanism for learning, direct evidence for this relationship is minimal, due to the paucity of information about the functions of hippocampal neuronal systems.

In the present series of experiments, direct electrical stimulation of the perforant path (PP) served as a discriminative stimulus (DS) signalling the availability of food pellets, contingent upon an operant response to the food cup. Population spikes, recorded from electrodes positioned in the dentate gyrus (DG) ensured that the DS produced activation of PP-DG synapses. The PP-DG system was chosen because it provides a nearly ideal preparation in which to observe or produce LTP.

In the first experiment, the current intensity of single (100 μsec) pulses to the PP of chronically implanted rats was adjusted to evoke asymptotic population spikes in the DG. At the end of training for 10 days (40 trials/day), all animals responded immediately after, and not before the brain stimulation. This distribution of responses indicated that the animals could indeed use the PP stimulation as a DS.

The second experiment was designed to determine whether LTP, produced by tetanic stimulation, would facilitate the acquisition of the discrimination. Current intensities in this study were adjusted to evoke a sub-maximal population spike. The tetanic stimulation used to potentiate these responses was delivered as 10 trains of 10 pulses (200 Hz). These trains served as the DS's of the first 10 trials for the experimental group. The control animals received the usual single pulse stimulation on these trials. All subsequent DS's for all animals were single pulses. After 14 days of testing, four of the five tetanized animals were discriminating the PP stimulation at criterion levels while only one of the control animals showed similar performance.

These data indicate that LTP can facilitate the behavioral response to information mediated by PP synapses. It is suggested that LTP may provide a neural mechanism for behavioral changes associated with learning.

Bliss, T.V.P., Trends in Neuroscience, 1979, 2, 2, 42-54.

245.10 LONG LASTING FACILITATION OF A MONOSYNAPTIC RESPONSE IN THE MAGNOCELLULAR MEDIAL GENICULATE NUCLEUS OF THE ANESTHETIZED CAT. R. A. Gerren* and N. M. Weinberger. Dept. Psychobiology, University of California, Irvine, CA 92717.

The effects of high frequency electrical stimulation on a short latency response, recorded in the medial geniculate magnocellularis (MGm) to stimulation of the brachium of the inferior colliculus (BIC), were investigated in the anesthetized (40 mg/kg sodium pentobarbital, I.P.) and paralyzed (12 mg/kg gallamine triethiodide, I.V.) cat. Test stimuli (0.2 Hz, 0.1 ms) delivered to the BIC for approximately 20 min. prior to the presentation of a high frequency train (300 Hz, 285 ms), evoked responses in MGm which were stable in amplitude (50-200 μV) and latency (0.94 ± 0.08 msec) during this baseline period. Several changes in the BIC evoked MGm response were observed following the high frequency train. Initially, either a short lasting (15-30 sec) facilitation or depression of the MGm response amplitude was observed. In either instance, the short lasting amplitude change was replaced by a long lasting facilitation of the MGm response amplitude, which reached an average maximum facilitation of 141.8 ± 10.7% of the baseline values at an average of 21.5 ± 5.2 min. following the train. The duration of this long lasting facilitation was as short as 23 min. and as long as 4.5 hr. In addition to the observed amplitude facilitation following the train, the latency of the MGm response decreased by an average of 0.036 ± 0.007 ms, 40 min. after the train.

An additional investigation indicates that single units in the MGm can be driven with short latencies (1.2-3.0 msec) by BIC stimulation. Following a high frequency train, decreases in latency and variance of latency were observed. Additionally, single units which fired only once to BIC stimulation before the train were observed to fire in short bursts (2 or 3 spikes) following the train. These effects have been recorded for more than 1 hr. These findings suggest that the amplitude facilitation and decrease in latency of the monosynaptic response following a high frequency train are directly related to changes occurring in the same population of MGm neurons, as opposed to the recruitment of another population of MGm neurons.

The implications of a long lasting facilitation of the BIC-elicited MGm response are as yet unknown. It may be that this facilitation is related to the specific physiological plasticity of the MGm during behavioral learning (Ryugo & Weinberger, Behav. Biol. 22:275, 1978). Also, this phenomenon may be related to the long-term potentiation previously observed in the hippocampus (Bliss & Lømo, J. Physiol. 232:331, 1973). We thank Bill Hopkins for his assistance.

245.11 SINGLE-UNIT ACTIVITY RELATED TO SHORT-TERM MEMORY OF TONES (STMT), IN THE AUDITORY CORTEX OF THE MONKEY. Y. Gottlieb*, E. Vaadia* and M. Abeles* (SPONS; S. Schuetze). Hebrew Univ. Hadassah Med. Sch., Jerusalem, Israel.

Several studies of short-term memory (STM) suggest that (a) STM depends on the attention level of the subject and (b) the auditory cortex is required for STMT.

We trained a Baboon monkey to perform a task which required him to remember the frequency of a tone for 1 sec. As the monkey learnt the task, it was prepared (under anesthesia) for single-unit recordings. Beginning 1 wk later, 127 units in the auditory cortex were studied while the animal performed the STMT task. Each unit was also studied during a control session. Peri-stimulus time (PST) histograms and auto-renewal density functions were computed for the two behavioural states.

PST histograms of 50% of the cells were dependent on tone frequency for 1 sec after its presentation in both STMT and control trials.

PST histograms of 36% of the cells differed from background for 1 sec after stimulus presentation during STMT trials only.

In response to paired stimuli (one second apart), 23% of the cells could distinguish pairs with identical tones from pairs of different tones, but only during STMT trials. Clear reverberatory activity could not be demonstrated in the activity of any cell.

On the basis of the results we suggested two models for the mechanism of STMT: (a) Non-attention dependent STMT. This mechanism can store information by a firing rate code. (b) Conditioned STMT. This mechanism is conditional on the animal's attention. It explains how neural activity which reflects attention processes can facilitate STMT.

245.12 CONDITIONED MODIFICATION OF AVIAN DORSAL GENICULATE NEURONS IS A FUNCTION OF THEIR RESPONSE TO THE UNCONDITIONED STIMULUS. C.M. Gibbs*, D.H. Cohen, J. Broyles* and A. Solina*. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, Stony Brook, N.Y. 11794.

Visually conditioned heart rate change in the pigeon has been developed as a vertebrate model for cellular studies of learning. In this system, the ascending visual pathways transmit the conditioned stimulus (CS) information, and the thalamic relays of at least two such pathways show training-induced modification. In contrast, the maintained and evoked discharge of retinal ganglion cells are invariant over training. Reported here are further studies of the principal optic n.(OPT), the avian dorsal geniculate homologue and thalamic relay of the thalamofugal system.

Upon isolating the activity of a single cell in a behaviorally naive animal, ten 6-sec pulses of whole-field illumination were given. Presented next were 40 such lights followed by 0.5-sec foot-shocks (conditioning) or 40 unpaired lights and shocks (sensitization). This was followed by five 50-msec foot-shocks.

All OPT neurons responded to light onset at latencies of 24-70 msec ($\bar{x}$ = 38 msec), 38 with increased (Type I) and 16 with decreased (Type II) discharge. 94% of the cells also responded to foot-shock, the unconditioned stimulus (US), at latencies of 60-300 msec ($\bar{x}$ = 109 msec), 30 with increased and 21 with decreased discharge.

We reported previously that the light-evoked response of most OPT neurons is enhanced by conditioning and attenuated by non-associative training. However, new data suggest this modifiability is influenced by the response to the US. For example, 89% of Type I units responding to the US with decreased discharge showed rapid augmentation (3-6 CS-US pairings) of their light-evoked response during conditioning, while Type I units with increased discharge to the US showed either response attenuation or only a gradual enhancement later in training. Moreover, two such cells which were unresponsive to the US showed no change. Such interactive effects were not confounded by differences in initial CS-evoked responses or by differential changes in maintained activity. Although the sample size for Type II cells precluded statistical analysis of interactive effects, similar trends were observed.

This study confirms our previous report of: (a) training-induced modification of OPT neurons, most of which are likely to be retinorecipient, and (b) the US responsiveness of most OPT cells. It further suggests that: (a) convergence of CS and US inputs is necessary for training-induced modification; (b) there are at least two sources of US input to OPT; and (c) these inputs are differentially effective for training-induced change. We are identifying the cells of origin of the US inputs to allow study of the effects of their selective interruption upon conditioned changes of OPT cells. (Supported by NSF grant BNS8016396.)

246.1 NEURAL SUBSTRATES OF THE CLASSICALLY CONDITIONED RABBIT NICTITATING MEMBRANE PREPARATION: TRIGEMINAL SYSTEM AFFERENTS.
Y. Torigoe*, W. Wenokor*, and C. F. Cegavske. Department of Psychology, SUNY-Binghamton, Binghamton, NY 13901.

The two studies reported here are part of a series of experiments designed to characterize the unconditioned response (UCR) pathway in this preparation. The studies identify the sensory projections into the brainstem from the cornea, and from the area of the face innervated by the supraorbital nerve (SON) (a subdivision of the ophthalmic part of the trigeminal system).

These projections were demonstrated with horseradish peroxidase (HRP) mixed with dimethylsulfoxide (DMSO) in normal saline solution. The HRP was injected into all parts of the cornea with a 30-gauge needle and applied to the SON by encapsulating the cut end of the nerve together with the tracer. After corneal injections the animals were sedated with Acepromazine until sacrificed. In both studies, electrical stimulation (of cornea or nerve) was used to enhance transport, the survival period was two days, and the brain tissue was processed in tetramethylbenzidine.

Excellent labelling was observed in the trigeminal ganglion and in the brainstem. In the ophthalmic part of the ganglion the cells from the cornea study (about 20% of the number seen after SON transport) occupied a sub-area of the SON-cell distribution.

In the brainstem the projections from both studies were similar in the following ways. Transport was seen in the ventral part of both the principal and spinal nuclei, and extended into the dorsal part of the spinal nucleus caudal to the obex. It was also seen in an area lateral to the motor trigeminal nucleus, adjacent to the dorsal part of the facial nerve, between the trigeminal and facial nuclei, in the reticular formation close to the spinal nucleus at all levels, in lamina I (marginal layer) at about the level of the obex, and in the lateral part of the nucleus of the solitary tract. At more posterior levels the projections became less dense and were distributed both dorsally and ventrally.

The brainstem projections were different in the two studies as follows. Relative to the cornea study the SON study had larger (usually overlapping) projection fields, had a projection area (from facial nerve to obex) that extended dorsomedially along both sides of the spinal nucleus' ventral boundary with the reticular formation, had projections in lamina IV that were ventral to those from the cornea, and had projections that extended about 19 mm caudal to the obex instead of 14 mm.

Two main conclusions of these studies are: the data are not consistent with the view that the trigeminal system has a precise somatotopic organization; and, the internuncials mediating the UCR should be found within the projection areas identified here.

246.2 FORWARD LOCOMOTION IN THE DIENCEPHALON AND MESENCEPHALON MAPPED BY ELECTRICAL STIMULATION. S. M. Parker,* R. C. Russo,* J. W. Mink and H. M. Sinnamon. Lab. of Neuropsychology, Wesleyan University, Middletown, CT 06457.

Locomotion has been reported to be elicited by stimulation in several ventral diencephalic sites including the medial and lateral hypothalamus and the subthalamic region in the area of the zona incerta nucleus. The purpose of this study was to survey these regions caudal to the anterior hypothalamus in order to determine if anatomically distinct locomotor systems existed and the course of their trajectory to the midbrain.

Long-Evans rats (N=26) were anesthetized with Chloropent (3-4 ml/kg) and subjected to stereotaxic surgery in which 3 or 6 stainless steel (125 μm) monopolar electrodes were implanted. Following at least 5 days recovery the sites were tested for locomotion elicited by constant current cathodal stimulation at 50, 100, 200 and 300 μA and 50, 100 and 154 Hz pulse frequency. The pulse duration was 0.5 msec. The test apparatus was a 27 X 9 X 24 cm chamber containing a 7 cm wide treadmill belt. Each site was tested under two separate stimulation conditions with each combination of current and frequency tested once. In the first condition, a 5 sec. train of stimulation was delivered no more often than every 20 sec. In the second condition, 20 trains of 1-sec. duration were delivered every 4 sec. In this way locomotion elicited both directly and as an aftereffect (post) could be examined. Both direct and post locomotion were scored as either absent or present at each stimulation condition.

Direct locomotion was elicited at 34 of 93 sites. Post-stimulation locomotion was elicited at 58 sites, 31 of which also showed direct locomotion. The majority of these most effective sites appeared to be concentrated among ventromedial regions of the diencephalon and mesencephalon, including the interpeduncular nucleus, the ventral tegmental area, the mammillary bodies, the pre-mammillary nucleus and the posterior, dorsomedial and ventromedial nuclei of the hypothalamus. The zona incerta nucleus and the immediately surrounding areas were also highly effective. The ventromedial thalamus and the medial forebrain bundle were effective in producing only post-stimulation locomotion. Stimulation of the fields of Forel and the area posterior to the zona incerta was ineffective, and thus the course of the presumed output to the midbrain is yet to be determined. Very few sites in either the substantia nigra or cerebral peduncle were effective. This pattern indicates that locomotion may be elicited from widespread areas in the ventral midbrain and diencephalon. Despite the large number of sites tested, simple anatomical distinctions between these effective sites are not yet apparent.

246.3 TOPOGRAPHICAL ORGANIZATION OF THE FIBERS WITHIN THE STRIA TERMINALIS IN THE CAT BRAIN. S. Beaulieu, P. Langelier*, A. Parent, L.J. Poirier and R. Boucher. Lab. de neurobiologie, Hôpital de l'Enfant-Jésus, Québec, Qué., Canada, G1J 1Z4.

Taking advantage of the property of lesioned fibers to transport horseradish peroxidase (HRP) both retrogradely and anterogradely, HRP (Sigma type VI, 50% solution) was injected (0.02 ul) directly in the stria terminalis (S.T.) at the level of the body of the caudate nucleus. The survival time was 24 hrs in all experiments. The benzidine dihydrochloride or tetramethylbenzidine was used as the chromogen. Wheat germ agglutinin-horseradish peroxidase (WGA-HRP) was used in a few animals. Tritiated leucine (20-50uCi in 0.06-0.5 ul) was injected in the bed nucleus of the stria terminalis (BNST), the nucleus of the lateral olfactory tract (NLOT) and in various areas of the amygdala in order to trace the efferent projections from these structures. Standard autoradiographic procedures were used. In other experiments lesions of the S.T. were made and, 3 days later, the acetylcholinesterase (AChE) activity within these fibers was revealed histochemically in diisopropyl fluorophosphate (DFP) pretreated (1.6 mg DFP/kg, 6-9 hrs before sacrifice) cats. Injections of HRP interrupting most fibers of the S.T. are associated with very intense labeling of the neurons of the NLOT. The medial part (magnocellular division) of the central nucleus contains a large number of labeled neurons. The lateral part of the central nucleus, the medial and cortical nuclei and part of the basal nucleus of the amygdala as well as the amygdala-hippocampal area and the BNST contain a moderate to low number of labeled cells. On the basis of injections of HRP involving different parts of the S.T. we may infer that the dorsomedial part of the S.T. contains fibers from the basal nucleus and the amygdalo-hippocampal area. A majority of the efferent fibers of the amygdala coursing in the lateral part of the S.T. originate in the central nucleus. Autoradiographic experiments complement these data. Among other things the BNST is one of the main sources of the afferent fibers to the amygdala. They course in the lateral part of the S.T. Histochemical findings demonstrate the presence of AChE-rich fibers which course predominantly in the lateral part of the S.T. and end in the amygdala. An attempt is being made to localize the exact origin of these fibers by using the Mesulam method ('76) which allows to visualize both AChE and HRP. The findings of the present study suggest that the fibers coursing within the S.T. are organized according to a complex pattern. The lateral part of the S.T. contains amygdala afferents from the BNST whereas the dorsomedial part of the S.T. contains efferents arising principally from the basal nucleus and amygdalo-hippocampal area. Also, the NLOT appears to contribute heavily to this major pathway of the limbic system.
(Supported by the MRC).

246.4 LABELING KNIFE CUTS USED TO TRACE A PATHWAY NECESSARY FOR LORDOSIS IN THE HAMSTER. C. W. Scouten and C. W. Malsbury. Dept. of Psych., Memorial University of Newfoundland, St. Johns, NF, CANADA A1B 3X9.

There has been no practical method of scanning an entire brain for the locations of cell bodies whose axons have been cut or injured. Partly because of this technical limitation, it has been difficult to assign the cause of functional deficits following a lesion to damage to specific cell groups or pathways. The cells in the zone of necrosis surrounding the lesion represent only a subset of all cells directly injured. Cells in distant locations whose axons merely pass through or near the lesion may also be directly damaged, and thus may be the cells whose damage caused the functional deficit. However, the locations of these cells are not disclosed by the standard histological analysis.

We now report a labeling knife cut technique which allows us to observe the behavioral effects of a stereotaxically-placed knife cut, and then scan the brain for all directly affected cells. An axonal transport tracer (1 ul of 2% HRP in water) is allowed to dry on the blade of an extended wire knife (DKI) prior to making a cut. Behavior is tested after 48 hours, and the animal is then sacrificed and the brain perfused and reacted in the standard manner (Mesulam, M.M., J. Histo. Cytochem. 26:1281, 1978)

We are now using this technique in the analysis of a hypothalamic pathway essential for lordosis in the female hamster. Unilateral sagittal plane knife cuts medial or lateral to the medial forebrain bundle at the level of the supraoptic commissures impair lordosis in response to stimulation of the contralateral, but not the ipsilateral, flank (Ostrowski, Scouten and Malsbury, Physio. Behav., in press, 1981). Unilateral labeling cuts were made through each of the two lateral positions in individual females. Some of the areas containing labeled cells are common to both types of cuts in females showing behavioral deficits. These include the peripeduncular nucleus, the dorsal raphe, the ventral tegmental area, the ventral premammillary nucleus, the lateral ventromedial hypothalamus, and parts of the amygdala. The areas labeled by both cuts contain populations of cells that project into or out of the hypothalamus at the level of the SOC. The cells whose axons form the pathway(s) necessary for lordosis must therefore comprise a subset of this population.

246.5 SEPTAL LESIONS MODIFY C.N.S. CHOLINERGIC-DOPAMINERGIC PHARMACOLOGICAL RESPONSES. R. J. Carey. Veterans Administration Medical Center, Syracuse, New York 13210.

Administration of 0.5 mg/kg d-Amphetamine and 0.25 mg/kg Scopolamine produced equivalent degrees of hyperactivity in intact rats (N=8). The hyperactivity effects of these two drugs, however, proved to be strongly modified by septal lesions. Rats with septal lesions (N=8) became much more active than controls after 0.5 mg/kg Amphetamine, but did not exhibit any hyperactivity after the 0.25 mg/kg injections of Scopolamine. This differential effect of septal lesions on Amphetamine and Scopolamine was also observed across 3 dose levels of each drug (0.25, 0.5 and 1.0 mg/kg d-Amphetamine and 0.125, 0.25 and 0.5 mg/kg Scopolamine.) Thus, septal lesions appear to significantly alter cholinergic-dopaminergic balance in the brain. These observations suggested that septal lesions might modify the effects of cholinergic-dopaminergic imbalances produced by 6-hydroxydopamine (6-OHDA) lesions. Bilateral 6-OHDA injections into the nucleus accumbens (N=8) attenuated both Apomorphine (.125, .25 and .5 mg/kg) induced stereotyped behavior and Haloperidol (2.5 mg/kg) induced catalepsy. If the 6-OHDA lesions of the nucleus accumbens were made in combination with septal lesions, however, the effects of the apomorphine and haloperidol were restored to levels of control rats. Thus, a septal lesion reversed the manifestations of a dopamine deficiency, thereby providing additional evidence that this limbic system structure is important in cholinergic-dopaminergic balance.

246.6 MESOLIMBIC MECHANISMS OF BEHAVIORAL SUPERSTITION. J. A. Devenport* and L. D. Devenport. (SPON: J. A. Andrezik). Dept. Psychiat. & Behav. Sci., Univ. Okla. Health Sciences Ctr., Oklahoma City, OK 73190.

The hippocampus helps to protect against erroneous response learning and it seems to do this by promoting behavioral variability (Devenport & Holloway, J. Comp. Physiol. Psychol. 94:691, 1980) such that alternative rates, places, topographies, etc., are sampled and compared. Variability permits the detection of redundancies, superstitions, and more favorable strategies. We have adduced evidence to the effect that the hippocampus modulates behavioral variability by opposing reward-induced stereotypy (Devenport et al., Science, in press). Functional and anatomical considerations suggest that the hippocampus and stereotypy mechanism interact within the mesolimbic forebrain. If this is the case, then lesions here should mimic hippocampal lesions. Electrolytic lesions were made in various mesolimbic forebrain sites as well as in the superior colliculus and hippocampus. Rats with neocortical ablation were also prepared.

Susceptibility to superstition was assessed by daily 30 min exposures to a fixed-time 100 sec schedule of noncontingent pellet delivery. Testing occurred in operant chambers where gratuitous responses could be sampled and automatically recorded. Rats with extensive hippocampal damage and those with lesions of the nucleus accumbens (NA) and nucleus interstitialis striae terminalis (NST) developed superstitious bar-pressing and other responses. Their superstition was in marked contrast with groups bearing damage in the neocortex, olfactory tubercle, and superior colliculus. We suggest that the NA and NST are sites where the hippocampus and reward systems converge in functional opposition.

246.7 AN AUTORADIOGRAPHIC STUDY OF THE EFFERENT CONNECTIONS OF THE CENTRAL NUCLEUS OF THE MONKEY AMYGDALA. D.G. Amaral[1] and J.L. Price. Dept. of Anat. & Neurobiol., Washington Univ. Sch. of Med., St. Louis, MO 63110, [1]The Salk Institute, San Diego, CA 92138.

As part of an ongoing study of the efferent connections of the amygdaloid complex in the primate, we have injected small amounts (100 nl) of ^{3}H-amino acids into the central nucleus of the cynomolgus monkey (Macaca fascicularis). After a two-week survival period the animals were sacrificed and the brains processed for the autoradiographic demonstration of axonal projections. A small ^{3}H-amino acid injection, which is largely confined to the central nucleus, leads to the labeling of a number of brainstem structures with fibers extending caudally to the spino-medullary junction. Specifically, in the forebrain, the central nucleus projects heavily to the nucleus of the stria terminalis, the basal nucleus of Meynert, the horizontal limb of the nucleus of the diagonal band and more lightly to the substantia innominata and the preoptic area. In the hypothalamus, label is found over the dorsomedial nucleus, the perifornical region, the lateral hypothalamic area, the supramammillary region and most heavily in the paramammillary nucleus. The nucleus centralis medialis of the thalamus receives a projection as does the ventrolateral quadrant of the nucleus reuniens. In the mesencephalon, there is fairly heavy labeling within and dorsal to the substantia nigra pars compacta and to the peripeduncular nucleus; there is lighter label among the cells of the ventral tegmental area and the midbrain central gray substance. More caudally, fibers from the central nucleus travel in the lateral tegmental reticular fields and contribute collaterals to the raphe nuclei, the central gray substance and the medial pulvinar. One of the heaviest terminal zones is the parabrachial region of the pons; both the lateral and medial nuclei receive a prominent input. Only the ventral aspect of the nucleus locus coeruleus receives a substantial projection but there is also labeling of the subcoerulear region. Finally, there is very heavy labeling of the nucleus of the solitary tract and of the immediate surround of the dorsal motor nucleus of the vagus nerve. We have also determined that the lateral, basolateral and basal accessory amygdaloid nuclei and the periamygdaloid area all send intra-amygdaloid projections to the central nucleus. Thus, the present findings, taken together with recent reports of widespread projections from the temporal cortex to the amygdala, demonstrate a potentially trisynaptic route between temporal association neocortex and a variety of brainstem nuclei, many of which are related to autonomic functions.

246.8 EFFECTS OF ELECTRICAL STIMULATION OF THE HIPPOCAMPAL FORMATION UPON THE EXTENT OF THE TRIGEMINAL SENSORY FIELD PRESENT DURING ATTACK BEHAVIOR IN THE CAT. R.E. Watson, A. Siegel, H. Edinger, C.H. Block and S.L. Stoddard-Apter. Departments of Physiology and Neuroscience, N.J. Medical School, Newark, N.J. 07103.

That the dorsal and ventral hippocampus are capable of differentially modulating hypothalamically-elicited quiet biting attack (QBA) has previously been demonstrated (Siegel and Flynn, 1968). Additionally, it has been shown that stimulation of QBA sites in the hypothalamus can modify the trigeminal somatosensory fields around the region of the lipline that are normally activated during the course of QBA, contributing to the successful completion of the attack behavior (MacDonnell and Flynn, 1966). In a recent analysis, Block, et al. (1980) demonstrated that sensory fields of the lipline supplied by the trigeminal nerve were expanded by the concurrent stimulation of amygdaloid sites facilitatory to QBA and constricted following stimulation of inhibitory amygdaloid sites. The present study was conducted to ascertain whether similar mechanisms are exerted upon the effective sensory fields following stimulation of hippocampal sites which modulate hypothalamically-elicited QBA.

Electrodes for stimulation and recording were implanted bilaterally in the dorsal and ventral hippocampal formation and hypothalamus under aseptic conditions in cats. Postoperatively, stage I of the experimental protocol consisted of identifying sites in the hippocampus which significantly modulated ($p < 0.05$) hypothalamically-elicited QBA. In stage II, the lateral extent of the lipline that, when probed, could elicit the jaw-opening component of QBA, was determined with hypothalamic stimulation alone or with the concurrent stimulation of hypothalamus and hippocampus. Preliminary results indicate that stimulation of ventral hippocampal sites which facilitate QBA significantly expanded the effective trigeminal sensory fields while stimulation of dorsal hippocampal sites which inhibited QBA had little or no effect upon the size of the trigeminal sensory fields. Latencies for the jaw-opening response were not affected by stimulation of any region of hippocampus. It thus appears that only the ventral hippocampus contributes to the modulation of hypothalamically-elicited QBA by acting upon sensory components of the response mechanism.

The neural systems metabolically activated following stimulation of hippocampal sites which effectively modulate QBA are currently undergoing examination with the use of ^{14}C-2-deoxyglucose autoradiography.

246.9 THE NEURAL BASIS OF ESCAPE BEHAVIOR ELICITED FROM THE FELINE HYPOTHALAMUS. S. Fuchs, A. Siegel, and H. Edinger. Depts. of Physiology and Neurosciences, College of Medicine and Dentistry of N.J., Newark, New Jersey, 07103.

The feline escape response is characterized by pupillary dilatation followed by a vigorous attempt by the cat to jump out of the observation chamber. An approach involving the methods of electrical brain stimulation, ^{3}H-leucine radioautography, and ^{14}C-2-deoxyglucose radioautography was utilized to describe the neural pathways mediating flight behavior. The principal paradigm involved the initial identification of an escape response by hypothalamic stimulation with a moveable electrode. Following identification of this behavior, an injection of ^{3}H-leucine was placed through a Hamilton syringe at the position occupied previously by the electrode tip and the efferent projections from hypothalamic cell bodies were traced. In order to further describe the nature of the functional projections, ^{14}C-2-DG was injected systemically in separate animals from which escape behavior was elicited and the metabolically-activated pathways were identified.

The sites from which flight behavior was elicited were located throughout the entire rostro-caudal and medio-lateral extent of the dorsal hypothalamus. The pathways associated with escape behavior from the dorsal hypothalamus appeared to supply rostral forebrain sites which included the septum, diagonal band, bed n. of the stria terminalis, preoptic region, substantia innominata, and medial amygdala. The first-order efferent fibers supplying the amygdala appeared to reach their target by two routes-- the stria terminalis and through axons passing in a reverse direction in the ventroamygdalofugal pathway. Fibers were distributed also to the anterior, perifornical, ventromedial, and posterior hypothalamic regions. It should be noted that labeled fibers were distributed caudally to the centrum-medianum--parafascicular (cm-pf) region of thalamus and were also traced downstream to the midbrain central gray and central and ventral tegmental fields. The results point to the likelihood that structures identified previously with the control of flight behavior such as cm-pf, midbrain central gray, and specific nuclei of the basal forebrain receive first-order projections from dorsal hypothalamic sites which, upon stimulation, can elicit an escape response.

246.10 FUNCTIONAL ACTIVATION OF THE MEDIODORSAL THALAMIC PROJECTION SYSTEM IN THE RAT: A ^{14}C-2-DEOXYGLUCOSE ANALYSIS. M. Brutus, R. Watson, S. Weiner* and A. Siegel. Dept. of Neurosciences, N.J. Medical School, Newark, N.J. 07103.

Previous studies have indicated that stimulation of the mediodorsal thalamic nucleus (MD) powerfully modulates hypothalamically-elicited aggressive behavior. In order to provide greater insight into the possible mechanisms underlying MD control of hypothalamic processes, the present study utilized the ^{14}C-2-deoxyglucose (2-DG) radioautographic tracing method to functionally characterize pathways and target structures activated following electrical stimulation of various sites within the MD.

Nembutal anesthetized (45 mg/kg) rats were injected with 2-DG prior to administration of an experimental paradigm which consisted of 45 minutes of electrical brain stimulation (200uA, 62.5 Hz, 1 msec biphasic pulses) delivered for alternating 30 sec. on and off periods. Standard procedures were utilized for the removal and processing of brain tissue for X-ray autoradiography.

Stimulation sites within MD were grouped as follows: rostral MD, lateral and medial aspects of central levels of MD, and posterior MD. Sites within control animals included the n. reuniens, reticular, ventromedial and anteromedial thalamic nuclei. In order to determine the degree to which changes reflected antidromic activation of cortical efferents, stimulating electrodes were also placed in the anterior cingulate, sulcal and medial prefrontal cortices.

Stimulation of any region within MD resulted in the activation of fiber bundles supplying the ventral aspect of the reticular nucleus, ventromedial thalamic nucleus, medial aspects of the nucleus accumbens and medial and sulcal prefrontal cortices. The most intense labeling of the sulcal cortex was associated with stimulation of central levels of MD. Stimulation of wide regions within MD also appeared to result in activation of the midline thalamic nuclei and of fibers passing ventrolaterally in the inferior thalamic penduncle to the vicinity of the far lateral preoptic region, substantia innominata and horizontal limb of the diagonal band. The data further suggests the possibility that medial MD stimulation may also activate descending fibers within periaqueductal central gray and neighboring regions of the raphe system.

The data suggests the likelihood that MD inputs into the perifornical lateral hypothalamus in the rat are indirect ones and probably involve such interneurons as the midline thalamic nuclei and such basal forebrain regions as the diagonal band nuclei, n. accumbens and substantia innominata. (Supported by N.I.H. Grant NS07941-12).

246.11 THE MEDIAL FOREBRAIN BUNDLE OF THE RAT. R. Nieuwenhuys[X], J.G. Veening[X] and L.M.G. Geeraedts[X](SPON: P.G.M. Luiten).
Dept. of Anatomy, Univ. of Nijmegen, Nijmegen, The Netherlands.

The medial forebrain bundle (MFB) may be considered as the central longitudinal pathway of the limbic forebrain-midbrain continuum. Extending from the tuberculum olfactorium to the ventromedial part of the tegmentum mesencephali this bundle traverses the lateral hypothalamic area. Although at present a wealth of information is available on the manifold origins and sites of termination of the axons constituting the MFB, relatively little attention has been given to the bundle itself, i.e. to its boundaries, its fiber composition and to the spatial arrangement of its constituent components. In order to facilitate the study of these aspects the main trajectory of the MFB was analysed in normal Klüver-Barrera and Bodian stained material. A detailed atlas of the bundle and its surroundings, comprising sections at ten equidistant levels, was prepared. This atlas has provided the basis for an analysis of the extensive collection of experimental material present in the Dept. of Anatomy and Neurobiology, Washington University, St. Louis, consisting of serially sectioned brains of rats which had received a single injection of tritiated amino acids in areas known to contribute fibers to the MFB. This analysis, which has been carried out by one of us (J.G.V.), in cooperation with L. Swanson and M.W. Cowan, has revealed that most of the 20 components investigated occupy a specific and rather stable position in an overlapping pattern. Ascending components showed a clear preference for the dorsal half of the bundle. Some components (origin e.g. the medial preoptic area and the various hypothalamic nuclei) distribute their fibers diffusely over a large area, whereas others (origin e.g. olfactory tubercle, magnocellular preoptic nucleus) were found to occupy only a restricted part of the MFB. The results obtained so far suggest that the various neuron groups in the lateral hypothalamic area receive a specific input, which is directly related to their position within the MFB.

246.12 EVOLUTION OF THE HUMAN ANTERIOR THALAMIC COMPLEX: RESULTS OF MORPHOMETRIC AND ALLOMETRIC ANALYSES. E. Armstrong* and M. St. Onge*, Dept. of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70117 (SPON: B. V. Updyke).

Initial quantitative analyses of Nissl stained serial sections of the dorsal thalamus among humans and apes showed that the human thalamic limbic nuclei (anterior principal (Ap) and lateral dorsal) contain more neurons than could be accounted for on the basis of brain size. The finding was interpreted as showing that during hominid evolution Ap neurons were preferentially increased (Amer. J. Phys. Anthro., 52:43, 1980). Data from an expanded series of hominoids continue to show that taxonomic grouping predicts the number of neurons in the human Ap better than does brain weight and an enlargement of an ape brain to human dimensions predicts fewer neurons than observed. Prosimian, New World and Old World monkeys were also studied. In this report the human and ape Ap is considered to be homologous, as recipient of mamillary body and subicular inputs, to the non-hominoid anterior ventral (AV), anterior medial (AM), and anterior intermedial (IAM) nuclei. Analyses based on AV data alone show the human Ap to be even more derived (less predicted by the overall size of the brain) than when the combined AV and AM data are used. Only Tarsius was observed to lack the typical non-hominoid AV and AM divisions. Comparing Ap volume to body size among primates produces a strong correlation with body weight, but with humans having a larger Ap volume than expected for a primate of our body size. In contrast, other human limbic structures such as the septum (Andy and Stephan, J. Comp. Neurol. 126:157, 1966) or the amygdala (Stephan and Andy, Acta Anat., 98:130, 1977) have a volume that is expected for a primate of our body size. Comparing Ap volume to brain weight, however, shows the human Ap to be as large as one would predict for a primate brain of human size. A given volume of nervous tissue is composed of many features and one which can be measured with relative ease is the number of neurons. The human Ap has many more neurons than the correlation of neuronal numbers to brain weight among primates predicts. The correlations between numbers of neurons and brain weight in New World monkeys came closest to predicting human values. Given the larger proportion of Am to Ap among New World monkeys than in humans and the lack of any fossil record indicating a close ancestral relationship between New World monkeys and hominids, the similar relationship between number of Ap neurons and brain weight in these two taxonomic groups is best interpreted as homoplasy. During human evolution Ap increased its numbers of neurons more than the brain expanded. Supported by the Southern Regional Education Board and NIH BRSG 449-89-5148.

246.13 EFFECT OF KINDLING AND POSTTRIAL HIPPOCAMPAL STIMULATION ON DISCRIMINATION LEARNING. Mauro Caudarella & J. B. Bryer*. Bucknell U., Lewisburg, PA. 17837

Repeated daily brain stimulation ("kindling") leads to permanent potentiation of synaptic transmission, especially in limbic structures. Behavioral effects have received less attention although Campbell & Milgram (Physiol. Behav. 1980, 24, 1115) have shown that potentiating hippocampal (HPC) stimulation facilitates acquisition of HPC self-stimulation. Caudarella, Campbell & Milgram showed that posttrial HPC stimulation facilitates passive-avoidance learning. Since this latter effect was obtained in animals that had had prior HPC self-stimulation experience, the present study tested the hypothesis that prior HPC kindling would enhance the facilitation of learning produced by posttrial HPC stimulation. Thirty-nine rats were implanted with a bipolar electrode in dorsolateral HPC (CA3). Twenty received 1 sec of 30μA sine-wave stimulation twice a day, 4-6 hr apart, for 14 days. The other 19 were handled identically but not stimulated. Then, all rats were trained in a standard Skinner-box lever-pressing task for 20 min/day with continuous reinforcement until they had performed 100 responses. The next day each rat was subjected to a discrimination training session: reward was given during only 1 of 2 alternating 30-sec light-on and light-off periods. Immediately after the 15-min session half the rats in each pretreated group (kindled and not kindled) received 80 sec of 5μA HPC stimulation in a different box; the others were handled identically but not stimulated. All rats were tested in a further session 7 days later. Discrimination ratios (no. of correct lever presses/total no. of responses) indicated a significant facilitatory effect of prior stimulation experience; furthermore, the combination of pretrial and posttrial stimulation was significantly better than either posttrial stimulation alone or no stimulation at all. Thus learning was facilitated by both types of stimulation, although pretrial stimulation (kindling) had by far the greater effect.

246.14 HUMAN AUDITORY BRAINSTEM RESPONSES DURING AUDITORY LATERALIZATION AND SELECTIVE ATTENTION TASKS. G.C. Galbraith and D.G. Kim*. MRRC UCLA Research Group, Pomona, CA. 91769

Lukas (Psychophysiol., 1980, 17, 444-452) reported an effect of selective attention on the auditory brainstem response (ABR). During visual attention Wave V latency was increased and amplitude decreased to a 2000 Hz sine stimulus, but not to an 8000 Hz stimulus. Lukas notes "...that within the inferior colliculus, neurons with best frequencies below 3000 Hz are critically sensitive to shifts in interaural phase differences and therefore may be involved with sound localization. It appears that these neurons which are involved in sound localization may be inhibited during concentrated visual attention" (p. 449).

In our laboratory we have been studying ABR correlates of auditory lateralization (stimuli presented through headphones). In previous pilot studies we found evidence for differential ABR patterns in subjects with high and low discriminability for auditory lateralization. Discriminability was quantified by means of the d' statistic derived from signal detection theory. Stimuli in the psychophysical task were brief (0.1 ms) clicks; 65 dB to the left ear, and either 65 or 70 dB to the right ear. Nineteen subjects judged whether the stimulus was lateralized to the center of the head (65-65 dB) or to the right ear (65-70 dB). During the ABR recording the left ear was stimulated at 65 dB, but the right ear received 65, 75, or 85 dB. Results showed that ABR amplitudes for high d' subjects (greater discriminability) showed a reducing pattern (decreased amplitudes) for the 65-85 dB condition.

In the above study it was appropriate to use relative intensity differences between the two ears since this is an essential cue in the localization of high frequency stimuli such as brief clicks. For lower frequency stimuli, however, such as a 2000 Hz sinusoid, phase angle differences become important. In the study to be reported 20 subjects will be required to lateralize 2000 Hz sine stimuli (2-cycle tone bursts) which differ in phase angle. As before, ABR patterns will be compared with auditory lateralization discriminability. In addition, these same subjects will perform in a selective attention task to assess possible changes in Wave V latency and amplitude. Since data will be available on the same subjects for both auditory lateralization and the effects of selective attention, it will be possible to directly test the hypothesized covariance of these behaviors.

247.1 THALAMIC PROJECTIONS TO THE SOMATOSENSORY CORTEX OF THE ECHIDNA, TACHYGLOSSUS ACULEATUS. P. S. Ulinski. Dept. Anatomy and Committee on Neurobiology, Univ. Chicago, Chicago, IL. 60637.

Evoked potential studies (Lende, 1964, J. Neurophysiol., 27: 37; Allison and Goff, 1972, Arch. ital. Biol., 110: 195) have shown that echidnas have a single, topographically organized somatosensory area (SMI) that spans a large, mediolaterally oriented sulcus called sulcus alpha. The representation of the trunk and proximal extremities lies on the gyrus caudal to sulcus alpha, but the representations of the distal limbs and beak point rostrally and extend onto the rostral bank of the sulcus. This study examines the cytoarchitecture and thalamic afferents of SMI in Tachyglossus.

The physiologically defined SMI contains two cytoarchitectonic fields. The caudal field extends across the gyrus posterior to sulcus alpha and onto the floor of the sulcus. It has a well developed layer 4 and a relatively small number of medium sized pyramidal cells in layer 5. The rostral field extends from the floor of sulcus alpha onto its rostral bank. It also has a well developed layer 4, but has a larger number of large pyramidal cells in layer 5. Layer 4 thins as it is followed onto the crown of the gyrus rostral to sulcus alpha. The remainder of this gyrus contains a single cytoarchitectonic field with a thin layer 4 and a layer 5 that is heavily populated with large pyramidal cells. This field corresponds to the physiologically defined motor cortex.

Thalamic afferents to SMI were examined by placing pressure injections of horseradish peroxidase (HRP) into the two cytoarchitectonic fields. An injection that involved both fields retrogradely labelled neurons throughout the ventrobasal nucleus of Welker and Lende (1980, in Comparative Neurology of the Telencephalon). Neurons of all sizes were labelled and their axons could be traced to the injection site in a well ordered pattern. An injection restricted to the caudal field labelled a band of neurons that extended rostrocaudally throughout the ventral part of the ventrobasal nucleus. An injection restricted to the rostral field labelled a band of neurons situated dorsally in the ventrobasal nucleus. No other thalamic groups contained labelled neurons comparable to the labelling seen in the intralaminar or posterior nuclei following an HRP injection into SmI of some marsupial or placental mammals.

These results suggest that the ventrobasal nucleus in Tachyglossus may contain two zones, each of which projects to a distinct cytoarchitectonic field in SMI. (Supported by NSF Grant INT 81-02645 and funds from the School of Anatomy of the University of New South Wales)

247.2 CORTICAL AND THALAMIC CONNECTIONS OF RAT BARRELFIELD CORTEX. J.L. Uhr*, J.K. Chapin, C.-S. Lin and D.J. Woodward. Dept. of Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235.

Neurophysiological studies in this laboratory have shown that sizes of receptive fields (RF's) in the rat primary somatosensory (SI) cortex are much larger in layers V and VI than in layer IV. The aim of this study was to establish an anatomical basis for this phenomenon.

Cortico-cortical and thalamocortical projections were determined by iontophoretic HRP injections (2.5 μamp for 30 min-1 hr) into electrophysiologically identified sites in the whisker region of either SI barrelfield cortex or VB thalamus. To increase HRP uptake and transport, 1-3% lysophosphatidyl choline was added to a 20-30% solution of HRP before injection. Brain sections were pretreated with 0.5% $CoCl_2$ before reacting with DAB to enhance visualization of both dendritic and axonal branching patterns of labeled cells.

Injections into the thalamus resulted in large numbers of orthogradely labeled axons in layer IV and lower layer III, in a pattern corresponding to the aggregates of granule cells defining the centers of barrels. Observations of individual axons, easily seen in less densely labeled areas, showed that a few axons terminated in layer I. Some axons projected to more than one barrel by branching in the subcortical white matter.

Injections which included layers V and VI of the barrelfield region (electrophysiologically identified according to the whisker(s) represented), produced retrogradely labeled pyramidal cells in layers III, IV, and Vb of the columns adjacent to the injection sites. The layer III cells were located at the periphery of the adjacent columns, whereas the layer IV cells were clustered at the centers of the columns. Layer Vb cells were also aggregated in the centers of the columns. Axons of layer III cells could be followed down to layer V of the same column, where they collateralized and gave off terminals before extending to the injected region. Axons of layer V cells extended into the white matter, with collaterals projecting through layers V and VI to the injection site. HRP filled axons were also observed which extended longer distances (up to 3 mm). Axons connecting adjacent columns or more distant regions generally traveled in layer V or VI. Apical and basal dendrites of labeled cells spread up to 100 μm, but never extended as far as centers of adjacent barrels.

In conclusion, this data suggests that the larger size of RF's in layer V could be best explained by intracortical projections from cells in layers III, IV and V to layer V cells in adjacent columns. Supported by NIAAA AA-0390 and the Biological Humanics Foundation.

247.3 THALAMIC PROJECTIONS OF THE POSTERIOR PARIETAL AREA IN THE DOG: AFFERENT ORGANIZATION AND ACETYLTHIOCHOLINESTERASE HISTOCHEMISTRY. R.S. Lewis, S.T. Sakai, and D. Tanaka Jr., Departments of Anatomy, Psychology and Neuroscience Program. Michigan State University, East Lansing, Michigan 48824

The posterior parietal association area (PPA) has been shown to maintain connections with a large number of divergent thalamic nuclei and multiple cortical areas, suggesting that it may be involved in the integration of complex sensorimotor information. The present study in the dog forms part of a continuing investigation into this cortical association area in different carnivore species. Thalamic connections were mapped using the horseradish peroxidase (HRP) tracing technique. Thalamic nuclei were defined by both Nissl stains and acetylthiocholinesterase (AChE) histochemistry. In some cases, an additional series of sections was histochemically processed for both HRP and AChE.

Following HRP injections of the PPA, labelled neurons were distributed in a patch-like configuration throughout much of the dorsolateral extent of the ventral anterior (VA), ventral lateral (VL), lateral posterior (LP), and Pulvinar (Pul) nuclei. The thalamic projections to PPA were topographically organized such that injections into rostral PPA labelled a greater number of cells in VA-VL while caudal PPA injections labelled cells primarily located in LP and Pul. In addition, injections of the lateral gyrus resulted in patches of labelled cells located slightly more dorsolateral to those observed following injections located in the middle suprasylvian gyrus. HRP labelled neurons were also observed in the central lateral (CL), paracentral (Pc), lateral dorsal (LD) and lateral part of the mediodorsal (MD) nuclei.

Moderate AChE staining was observed in VA-VL, LP, and Pul while Pc, CL, and part of MD displayed a denser AChE stain. HRP positive neurons were found principally in thalamic areas displaying a positive AChE reaction.

The convergence of projections from multiple thalamic nuclei upon the PPA in the dog is by and large consistent with data reported in the cat and raccoon and supports the hypothesis that the PPA is involved in sensorimotor integration.

(Supported by NINCDS Grants 12463 and 16991)

247.4 CROSS-MODALITY CONVERGENCE AMONG MONOSYNAPTIC THALAMOCORTICAL INPUTS TO AREA 3a. P. Zarzecki, Dept. of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

A convergence of inputs from deep and cutaneous afferents upon individual neurons of area 3a was concluded from a previous study using extracellular recordings (Neurosci. Abstr. 1979). In that study subthreshold inputs were detected only indirectly by the examination of changes in neuronal excitability and it was not possible to determine the synaptic coupling from the thalamus. We have now examined, by intracellular recording in Nembutal anesthetized cats, the responses of neurons of area 3a to stimulation of several forelimb muscle and cutaneous nerves. Intracellular recordings were made within the zone of cortex where the surface potential evoked by the contralateral deep radial nerve had its peak amplitude. All recorded neurons were histologically confirmed to be within cytoarchitectonic area 3a. Latencies of PSPs were measured from the incoming thalamocortical volley recorded from the cortical surface and evoked by each nerve. Monosynaptic thalamocortical connections were presumed for PSPs with intracortical delays of 1.0 ms or less.

Nineteen neurons of layer III were tested for synaptic inputs from each of the different stimulated nerves. EPSPs with intracortical delays of 1.0 ms or less were recorded from 15 neurons. Thirteen of these neurons had presumed monosynaptic thalamocortical EPSPs evoked from group I muscle afferents and also from low threshold (2.0 x T) cutaneous afferents. Thus, monosynaptic thalamocortical inputs to layer III neurons were common, but modality specificity was rare (2 of 15 neurons). Among 11 neurons of layer V only 4 had EPSPs with intracortical delays of 1.0 ms or less and only 2 had monosynaptic EPSPs evoked by both low threshold muscle and cutaneous afferents. On the other hand, convergent inputs to all 11 layer V neurons were demonstrated with stronger stimulation of peripheral nerves or in longer latency EPSPs.

In conclusion, layer III neurons of area 3a commonly receive cross-modality convergence by a monosynaptic path from the thalamus. Layer V neurons may receive their longer latency convergent inputs via cortical interneurons or a more slowly conducting direct thalamocortical path.

247.5 DEVELOPMENT OF NEOCORTICAL CIRCUITRY: GABA-TRANSAMINASE REPLACES AChE IN THE BARREL CENTERS. D.A. Kristt and J.V. Waldman*. Dept. of Pathology, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

This study was undertaken to examine the developmental time course for GABA-t staining in somatosensory cortex of the rat. Rats, ranging in age from 6 dpn to adulthood, were examined in this study. This method, described by Van Gelder [1965], was used to demonstrate GABA-t in 10 μm frozen sections. Coronal and tangential sections through primary somatosensory cortex (SmI) were examined. No "staining", i.e., reaction product, was apparent when the incubation medium lacked γ-aminobutyric acid (GABA). Also, specific GABA-t inhibitor ethanolamine-o-sulfate similarly prevented the reaction from taking place. In some animals, alternate sections were stained with cresyl violet to aid in evaluating laminar staining patterns in relation to cytoarchitectonics. Before 22 days of age, cortex has a uniform light blue color which represents the reaction product. At this time, the neostriatum is quite darkly stained. The barrels are not identifiable in GABA-t stained material. In contrast, they can be seen in preparations stained for Nissl [Rice and Van der Loos, 1977, mouse], AChE [Kristt, 1979], or succinic dehydrogenase [Killackey and Belford, 1979], beginning at 3 dpn. By 22 days of age, in coronal sections stained for GABA-t, one can clearly see darker foci approximately 200 μm in width separated by a clear space of approximately 50 μm. These foci extend for approximately 300 μm in the depth of layer IV. They can be followed in serial coronal sections. In addition, they appear to correspond to roughly circular, similarly stained foci noted in tangential sections through the SmI barrel field. In short, the dimensions, localization among the cell layers, and distribution in the barrel fields would suggest that these GABA-t positive foci correspond to the neuropil in the barrel centers. Unfortunately, there was too little information available to be able to conclude that these fibers are GABAergic, and GABA-t is not exclusively localized to GABAergic synapses. However, what is particularly interesting is the observation that the early-appearing AChE positivity of fibers within the barrel centers disappears in the same period that GABA-t staining of fibers first appears in the same foci. Future work is needed to determine whether this represents a cholinergic-GABAergic developmental interaction.

247.6 EVIDENCE FOR INCOMPLETE REORGANIZATION OF THE S-I FOOT REPRESENTATION FOLLOWING SCIATIC NERVE SECTION IN THE ADULT RAT. J. T. Wall, C. G. Cusick*, and J. H. Kaas. Depts. of Psychology and Anatomy, Vanderbilt University, Nashville, TN 37240.

Studies of chronic peripheral deafferentation in adult mammals demonstrate that somatosensory neurons normally representing the denervated skin become activated from neighboring skin areas having normal innervation. Studies from adult primates indicate that cortical representations of denervated skin areas become entirely reactivated by cutaneous inputs within several weeks, but it remains unclear whether such complete reorganization is a general feature of post-injury adjustment. The present study investigates the cortical organization of adult rats which had chronically undergone partial denervation of the hindfoot to determine if the representation of the denervated skin becomes completely reactivated by cutaneous inputs within the time period suggested by the primate results.

As established by peripheral nerve recordings from normal rats, most of the hindfoot innervation is supplied by the sciatic nerve with a relatively smaller contribution from the saphenous nerve. Partial denervation of one hindfoot was produced in adults (> 3 months old) by cutting and ligating the sciatic nerve following which the organization of the hindfoot representation was determined. Rats were anesthetized with ketamine hydrochloride and receptive fields were defined with light tactile stimuli for clusters of neurons located in the middle cortical layers at approximately 80 vertical penetration sites spaced 150-300 μ apart.

Compared to 5 normal adults, results from 5 rats deafferented for 20-157 days indicate the following. (1) The area of cortex representing the skin of the saphenous nerve (range = .32-.68 mm^2) is larger than the comparable area in normal rats (range = .08-.20 mm^2). (2) The area of cortex representing the skin of the saphenous nerve is smaller than the combined areas of representation for the saphenous and sciatic nerves in normal rats (range = .86-1.19 mm^2). (3) The receptive fields are located almost exclusively over skin regions coinciding with the normal saphenous distribution.

These observations suggest that deafferentation in adult rats results in an incomplete cutaneous reactivation of the cortical representation for the denervated skin during the first few months after injury. From receptive fields defined with light tactile stimuli it does not appear that the sciatic skin became reinnervated to any major extent. If results from rats and primates can be compared, these studies indicate that variables in addition to the time following denervation contribute to the degree of central reorganization following peripheral injury.

247.7 SELECTIVE EFFECTS OF ALCOHOL ON RESPONSES OF SINGLE UNITS IN SOMATOSENSORY CORTEX. John K. Chapin and Donald J. Woodward. The Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235.

This study was conducted to determine the effect of alcohol intoxication on sensory responses of single units in the somatosensory (SI) cortex of awake, freely moving rats.

One aim was to compare the effects of alcohol with those of other anesthetics. Post-stimulus time histograms of units recorded in the SI forepaw area were generated either by natural touch of the forepaw with a hand held probe or by stimulating through bipolar electrodes surgically implanted under the skin of the paw. Histograms derived from both these methods were quite similar. These generally featured a short latency excitatory response which was divisible into an initial peak (Ela; from 7-15 msec) and a second peak (Elb; 17-45 msec). Experiments involving lesions of the cuneate nucleus indicated that the Ela peak is derived from sensory information reaching the cortex via dorsal column- medial lemniscal pathways, whereas the Elb peak arrives via extralemniscal pathways. Under halothane or nembutal anesthesia the Elb peak was selectively abolished. Administration of alcohol (1.5 gm/kg body weight by I.P. injection of 10% saline solution) produced active staggering behaviors in rats. This dose produced a slight diminution in the amplitude of the Ela peaks of the histograms produced by paw stimulation, but completely abolished the Elb peak. Thus, although the animals were still awake, alcohol produced an effect in the SI cortex similar to doses of anesthetic agents which caused unconsciousness.

A second aim was to observe the effects of alcohol intoxication on the selective inhibition of somatic sensory input to the cortex. In previous studies we have shown that transmission of cutaneous sensory information from the paw to the cortex during movement is subject to a time varying pattern of sensory suppression which selectively "gates in" only certain sensations. As a consequence of this phenomenon, histograms generated by random stimulation of the paw during running show a marked decrease in the overall sensory responsiveness of the cortical neurons compared with histograms obtained from similar stimulation during resting behavior. After alcohol administration, however, histograms of the sensory responses of single cortical units to paw stimulation, even during intense motor activity, were nearly the same as during rest.

Our hypothesis is that alcohol may compromise function in a specific system which, when it is functionally suppressed, leads to failures in transmission of long latency sensory responses in the cortex and also of selective cortical sensory gating mechanisms. Supported by NIAAA grant AA-0390 and an award from the Biological Humanics Foundation.

247.8 REGIONS OF THE SOMATIC CORTEX THAT AFFECT SUPERIOR COLLICULUS CELLS IN THE CAT. H.R. Clemo and B.E. Stein, Dept. of Physiology, Medical College of Virginia, Richmond, Va 23298.

Visual corticotectal fibers are known to account for many of the specialized features in the superior colliculus. It has been assumed that the somatic corticotectal system would function in a similar fashion. Despite this expectation a previous study demonstrated that while cooling primary visual cortex had a profound effect on the activity of visual cells in the superior colliculus, cooling primary somatic cortical areas (SI-SIII) did not change the activity of somatic cells here (Stein, 1978). It now seems possible that the descending somatic input to the superior colliculus originates predominantly from areas outside the 'primary' somatic cortices. In the present study an attempt was made to compare the effects of stimulation of different somatic cortical regions upon cells in the superior colliculus. Particular attention was paid to the anterior ectosylvian sulcus which may be a significant source of descending somatic input to the superior colliculus.

The response of somatic cells in the superior colliculus to single electrical pulses (0.2 msec, 10-900 μA) delivered to different somatic cortical regions were recorded with glass-coated tungsten microelectrodes. Superior colliculus neurons were excited by stimulation at 341 cortical sites with an average latency of 3.01 msec ± 1.21. They were activated by stimulation of primary somatic areas SI and SII with average latencies of 5.0 and 2.8 msec respectively, at stimulus thresholds of 200-900 uA. However, the shortest latencies ($\bar{x}$=2.5 msec), lowest stimulus thresholds (less than 100 uA) and greatest number of effective stimulation sites (242/341) were found in the anterior ectosylvian sulcus. These were located primarily in a 2 mm^2 area deep in the superior wall and fundus of the anterior ectosylvian sulcus. A somatotopic map (SIV) has been located in the anterior ectosylvian sulcus which consists of relatively small, discrete, receptive fields on the contralateral body (see Clemo & Stein, 1980). In the fringe areas of this region somatic neurons have large receptive fields which are often bilateral. It was in this fringe area that sites with the lowest stimulus thresholds were located. Preliminary observations indicate that the receptive fields of these corticotectal neurons are larger than, but encompass, the receptive fields of the collicular neurons they activate.

248.1 CHANGES IN RESPONSES OF LATERAL GENICULATE CELLS FOLLOWING THE ABOLITION OF THE VISUAL CORTEX IN RATS. S. Molotchnikoff, F. Tremblay*and F. Leporé. Département de Sciences biologiques, Université de Montréal. Montréal, Québec, Canada.

Numerous histological investigations carried out on most mammals have demonstrated that the Lateral Geniculate Nucleus (LGN) and Visual Cortex (VC) have reciprocal relationships. The role of the corticogeniculate fibers is far from being defined. The aim of the present study was to analyze the contribution of VC on responses of LGN cell's in anesthetized and paralyzed hooded-rats. Unitary activity was recorded with glass micropipettes filled with NaCl (2 M). Receptive fields were mapped on a X-Y display screen positioned 30 cm from the eye. Cortical functions were abolished by a topical application onto its surface of KCl (3 M). The elimination of EEG activity and visual evoked potentials confirmed that the VC was unresponsive to light flashes. Receptive fields were mapped prior to and following cortical depression.

An analysis of the results indicated that the on response of the surround of most (6/2) OFF-center cells diminished or was completely abolished. In contrast the off-response remained unmodified or even slightly enhanced. The reverse was observed in half of the cells with ON-center receptive fields. In the remaining on-center cells the center response also declined. Thus, the differential effect of cortical depression is to modify the concentric organization of receptive fields. This differential reduction of on or off discharges was often accompanied by a broadening of the area from which the unaltered response was elicited. In geniculate cells that exhibited non-concentric organization (N = 14) their responses were virtually unaffected by cortical depression.

These results are very similar to those obtained on rabbits (Brain Res. 193: 383-399, 1980; J. Neurosci. Res. 5: 419-429, 1980) and cats (Exp. Brain. Res. 32: 345-364, 1978). Consequently, it appears that in all three species corticofugal influences affect center-surround relationships.

248.2 EFFECTS OF CORTICOGENICULATE FEEDBACK ON CENTER-SURROUND BALANCE AND SPATIAL TUNING OF MONKEY LGN CELLS. J. W. McClurkin*, R. T. Marrocco, and R. A. Young*. Dept. of Psychology, Univ. of Oregon, Eugene, OR 97403.

We have recently shown (Marrocco et al., 1979, Soc. Neurosci. Abstr; Marrocco et al., in press) that the responsivity of monkey lateral geniculate cells (LGN) can be altered by visual activation of the corticogeniculate pathway. A radial grating not directly exciting the LGN cell produced either an inhibition or excitation (or no change) in the response to a small, central flashing spot. The grating effect was abolished by cortical cooling. The present report examines whether the grating effect has differential effects on center and surround and if the changes in balance are reflected in the spatial selectivity of the LGN cells.

Using standard electrophysiological recording techniques, LGN cell responses were measured with the radial grating either stationary or moving radially. The grating was absent from a central aperture whose diameter was chosen to be slightly larger than the receptive field surround. The LGN cell receptive field was directly stimulated with light or dark spots or annuli, or with drifting sine wave gratings presented in the radial grating window. In each case we compared cell responses in the presence of the moving grating to those obtained with the stationary radial grating.

Using spots and annuli inside the moving radial grating, three types of effects were found: I) decreased central response, no effect on surround; II) decreased central response, increased surround response; III) increased central response, decreased surround response. These changes in center/surround balance were paralleled by changes in spatial selectivity. Cells showing Type I effects had uniformly depressed contrast sensitivity functions; Type II cells showed selective inhibition to low spatial frequencies; Type III cells showed uniformly increased (higher sensitivity) spatial selectivity. If it is assumed that the dimensions and relative strengths of center and surround are prime determinants of spatial selectivity, then the changes found with spots and annuli accurately predict the alterations in the contrast sensitivity functions. Our results thus suggest that LGN cell spatial selectivity may be determined by cortical input as well as retinal influences. Supported by NIH grants EY 01286-06 and 5T32 GM07257.

248.3 EXCITATORY AND INHIBITORY EFFECTS OF LUMINANCE SHIFTS ON LGN NEURON RESPONSES UNDER SIMULATED EYE MOVEMENT CONDITIONS. D. Impelman*and B.A. Brooks. Dept. Phys., UTHSC, San Antonio, Texas.

Both local and global masking effects reduce visual sensitivity during eye movements; foveal sensitivity is reduced by luminance changes localized to the central retina as well as by changes in luminance limited to the peripheral retina, ten to twenty degrees eccentric to it(B.A. Brooks et al, ARVO Abstracts). Peripheral luminance shifts evoke transient excitatory responses in retinogeniculeate neurons. Center responses to test flash stimuli in the fixated eye are reduced by temporal interactions with the periphery response(Exp. Brain Res, 31:235-248). The excitatory periphery effect is characteristic of Y neurons and appears to be related to the shift mechanism of Y subunits that responds to changes in luminance rather than luminance levels both within and beyond their receptive field boundaries(J.P. 289:299-310). During saccades across full field vertical gratings Y neurons respond with a burst discharge similar to the shift response(J.P. 250:579-95). The response of complex cells during saccades over patterned visual fields is also a brisk excitation while simple cells respond with an inhibition which persista throughout the duration of the eye movement(Vis. Res. 20:553-56). These findings suggest that full field shift effects reduce visual responses during saccades either by temporal interactions of excitatory responses and/or by inhibition produced by activation of Y neurons which then inhibit X cell responses. In the present study we have looked at excitatory and inhibitory shift effects in cat LGN neurons under simulated eye movement conditions to find out to what extent excitatory and/or inhibitory interactions in X andY neurons contribute to masking effects during saccades under full field conditions. Responses to displacements of peripheral(.4c/d) and full field(.4-2c/d) gratings at saccadic velocities were obtained. (The space average luminance of the gratings was .1logfL and background luminance was -1 logfL.) Test flash stimuli were chosen to demonstrate either excitatory or inhibitory effects. 91% of the X cell responses to saccadic displacements of full field gratings were center responses to local luminance levels during and after the movement. Both excitatory and inhibitory response attenuated excitatory test flash responses. Weak inhibitory shift effects observed in 9% of the X cells also reduced test flash responses. Although excitatory shift responses were recorded from Y neurons a secondary burst discharge during saccades was not. The neural mechanism for the shift effect and the secondary burst discharge may not be the same. It appears that in most LGN X cells under full field conditions, center responses to local luminance levels may mediate their sensitivity changes during saccades.

248.4 VISUAL RESPONSES OF SINGLE UNITS IN THE LATERAL PULVINAR OF MACAQUE MONKEYS. G. Felsten, D. Burman*, K. Yoshida and L. A. Benevento. Department of Anatomy, University of Illinois, College of Medicine, Chicago, Illinois 60680.

Single unit recordings were made throughout the lateral pulvinar (PL) of paralyzed macaques maintained on 70% N_2O/30% O_2. This report does not include results from the retinotopically organized subdivision of the lateral pulvinar (PLα), which is adjacent to the inferior pulvinar, but includes those from the portion of PL which forms the lateral aspect of the caudal thalamus, including subdivision PLγ (Neurosci. Abst. 3 (1977) 573). Approximately 50% of the units responded to moving or stationary visual stimuli. Most had uniform receptive fields, 30% of which were smaller than 15°, while 50% were larger than 35°. Some were as large as 150° (long axis), and a few units could be influenced by a visual stimulus placed almost anywhere in the visual field. Over half the receptive fields were bilateral, the rest ipsi- or contralateral. There was no apparent retinotopic organization; many receptive fields overlapped and most were clustered about the area of central vision. Although most units were binocular, the contralateral response was dominant in 41% of the units; the ipsilateral response was dominant in 31%. In some penetrations, nearly all of the units were predominantly or exclusively driven by one eye alone. Binocular interactions were varied and complex, and often unpredictable from the monocular responses. For example, a unit could be inhibited by one eye, unaffected by the other and excited by binocular stimulation. A minority of units were orientation selective. On the other hand, several classes of cells with unusual or distinctive properties were found. Of the units sensitive to tangentially moving stimuli, one subgroup gave sustained excitation or inhibition to static levels of luminance or darkness, and another subgroup was sensitive to stimuli which moved in depth, i.e., toward or away from the eyes. For many units, the response to one class of stimuli was seemingly unrelated to the response to another class. It may be that different wiring diagrams describe these different afferent inputs. Color sensitive neurons exhibited opponent-process properties. One group was excited by some monochromatic lights, but inhibited by complementary wavelengths. Another group was excited by white light, but inhibited by monochromatic lights. Several latency classes were recognized which correlate with the response properties mentioned. For example, color units fell into the short (45-65 msec) and middle (85-120 msec) latency range, while units with unusual movement properties or binocular interactions had the longest latencies (155-235 msec). These differences are taken to reflect midbrain versus cortical inputs. (Supported by grant EY 2940 and Fellowship PHS EY 5504.)

248.5 EFFECTS OF SUPERIOR COLLICULUS AND STRIATE CORTEX LESIONS ON THE VISUAL RESPONSE PROPERTIES OF INFERIOR PULVINAR NEURONS IN THE MONKEY. D. B. Bender* (SPON: C. J. Smith). Division of Neurobiology, Physiology Dept., SUNY/AB Med. Sch., Buffalo New York 14226.

In the macaque, we have previously shown that the inferior pulvinar contains a complete representation of the contralateral hemifield. Both striate cortex and the superior colliculus project topographically onto this nucleus in a manner consistent with its retinotopic organization. We have also shown that about 2/3 of inferior pulvinar neurons are sensitive to stimulus orientation or direction of movement, while about 1/3 lack such sensitivity, responding equally well to all orientations and directions of movement.

In the present study, we wished to determine whether the input from cortex or colliculus is essential for the visual properties of pulvinar neurons. Accordingly, inferior pulvinar cells were studied in the anesthetized, immobilized macaque following lesions of either striate cortex or the superior colliculus.

Following unilateral striate cortex lesions, cells in the ipsilateral inferior pulvinar were no longer visually responsive. The range of spontaneous activity, however, appeared normal. There was no recovery of visual responsiveness up to four months following the lesion.

By contrast, large bilateral superior colliculus lesions did not eliminate the visual responses of pulvinar cells. Following colliculus lesions, the retinotopic organization in the inferior pulvinar was unaffected. Furthermore, directional, oriented, and non-oriented cells were all present.

These results suggest that striate cortex, but not the colliculus, is essential for the visual responsiveness of inferior pulvinar cells in the immobilized monkey.

248.6 EFFECTS OF SUPERIOR COLLICULUS (SC) AND PULVINAR (P) LESIONS ON VISUAL SEARCH IN CYNOMOLGUS MONKEYS. M. Azzato*, C. Leiby*, C. Butter, D. Bender*, and D. Shirley*. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI, 48109, Dept. of Physiology SUNY Medical School, Buffalo, NY, 14226.

To determine whether the SC and P participate in integrative functions underlying visual search, four monkeys were tested in a visual search task before and after receiving electrolytic SC, sham SC, or P lesions. The task was performed as follows. After a small, dim light spot appeared on the center panel, the monkey pressed it to initiate each trial. The target pattern (a circle) was then projected at varying eccentricities (5-55° from the center panel) on one of two screens located on either side of the center panel. Varying numbers of irrelevant patterns (0, 1, 3, 5, 7, 9 or 39) were also presented on the screens. All the patterns were either high contrast (16.1 cd/m^2) or low contrast (0.4 cd/m^2) relative to the ambient illumination on the screens (0.3 cd/m^2). Water reward was given only for pressing the screen on which the circle appeared. After the monkeys learned to perform the task well, their reaction times (the time from pattern presentation to the choice response) increased with a) number of irrelevant patterns and b) target eccentricity on one or both screens, suggesting that the monkeys systematically searched for the target. The slopes of these RT functions were somewhat steeper when low contrast, as opposed to high contrast patterns were presented. One monkey received a sham lesion, after which it showed no performance changes. This monkey and a second one then received SC lesions. Postoperatively, as before surgery, their RTs increased both with target eccentricity, suggesting that their search patterns were unaltered, and with number of irrelevant patterns. However, the slopes of these functions were steeper than they were preoperatively, whether the patterns were high or low contrast. Both monkeys with SC lesions also showed a striking increase in errors (pressing the screen on which the target did not appear), but only when eccentric targets and many irrelevant patterns were presented at low contrast. Errors did not increase when no irrelevant patterns were presented, so that the task was simply light detection, or when the target was presented on the part of the screens near the center panel. The RT changes could be due to deficits in saccadic movements. However, the SC-lesioned monkeys' selective increase in errors to eccentric, low contrast targets surrounded by many irrelevant patterns suggests an impairment in identifying the target or selecting it under these conditions as a stimulus for a saccade. No reliable performance changes were found in two monkeys after P lesions intended to include the tectorecipient zone.

248.7 THE ORIGIN OF THE CROSSED CORTICO-COLLICULAR PROJECTION IN THE CAT. B.R. Payne and N. Berman. Departments of Physiology/Biochemistry and Anatomy. Medical College of Pennsylvania. PA.

The superficial layers of the superior colliculus of the cat receive a direct visual input from the two retinae and indirect visual input via the two visual cortices. These projections have been shown to maintain correct retinotopic fidelity with each other (Payne & Berman, Anat. Rec. 199). We were interested in determining the exact location of the cells which form the crossed cortico-collicular pathway from the visual cortex. In addition, since the superior colliculus has been shown to contain cells which respond to other sensory modalities besides vision in the deeper layers, we were interested in determining which cortical regions send a projection to the contralateral superior colliculus. The retrograde transport of horseradish peroxidase (HRP) was used to achieve this goal. Since the needle passed through the cortex on its way to the superior colliculus it is possible that leakage of HRP into the cortex could result in labelled cells in the contralateral cortex. To overcome this possibility the corpus callosum was cut. Electrophysiological recording techniques were used to map receptive fields and to guide the placement of the injection needle into the rostal portion of the superior colliculus. Between half and one microliter of a 50% solution of HRP was injected at 4 sites. The tissue was reacted with tetramethyl-benzidine and hydrogen peroxide. In the visual cortex the largest numbers of labelled cells were observed in the lateral suprasylvian visual areas, although labelled cells were also seen in areas 17,18 and 19. Large numbers of labelled cells were also observed at several other contralateral cortical locations including the dorsal part of the posterior ectosylvian gyrus, the dorsal and anterior ectosylvian gyrus, the anterior sylvian gyrus and the lateral bank of the sylvian and rhinal sulci. In addition, large numbers of labelled cells were observed in the medial bank of the presylvian sulcus, ventral bank of the cruciate sulcus and on the medial surface of prefrontal cortex. Electrophysiological recordings in many of these regions have shown that the cells respond to more than one stimulus modality and have bilateral receptive fields. Electrical stimulation of these areas also induces eye or head movements. These results show that the superior colliculus receives inputs from a large number of regions of the contralateral cerebral cortex and the regions with the heaviest projections are those involved in orienting movements.

248.8 CORTICAL AND INTERTECTAL INFLUENCES ON VISUALLY-GUIDED BEHAVIOR. B.E. Stein, S. Hardy* and S.B. Edwards. Department of Physiology, Medical College of Virginia, Richmond, VA 23298 and Department of Anatomy, University of Virginia School of Medicine, Charlottesville, VA 22908.

Extensive lesions of the occipitotemporal cortex produce neglect of stimuli in the contralateral visual field. This orientation deficit is ameliorated by destruction of the opposite superior colliculus or by splitting the intertectal commissure (Sprague 1966, Sherman 1974). In the present investigation we sought to determine the specific areas of cortex and colliculus responsible for this phenomenon. The visually-guided behavior of normal and lesioned cats was assessed using a perimetry device (Sprague & Meikle, '65). Ablations were made in various areas of the right cortex. When an orientation deficit in the contralateral (left) visual field was observed a lesion was placed in the superior colliculus contralateral to the cortical ablation. Visually-guided behavior was evaluated once again. We found that primary visual cortex need not be disrupted to produce a complete contralateral visual neglect. Only a band of cortex along the middle suprasylvian gyrus and sulcus had to be removed to produce this behavioral dysfunction. Furthermore, only partial lesions of the colliculus were necessary to restore visually guided orientation. Surprisingly, the reinstatement of visually-guided orientation was not predictable by referring to the region of the visual field represented in the lesioned portion of the colliculus. Thus, removal of the posterior ¼ of the left superior colliculus reinstated visually-guided behavior in all portions of the left visual field. Electrophysiological recordings confirmed that the remaining portion of the lesioned colliculus was functional.

248.9 SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE RODENT VISUAL SYSTEM. L. K. Laemle, S. C. Feldman, and E. Lichtenstein*. Dept. of Anatomy, CMDNJ-New Jersey Medical School, Newark, N.J. 07193 and the Hospital for Joint Diseases, New York, N.Y. 10035

The presence of somatostatin-like (SRIF) immunoreactivity was investigated in the central visual pathways of three species of rodents: mouse, guinea pig, and rat.

Brains of adult animals were fixed in Bouin's solution, embedded in paraffin, and sectioned in either the coronal or saggital plane. SRIF was localized using a highly specific antiserum to the peptide and the unlabeled antibody enzyme technique of Sternberger. Staining was judged specific by the absence of DAB reaction product in neuronal elements following adsorption of the antiserum with synthetic SRIF. Data was evaluated in terms of SRIF-synthesizing neurons as judged by the presence of DAB reaction product specific for the peptide, in the perikaryon and in neuronal processes, SRIF-containing fibers, and neurons which appeared to be innervated by SRIF-containing fibers.

Immunoreactivity was observed in the lateral geniculate nucleus, pretectal area, superior colliculus, and visual cortical areas. In the superior colliculus, a dense plexus of SRIF-containing fibers and innervated neurons was present throughout the superficial layers. In the intermediate and deep layers, SRIF fibers and innervated neurons were moderately dense adjacent to the midline, and sparsely distributed otherwise. SRIF-synthesizing cells were observed in all collicular layers. In the visual cortical areas, SRIF-containing fibers and innervated neurons were most abundant in the superficial layers. SRIF-synthesizing neurons were present in all cell layers and in a variety of cell types including pyramidal cells in layer V of the striate cortex. In the lateral geniculate nucleus we were unable to locate either SRIF-synthetic or SRIF-innervated cells, and only sparsely distributed SRIF-containing fibers. We decided, therefore, to examine similar preparations of prenatal rat brain. In the prenatal brain, just before birth, SRIF-synthetic neurons were observed in the lateral geniculate nucleus in contrast to the adult. In addition, SRIF-containing fibers and SRIF neurons were more prominent in the superior colliculus.

This is the first demonstration of somatostatin in the central visual pathway. (Supported by NIH grant 5R01 EY01174 to Dr. Laemle, and a grant to Dr. Feldman from the Foundation of the College of Medicine and Dentistry of New Jersey).

248.10 ANATOMICAL MAPPING OF REPRESENTATIONS OF THE VISUAL FIELD IN AFFERENT PROJECTIONS TO THE VISUAL CORTEX OF THE CAT. K.Albus and G. Meyer*. Dept.Neurobiol., MPI Biophys.Chem., 34Göttingen, FRG.

Small amounts of horseradish peroxidase(0.1-0.4µL) were injected into various parts of the representations of the visual field (VF) in areas 17,18 and 19. VF maps were then prepared in subcortical and cortical areas on the basis of the distribution of HRP labelled cells.

The N. lateralis post. thalami (LP) contains two complete VF representations. One occupies the middle third of the nucleus, the other the lateral third and adjacent parts of the Pulvinar(PUL). In both representations the upper hemifield(UF) is located dorsomedially, and the lower hemifield(LF) ventrolaterally from the area centralis(AC) and the horizontal meridian(HM). The vertical meridian(VM) forms the border between both representations.

The PUL contains one complete representation of the VF, which occupies only the lateral half of the nucleus. The projection columns in PUL for AC, LF and HM run from caudoventral to rostrodorsal; therefore, the vertical dimension of the VF is represented in a caudodorsal to rostroventral direction. The VF periphery extends medially from the VM, which is represented at the very lateral border of PUL.

The caudal third of the Claustrum (CL) contains a complete representation of the VF. The upper VM occupies a centre position in the caudal third of the visual CL. The AC is represented in the dorsomedial corner at the transition between caudal and middle third, and the lower VM extends through the rostral third of the visual CL, being located 0.5-1.0mm below the dorsal margin of the nucleus.

The medial part of the lateral suprasylvian area (LSAmed)contains a complete representation of the VF, and this extends over the medial bank of the middle suprasylvian sulcus(SSSmed) and the lateral third of the adjacent gyrus. The AC is represented in the caudal end of the SSSmed and continues rostrally into a large representation of the HM. Still further rostrally and proceeding from lateral to medial, are found the lower VM, the LF periphery, the UF periphery and the upper VM.

The lateral part of LSA(LSAlat), and the areas 21 and 20 contain only partial representations of the VF. In LSAlat the UF is not represented, whereas in areas 21 and 20 larger parts of the LF are lacking. It has been found, that area 20 sends projections only to area 19, whereas LSAlat, LSAmed and area21 send projections to both areas 18 and 19.

Some differences were noted between the anatomical maps and maps derived from physiological recordings. These might reflect differences in sensitivity between the methods used and/or differences in the interpretation of data.

248.11 THALAMIC PROJECTIONS TO VISUAL AREAS I AND II IN THE RABBIT. Theodore G. Weyand and Harvey A. Swadlow. Dept. Psychol.(U-20), Univ. Conn., Storrs, Conn. 06268

Thalamo-cortical projections to visual areas I and II (V-I, V-II) were studied using horseradish peroxidase (HRP) as a retrograde label. Tetramethyl benzidene was used as the chromagen. Multiple-unit mapping procedures were utilized to guide the injection of small quantities (0.04-0.15 µl) of HRP into specified regions of V-I or V-II of Dutch rabbits. As found by Karamanlidis and Giolli (Exp. Brain Res., 29: 191-199, 1977), injections restricted to V-I revealed a prominent topographical projection from the dorsal lateral geniculate nucleus (LGNd)*. Consistent projections were also found from the ventral lateral nucleus (VL), posterior thalamic nucleus (Po) and pulvinar (Pul). Injections restricted to V-II revealed consistent projections from VL, Po and Pul. In addition, following injections into V-II, a narrow zone of fibers interfacing the LGNd with the Pul contain significant numbers of labeled cells.

Our results therefore indicate that VL, Po and Pul each project to both V-I and V-II. Our data also indicate that the projection from VL to V-II is more extensive than that to V-I. Studies using double retrograde labels would prove useful in determining whether individual neurons within these nuclei project to both V-I and V-II.

* We have adopted the nomenclature of Giolli et al. (J. Comp. Neurol., 180: 743-752, 1978)

248.12 ASSESSMENT OF VISUAL PATHWAY MISROUTING IN HUMAN ALBINISM. P. A. Apkarian, D. Reits*, H. Spekreijse* and D. van Dorp*. The Netherlands Ophthalmic Research Institute, 1005 EK Amsterdam, The Netherlands.

Abnormal decussation of temporal retinogeniculostriate projections associated with albinism can be detected in the potential distribution of the visual evoked potential (VEP). Following monocular stimulation misrouted optic pathway projections produce VEP asymmetry across the occipital left and right hemispheres.

Under optimized stimulus and recording conditions a quantitative range of VEP asymmetry values was obtained in albino observers (N>50) and in normally pigmented controls. Pattern appearance/disappearance and pattern reversal VEPs were recorded from five electrodes positioned at equal intervals of 3 cm in a horizontal row across the scalp. The resultant potential distributions of the significant parts of the response were fitted with a polynomial. The difference in the location of the extreme of the polynome upon left and right eye stimulation was used as an objective indicant of asymmetry. In the controls this difference proved to be less than 1 cm; in albinos differences greater than 6 cm were typically found. As concomittant oculomotor disorders are characteristic in albinism, eye movements also were recorded and the cross spectra between left and right eye movements were obtained.

Asymmetry was found to be specific to particular VEP components within a given response profile. Under pattern appearance/disappearance conditions, e.g. the asymmetry is primarily evident in the first positive component; later components typically yield symmetric responses and/or reverse asymmetry. The degree of asymmetry was found to vary as a function of several stimulus determinants including retinal eccentricity, pattern size and orientation. Asymmetry was also examined in relation to age, acuity and albino phenotype. Left and right half field stimulation can mimic in normal observers the asymmetries found with full field stimulation in albinos.

248.13 EXTRAGENICULATE VISUAL PATHWAYS TO RETROSPLENIAL CORTEX IN THE RAT. Scott M. Thompson,* Steven C. Baker,* and Richard T. Robertson. Department of Anatomy, College of Medicine, University of California, Irvine, CA 92717. (Sponsored by Earle A. Davis, Jr.)

The extrageniculate visual projections from the pretectal complex to retrosplenial cortex via the lateral dorsal nucleus (LD) of the thalamus were examined using retrograde axonal transport of horseradish peroxidase (HRP). Small iontophoretic injections of HRP were placed at various locations within the dorsal or ventral subdivisions of retrosplenial cortex or within LD. Following 2 day survival times, frozen sections were processed for HRP histochemistry using benzidine dihydrochloride as the chromagen.

HRP injections in retrosplenial cortex produced retrogradely labelled cells within the anterior, lateral dorsal, midline, and intralaminar thalamic nuclei. Projections to retrosplenial cortex originate from LD in a partially overlapping, topographical arrangement. The ventral subdivision of retrosplenial cortex (vRSP, area 29c) receives a projection primarily from the medial half of the anterior 2/3's of LD. The dorsal subdivision of retrosplenial cortex (dRSP, area 29d) receives projections primarily from the posterior 2/3's of LD. Further, rostral injections of dRSP result in labelled cells within the rostral and medial portion of this posterior zone of LD, while caudal injections of dRSP result in labelled cells within the caudal and lateral portion of this posterior zone.

Injections of HRP within LD result in labelled cells within the pretectal complex. The number and distribution of labelled cells vary with the location of the injection. HRP injections in the caudal and lateral parts of LD (i.e., the portion of LD that projects to the caudal parts of dRSP cortex) produce the largest number of labelled cells within the pretectum. These labelled cells tend to be concentrated in the retino-recipient regions of the pretectum. HRP injections in the rostral and medial portions of LD (i.e., the portion of LD that projects to the vRSP and rostral dRSP cortices) produce relatively few labelled pretectal cells, which are located primarily in the non-retino-recipient regions of the pretectum.

These data suggest that visual information from the pretectal complex is relayed primarily via the caudal and lateral regions of the lateral dorsal nucleus to the posterior parts of dorsal retrosplenial cortex.

248.14 CONNECTIONS OF THE PRIMARY VISUAL CORTEX WITH THE DORSAL PARASUBICULUM IN THE RABBIT. H. Holländer. Dept. Neuromorphology, Max-Planck-Institute of Psychiatry, 8000 Munich 40, F.R.G.

The rabbit parasubiculum (Brodmann's area 49) is a narrow strip of cortex intercalated between the presubiculum and the entorhinal cortex. The region was studied cyto- and myeloarchitectonically in transverse, parasagittal and horizontal series of normal material. By means of anterograde transport of horseradish peroxidase and tritiated leucine it was found that there is a projection from the primary visual cortex to the dorsal part of the parasubiculum, mainly to its first layer. Medium sized nerve cells which were retrogradely labelled with HRP were found in the same region in the lower external principal layer and the upper lamina dissecans. This finding indicated that there is also a projection back from the dorsal parasubiculum to the primary visual cortex.

248.15 DIFFERENTIAL PROJECTIONS FROM CORTICAL VISUAL AREAS TO THE NUCLEI OF THE ACCESSORY OPTIC SYSTEM IN THE CAT. R. R. Marcotte and B. V. Updyke. Dept. of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

In the course of studying cortico-thalamic projections of the lateral suprasylvian visual areas in the cat, we noted differential projections from these areas to the nuclei of the accessory optic system. Areas AMLS, ALLS, PMLS, PLLS, DLS, 20a, 20b, 21a and 21b, as identified by Palmer et al. (J. Comp. Neurol. 177:237, 1978) and Tusa and Palmer, (J. Comp. Neurol. 193:147, 1980) were identified by electrophysiological mapping prior to injecting tritiated proline. Additional autoradiographic material from cases involving areas 17, 18, 19, the crown of the middle suprasylvian gyrus and the splenial sulcus were also examined for evidence of projections to the accessory optic system.

The presence of terminal labelling within the accessory optic nuclei was detected in 16 of 53 injection cases. Terminal labelling was most often associated with large injections (> 30 µCi) of high specific activity precursor (> 100 Ci/mmol) and after survival of 40-48 hours.

Injections of areas AMLS, PMLS, 21a and 21b resulted in terminal labelling within the medial, lateral and dorsal terminal nuclei. Injections of area PLLS resulted in labelling only within the lateral terminal nucleus. Large injections of the 17/18 border resulted in terminal labelling only within the medial terminal nucleus. No terminal labelling was detected following smaller injections restricted to area 17, 18 or 19. Large injections of high specific activity label in areas ALLS, DLS, 20a, 20b, the crown of the middle suprasylvian gyrus, and splenial sulcus also failed to yield terminal labelling within the accessory optic nuclei.

These results suggest that only selected cortical visual areas influence activity of the accessory optic nuclei via descending projections. The accessory optic system has been implicated in the control of visual reflexes. Thus direction-specific deficits in horizontal optokinetic nystagmus following bilateral aspiration of visual cortex (Wood, Spear and Braun, Brain Res. 60:231, 1973) may be related, in part, to disruption of the corticofugal projections described above.

248.16 THE PROJECTION FROM STRIATE AND PRESTRIATE VISUAL CORTEX ONTO THE PONTINE NUCLEI IN THE MACAQUE MONKEY. W. Fries+ (SPON: E. Pöppel) Dept. of Anatomy, University College London, and Institute for Medical Psychology, University of Munich (FRG).

The neocortex of mammals is linked with the cerebellum via the pontine nuclei (PN). Early studies on the visual cortical projections to the PN demonstrated only a minor, if any, contribution of the striate cortex. The main source of the visual cortical input to the PN appeared to be the prestriate cortex. Recently, the prestriate cortex of monkey has been described to consist of several distinct visual areas which are regarded as functionally specialized (Zeki, Nature 274,1978). We studied how these areas contribute to the pontine projection by injecting H^3-proline or HRP into the prestriate cortex for anterograde tracing.

Terminal labelling was located in the dorso-lateral part of the rostral two thirds of the pons. The density and the rostro-caudal extent varied depending on the cortical area injected. Confirming earlier reports, no projection was found from the central 10^{o} of the striate cortex (V1), but a small projection appeared after more peripheral injections. There was again no projection from central V2, nor from the V2/V3 border representing about 30^{o} eccentricity. A fairly strong projection was found to originate from V3A in the anterior bank of the lunate sulcus. The V4-complex had only a minimal projection from its rostral border region. However, the anteriorly adjoining area V5 had a powerful projection to the PN. These results suggest that all visual areas, with the possible exception of V2, take part in the pontine projection, but there are areal differences. It appears that the cortical representations of central parts of the retina are spared from this projection. However, HRP injections into V5 (the motion area) which resulted in strong terminal labelling in the pons, showed that the injected area received input from foveal striate cortex. HRP injections into V4 (the colour coding area) which similarly received input from foveal striate cortex, produced virtually no labelling in the pons. It might therefore be that topographical factors are less relevant than functional properties in determining the strength of the visual cortico-pontine projection.

248.17 THE VISUAL CORTICAL PROJECTION TO THE STRIATUM IN THE GOLDEN HAMSTER. D. C. Kuo, J. D. Polcer*, R. W. Rhoades, S. E. Fish, T. J. Voneida and D. K. Goodman*. Dept. of Anatomy, CMDNJ-New Jersey School of Osteopathic Medicine and Rutgers Medical School, Piscataway, NJ 08854; Neurobiology Prog., Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Large injections of radioactive amino acids into the posterior neocortex revealed that in hamster, as in rat (Webster, J. Anat., 165, 1961), this region projected to the caudal striatum. Smaller, electrophoretic deposits of [^{3}H]-leucine into areas 17, 18a and 18b demonstrated further that all of these cortical areas sent axons to the posterior striatum. These small deposits also showed that the visual corticostriatal projection was topographically organized, at least along the superior-inferior axis of the cortical visual field representation. Caudal visual cortical deposits yielded labelling in the most posterior part of the striatum while anterior deposits resulted in more rostral striatal labelling. The autoradiographic experiments, revealed, however, that the visual corticostriatal projection was not strictly point-to-point. Even the smallest [^{3}H]-leucine deposits resulted in several discrete patches of striatal labelling.

In a complementary series of experiments, small deposits of horseradish peroxidase (HRP) were made into the caudal striatum. These injections produced HRP labelled neurons in areas 17, 18a and 18b. The labelled cells were, in most cases, pyramidal neurons located in the upper portion of lamina V. The HRP data revealed a topographic organization for the corticostriatal projection similar to that observed in the autoradiographic material.

In cat (Jayaraman, Brain Res., 195, 1980) it has been shown that neurons in the caudate, putamen and globus pallidus send axons to the auditory cortex. To determine whether or not the hamster's visual cortex was innervated by the striatum we made injections of HRP into the visual cortex, and [^{3}H]-leucine deposits into the striatum. Neither series of experiments provided any evidence for a striato-visual cortical projection in the hamster.

248.18 COMPARTMENTALIZATION OF CORTICAL INPUTS TO THE THALAMIC LATERAL GROUP OF THE HAMSTER. Roberto Lent* (SPON: Walter Rosenblith). Department of Psychology, M.I.T., Cambridge, MA 02139.

Hodological and histochemical work in cats and monkeys has led to the notion that the thalamic lateral group is a complex structural entity whose inputs are compartmentalized in distinct regions. I was interested in testing the generality of this idea, beginning with an investigation of the pattern of projections from posterior cortical regions to the lateral group in hamsters.

I have made focal cortical lesions in the left hemisphere and restricted injections of tritiated proline in the right hemisphere of 10 adult hamsters. After adequate survival times, the animals were sacrificed and perfused with fixative. Four series of adjacent sections were collected after the brain was frozen and cut coronally, to be processed respectively by the autoradiographic technique, the Fink-Heimer procedure I, the Gallyas myelin stain and the Nissl (cresyl-violet) technique.

Results have revealed that both the nucleus lateralis anterior (LA) - often referred to as lateralis dorsalis or simply lateralis - and nucleus lateralis posterior (LP) receive afferents from ipsilateral posterior cortical regions. In both nuclei, inputs from the striate cortex (V_1), area 18b (V_M) and the parietal cortex (areas 7 and 2) are partially segregated in different subregions. Thus, V_1 projects to a laterodorsal part of LA, while V_M projects to a small medial band and areas 7 and 2 to a ventromedial region continuous with dorsal aspects of the somatosensory thalamus. In LP, V_1 projects topographically to the rostral half of the nucleus occupying its whole depth, while V_M projects to a restricted lateral band situated within the caudal tecto-recipient zone of LP. The parietal cortex input occupies only the ventral half of rostral LP, largely overlapping the V_1 terminal fields.

These findings suggest that compartmentalization of inputs in the thalamic lateral group may be a general mammalian feature. They also point to the possibility of using this feature to establish homologies of extrageniculate pathways in mammals. It is known that LP is part of an ascending tectothalamic pathway that reaches the visual cortex, while LA participates in a pretectothalamocortical pathway that instead reaches the limbic cortex. The existence of compartmentalized cortical feedback to these thalamic nuclei may mean that these ascending systems convey specialized, multi-channeled sensory information to their cortical target areas.

248.19 CORTICAL CONNECTIONS FROM THE STRIATE CORTEX IN THE GRAY SQUIRREL: DEFINITION OF EXTRASTRIATE CORTICAL VISUAL AREAS. V.M. Montero and K.D. Cliffer. Dept. Neurophysiology, Univ. Wisconsin, Madison, WI 53706, and J.F. Bell Museum Nat. History, Univ. Minnesota, Minneapolis, MN 55455.

The distribution of cortical connections from area 17 to the ipsilateral cortex in the gray squirrel was studied to define the location of extrastriate cortical visual areas. From single injection sites of 3H-proline in area 17, autoradiograms show labeled projections in several extrastriate cortical areas. These areas occupy the following positions with respect to the striate cortex, and are named accordingly: posterior (P), posterolateral (PL), mediolateral (ML), laterolateral (LL), anterolateral (AL) and anteromedial (AM). In addition, there are projections to retrosplenial (RS), dorsal pararhinal (PR) and anterotemporal (AT) cortices. Areas P, PL, ML and AL are located from caudal to rostral in architectonic area 18, area LL is in architectonic area 19, and area AM is in anteromedial peristriate cortex. Area AT is in a region rostral to 19 and dorsal to architectonic area Ta. Projections from different retinotopic regions of area 17 are established into each of the extrastriate areas with varying degrees of convergence, and projections from a single striate cortex site diverge into multiple patches within most extrastriate areas.

The similarities in the distribution of striate cortical projections in the gray squirrel (family Sciuridae) with those found in rodents of families Muridae and Octodontidae (rat, Montero et al. Brain Res. 53:202,'73; Octodon degus, Kuljis et al. Neurocirugia, in press), and in the rabbit (Montero and Murphy, Anat. Rec. 183:483,'76), suggest a general pattern of visual cortex organization in Rodentia and Lagomorpha. We call this a "rodent type" of visual cortex organization. This pattern is different in several respects from the distribution of striate cortical connections seen in the cat (Montero, Brain Behav. Evol. 18,'81) and in rhesus and owl monkeys (V.M.M. unpublished). For example, besides other differences, in the cat and monkey there are no direct striate cortical projections to the retrosplenial cortex. In the gray squirrel, however, there is a higher degree of divergence in these connections than in the rat and rabbit. This property is similar to the divergence found in striate-extrastriate connections in the cat and monkey (Montero, J. Comp. Neurol. 189:45,'80).

249.1 PROPERTIES OF JUNCTIONAL AChR THAT NEWLY APPEAR AFTER DENERVATION IN VITRO. A. Olek and N. Robbins. Anat. Dept.,Case Western Reserve Med. Sch., Cleveland, O. 44106

In rat diaphragm muscles the number of junctional acetylcholine receptors (AChR), as assayed by ^{125}I-alphabungarotoxin (*BTX) binding, increases by as much as 80% in diaphragm strips after 42 hrs. in organ culture. The presence of a 2 cm. long nerve stump prevents this increase in AChR (Olek and Robbins, 1981, Neuroscience, In press).

By exposing existing surface AChR to unlabelled alphabungarotoxin (BTX) prior to the expected increase in junctional AChR, we were able to characterize certain properties of the population of AChR that appeared after denervation: 1) The new population of junctional AChR was functional. Bath application of acetylcholine (.5mg./ml) produced a membrane depolarization at the endplate in diaphragm strips without a nerve stump (-N), while no acetylcholine response could be elicited in strips with a 2 cm. nerve stump (+N), even at 2-5 times the dosage. The acetylcholine response in -N strips was maximal at the endplate and declined to 0 at distances greater than 75 micra. The maximal endplate response in -N strips to a given dose of acetylcholine was approximately 50% of that produced in a freshly dissected diaphragm. In -N strips demonstrating a junctional acetylcholine response, the binding of *BTX was found to be 40-80% that of innervated muscle. Both the response to acetylcholine and *BTX binding in the new population of junctional AChR could be blocked by unlabelled BTX. 2) The appearance of new junctional AChR was rapid. After cold block of pre-existing AChR, a detectable junctional response to acetylcholine developed within a 2 hour time period, as did the appearance of junctional *BTX binding sites. 3) The turnover of the new population of junctional AChR was slow relative to that of extrajunctional AChR. The new population of AChR was labelled with *BTX and the number of junctional AChR was then monitored at 0, 8, and 15.5 hours in organ culture. Little *BTX binding (< 15%) was lost from the endplate between 0 and 15.5 hours, indicating that the new junctional AChR turned over more slowly than typical extrajunctional AChR.

Since there is close correspondence between the appearance of new *BTX binding sites and physiological sensitivity, it is likely that a mechanism exists for rapid insertion of functional AChR at the motor endplate. Since this insertion is nerve stump dependent, a novel mechanism for the rapid neural regulation of junctional AChR may be indicated.

249.2 ALTERATIONS IN ENZYMATIC ACTIVITIES AS A RESULT OF CROSSING OF ELECTRICALLY SILENT NERVES TO FAST AND SLOW MUSCLES. L. Eldridge*, K. Baldwin*, M. Liebhold* and W. Mommaerts (SPON: E. Decima). Depts. Physiol., Univ. of California, Los Angeles, California 90024 and Univ. of California, Irvine 92717.

To assess the ability of nerves to specify fast and slow properties of skeletal muscle by trophic signals, some biochemical and histochemical effects of nerve-crossing were examined in a cat preparation in which the electrical activity of the motoneurones had been permanently silenced by a surgical spinal cord isolation (SI). In the SI cats, all dorsal roots between two cord transections enclosing the 5th lumbar through the 3rd sacral cord segments were severed. Control cats underwent either bilateral dorsal rhizectomy including L5 through S3, cord transections at the borders of the region L5 through S3, or no spinal surgery. The nerves to fast (F) flexor hallucis longus and slow (S) soleus muscles were crossed (X) in one leg of each cat. In the contralateral leg (U), the nerves to these muscles either remained intact or were severed but reconnected in their original positions. All surgical operations on a given cat occurred within the same day. Eight months after surgery, the F and S muscles were removed for testing. They were assayed biochemically for the activities of lactate dehydrogenase, α-glycerophosphate dehydrogenase citrate synthase, and Ca^{++} activated myosin ATPase and for the susceptibility of myosin ATPase to inactivation by alkaline preincubation. The muscles were examined histochemically with regard to the proportion of fibers staining heavily for ATPase activity after alkaline preincubation. A complex pattern of results emerged from analysis of the 6 assays on 2 muscle types after 2 arrangements of nerve connections and 4 spinal treatments. Comparison of the U muscles of normal cats to those of the cats with spinal surgeries showed significant changes in enzyme activities as a result of the surgeries themselves, especially the SI. Nerve crossing was effective in all treatment groups. In 47 of the 48 comparisons between X and U means, the X mean was closer to that of normal muscles of the opposite type (F vs. S) than was the U mean. The fact that all 12 of the differences between the X and U means in the SI cats were in the same direction as the X-U differences in the normal cats indicates that the nerve can influence enzyme properties by some means other than its own electrical activity or the electrical and contractile activity it evokes in its muscle. However, that the effects of both the spinal surgery and the nerve crossing varied greatly with enzyme muscle, and spinal treatment suggests that activity is also heavily influencing enzyme activity, and that the 4 enzymes studied differ as to the types and relative amounts of control exerted by activity and trophic factors. 249.4 SENESCENT NEURONS PROMOTE NON-NEURONAL PROLIFERATION IN DISSOCIATED CENTRAL NERVOUS SYSTEM CULTURES. R.J. Riopelle. Queen's University, Kingston, K7L 2V8, Canada.

One of the delayed responses of the central nervous system to a variety of insults is glial proliferation or gliosis. In certain conditions, there would appear to be a reasonable correlation between the degree of neuronal loss and the degree of gliosis. This observation might suggest that neuron death is one trigger of glial proliferation.

Mechanically dissociated eight-day embryo chick spinal cords were incubated for varying periods of time in embryo gut extract-supplemented, but otherwise chemically defined medium, on a polylysine substrate (Riopelle, R.J. and Cameron, D.A., J. Neurobiol. 12, 175-186, 1981). Polylysine inhibits attachment, and the chemically defined culture medium inhibits proliferation, of non-neuronal cells (Bottenstein, J.E. et al, Exp. Cell Res. 125, 183-190, 1980). The neurite bearing cells were allowed to incubate without changing the culture medium for periods of 12-15 days.

In all neuron cultures, some non-neuronal cells are seen, but their location on the culture dish is confined to areas beneath neuronal processes. As the cultures age, neuron morphology changes with the processes becoming smaller in diameter and beaded or varicose. As process varicosity becomes prominent, there is an increase in the number of non-neuronal cells in juxtaposition to the processes. Process beading is a prelude to the disappearance of neurons, and as the latter occurs, large numbers of non-neuronal cells appear and eventually comprise the only surviving cell types.

Non-neuronal cells cultured in the absence of neurons and in the presence of gut extract-supplemented but chemically defined medium show very low plating efficiency, and no proliferation, and have disappeared by 7-10 days.

These data suggest that non-neurons can survive in limiting conditions in the presence of intact neurons but undergo a proliferative burst as the neurons become senescent and disappear.

This work has been supported by MRC, Canada.

249.5 IN VITRO SYNTHESIS OF NERVE GROWTH FACTOR SUBUNITS BY MOUSE SARCOMA LINE S180. J. R. Perez-Polo, E. Barklis* and K.Werrbach-Perez*. Department of Human Biological Chemistry and Genetics, Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550.

The Nerve Growth Factor (NGF) is necessary for the differentiation and maintenance of vertebrate sympathetic and embryonic sensory neurons. When isolated from mouse submaxillary gland, human placenta at term or guinea pig prostrate, NGF is a subunit containing protein. In mouse submaxillary gland and human placenta at term, NGF is made up of three dissimilar subunits called α, β and γ. The β subunit expresses arginyl-esteropeptidase activity and has been suggested to process larger pro-β forms into the active β species.

In order to better define the processing properties of NGF and study regulatory features of the synthesis and processing of NGF, we studied the synthesis of NGF by the mouse S180 sarcoma line in vitro. NGF subunits synthesized de novo in the presence of ^{35}-methionine were isolated from cell pellets by monospecific antibodies bound to sepharose. We were able to show that the S180 line synthesized α, β and γ molecules indistinguishable from α, β and γ NGF isolated from mouse submaxillary gland in terms of antigenic properties, physicochemical properties as determined by dynamic isoelectric focusing, as well as biological activity. This is the first demonstration that the subunits of NGF are synthesized and secreted by a single cell as a 7S complex similar to that isolated in the mouse submaxillary gland. Taken together, these results are consistent with the hypothesis that assembly of NGF as an $\alpha_2\beta\gamma_2$ oligomer is an intracellular event and that the oligomer is secreted as an inactive storage form of NGF activity.

Supported in part by NIH grants NS14034 and NS15324, RCDA (NS00213) to J. R. P-P. and Robert A. Welch Foundation H698.

249.6 BIOCHEMICAL AND MORPHOLOGICAL CHARACTERIZATION OF SYMPATHETIC NEURONS GROWN ON CHEMICALLY DEFINED MEDIUM. L. Iacovitti, T.H. Joh, M.I. Johnson, and R.P. Bunge Dept. of Anat. & Neurobiol., Washington University School of Medicine, St. Louis, Missouri 63110 Lab. Neurobiol. Cornell Univ. Med. Coll. New York, N.Y.

Individual sympathetic neurons derived from perinatal rat superior cervical ganglion (SCG) express a mixed adrenergic-cholinergic phenotype when grown under certain culture conditions (Higgins, et al. J. Neurosci. 1:126-131, 1981). Transmitter expression in these cells is critically influenced by a number of undefined components present in the culture medium. In the present study we sought to determine whether SCG neurons grown on a chemically defined serum-free medium similarly express properties of two transmitter systems.

To address this issue, principal neurons were dissociated from perinatal rat SCG and established in culture for up to 7 weeks in the absence of all other cell types. Cultures were maintained in 7% CO_2 at 35°C on chemically defined serum-free medium (Bottenstein and Sato, PNAS 76: 514-517, 1979) supplemented with 2.5S NGF.

Under these culture conditions, SCG neurons continued to express a number of characteristic adrenergic properties. Tyrosine hydroxylase (TH) activity increased linearly with time in vitro reaching levels similar to those found in serum and embryo extract-supplemented cultures. Dopamine-β-hydroxylase activity and endogenous norepinephrine levels also rose in culture but reached only 30% and 2% of those values measured in supplemented medium. Ultrastructural examination of neurons in serum-free cultures revealed a predominance of dense-cored vesicles in synaptic profiles following $KMnO_4$ fixation. In addition, immunocytochemical localization of TH with specific antibodies demonstrated that essentially all neurons contained this adrenergic enzyme for up to 7 weeks in vitro.

SCG neurons grown on a defined medium, unlike those grown on supplemented medium, did not acquire cholinergic properties in culture. These neurons did not contain detectable levels of the specific acetylcholine-synthesizing enzyme, choline acetyltransferase, and synaptic profiles contained few vesicles with a clear morphology. In addition, evidence has been presented elsewhere that these neurons do not form cholinergic synaptic interactions (although frequent electrotonic junctions are observed) (Higgins, et al. this volume).

We conclude that SCG neurons, grown under serum-free culture conditions, develop properties characteristic of adrenergic neurons and do not express a mixed adrenergic-cholinergic phenotype. (Supported by NIH Research Grant NS14416 and Training Grant NS07027).

249.7 RESPONSES OF PRIMARY RAT MUSCLE CULTURES TO SOLUBLE EXTRACTS FROM CENTRAL NERVOUS TISSUE SEEN BY LIGHT AND ELECTRON MICROSCOPE AUTORADIOGRAPHY. M. M. Salpeter, S. Spanton* and T. Podleski*. Section of Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853.

Soluble factors extracted from brain and spinal cord cause an increase in the site density and number of high density clusters of acetylcholine receptors (AChR) on both cloned L_5 muscle cells (Podleski et al., PNAS 75:2035, 1978) and cultured chick primary muscle cells (Jessel et al., PNAS 76:5397, 1979). Conditioned medium from neuroblastoma-glioma hybrids also causes an increase in the number of AChR clusters on rat primary cells but little increase in site density (Christian et al., PNAS 75: 4011, 1978). We examined the responses of primary rat cells to fetal or newborn rat central nervous tissue extract using quantitative light and electron microscope autoradiography. We found that: (1) As with neuroblastoma-glioma conditioned medium, primary rat cells respond mainly by the formation of high density clusters although a 1.5 to 2-fold increase in average site density was seen by light autoradiography which appeared to involve, at least in part, a slight decrease in receptor degradation rate. (2) Both a high (>70,000 daltons) and a low (<10,000 daltons) molecular weight fraction induced the clusters on primary cells, whereas an intermediate weight fraction did not. (3) By EM autoradiography, we determined that in controls the average AChR site density and the number of clusters were higher at the bottom of the cell, whereas in extract treated cultures, both were higher at the top of the cell. (4) Extracts caused no cellular specialization except possibly an increase in basal lamina profiles and frequent bulges (or membrane out-pocketing) in the region of the induced AChR clusters. (5) By labeling the receptors prior to the addition of extract, we could demonstrate a redistribution of preexisting receptors within 3 hrs. (6) In receptor clusters on control muscle, the highest receptor density (averaged over the unit tabulation area of $\sim 40\mu m^2$) did not exceed $\sim$5,000 sites/μm^2, whereas within the clusters induced after extract treatment, AChR site density reached values of 15,000-21,000 sites/μm^2.

Thus, in primary rat muscle cultures, the soluble nerve extract mimics innervation in its ability to cause a rapid redistribution of AChR's, reaching site densities equal to that at innervated nmj's.

249.8 THE EFECTS OF UNILATERAL IXth NERVE DENERVATION ON THE DEVELOPMENT OF RAT CIRCUMVALLATE TASTE BUDS. M. A. Hosley and B. Oakley, Neuroscience Lab. Bldg., Div. of Biol. Sci., Univ. of Michigan, Ann Arbor, MI 48109.

The effects of early glossopharyngeal (C.N. IX) nerve denervation on the formation of taste buds was investigated by performing unilateral denervations in young rat pups (Rattus norvegicus) at age 3 d post-partum (p.p.); attempts at bilateral denervations were unsuccessful due to a 100% mortality rate. There were no discernible differences in the mortality rates of normal, sham operated or unilaterally denervated animals. Experimental animals were sacrificed at 5, 10, 15, 21, 33 and 45 days p.p. and control animals at 0, 3, 5, 10, 21 and 33 days p.p. with circumvallate (CV) taste buds counted to assay for the effects of denervation.

Unilateral denervation in adult animals results in a 10%-12% loss of taste buds (other researchers) while complete (bilateral) denervation results in a 100% loss of taste buds due to the trophic dependency of the taste buds upon an intact nerve supply. At 21 days p.p., experimental animals had a 50% deficiency in the CV taste bud population in comparison with controls ($p \leq 0.01$). This deficiency in the taste bud population indicates the developmental need for the entire nerve supply and the limited trophic capacity of an individual IXth nerve to act in the forming and maintaining CV taste buds. Since the taste buds which do form are distributed throughout the CV papilla, the deficiency does not result from an inability of the remaining IXth nerve to reach the areas of the taste bud precursors. Additional studies indicate that equivalent deficiencies in taste bud numbers can be produced by unilateral denervations performed at 1, 2, 4, 5, or 6 days p.p. The deficiency in taste buds remains through at least age 45 d p.p., indicating that the deficiency is permanent in nature and that a "critical period" for the induction of taste bud formation may exist. This period would represent a time span during which the nerve supply must interact with the taste bud precursors to establish the precursors' potential to differentiate into taste buds.

Supported in part by NIH Grant NS-07072 and University of Michigan, Rackham Block Grant.

249.9 DETERIORATION OF GUSTATORY RESPONSES AND NERVE ULTRASTRUCTURE FOLLOWING SPECIFIC ACTION OF COLCHICINE UPON GUSTATORY AXONS. H. E. Sloan, S. E. Hughes* and B. Oakley. Div. Biol. Sci., Neuroscience Lab Bldg, Univ of Mich, Ann Arbor Mi 48109

A silastic nerve cuff containing 1% colchicine was placed around the combined lingual-chorda tympani nerve of the Mongolian gerbil (Meriones unguiculatus). Three days of nerve exposure to colchicine reduced the summated gustatory responses recorded from the chorda tympani nerve in the middle ear by at least 60% and produced detectable ultrastructural changes in the lingual-chorda tympani nerve. There was a loss of microtubules, an increase in neurofilaments, and some loss of the longitudinal orientation of the neurofilaments. The axoplasm was shrunken distal parts of the colchicine treated axons; axon cross-sectional area was significantly less than in control cuffed nerves ($p<.001$). The axoplasm also showed an increase in electron density as well as the presence of floccular material. Nerve cuffs lacking colchicine had little effect on chorda tympani taste responses or nerve ultrastructure. We believe colchicine acted on the nerve trunk, and not the taste buds, to reduce taste responses because ^{3}H-colchicine levels were indistinguishable on the two sides of the tongue whereas functional and structural impairment was always restricted to the ipsilateral side. Normal taste responses were obtained 8 and 15 days after application of cuffs containing 1% lumicolchicine, an isomer of colchicine which lacks tubulin binding properties. This suggests that colchicine acted by a specfic disruptive effect upon axonal tubulin. After 8 and 15 days of colchicine treatment, ipsilateral chorda tympani taste responses and fungiform taste buds were nearly absent and substantial pathological changes were evident in nerve ultrastructure. There was additional shrinkage and densification of the axoplasm, deterioration of mitochondria, disruption of myelin, and a further increase in neurofilaments accompanied by greater disorientation. We conclude that colchicine had a specific action upon tubulin of gustatory axons which led to a loss of taste responses and taste buds. Supported in part by NIH Grant NS-07072.

249.10 ACETYLCHOLINE RECEPTOR AGGREGATION PROTEIN DEFICIENCY: A CLONALLY INHERITED DEFECT IN SYNAPSE FORMATION. N.A. Busis, M.P. Daniels, H.C. Bauer, P. Sonderegger*, A.E. Schaffner, and M. Nirenberg. Lab. of Biochem. Genetics, NHLBI; and Lab. of Devel. Neurobiol., NICHD, NIH, Bethesda, MD 20205.

Neuroblastoma x glioma NG108-15 hybrid cells form synapses with cultured rat skeletal muscle cells and release a protein into the medium that induces nicotinic acetylcholine receptor (AChR) aggregation on myotubes. Four additional synapse-forming neuroblastoma or hybrid cell lines and 12 lines that form few or no synapses with myotubes but synthesize and release acetylcholine (ACh) were cocultured with myotubes and myotube AChR aggregates were visualized with rhodamine-conjugated α-bungarotoxin. Thirteen cell lines, including all lines that form many synapses, induced AChR aggregation. N4G-Ba, N4G-Ca, and 141-3 cells, derived by fusion of N4TG-3A mouse neuroblastoma cells with C6BU-1 rat glioma cells, form few synapses and did not induce AChR aggregation, nor did the parental N4TG-3A or N4TG-1 neuroblastoma cells. Medium conditioned by N4G-Ba, N4G-Ca, 141-3, N4TG3-A, or N4TG-1 cells and homogenates of the cells also lacked AChR aggregation activity. Cells without AChR aggregation activity did not inhibit AChR aggregation induced by other cell lines. Ultrastructural studies revealed that all cell lines examined that induce AChR aggregation contain large dense core vesicles 100-200 nm in diameter and small clear vesicles 60 nm in diameter. In contrast, small clear vesicles but few or no large dense core vesicles were detected in N4G-Ba, N4G-Ca, and 141-3 cells. Large dense core vesicles were also not detected in N4TG3-A and N4TG-1 cells. N4G-Ba cells formed few synapses on myotubes with low miniature end-plate potential (mepp) frequencies as detected by intracellular recording from the myotubes. Coculture of N18TG-2 cells, which release AChR aggregation protein but have low choline acetyltransferase activity and do not form synapses on myotubes, with N4G-Ba cells and myotubes increased the average mepp frequency by 227%, the proportion of myotubes innervated by 153%, and the number of AChR aggregates per myotube by 354%. These results demonstrate cooperative interactions between cells with different kinds of defects in synapse formation and suggest that N18TG-2 cells release the AChR aggregation protein from large dense core vesicles thereby increasing myotube sensitivity to quanta of ACh secreted by N4G-Ba cells. Thus, both molecules that specify neurotransmitter receptor position and neurotransmitters may be released from one or more presynaptic cells, and may be required for the formation and function of certain classes of synapses.

249.11 FATE OF AFFERENTS TO THE DENTATE GYRUS FOLLOWING DESTRUCTION OF DENTATE GRANULE CELLS WITH COLCHICINE. Richard B. Goldschmidt * and Oswald Steward. (SPON: Lennart Heimer) Dept. of Neurosurgery and Anatomy, University of Virginia School of Medicine, Charlottesville, VA 22908.

Injections of colchicine into the dentate gyrus (DG of adult rats preferentially destroy dentate granule cells (Goldschmidt & Steward, PNAS 77: 3047, 1980). In the present study, we evaluate the fate of some of the normal afferents to the granule cells to determine whether they survive the destruction of their normal synaptic targets, and whether they form "ectopic" connections similar to those described after destruction of granule cells in developing animals (Laurberg & Hjorth-Simonsen, Nature 269:158, 1977; Gerbrandt et al. Exp. Neurol. 62:122, 1978).

Adult male rats were given two injections into the DG of one side consisting of 3ug of colchicine in 0.6ul of deionized water. Entorhinal and commissural afferents to the DG were traced by the aid of anterogradely transported HRP following injections into the ipsilateral entorhinal cortex (EC) and contralateral hippocampus 60-70 days following the colchicine injections. Animals survived two days after the HRP injection and the brains were processed according to the TMB and Hanker-Yates methods.

Despite the absence of granule cells and shrinkage of the DG molecular layer (terminal zone of EC and commissural afferents), the injections in both sites resulted in labeled terminal fields in what remained of the dentate molecular layer. The density of labeling and width of the terminal zones appeared considerably reduced, particularly in the free blade of the dentate gyrus, where the molecular layer was markedly shruken. Commissural and EC projections to the hippocampus proper, as well as fibers passing through the region of the colchicine injection, appeared intact. Ectopic terminal fields similar to those observed after granule cell destruction in developing animals were not observed, and there was no noticeable increase in the density of the normally sparse pathway from EC to the contralateral DG.

The preferential distribution of labeling in the molecular layer of the hidden blade, near where hilar interneurons are located, suggests that there may be a preferential survival of terminals which are able to maintain synaptic contact with some neuron (hilar interneuron).

Supported by NIH Grant R NS12333-06, and RCDA 1 K04 NS00325 to O.S.

249.12 TURNOVER OF ACETYLCHOLINESTERASE IN INNERVATED AND DENERVATED RAT DIAPHRAGM S. G. Younkin, Dept. of Pharmacology, Case Western Reserve University, Cleveland, Ohio 44106

The aims of this study were 1) to compare the rate of degradation of junctional and non-junctional AChE in innervated muscle, and 2) to determine if denervation alters the degradation of junctional and/or non-junctional AChE. There is very little junctional AChE in rat diaphragm so AChE could not be pulse labelled with radiolabelled amino acids and followed in the conventional way. A label for AChE was needed which ideally would 1) be specific for AChE, 2) be easily measured, 3) form a stable complex with AChE, and 4) have minimal effect on the degradation of AChE. Echothiophate meets these criteria reasonably well, and was administered intravenously through the tail vein to label the AChE in rat diaphragm. Echothiophate diethylphosphorylates the active site of AChE thereby inactivating it. Labelled (diethyl-phosphorylated) AChE was measured at various times after labelling by removing the diaphragm, solubilizing and assaying AChE, and then determining the increase in AChE activity caused by treatment with pralidoxime, a drug that rapidly and completely reactivates diethylphosphorylated AChE. In this procedure labelled AChE is measured by determining the AChE activity revealed by pralidoxime treatment so the label is easily measured and is as specific as the AChE assay. The stability of the labelled AChE was evaluated by labelling muscle homogenate with echothiophate, dialyzing overnight to remove echothiophate, and measuring the rate of reappearance of AChE. Under these conditions label was lost spontaneously with a half-time of 27 hours. If echothiophate altered the degradation of AChE, a change in the level of total AChE would be expected. The measurement of label with this procedure requires the measurement of total AChE, and total AChE did not change. The AChE in innervated and denervated hemidiaphragms was labelled as described above and the forms of labelled junctional and non-junctional AChE were evaluated as described earlier (Takach and Younkin, abstract this session). In innervated muscle junctional AChE (both asymmetric and non-extractable) was degraded very slowly; label was lost at very nearly the rate of spontaneous dissociation measured in homogenates. . During the rapid loss of junctional AChE 1-2 days after denervation the rate of degradation of junctional AChE increased dramatically, but by 3-4 days after denervation it was again like that in innervated muscle. Non-junctional AChE was lost with a half time of about 1 day in innervated muscle, but no change was observed during the loss of non-junctional AChE 1-2 days after denervation.

249.13 INHIBITION BY CEREBRAL NEURONS OF [^{3}H]-THYMIDINE INCORPORATION INTO CHOROID PLEXUS CELLS IN VITRO. G. R. Hanson, L. M. Partlow* and P. L. Iversen. Dept. of Pharmacology, College of Medicine, University of Utah, Salt Lake City, UT 84132.

Neurons prepared from the cerebral hemispheres of 10-day chick embryos by a method similar to that of McCarthy and Partlow [Brain Research 114 (1976) 391-414] have been reported to be mitogenic for embryonic chick glial cells isolated from various parts of the nervous system. In contrast, we have found these neurons inhibit the proliferation of cells isolated from the choroid plexus of 10 day chick embryos. Thus, the presence of postmitotic cerebral neurons resulted in a decrease of up to 77% in thymidine incorporation by choroid plexus cells. This inhibitory effect was found to be directly dependent on the concentration of cerebral neurons. The lack of a similar inhibitory effect as a result of addition of similar numbers of either optic lobe and sympathetic neurons suggests that this interaction is a specific cell-cell phenomenon. The neuronal inhibition of thymidine incorporation into choroid plexus cells did not involve the release of a diffusable factor into the culture medium.

Addition of the sonicate of cerebral neurons to choroid plexus cultures resulted in an inhibition of thymidine incorporation of up to 54%. The inhibitory factor released by sonication was found to be heat stable. Similar inhibitory factors were not found in disrupted sympathetic and optic lobe neurons.

These results demonstrate that embryonic cerebral neurons can exert both stimulatory and inhibitory influences on dividing cells present in the developing cerebral hemispheres. Thus, these neurons might have an important regulatory role in mediating the development of the brain.

249.14 THE DIFFERENTIATION AND INNERVATION OF OTOCYSTS TRANSPLANTED TO OPTIC TECTA OF CHICK EMBRYOS. Mark C. Whitehead. Dept. of Anat. UConn Health Ctr., Farmington, Connecticut 06032.

Developing cochlear and vestibular ganglion cells become morphologically distinguished and form very different synaptic endings in the ear while their axons form distinctive synapses centrally on specific medullary neurons. The present study investigates the extent to which ganglion cells and their peripheral connections can develop when otocysts (embryonic inner ears) are confronted with inappropriate or absent central targets.

Otocysts with their associated ganglia and surrounding mesenchyme were removed from quail or White Leghorn chick embryos at 2½-3 days of incubation. They were transplanted either to the chorio-allantoic membrane or to the superficial or ventricular surfaces of the optic tecta of 2½-5 day host chick embryos. At the times of transplantation, vestibulocochlear ganglion cells have not connected with the brain or the undifferentiated epithelium of the ear. Neither have the superficial tectal layers received the bulk of their retinal input.

In all locations, the otocysts developed organotypically; vestibular cristae were distinguished from cochleae. These areas were histotypic as well, with thick receptor epithelia containing hair cells adjoining thinner areas of lining epithelia. Compared with normal ganglia, only a variable fraction of ganglion cells survive in the transplanted otocysts. However, these cells, in reduced silver stains, have fibers which gather as fascicles and innervate, selectively, only receptor epithelia, sometimes after wandering for long distances below the lining epithelia. Different ganglion cell types differentiate; the largest of these send "colossal" fibers into the cristae where they form calycine endings. In the Feulgen-stained quail-chick chimaeras, tectal and ear tissues did not intermix, but in both superficial and deep implants, neurons of the deep tectal layers became apposed to areas of donor epithelium. Afferent and efferent connections of the ectopic ears were seen with silver stains. Tectal axons from deep layers were similar to the fibers of ganglion cells in that they sent endings only into sensory epithelia, often after streaming over the cartilage of the otocysts and below the basal lamina of their lining epithelia. Optic axons, despite their proximity, never innervated the otocysts. Axons from the ectopic ganglion cells sometimes grew out of the otocysts and, because of their relative thickness, could be followed into deep tectal layers.

These findings demonstrate that ganglion cell types and at least some appropriate peripheral endings can differentiate in the absence of normal central targets. Nonspecific but, nevertheless, selective factors result in afferent and efferent connections of the ectopic otocysts with deep tectal laminae.

249.15 FORMS OF ACHE IN RAT DIAPHRAGM AFTER DENERVATION P.L. Takach*, S.G. Younkin and T.L. Rosenberry*, Depts. of Anatomy and Pharmacology, Case Western Reserve Univ., Cleveland, O. 44106. (Sponsor: L.H. Younkin).

Innervation has a profound influence on mammalian skeletal muscle acetylcholinesterase (AChE), but it is not known if this influence is exerted at the level of synthesis, assembly, secretion, or degradation. There are 3 collagen-tailed asymmetric forms (16S, 12.5S, 8.5S) and 3 globular forms (10S, 6.5S, 4S) of AChE that can be extracted from mammalian skeletal muscle. Skeletal muscle also contains non-extractable AChE. This AChE has previously been ignored but is of interest because it has properties that suggest it is predominantly associated with the basal lamina at the NMJ. To clarify the nature of the neuronal control of AChE, we examined the forms of AChE in rat diaphragm after denervation. Diaphragms were removed, divided into endplate-containing (+EP) and endplate-free (-EP) regions, and subjected to a sequential extraction procedure. Globular forms were first extracted into buffered detergent at low ionic strength and asymmetric forms were then extracted into buffered detergent at high ionic strength leaving the non-extractable AChE behind. Individual forms were then analyzed by velocity sedimentation on 5-25% isokinetic sucrose gradients. Non-junctional AChE was measured directly in -EP muscle and junctional AChE was evaluated by subtracting non-junctional AChE from the total AChE in +EP muscle. Of the total AChE in innervated muscle 27% is junctional AChE (12% asymmetric forms, 7% globular forms, and 8% non-extractable AChE) and 73% is non-junctional AChE (12% asymmetric forms, 58% globular forms, and 3% non-extractable AChE). Junctional asymmetric, globular, and non-extractable forms each have a distinct response to denervation which differs both in time course and magnitude from that seen in non-junctional forms. Each component of non-junctional AChE decreases in the first day after denervation whereas the corresponding components of junctional AChE do not. Non-junctional asymmetric, globular and non-extractable AChE fall to 38%, 50%, and 77% of normal respectively by 3 days after denervation whereas the fall in the corresponding junctional forms is to 23%, 9%, and 42% respectively. Analysis of individual asymmetric forms in +EP muscle revealed that the 8.5S form, which is barely discernible in innervated muscle, actually rises transiently between 1 and 3 days after denervation while the 16S and 12.5S forms are decreasing dramatically. Junctional and non-junctional asymmetric and globular forms slowly return toward normal 3-14 days after denervation. These results are consistent with the hypothesis that denervation causes a transient increase in the rate of degradation of junctional AChE.

249.16 THE APPEARANCE OF MUSCLE DERIVED PROTEINS IN NERVE AND THEIR ENHANCEMENT WITH α-BTX IN VIVO. Katrina Gilmer-Waymire* & Stanley H. Appel (SPON: J.C. Waymire). Dept. of Neurology & Prog. in Neurosci., Baylor College of Medicine, Houston, TX 77030.

Skeletal muscle from young rats possess protein(s) which enhances neuron cell survival, neurite extension, and acetylcholine synthesis in cultured spinal cord. The present experiments were designed to complement these in vitro observations, namely to assess whether protein synthesized in muscle can be taken up by nerve endings and can migrate by retrograde axonal flow in vivo. The sciatic nerves of Sprague-Dawley rats were ligated and injected with 100 μCi ^{35}S-meth into the adjacent gastrocnemius. Five days later the muscles and proximal and distal sides of the ligated sciatic nerve were removed. In all experiments a 2-3 fold increase of acid precipitable radioactivity was detected in total homogenates below the ligature compared to above the ligature. Two-thirds of the radioactivity and homogenates below the ligature was in a 32,000 gxhr pellet and one-third was in the supernatant. On SDS polyacrylamide gel electrophoresis, the supernatant radioactivity below the ligature migrated as two distinct peaks of 60,000 and 90,000 daltons. To support the muscle origin of the below ligature radioactive proteins, dialyzed supernatant extracts of muscle injected with ^{35}S-meth were injected into rats whose sciatic nerves had been ligated but had not previously been injected with ^{35}S-meth. These rats injected with ^{35}S-labelled muscle proteins also exhibited an uptake of radioactivity into sciatic nerve. Animals were injected with α-BTX (2 μg) immediately prior to the injection of ^{35}S-meth. α-BTX was chosen because it reacts specifically with the muscle nicotinic AchR and has been demonstrated to induce nerve sprouting. Animals injected with α-BTX demonstrated a 60% increase in ^{35}S-meth incorporation into proteins extracted from muscle and a 2-fold increase in radioactive proteins below the ligature compared to rats not injected with α-BTX. As a confirmation that α-BTX had a functional effect on nerve metabolism, the effect of daily gastrocnemius injection of α-BTX on nerve choline acetyltransferase (CAT) activity was assessed. After 1 week rats injected with α-BTX contained 2 times the level of CAT in their sciatic nerves compared to controls. Thus, proteins derived from muscle do appear to be taken up by nerve and pass in a retrograde fashion. α-BTX enhances the incorporation of radioactivity of such proteins in muscle, increases their appearance in nerve, and enhances nerve CAT activity. These data suggest that the effects of α-BTX on sprouting noted by Holland & Brown and the enhanced CAT activity noted by us may be explained by proteins derived from muscle which are taken up by nerve and migrate by retrograde axonal flow.
(Supported by the Hartford Foundation 470-G09281).

249.17 ROLE OF PERIPHERAL TARGET IN DEVELOPMENT OF SENSORY NEURONS. March D. Ard and D. Kent Morest. Dept. of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032.

Neuronal cell bodies have been counted in the auditory and vestibular ganglia following fixation in a formaldehyde mixture, embedding in JB-4 plastic (Polysciences), sectioning at 5μm, and staining with toluidine blue. Counts were corrected for cells split between sections. In the combined auditory and lagenar (cochlear) ganglion of 3 two-week hatchling chicks (P14) there were 9140 ± 960 neurons($\bar{X}$ ± SD), and in the vestibular ganglion, 8610 ± 108. In 3 eight-day embryos (E8) there were 11170 ± 330 cochlear neurons and 12687 ± 2111 vestibular neurons. This cell loss, 18% in the cochlear and 32% in the vestibular ganglion, was significant at $p<0.05$ (Student's t-test). Mean size of neuronal perikarya increases during this period by 89% among the cochlear and 100% among the vestibular cells. The percent loss of cochlear ganglion cells is identical to that in the cochlear nucleus (nucleus magnocellularis) of the chick between E11 and E13 (Rubel et al., JCN '76).

Stato-acoustic ganglia at E3½-4 have been explanted and cultured for two weeks either alone or in combination with the developing receptor epithelium (otocyst) or in combination with otocyst and medulla. Surrounding mesenchyme was preserved in the explants. The medium was Dulbecco's modification of Eagle's medium with approximately 40mM [K^+], 10% newborn calf serum, 10% chick embryo extract, and ferrous sulphate, ascorbic acid, cortisone, and penicillin in 5% CO_2 in air. Observations of such cultures consistently revealed histological differentiation of sensory neurons and receptor epithelium. In three explants of single ganglia only 460-550 neurons survived. In three explants, each containing an otocyst in addition to the ganglion, 1710-2020 neurons survived. Including pieces of medulla containing the cochlear and vestibular nuclei with the otocyst and ganglion did not increase the survival of ganglion cells in four cultures. Thus the preliminary results suggest that the peripheral target tissue plays a role in trophic support of the stato-acoustic ganglion cells. (Supported by USPHS grant no. 5 RO1 NS14354 and Univ. of Conn. Research Foundation.)

249.18 THE DEVELOPING HIPPOCAMPUS IN CELL CULTURE W.Seifert, B.Ranscht*, H.J.Fink*, H.W.Müller*, F.Förster

Friedrich-Miescher-Labor.,Max-Planck-Institute, Tübingen, W-Germany.

The hippocampus consists of only few major classes of neurons. At a certain developmental stage of the fetal rat brain, only pyramidal and basket neurons will survive together with glial cells and develop in dissociated cell cultures. In this system we are studying:1) morphological and biochemical development of neurons, 2) synapse formation and the neurotransmitter Gaba and Glutamate, 3) trophic interactions between glial and neuronal cells.

Identification of cell types in culture was carried out by immunofluorescence with specific antisera directed against neurons, astrocytes or oligodendrocytes. For oligod. we used a monoclonal antibody developed in our laboratory (B.Ranscht,P.Clapshaw,W.Seifert - Hoppe Seyler's Z.Phys.Chemie, 361, 1327, 1980). In addition the activity of 2'3'-CNPase was followed both in vivo and in vitro and the enzyme localized in specific cell types (H.W.Müller,P.Clapshaw,W.Seifert, J.Neurochem., June 1981).

By using serum-free, hormone supplemented media we have obtained about 90 % pure neuronal cultures. In these cultures we studied the uptake of Gaba and Glutamate by specific cells. We also followed the pattern of gangliosides during neuronal development. As shown previously in our laboratory, gangliosides may exhibit trophic effects on neuronal cells and significant changes in their pattern during development (H.J.Fink and W.Seifert, Hoppe-Seyler's Z.Phys.Chemie, 361,1280,1980, W.Seifert- "Gangliosides in Nerve Cell Cultures" in 'Gangliosides in Neurol.Function...',Raven Press,1981).

We also demonstrated a trophic interaction between glial cells and neurons in this culture system: astrocytes seem to produce a soluble neurotrcphic factor, which stimulates outgrowth of processes from these hippocampal neurons (W.Seifert, N.Buckley, B.Ranscht - Hoppe-Seyler's Z.Phys.Chemie 361, 333, 1980; manuscript in preparation).

250.1 TWITCH AND TETANIC RESPONSES OF SKELETAL MUSCLE FROM PARALYZED CHICK EMBRYOS. B.T. Stokes, P.J. Walters* and P.J. Reiser*. Dept. of Physiology, Ohio State University, Columbus, Ohio 43210.

The isometric contractile properties of 18 chick posterior latissimus dorsi (PLD) muscles have been studied at day 19 of embryonic development. These embryos were paralyzed from day 8 of incubation by injections of 3.0 mg/250 µl of d-tubocurarine (Sigma, Inc.) or 100 mg of α-bungarotoxin (Miami Serpentanium) given every two days until day 16. Activity measurements made in a humidified-temperature controlled environment at the time of injection and at day 18 confirmed the absence of embryonic motility. All muscles were studied in vitro in a modified chick ringer solution maintained at a bath temperature of 24.2±0.2°C (mean ± S.E.). The beak length and yolk absorption of all embryos confirmed they were at stages consistent with 19 days of incubation. Blotted mass of these muscles was, however, decreased by over 300%. Alterations in normalized peak tension. (P_{ot}), time to peak tension and ($t_{P_{ot}}$) and time to half relaxation ($t_{\frac{1}{2}R}$) were characterized in twitch responses; normalized peak tension (P_o) and time to half peak tension ($t_{\frac{1}{2}P_o}$) in tetani. Twitch force (P_{ot}) in muscles from curarized embryos remained the same, $t_{P_{ot}}$ increased by over 110%; $t_{\frac{1}{2}R}$ increased by greater than 700%. Tetanic force (P_o) was depressed by 50% while $t_{\frac{1}{2}P_o}$ decreased by 13%. The major effects of such manipulations therefore is to drastically increase the time to half relaxation during a twitch response. Since we have previously shown that $t_{\frac{1}{2}R}$ becomes progressively less from day 15 to 19 in embryonic development, it appears that inactivity markedly affects the development of this parameter. Muscle activity may therefore be a primary determinant of the development of calcium sequestering ability by the sarcoplasmic reticulum. The effects of inactivity on the maximum velocity of shortening in these muscles is currently under investigation.
(Supported in part by the Muscular Dystrophy Association and the National Science Foundation.)

250.2 INFLUENCE OF ELECTRICAL INACTIVITY AND DENERVATION ON THE FORMATION OF ACETYLCHOLINE RECEPTOR CLUSTERS IN EMBRYONIC RAT MUSCLES. L. Ziskind-Conhaim. Dept. of Physiology, University of California Med. Sch. San Francisco, CA 94143.

I have studied the role of electrical activity and of activity-independent neural effects in regulating the distribution of acetylcholine receptors (AChRs) on intercostal muscle fibers of rat embryos. Segments of thoracic body wall including intercostal muscles, ribs and the adjacent segments of spinal cord (S.C.) were explanted from 15-day rat embryos and maintained in organ culture for up to 6 days (Ziskind-Conhaim, L., and Dennis, M.J. Develop. Biol. 84, 1981). At embryonic day (ED) 15 the distribution of AChRs, determined by autoradiography after labeling the AChRs with ^{125}I-α-bungarotoxin, was uniform along the entire length of muscle fibers. However, after culturing ED 15 muscle-S.C. explants for one day, a single AChR cluster was found at the midregion of each fiber at the site of nerve-muscle contact. This junctional AChR cluster was maintained for at least 4 days in organ culture. Thus, AChR clusters can form at synaptic sites in vitro. The time course of their formation is similar to that seen in vivo.

I compared the formation of such AChR clusters to that which occurred: a) in the presence of tetrodotoxin (TTX) which blocked nerve action potentials and b) in muscles cultured without the S.C. After one day in the presence of TTX, 72% of the fibers had a central AChR cluster and 8% had one or more extrajunctional clusters. By the second day in culture clusters were detected on all muscle fibers, and by the fourth day 70% of the fibers had multiple AChR clusters. The pattern of AChR aggregation was different on muscles cultured without the S.C. After one day in culture 67% of the fibers did not have any pronounced clusters and 33% had one or more receptor aggregates (compared to 93% seen with S.C. and 80% with S.C. in the presence of TTX). By the second day 40% of the fibers still did not have any clusters, 15% had a single AChR cluster, and 45% had more than one site of receptor accumulation. Thus, the initial appearance of AChR clusters on aneural fibers was delayed and then when aggregates did develop, they were usually in multiples.

My results indicate that innervation has two distinct regulatory effects on formation of AChR clusters. First, a primary AChR cluster is formed beneath the motor axon terminals. The formation of this cluster requires the presence of nerve terminals, but is independent of neural electrical activity. Second, electrical activity is necessary to prevent the formation of secondary AChR clusters that develop at random sites along inactive muscle fiber surface. These appear after the time the primary cluster normally forms. Supported by NIH grant NS-16033.

250.3 EFFECT OF A DAILY REGIMEN OF TETANIC CONTRACTIONS, INDUCED VIA PERIPHERAL NERVE STIMULATION, ON PROPERTIES OF IMMOBILIZED RAT SOLEUS MUSCLES. P.F. Gardiner, M. Lapointe*, and D. Gravel*. Département d'éducation physique, Université de Montréal. Montréal, Québec, Canada H3C 3J7.

It is generally assumed that at least part of the loss in muscle mass, and alterations in muscle enzyme proteins that occur in the slow-twitch soleus muscle as a result of imposed neuromuscular disuse is attributable to the concomitant decrease in the quality and/or quantity of the mechanical events normally occurring at the muscle. In an attempt to determine the importance of the lack of tension-generating episodes in the soleus muscle changes associated with disuse, female Sprague-Dawley rats were treated to either a unilateral hindlimb immobilization condition (gp. I) or an immobilization condition, supplemented with electrical stimulation-induced tetanic contractions (gp. IS). Hindlimb immobilization was induced using plaster casts (knee=110°, ankle=90°), for 4 wks. In group IS, soleus muscles were stimulated to contract in the cast by means of fine-wire electrodes, chronically implanted around the sciatic nerve at the level of the sciatic notch. Daily stimulation, performed with the animal under Na pentobarbitol anesthesia, consisted of trains of impulses (DC square waves, .2 ms duration, 50 Hz) lasting 0.5 s, at a frequency of 0.4 Hz, for 20 minutes. The degree of soleus atrophy, compared to control (C) muscles, was not different in comparing group I (65.2±3.3%) and group IS (61.9±2.3%). Histochemical analysis of soleus muscles revealed that group I muscles contained a significantly smaller proportion (58.9±2.0%) of slow-twitch fibers, compared to C (75.4±2.1%), while the corresponding proportion from group IS (65.9±2.7%) was not different from C. Isometric contractile properties of the soleus measured in situ at 37±.5°C revealed that immobilized muscles had significantly faster time-to-peak tensions (I=30.7±1.1; IS=30.8±0.7; C=34.0± 0.2 ms), and were less fused at 15 and 25 Hz. Immobilization had no significant effects on specific tetanic tension (N/g muscle), on twitch or tetanic dP/dt estimates, half-relaxation time, or on the form of the force-frequency curve. On a 20-minute stimulation regimen similar to the daily protocol used, no differences existed among I, IS and C muscles in relative force measured at 4 and 20 minutes. The results suggest that supplementation of high-tension contractions to an immobilized soleus muscle does not significantly attenuate the progress of muscle atrophy, but may play a role in reducing the fiber-type changes that occur. This latter phenomenon may be an effect of muscle mechanical activity, or of alteration of motoneurone metabolism caused by the electrical stimulation. (Supported by Muscular Dystrophy Association of Canada, and NSERC).

250.4 EMG RESPONSE OF FAST AND SLOW EXTENSORS IMMOBILIZED AT DIFFERENT LENGTHS. M. Fournier*, R. R. Roy*, H. Perham* and V. R. Edgerton (SPON: M. A. B. Brazier). Dept. of Kinesiology, Univ. of California, Los Angeles, CA 90024.

Limb immobilization is often used as a model of disuse. However, the adaptation of skeletal muscle to immobilization is largely dependent upon the position at which the joints are fixed. Therefore, the purpose of this study was to determine the effects of hind-limb immobilization in different positions on the electrical output of slow and fast muscles.

Nine female rats had the soleus (SOL) and the medial gastrocnemius (MG) muscles chronically implanted with bipolar recording electrodes, and were randomly assigned to one experimental group of bilateral immobilization: ankle extensors in a shortened (S), lengthened (L), or neutral (N) position. An external brace was used to fix the knee and ankle joints at the desired angle. Electromyographic (EMG) activity of SOL and MG was recorded simultaneously during a 15 minute period each hour for 24 hours, before and 7, 17, and 28 days after immobilization. Raw EMG data was rectified and integrated (IEMG, time constant=200 msec.), and summated for each 24 hours. Pre-immobilization data for each group was used as a control value for comparison with post-immobilization data (Table 1: expressed as % change from control value). Group S showed the largest decrease in IEMG for both muscles and no recovery over time. Group L had the smallest decrease in IEMG and showed different recovery patterns for the SOL and MG. The MG of groups N and L showed a tendency to return to a normal level of activity after 28 days. These results suggest that the EMG response to limb fixation is dependent upon the type of muscle (fast or slow), the length at which the muscle is immobilized and the duration of immobilization. These factors may be important to consider when using immobilization as a model of disuse.

Table 1. % of IEMG Activity Change from Control Value

	DAYS				DAYS		
SOL	7	17	28	MG	7	17	28
N	-44	-34	-53	N	-35	-35	- 5

S	-66	-77	-74	S	-64	-64	-57

250.5 FIBER TYPE GROUPING IN THE SOLEUS MUSCLE OF CATS FOLLOWING SPINALIZATION OR CROSS-REINNERVATION. H. W. Goforth Jr.* and V. R. Edgerton*. (SPON: S. H. Chandler). Dept. of Kinesiology, UCLA, Los Angeles, CA 90024.

The spatial arrangement of fiber types in a mammalian skeletal muscle has been shown not to be randomly distributed. Normal mixed muscles have been shown to exhibit uniformly distributed fiber type patterns (James, J., Neurol Sci., 14:381, 1971) while pathological muscles often demonstrate varying degrees of fiber type grouping. These findings suggest the existence of regulatory mechanisms which produce a non-random (uniform) fiber pattern in normal mixed muscles. The present study was designed to determine the spatial distribution of fast twitch fibers found in the normally homogeneous slow twitch soleus muscle of cats subjected to chronic spinalization (low thoracic; 4 to 18 months, n=3) or cross-reinnervation (via flexor hallucis longus nerve; 18 months, n=4). Spinalization and cross-reinnervation resulted in the conversion of 32 ± 4 and 14 ± 9%, respectively, of the fibers to fast twitch as determined by histochemical staining for myosin ATPase (preincubation at pH 10.4 and 4.2). Measurements of distances between nearest neighbor fast twitch fibers were made from photomicrographs containing an average of 839 ± 178 fibers. The ratio of the observed distance to the expected distance, the dispersion index R, was used as an index of deviation from a random distribution where; R= 1.0 random, R<< 1 grouping and R>> 1 uniform (Clark and Evans, Ecology, 35:445, 1954).

Both spinalization and cross-reinnervation produced significant ($P < .001$) fast twitch fiber type grouping (R= 0.150 and R= 0.342, respectively). Spinalized cats demonstrated significantly greater ($P < .001$) fiber grouping compared to cross-reinnervated cats.

This study demonstrates that alterations in the spatial distribution of fiber types produced by spinalization or cross-reinnervation can be quantitatively described and statistically compared. Regulatory mechanism(s) exist in normal mixed muscles of rabbit and guinea pig which maintain a uniform fiber type distribution pattern (James, J., Neurol. Sci., 14:381,1971). The results of this study indicate that when an originally homogeneous slow twitch muscle is converted into a mixed muscle by spinalization or cross-reinnervation the mechanism(s) regulating uniform distribution do not appear to operate (even after 18 months).

250.6 MATURATIONAL CHANGES IN MOTOR NERVE ENDINGS IN NORMAL AND EXERCISED RATS. K.E. Stephens* and C.D. Tweedle. Dept. of Anatomy, Michigan State University, E. Lansing, MI. 48824.

Morphological change in neuromuscular axonal terminals was examined using a combined silver-cholinesterase stain in 100 male, Sprague-Dawley rats. Predominantly slow-twitch (adductor longus and soleus) and fast-twitch (gastrocnemius and rectus femoris) muscles were taken from sedentary animals at 6-28 weeks of age as well as from rats subjected to 4-16 weeks of intense endurance exercise. The exercise program initiated at 12 weeks of age (post-pubertal) was progressive in nature with the final group of rats running a total of 2 hours per day, 5 days per week. Motor nerve endings were categorized into defined morphological classes independently by the two investigators and the data were subsequently statistically analyzed. The number of accessory endings (an axon with one or more thin branches ending in one endplate on a single muscle fiber) increased significantly in slow-twitch muscles from 6 to 16 weeks, at which time it plateaued in the soleus and slightly decreased in the adductor longus. In fast-twitch muscles the increase ceased at 12 weeks of age, with a subsequent leveling off after that. Double endings (one axon giving rise to two endplates on one muscle fiber) also increased in the predominantly slow muscle up to between 20 and 24 weeks. Conversely, fast-twitch muscle displayed no such increase and, indeed, displayed less than 1% double endings after puberty. The number of branched endings (2 muscle fibers innervated by a single axon) appeared to decrease in the adductor longus muscle between 6 and 20 weeks of age, and thereafter increased slightly. The soleus muscle showed a similar significant increase between 16 and 20 weeks of age, as well as between 24 and 28 weeks of age. Branched endings in fast-twitch muscle decreased to below 1% of endings present between 6 and 16 weeks of age and remained at that level. Simple endings (one axon ending in a single endplate on a muscle fiber) decreased significantly between 6 and 20 weeks in slow-twitch while in fast-twitch muscles the decrease was seen between 6 and 12 weeks of age. Examination of exercise data indicated few changes could be brought about by functionally overloading the muscles. This study indicates that 1) significant differences exist in the neuromuscular axonal terminals of post-pubertal fast-twitch and slow-twitch muscle: 2) there develops with post-pubertal maturation an increase in the complexity of these terminal patterns in slow-twitch muscle not present in fast-twitch muscle: 3)exhaustive endurance exercise appears to have little effect on the modification of motor nerve endings. This indicates that normal maturational nerve ending changes are not due to alterations in neuromuscular activity. (Supported by NSF).

250.7 THE EFFECT OF UNILATERAL SCIATIC NERVE CRUSH ON ASCENDING PATHWAYS IN THE SPINAL CORD. L. J. Fisher* and M. W. Luttges. Department of Aerospace Engineering Sciences, University of Colorado, Boulder, CO 80309.

Gerren and Luttges (1979) reported that following sciatic nerve crush, time-dependent electrophysiological alterations occurred in both the spinal cord and the contralateral, undamaged sciatic nerves. Cross-spinal responses from damaged to undamaged nerves were similarly affected. The present experiments focus upon the possibility that supraspinal projections also may be altered by unilateral sciatic nerve damage.

Threshold levels of stimulation, 1-3 volts, elicited compound nerve responses with several components. The shortest latency component exhibited an estimated conduction velocity of 20 m/sec. Increasing stimulation voltage to 15 volt suprathreshold levels produced reliable decreases in the response latencies. Compared to control nerves, damaged nerves exhibited larger decreases in response latencies at 6 days postcrush. In contrast, a smaller latency shift was observed for damaged nerves at 9 days postcrush. The latency shift across voltage of both damaged and undamaged nerve responses did not differ from control when spinal influences were removed by nerve transection.

Nerve stimulation elicited thalamic responses which were recorded from indwelling electrodes bilaterally placed in the ventral posterior lateral region of the thalamus. Suprathreshold levels of stimulation as compared to threshold levels produced reliable decreases in thalamic response latencies. Thalamic responses ipsilateral to stimulation originating from either damaged or undamaged nerves showed larger latency shifts than the same pathways in control animals at 6 days postcrush. These latency decreases remained at 9 days postcrush. Similarly, the contralateral response from the undamaged nerve exhibited exaggerated response latency decreases which persisted from 6 to 9 days postcrush. The contralateral responses from the damaged nerve did not differ from control over the investigation time periods.

These results indicate that electrophysiological changes occurring at segmental levels are influencing thalamic responses following unilateral damage. This includes spinal alterations both ipsilateral and contralateral to nerve crush. All of the observed alterations, to date, are closely correlated to the time elapsing following unilateral nerve damage. Clearly, the spinal cord exhibits more comprehensive alterations following nerve damage than is generally acknowledged.

250.8 PLASTICITY OF MOTONEURON RECRUITMENT ORDER FOLLOWING SPINAL CORD TRANSECTION. R.G. Durkovic. Dept. Physiology, Upstate Medical Center, Syracuse, N.Y. 13210.

Caudal to spinal cord transection increases in recurrent inhibition (Goldfarb & Sharpless, Neuropharm. 10:413, 1971) and in monosynaptic EPSP size (Nelson & Mendell, J. Neurophys. 42:642, 1979) have been reported. These changes subsided within several weeks or months following transection. In the present study similar transient changes were observed in motoneuron recruitment order in the flexion reflex following spinal transection. The experimental preparation was the unanesthetized decerebrate cat with a T-10 spinal transection made either three months, two weeks, or immediately before decerebration.

Single electrical stimuli to cutaneous superficial peroneal or saphenous nerves were used to evoke the flexion reflex. Tibialis anterior (TA) motoneuron recruitment order was measured as a function of stimulus intensity two ways:

(i) Pairs of single motor unit EMG's were recorded by means of a fine bipolar needle electrode inserted into the belly of the TA muscle, and

(ii) Pairs of single TA nerve action potentials were recorded with bipolar hook electrodes from filaments of the cut and teased TA muscle nerve.

Over 400 determinations of recruitment order were made from pairs of motor unit EMG's and over 300 determinations from pairs of axon spikes, and the two methods gave the same results:

In acute spinal cats the smaller of the two action potentials of a pair was activated at a lower stimulus intensity in 80% of the cases.

In the two week chronics there was a reversal of recruitment order with smaller spikes having lower recruitment thresholds in only 43% of unit pairs.

In three month chronics normal recruitment order returned with smaller units activated at lower stimulus intensities in 82% of unit pairs.

Both EMG spike amplitude (Goldberg & Derfler, J. Neurophys. 40:879, 1977) and axonal action potential amplitude (Clamann & Henneman, J. Neurophysiol. 39:844, 1976) are thought to be related to motoneuron cell size. Thus, the present results suggest that a basic neurophysiological property (orderly recruitment of motoneurons from small to large) exhibits a transient alteration following spinal transection.

250.9 Dendritic Retraction Induced by Axotomy of Frog Spinal Motoneurons: A Golgi-Computer Reconstruction Study. B. M. Rosenthal* W.L.R. Cruce, and R.C. Carlsen. Neurobiology Dept., N.E. Ohio Univ. College of Medicine, Rootstown, OH 44272 and Dept. of Human Physiology, Univ. of California, Davis, CA 95616.

In a study of the physiological changes in synaptic input which follow frog lumbar motoneuron axotomy (Carlsen, Cruce, and Mendell, 76), we found that by 28 days after axotomy there was an increase in central reflex times for both the lateral column-axosomatic pathway and the dorsal root-axodendritic pathway. We suggested that this was due to diminished synaptic efficacy. In a subsequent electron microscopic investigation (Cruce and Kinney 79) we showed that synaptic coverage of the soma is reduced after axotomy. Preliminary to investigating synaptic coverage of the dendrites we decided to see if there was any retraction or shrinkage in the dendritic tree since this had been reported to occur in rat hypoglossal nucleus (Sumner and Watson, 71). The same cords which had been used in the physiological experiments were fixed by immersion in formalin for no more than 6 months, impregnated by the Golgi-Kopsch modification of Braitenberg, embedded in epon, and cut into 80 micra thick sections. (These cords had been prepared by transecting spinal nerve 9 or 10 prior to the experiments.) Only large ventral horn cells in the lateral motor column of the segment serving the axotomized root and which showed good silver impregnation were selected for study. The dorso-lateral dendritic tree, which arborizes in the region of dorsal root termination (Bregman and Cruce, 80) was traced in the X, Y, and Z planes with the aid of a computer-assisted microscope. Where necessary, we followed branches into adjacent serial sections. The unoperated side of the spinal cord provided control neurons. After 35 days the radial distance from the center of the neuron to the distal tip of the tree was reduced by 25% (from 640 $\pm$ 66 um to 480 $\pm$ 52 um). The radial distance to the peak of dendritic branching was reduced by 29% (from 340 $\pm$ 46 um to 243 $\pm$ 28 um) (Both significant at .025 level, paired t-test) It is possible that the Golgi impregnation did not fill the distal tips of the axotomized dendritic trees and therefore what we are measuring is a staining artifact, however the maximum number of branches did not change significantly (7.0 $\pm$ 2.28 to 7.4 $\pm$ 2.15) nor did the total length of the trees (2271 $\pm$ 587 um to 2018 $\pm$ 590 um). Our interpretation is that the entire dendritic tree has coiled in closer to the cell but has not lost any significant branches or length.

250.10 EFFECT OF SPINAL CORD ISOLATION ON α-MOTONEURON POPULATION IN QUIESCENT SEGMENTS. M. Liebhold* and L. Eldridge* (SPON: D. Junge), Dept. of Physiology, University of California, Los Angeles, California 90024.

The effect of prolonged deprivation of excitatory input on the α-motoneuron population of cat lumbosacral spinal cord was studied by using a spinal isolation (SI) procedure. In the SI, all dorsal roots between two cord transections enclosing the 5th lumbar through the 3rd sacral cord segments were severed intradurally. To maximize the health of the isolated region, the ventral artery of the cord was left intact. In order to prevent direct stimulation of the cord by pressure on the back or by movements of the cat, the width of the laminectomy was restricted to 2 mm, except in the areas of the transections, which were protected by adjacent dorsal spinous processes. This silencing procedure was effective: the muscles were in flaccid paralysis at all times, with no voluntary, reflex, or other activity detectable. Cats were sacrificed at 5 (N=2), 8 (N=3), 24 (N=1), 28 (N=1), and 36 (N=1) months after the SI surgery, and their cords compared to those from 8 normal cats. All cats were perfused intravitally with aldehydes. The entire 6th lumbar segment was sectioned at 10μ, and every tenth section Nissl-stained for study. Motoneurons of greater than 25μ mean diameter with a nucleolus visible were counted. The α-motoneurons in the left and right halves of the cords were counted separately to check for possible asymmetrical effects of the surgery, which was always performed from the left side of the cat.

There were gross pathological changes in the SI cords, including progressive atrophy and gliosis. By 24 months, the cords had lost more than 50% of their volume dorsal to the central canal; that remaining was primarily connective tissue and cysts. The ventral and lateral areas normally carrying descending tracts were occupied by non-reactive astrocytes. The α-motoneuron population, however, was almost completely normal. There was no statistically significant loss of α-motoneurons, even in the 24 to 36 month cats. The mean count per section was 12.3 (S.D. 2.61) for the SI cords and 13.0 (S.D. 1.34) for the intact. The left and right sides did not differ. The largest α-motoneurons in both SI and intact cords were 80μ. The Nissl substance in the SI cats looked normal, except in the 36 month cat, in which the grains were smaller. There was no evidence of vacuolization or pyknosis. We conclude that the α-motoneurons are very resistant to prolonged inactivity in an isolation preparation in which the cord retains the major elements of both its circulation and its bony protection.

250.11 MOVEMENT OF OPTIC TERMINALS OUT OF A LOCAL POSTSYNAPTICALLY-BLOCKED REGION IN GOLDFISH TECTUM. J.T. Schmidt. Dept. of Biol. Sci., SUNY Albany, Albany, N.Y. 12222.

Alpha-bungarotoxin has previously been shown to block the synapses of all three classes of retinal fibers in goldfish tectum, severely decrementing the field potentials produced by either photic or electrical stimulation. Quantitative current source-density analysis demonstrated that this was due to a blocking of synaptic currents into radially oriented tectal cells. Presynaptic volleys in the field potentials remain largely unaffected. Lack of a presynaptic effect was confirmed by unit recordings before, during and after the block. Small restricted zones of synaptic blockade were created by slow, low-pressure microinjection of toxin-Ringer solutions from a micropipette. The localized nature of the block was demonstrated by showing that outside the region field potentials were undecremented. Persistence of the bound toxin was demonstrated radioautographically after injection of iodinated toxin. Six days later it was still highly localized and concentrated in discrete synaptic lamina of the tectal neuropil. The lack of substantial diffusion is in agreement with its tight binding (~ 2 day half time of dissociation) and high affinity for the receptor (most of it probably rebinds nearby instead of diffusing away). At six to eight days, few if any optic terminals can be recorded in the toxin treated zone. Extensive mapping at 200 μm intervals however could show no scotoma in the visual field. Instead, terminals with receptive fields within the corresponding area could be recorded from surrounding tectal areas, along with the usual units recorded there, producing large multi-unit receptive fields. Thus all visual areas were still represented in the map. Apparently the optic terminals within the toxin blocked areas moved outward to colonize neighboring normal areas. By two weeks however, they can once again be recorded in the injection zone and the organization of the map is normal.

An actual movement of the terminals (rather than an electrical silencing of those branches in the toxin zone) can be demonstrated anatomically via anterograde filling of the fibers with HRP. Filling the entire optic nerve 5 to 8 days afterward demonstrated that the injected area of the tectum received a very sparse innervation. Examination at high power showed that the solidly filled fibers within that zone tended to run longer distances without branching and that fewer grape-like clusters of boutons emanated from them. After several weeks, the density of innervation was once again uniform. Control injection of Ringers alone produced neither a diminution of innervation in the injected zone anatomically nor a silent zone electrophysiologically, ruling out any damage due to the injection process itself. Supported by NIH grant EY03736 to J.T.S.

250.12 LOCALIZED βBTX APPLICATION PRODUCES A DENERVATED ZONE IN THE GOLDFISH OPTIC TECTUM WHICH IS INVADED BY SURROUNDING OPTIC TERMINALS. C.A. Lemere* and J.T. Schmidt (SPON: David Carpenter) Dept. of Biol. Sci., SUNY Albany, Albany, N.Y. 12222.

Local surgical denervation produces sprouting both peripherally (neuromuscular junction and sensory innervation) and centrally in the hippocampus, tectum, etc. In this study, sprouting was produced by local injection of a presynaptically-acting toxin, β-bungarotoxin (βBTX), a 22,000 MW basic protein. To localize the injection, units were recorded and their receptive fields plotted relative to the optic disc. Two sites, 400 μm apart, were injected with 1 μl of 10^{-7} M βBTX in Ringers at a depth of 150 μm below the surface. Low pressure to a micropipette of 10-15 μm tip diameter delivered this volume over 3 to 5 minutes. As at the neuromuscular junction, the presynaptic units (optic terminals) in the injected area fired spontaneously, decreased in amplitude, and gradually disappeared within one half hour. Optic terminals could be recorded caudal to the injection sites, indicating that βBTX did not interrupt conduction in axons travelling through the toxin-treated zone. Thus, the retinotectal map recorded at this time showed both a silent zone on the tectum and a corresponding scotoma in the visual field. Between 4 and 9 days later, optic terminals could once again be recorded at all points on the tectum (200 μm grid spacings). However, a scotoma, corresponding to the injection sites, remained in the visual field map, because units recorded in the injected zone had receptive fields outside the appropriate area of the visual field. By 15 days normal maps with no scotoma in the visual field were recorded.

Anterograde HRP filling of the optic nerve was used to visualize the optic fibers and terminals. The tectal surface was reconstructed from camera lucida drawings of transverse sections. Filling on day 0 showed two distinct uninnervated regions corresponding to the βBTX injection sites. These regions contained labelled degenerating debris rather than solidly filled fibers. Filling on day 9 showed 2 regions of sparser innervation, in an otherwise solidly filled tectal projection, corresponding to the region injected with βBTX. The electrophysiological results, in conjunction with these suggest that the toxin-induced degeneration of presynaptic terminals causes them to lose their postsynaptic sites to invading healthy terminals, 4 to 9 days after βBTX injections. But by 15 days, the damaged terminals regenerate to reclaim their appropriate zone on the tectum, pushing the invading terminals back to their original sites.

250.13 ELECTRICAL OR CHEMICAL STIMULATION OF VISUAL CORTEX PREVENTS OCULAR DOMINANCE SHIFT IN MONOCULARLY DEPRIVED KITTENS. C. Shaw and M. Cynader, Department of Psychology, Dalhousie University, Halifax, Nova Scotia B3H 4J1.

The mechanism(s) underlying the ocular dominance shift after monocular eyelid suture remain unexplained, but most models propose changes in lateral geniculate nucleus (LGN) afferents representing the sutured eye. Recently, Cynader & Mitchell (1980) suggested that post-synaptic changes in cortical cells may underlie this plasticity. We tested this possibility using electrical or chemical stimulation to alter the firing rate of neurons in visual cortex areas 17 and 18 during monocular deprivation beginning on day 49-54. Two kittens (electrical stimulation (ES)) had two pair of stimulating and ground electrodes implanted unilaterally into the visual cortex ipsilateral to the sutured eye. Two other kittens (glutamate (GL)) had a 0.5 M L-glutamate solution (pH 7.3-7.7) applied to the visual cortex ipsilateral to the sutured eye through a 30 gauge cannula attached to an osmotic minipump (0.5-1μL/hr; Alzet); the control cortex was infused with saline solution. The ES kittens were kept in the dark after surgery and allowed light exposure only during electrical stimulation (100 cps biphasic, 100-150 μA; 2ms duration), receiving 80 to 168 hours of exposure before unit recording on postnatal day 70-73. The GL kittens were kept on a normal light/dark cycle until just before the minipumps were exhausted (6 or 13 days) and then placed in the dark until unit recording on postnatal day 59-69. The results from all experiments were similar: Control cortices showed the usual shifts in ocular dominance; experimental cortices showed greater retention of binocularity (ocular dominance (OD) groups 2-6). The percentage of binocular neurons in the experimental cortices closely resembles that reported for normal kittens (Olson and Freeman, 1978), and neither orientation nor direction selectivity were altered indicating maintenance of pre-deprivation properties. The results suggest that stimulation of the visual cortex decreases the possibility for correlation between LGN input and cortical cellular response, thus largely preventing the shift in ocular dominance following eyelid suture. Further, the specificity of glutamate in activating cortical neurons, but not afferent fibers (Hess and Murata, 1974), suggests that this occurs post-synaptically.

Cortex	Kitten	No. of Neurons	% Binocular Neurons (OD Groups 2-6)
Control	ES	119	45
	GL	42	53
Experimental	ES	215	72
	GL	84	82

250.14 EFFECTS OF ENVIRONMENTAL MANIPULATIONS ON THE STELLATE CELL BRANCHING INDEX. B. Sonnier, A. Riesen, and T. Patterson. Dept. of Psychology, University of California, Riverside, CA 92521.

Percheron (1,2) proposes that stability of numerical parameters within a neuronal type indicate a central coding of neurons and that these parameters are important to specific functions and to the organization of behavior. Using Golgi and light microscope techniques, we investigated the use of the "branch index" as a tool for the evaluation of spineless stellate cell development in laminae II and IV of stumptail macaques reared in one of four environments providing differential amounts of motor and/or somatosensory stimulation. Samples were taken at 3 and 6 mons. of age from visual, S-I, S-II, M-I, M-II and premotor frontal cortex. These areas were also examined in monkeys reared for 3 mons. in the most restricted condition followed by 3 mons. in the colony control rearing condition (4), ie., reversal.

Preliminary data in Table I indicate the index is fairly stable within a narrow range (3.0-4.0) at 6 mons. in the colony control rearing condition, but it does vary with age and/or experimental condition. The index is lower at 3 mons., and it is higher in M-I and S-I in the control rearing condition. Index values for reversal animals tend either to lie between those of normal and experimental animals at 6 mons. or to be similar to those in the control condition at 3 mons. The similarity of the index values over all brain areas in the control condition is remarkable, and this is the only condition where normal behavior patterns developed. Manipulations of the environment appear to increase the variance of stellate index values between the brain areas of animals within a given experimental condition, and to increase the probability of developing abnormal behaviors.

TABLE I: LAMINAE IV STELLATE CELL BRANCH INDEX VALUES

	M-I	M-II	S-I	S-II	Visual	Frontal
Con 1-6 mons.	3.41	3.23	3.47	3.69	3.56	4.00
Con 2-6 mons.	3.60	3.38	3.67	3.78	3.82	3.97
Con 3-6 mons.	3.97	3.52	4.46	3.61	3.74	3.95
Control-6 mons.	3.97	3.76	3.85	3.60	3.76	3.82
Reversal	3.78	3.22	3.56	3.30	3.94	3.39
Con 1-3 mons.	3.35	2.79	3.42	2.76	3.70	3.06
Control-3 mons.	3.48	3.18	3.73	3.30	3.99	3.23

250.15 EFFECTS OF ENVIRONMENTAL MANIPULATIONS ON DENDRITIC DEVELOPMENT IN SPINELESS STELLATE CELLS OF STUMPTAIL MONKEYS: A PRELIMINARY REPORT. T. Patterson, B. Sonnier, and A. Riesen. Department of Psychology, University of California, Riverside, CA 92521.

In our laboratory, we have been investigating effects of environmental manipulations on neural and behavioral development in stumptail monkeys. Rearing conditions were designed to provide graded amounts of somatosensory stimulation and/or motor activity without visual deprivation. All monkeys were reared in one of the following conditions from one week after birth to 3 or 6 mons., except for reversals, which were reared in Con 1 for 3 mons. followed by 3 mons. in Con 4. Con 1: A 12" by 12" transparent Plexiglas cube with a grille floor, an attached bottle and food hopper, all of which provided minimal opportunity for object manipulation; Con 2: A 48" by 48" transparent Plexiglas cube, equiped as in Con 1; Con 3: A cube, as in Con 2, with the addition of ladders, a trapeze and various play objects; Con 4: A large colony room immediately adjacent to the other rearing conditions, where control animals were reared in full view of other experimental animals by their mothers, who were members of a socially stabilized mixed sex group.

Typically, monkeys in Con 1, 2 and 3 exhibit primate social isolation impairments by 3 mons., and their bizzare and stereotyped posturings show some correlation to degree of deprivation. Decreases in these behaviors were observed in reversal during the last 3 mons. in Con 4. There were significant effects of rearing on ratio and number of dendritic branches in S-I, M-I and M-II at both ages, but not in S-II, visual or frontal cortex, ruling out a generalized growth harmone effect. All measures tended to be larger at 6 mons., with the exception of primary branching. This was greater at 3 mons. and in reversal, but there were no rearing effects present at either age. Some loss of primary branches with maturation is implied by the decreases observed at 6 mons., however reversal animals did not show decreases. Other data for reversals tend either to fall somewhere between that of Con 1 and 4 animals at 6 mons. or to be similar to data from Con 4 at 3 mons. Con 3 had the most extensive branching in S-I, and these animals were comparable to those in Con 4 in other areas, with the exception of M-II. Branching trends in lamina II were similar to those found in IV. Con 3 animals engaged in bizzare behavior almost as much as those in Con 1 and 2, so too much growth may be as deleterious to some behavioral functions as too little. Over all, we feel our results support the idea that functional interactions with the environment play an important role in the modulation, control and validation of growth changes, and thus influence subsequent behavioral organization.

250.16 DIFFERENTIAL POST-SYNAPTIC CURVATURE IN OCCIPITAL CORTEX FOLLOWING DIFFERENTIAL REARING IN RATS. Fen-Lei F. Chang, Janice M. Wesa*, William T. Greenough and Roger W. West, Depts. of Psychol. and Anat. Sci. and Neur. and Behav. Biol. Prog., Univ. IL, Urbana-Champaign, IL 61820 and Dept. Psychol., Memorial Univ., St. John's, NFLD, Canada.

One way in which potential correlates of synaptic plasticity have been examined has been to observe whether they are altered following differential experience. Recently, Dyson and Jones (Br. Res., 183:43, 1980), proposed that the curvature of synapses, which shifted from presynaptic convexity toward presynaptic concavity in the cerebral cortex in rats as they matured, might be an indicant of plastic capacity of synapses. To examine effects of experience, independent of age, on this measure, we examined curvature of synapses in layers 1, 3, and 4 of occipital cortex of male littermate triplet sets of rats reared in complex (EC), social (SC), or isolated (SC) environments (rearing details: Greenough, West & DeVoogd, Sci., 202:1096, 1978). Micrographs randomly positioned within the layers (avoiding somata) were printed at 41,800x and coded to prevent experimenter bias. All transversely sectioned synapses in which the postsynaptic membrane and cleft were clearly visible were measured in 8 micrographs per layer from 11 triplet sets. Curvature was assessed as the inverse radius of the circle passing through the membrane at the 2 ends of the post-synaptic thickening (PST) and through the point of maximum deviation of the membrane from a straight line through the 2 end points, using a data tablet. Synapses with subsynaptic plate perforations (SSPP's, Greenough et al.) were analyzed separately from those with continuous PST's and those with complex curvatures (e.g., biphasically curving or invaginated) were excluded from analysis (2964 individual synapses were included).

Non-SSPP synapses on average were significantly more presynaptically concave (expressed as 1/r, in cm. at 41,800x below) in EC than in IC rats, while SC values were intermediate (Table). This is the type of synapse measured by Dyson & Jones. SSPP synapses were quite variable and did not differ statistically in curvature.

	Non-SSPP	SSPP	Combined
EC	0.243	0.125	0.232
SC	0.196	0.231	0.191
IC	0.177	0.136	0.173
	P<.05		.05<P<.10

250.18 INHIBITORY MODULATION OF LTP IN THE HIPPOCAMPAL DENTATE AREA OF AWAKE RATS. G. V. Goddard and M. Riives. Psychology Department, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1

Long-term potentiation (LTP) of the population spike response among granule cells of the facia dentata to input from the perforant path following high frequency synchronous activity in the perforant path fibers was prevented or greatly diminished by preceding or coincident high frequency stimulation of the contralateral hilus in awake freely moving rats. The extent to which LTP was diminished was greater when the onset of the contralateral train preceded the onset of the perforant path train than when they were nearly coincident, and there was no consistently measurable effect when the onset of the contralateral burst was delayed by 4 msec or more after the onset of the perforant path train.

A series of 29 rats with chronically indwelling electrodes were tested at varying intervals between contralateral and perforant path train onset. The population spike height during the conditioning trains as well as the amount of LTP induced by those trains were expressed as percentages of the values observed when perforant path trains were delivered alone. When the amount of LTP was plotted against the interval between contralateral burst onset and perforant path burst onset, the function was a smooth and gradual sigmoid increase from -8 msec (contralateral burst preceding) to +4 msec (perforant path burst preceding). This function did not parallel the function obtained when the population spike evoked during these conditioning trains was plotted against the same intervals. The population spike was blocked when the contralateral train onset preceding the perforant path train onset by as little as 1 msec, and was not blocked when the contralateral train onset followed the perforant path train onset by more than 1 msec.

Since the ability of the contralateral activity to diminish LTP at the various intervals did not correlate with its ability to diminish the population spike at these intervals, LTP is seen to be independent of action potentials in the post-synaptic neurons. In this sense, the LTP is not based on Hebb-type synapses in which the post-synaptic action potential is a necessary agent of change. On the other hand, since LTP of the perforant path was dependent on interaction between activity arriving from different sources, it involves an associational mechanism, like a Hebb synapse but, dependent on a mechanism of comparison that does not entail action potentials in the post-synaptic neuron.

250.19 FACILITATION OF AMYGDALOID KINDLING FOLLOWING PENTYLENETETRAZOL-INDUCED SEIZURES IN NEONATAL RAT PUPS. Mary E. Gilbert* and Donald P. Cain. (SPON: K.-P. Ossenkopp). Department of Psychology, University of Western Ontario, London, Ontario, CANADA, N6A 5C2.

The results of studies conducted in our laboratory have demonstrated that adult rats kindled by injection of pentylenetetrazol (PTZ) can be rendered more susceptible to seizures electrically kindled through the amygdala---the transfer facilitation effect (Cain, this conf.). The present study examined transfer facilitation of seizures induced very early in life to later kindling stimulation in adulthood. It is of theoretical interest and of clinical significance to discover if alterations in brain following seizure activity in the developing organism persist and influence the adult seizure susceptibility.

Single or multiple seizures were evoked by injection of PTZ in neonatal rat pups between 1 and 4 days of age. Following a 3-month growth period, these same animals, as adults, were implanted with bilateral electrodes in the basolateral amygdala. Kindling stimulation consisting of a 1-sec train of biphasic square-wave pulses at 60 Hz and at afterdischarge (AD) threshold was delivered once daily until a stage 5 generalized seizure occurred. Subjects pretreated with PTZ as neonates developed kindled seizures significantly faster than controls (means of 6.8 and 13.6 ADs respectively; $p < .001$). Seizure severity and the frequency of postictal discharge were also assessed during and after electrical kindling. The pretreated group displayed more severe seizures and a higher frequency of postictal seizure manifestations than the controls. No difference between the groups was observed in the AD threshold, but the generalized seizure threshold (minimum current intensity necessary to evoke a generalized seizure in a fully kindled animal) was significantly lower in the pretreated subjects (means of 48.6 μA and 118.0 μA respectively; $p < .001$).

These preliminary data suggest that seizure experience during the neonatal period can render subjects permanently more susceptible to electrically kindled seizures in adulthood. Similar findings in studies in which neonatal rats experienced hyperthermia-induced seizures (Gilbert, unpubl. data; Manetto, McCaughran & Schechter, Neurosci. Abst. 137.16, 1980) suggest that long term changes in the brain can result from early seizures induced by a variety of means.

Supported by a grant to D.P.C. from the Natural Sciences and Engineering Research Council of Canada.

250.20 ^{35}S - METHIONINE INCORPORATION INTO SPINAL CORD PROTEIN. Louis Stodieck* and M. W. Luttges (SPON: D. Groswald). Department of Aerospace Engineering Sciences, University of Colorado, Boulder, CO 80309.

The effects of sciatic nerve stimulation and unilateral sciatic nerve crush on uptake and incorporation of L-^{35}S - Methionine in mouse spinal cord were studied. Stimulation was delivered to the sciatic nerve at a voltage high enough to elicit a cross spinal response recorded from the contralateral nerve. Half the mice received unilateral sciatic nerve crush six days prior to testing. ^{35}S - Methionine was administered by low lumbar interthecal injection. After a two hour stimulation-labeling period, the lumbar cord was removed for processing. Tissue distributions of radioactivity were obtained from crude exogenous pool, intracellular free pool, and protein fractions. The protein fraction was dissolved in sample buffer containing SDS and subsequently electrophoresed on 8.75 - 18.75% polyacrylamide gels. The stained gels showed readily resolvable protein bands ranging in molecular weight from 10,000 to 240,000. ^{35}S - Methionine was found in all bands but exhibited significant variations between individual bands, suggesting variations in turnover rate. In experimental animals, specific activity was determined in ten individual bands for comparison across experimental conditions. The bands varied both in estimated molecular weight and presumed subcellular origin.

Total recovered radioactivity was found to vary by more than two orders of magnitude across animals despite the constancy of evoked cross spinal responses in all preparations. Autoradiographic data indicating that most label was associated with spinal grey matter exhibited similar variability in levels as well as the localization of radioactivity. To circumvent such problems, the distribution of radioactivity between the exogenous pool, the endogenous free pool, and protein fraction was expressed as a percentage. Although spinal injections seem to have consequences for the amount of ^{35}S - Methionine made available to the spinal tissue, they appeared to have little effect on the uptake or incorporation of the label or upon the mechanisms supporting cross-cord responses.

Neither stimulation nor nerve crush influenced the distribution of recovered radioactivity. Similarly, the relative incorporation of label into specific proteins did not vary as a consequence of nerve damage or stimulation. Methionine may exhibit uptake and incorporation characteristics which produce a different estimate of protein turnover than is commonly observed.

250.21 REGIONAL BRAIN GLUCOSE METABOLISM AND PROTEIN SYNTHESIS FOLLOWING IBOTENIC ACID LESIONS OF THE STRIATUM. K. A. Frey* and B. W. Agranoff (SPON: M. Johnston). Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

Intrastriatal injection of ibotenic acid (IBO), an excitotoxic conformationally restricted analog of glutamic acid, has been shown to result in a disappearance of striatal neurons without effects upon axons of passage or extrinsic nerve terminals (Schwartz et al., Exp. Brain Res. 37, 199-216, 1979). In the present study, we have examined the effects of striatal IBO lesions on regional cerebral glucose utilization and protein synthesis within the lesioned area as well as within distant brain structures. One week following unilateral striatal injection of 20 µg of IBO in a volume of 2 µl, rats were anesthetized with ether and a femoral artery and vein cannulated. After a 4 hr recovery period, animals received an intravenous bolus injection of either [^{14}C]2-deoxy-D-glucose (150 µCi/kg) or [1-^{14}C]L-leucine (300 µCi/kg), and timed arterial blood samples were obtained throughout a 45 min incorporation period. Brains were processed for quantitative autoradiography and regional rates of glucose metabolism (Sokoloff et al., J. Neurochem. 28, 897-916, 1977) or protein synthesis (Smith et al., Trans. Am. Soc. Neurochem. p. 94, 1980) determined for individual brain regions from the radioautograms and plasma precursor pool specific activities. Within the lesioned striatum there was a significant depression of both glucose utilization and protein synthesis, while ipsilateral brain regions receiving striatal projections (globus pallidus, entopeduncular nucleus, and substantia nigra) showed elevated glucose utilization and protein synthesis. The observed changes in glucose metabolic rates are consistent with a functional disinhibition of striatal projection sites following the removal of GABAergic input. The apparent increases in protein synthesis within these same regions may be related to the development of denervation supersensitivity which has been previously demonstrated by receptor binding techniques (Guidotti et al., Brain Res. 172, 566-571, 1979). This work was supported by Grant NS 15655. KAF is a trainee of NIH Grant I T32 GM07863.

250.22 RATS ARTIFICIALLY REARED WITH A BALANCED FREE-FATTY ACID DIET: A PRELIMINARY BEHAVIORAL, MORPHOLOGICAL, AND TELENCEPHALIC GOLGI EVALUATION. J. Diaz, G. Clark, F. Petracca*, and J. Schacher*. Dept. of Psychology, Univ. of Washington, Seattle, Wa. 98195.

The procedure of rearing rat pups exclusively by gastrostomy feedings and isolated from their mother and siblings has resulted in animals with somatic growth similar to their normally reared siblings but with significant differences in specific organ weights, including the brain. Behavioral differences between artificially reared animals (AR) and normally reared animals (NR) have also been demonstrated.

These behavioral and central differences between AR and NR animals were reduced when the formula fed to the AR animals was enriched with protein (Diaz, et al., Neurosci Abst, 6, 1980.) Evaluation of the standard diet fed to AR animals (Messer, et. al., J. Nutr., 98, 1969) reveals that in addition to low protein levels, the composition of the fats is inappropriate. The purpose of the present study is to evaluate artificial rearing with a formula enriched with protein and balanced amounts of short and long chained fatty acids.

4-day old female Long-Evans hooded rat pups were matched by weight and assigned to one of two groups: animals artificially reared and animals normally reared. All animals were weighed daily. On day 18, the animals were tested in an open field and then sacrificed. Peripheral organs were removed and weighed. The brain was removed, weighed, and prepared for a rapid Golgi according to the procedure of Scheibel. A microcomputer system was used to determine dendritic length and arborization from the neuron tracings.

The results indicate that somatic growth rates were not different for the AR and NR animals. However, peripheral organ weights were greater and brain weights were smaller for the AR animals compared to their NR siblings. The behavioral profile of the AR animals was also different than the NR animals. These differences between the AR and NR groups are similar to the differences observed when only protein was added to the diet of AR animals.

The analysis of the granule cells in the dentate gyrus indicated that there are no significant differences in dendritic length and dendritic arborization between the two groups. Analysis of cortical pyramidal cells is in progress and will be presented.

Despite significant decreases in whole brain weights in the AR animals, the quantitative and qualitative analysis of the Golgi material indicates that there are no gross neuronal abnormalities in animals that are artificially reared.

250.23 EFFECTS OF ENVIRONMENTAL ENRICHMENT ON RECOVERY OF LOCOMOTION FOLLOWING CORTICAL LESIONS IN RATS. J.M. Held, J. Gordon*, and A.M. Gentile. Teachers College, Columbia Univ., New York, NY 10027

Several factors influencing the rate and nature of motor recovery following damage to the motor cortex of rats have been identified; i.e., momentum, size, site, and symmetricalness of lesions (Gentile, et al., Beh. Biol., 1978, 22, 417-455; Gentile, et al., Soc. Neurosci. Abstr., 1980, 6, 650). The present study examined the role of environmental enrichment as a factor influencing recovery processes. Other investigators have demonstrated better recovery when immature animals were exposed postoperatively to an enriched environment (Will, et al., Physiol. and Beh., 1976, 16, 603-611). Extending these analyses, we evaluated the relative influence of pre- and postoperative enrichment on sparing and recovery of locomotor performance of mature rats after lesions of motor cortex.

Four groups of eight rats each were exposed to an enriched environment: 1) preoperatively, 2) postoperatively, 3) both intervals, 4) not at all. All animals within these four groups were administered bilateral lesions of sensorimotor cortex (18mm^2 each side). In addition, one sham operated group (eight rats) was exposed pre- and postoperatively to the enriched environment; a second control group (eight rats) had no exposure. The task on which all animals were trained preoperatively and tested postoperatively involved locomotion on a narrow elevated runway. The enriched environment was a 120cm x 120cm x 45cm wire mesh cage holding multiple apparatus for many gross motor activities but not for locomotion on narrow surfaces. Groups of rats were exposed to the enriched environment 2 hrs per day for 30 days during the immediate pre- and postoperative period. Postoperative testing began 31 days after surgery and continued until preoperative performance levels were achieved.

A combination of pre- and postoperative enrichment produced partial sparing, with rapid and full recovery; animals not receiving enrichment pre- or postoperatively were severely impaired and took considerable time to reattain criterion levels. Cinematographic analysis of high speed film data was used to examine movement patterns in order to elucidate processes underlying recovery. Both pre- and postoperative enrichment resulted in faster recovery on the locomotor task; however, it appeared that, of the two conditions, preoperative enrichment had a more potent influence on recovery. This finding suggests that the initial state of the system at the time of damage may be an important determinant of the extent of deficit and the rapidity of recovery.

250.24 DIFFERENCES IN THE CRIES OF DEAF AND HEARING KITTENS. C. Shipley*, J.S. Buchwald, E.C. Carterette* and J. Strecker*. (SPON: J.P. Segundo). Brain Research Institute, Mental Retardation Research Center, Departments of Physiology and Psychology, Univ. of Calif., Los Angeles, CA 90024.

Controversy presently exists as to whether the vocalizations of non-human mammals are formed in a purely reflexive fashion or are modulated by auditory feedback. Our approach to this issue has been to analyze andcompare the cries of normal and deaf animals during postnatal development.

We have studied the cries of 10 hearing-impaired kittens and those of 10 littermate controls. Experimental animals underwent bilateral destruction of the cochlea at 14 days of age. The results of the deafening procedure were assessed through recordings of the brainstem auditory evoked responses (ABRs). In the present series of animals, complete loss of ABRs was achieved in three cases; other animals had transmission losses varying from 30 to 70 db as measured by ABR thresholds.

The cries of the deaf or partially deaf kittens differ in several respects from those of normals. We are currently quantifying differences in the fine structure of the calls with digital filtering techniques. Preliminary spectrographic analysis of the calls suggests that the acoustic features of the cries of deaf animals (e.g., the fundamental frequency) are much less variable across calls than those of normal kittens. In several different behavioral contexts, the cries of deafened animals were also consistently louder and more numerous than those of littermate controls. Differences between deaf and normal kittens in the intensity of calls appears to reflect active modulation of loudness by normal animals. When control kittens were recorded during exposure to 80 db SPL white noise their calls were louder than during exposure to 60 db white noise or during recording without noise. These manipulations had no effect on deafened animals.

251.1 PURKINJE CELL ACTIVITY IN VERMAL AND PARAVERMAL CEREBELLUM OF MONKEYS DURING TRAINED SACCADIC EYE MOVEMENTS. J.G. McElligott, Dept. of Pharmacol. Temple Univ. Sch. of Med., Phila., PA 19140, and E.L. Keller, The Smith-Kettlewell Inst. of Vis. Sci., San Francisco, CA 94115

Two hundred cells were recorded from the cerebellum of two awake head-restrained monkeys trained to make saccades to visual targets. Sixty one of these neurons were Purkinje cells. Comparisons of firing patterns were made for saccades of different amplitudes, directions, and absolute positions along the primary axes. All of these cells were constantly active and 50% of them had a multi-component related response (excitatory and/or inhibitory modulation of the background activity). These modulations occurred during a period from 20 msec before the initiation to 200 msec after the termination of the saccade. The presence of a particular component was dependent on the direction and/or the absolute position of the saccade. In general, smaller amplitude saccades had smaller responses. These responsive cells were located either in the posterior vermis or a non-contiguous paravermal region 4-5 mm from the midline. None of these cells responded to the presentation of the visual targets or an alerting auditory stimulus at the beginning of each trial. Controls for the influence of afferent inputs were (1) recordings made during spontaneous saccades in the dark, and (2) determining that there were no attempted head movements during the trained saccadic movements. The climbing fiber response could be discriminated well enough in 22 Purkinje cells to reveal that its occurrence was unrelated to the saccades or the presentation of the sensory stimuli.

The firing patterns of these cells are similar to those previously obtained in the cat (McElligott, Soc. Neurosci.,1979) with the exception that in the monkey they were not influenced by auditory/visual inputs. The multi-component nature of the response and its dependency on the absolute position of the saccade is in accord with the notion that individual cells (1)are influenced by several extra-ocular muscles and (2) that a cell may be correcting for the inherent non-linearities of the extra-ocular muscles. (Supported by a grant from N.S.F.)

251.2 MOSSY FIBER RESPONSES OF PURKINJE CELLS IN THE CEREBELLAR FLOCCULUS OF THE ALERT, PIGMENTED RAT DURING OPTOKINETIC AND VESTIBULAR STIMULATION. Robert H.I. Blanks and Wolfgang Precht. Depts. of Anatomy and Surgery (Otolaryngology), Univ. of Calif., Irvine, CA 92717 and Inst. for Brain Research, Univ. Zurich, Zurich, Switzerland.

The mossy fiber activity of floccular Purkinje cells (P-cell) was studied in the alert, paralyzed rat (DA-HAN) during optokinetic (OKS) and vestibular stimulation. Of a total of 98 P-cells, which were activated by rotatory stimulation of the horizontal semicircular canals (type I and type II P-cells), the vast majority (71/98) responded to constant velocity OKS (0.5^{o}-20^{o}sec) produced by means of a horizontal shadow projector system. The remaining P-cells responded only to vestibular stimulation (19/98) and were unresponsive to OKS.

P-cells which responded to horizontal canal stimulation were, in general, distributed in a longitudinal zone in the middle of the unifoliate rat flocculus. The OKS response of these units was generally bidirectional and synergistic with the horizontal canal input. During constant velocity OKS the discharge of a few P-cells rose exponentially and outlasted the stimulus by 10-15 sec and thus resemble OKS responses of vestibular nucleus neurons. However, the majority exhibited two components of the same polarity: a phasic component (time constant 0.3-1 sec) at the onset and termination of the stimulus and a smaller tonic component with a longer time course (time constant 3-5 sec). Both components showed peak sensitivities with OKS velocities of 1.5^{o}-2^{o}/sec which is slightly higher (i.e., an extended sensitivity range) than the ca. 1^{o}/sec determined for vestibular nucleus neurons in the same preparation (Cazin et al., Pflugers Arch. 384, 31-38, 1980).

Given the short time constant phasic-tonic nature and extended sensitivity range of P-cell-OKS responses, these cells are best suited for generating oculomotor pursuit signals rather than sustaining the slow rising components of optokinetic nystagmus or optokinetic afternystagmus.

Supported by NIH grants EY-03018 and EY-00160, NATO grant 1918/1047(79)AG and funds from the Max Planck Society.

251.3 VISUAL RESPONSES OF EYE MOVEMENT RELATED NEURONS IN PRIMATE CENTRAL THALAMUS. M. Schlag-Rey and J. Schlag. Dept. of Anatomy and BRI, UCLA, Los Angeles, CA 90024.

The central thalamus of monkey (in and around the internal medullary lamina, IML) contains eye position and saccade-related neurons discharging in absence of visual input. The visual responsiveness of these and other neurons in close vicinity was studied in monkeys (Macaca nemestrina) trained to acquire, fixate and pursue a dim visual target (1.5^{o}) in various tasks.

1. Transient on- and off-responses (85-100 ms latency) were obtained from presaccadic neurons. Receptive fields were contralateral, large, with gradients of responsiveness declining around a restricted region of maximal sensitivity. This region was found at different degrees of eccentricity for different neurons and coincided with the movement field of these neurons. As previously observed in cats, this type of visual-oculomotor neuron discharged twice during trials where target acquisition was delayed beyond the normal time span of fixation reflexes (with no external event triggering the target saccade). In this case, the burst time-locked to stimulus onset often bore a striking resemblance to the burst time-locked to saccade onset. Some of these neurons gave signals purely retinotopically coded, others appeared influenced by eye or stimulus position.

2. A separate group of units, discharging tonically in relation to fixation and smooth pursuit, was found in the upper part of the IML. These units, mirror images of each other, were often found very close along the same microelectrode track. They had foveal or near foveal receptive fields and showed an exquisite resolution in modulating their firing rate as soon as the monkey relaxed its fixation with minute deviations of the gaze ($\pm$ 1 deg), suggesting that they may provide extremely sensitive error signals. The direction of gaze did not matter. The paroxysmal activation or suppression was never observed in darkness. The role of the stimulus in triggering or suppressing the firing was further attested by the constant delay with which the characteristic activity followed stimulus onset (100-150 ms latency) or the end of a targeting saccade. However, this activity (activation or suppression) could outlast the stimulus or even recur when the animal's gaze returned to the site where the stimulus had been, suggesting a role in intentional fixation.

These results bring evidence that the central thalamus is specifically involved in the voluntary control of the gaze. (Supported by USPHS grant EY 02305).

251.4 HEAD AND EYE MOVEMENTS EVOKED BY ELECTRICAL STIMULATION OF THALAMIC GAZE CENTER. H. Maldonado and J. Schlag. Dept. of Anatomy and BRI, UCLA, Los Angeles, CA 90024.

Electrical stimulation of the thalamic internal medullary lamina (IML) in awake, head-restrained cats evokes contraversive saccades. Unit recording in this region has disclosed the existence of cells discharging not only with eye movements (Ems), but also with head movements (Hms). Therefore, the effects of electrical stimulation of the IML were studied in head-free animals (i.e. able to rotate their head 60^{o} in the horizontal plane). Hms were recorded with a low torque potentiometer, Ems with implanted silver-silver chloride electrodes. Negative pulses of 0.2 ms at 250 Hz, 10 μA minimum current and in train of 50-500 ms duration were applied through tungsten microelectrodes, sometimes just after recording movement-related unit activity.

Three features were common to all eye-head movements evoked: (1) All evoked head rotations were contraversive and accompanied by ipsiversive compensatory eye movements; (2) If the eyes were initially deviated 7^{o} or more to the ipsilateral side, the first elicited movement always was a saccade to the center of the orbit or a few degrees upward contralaterally; (3) If the eyes were initially deviated 13^{o} or more contralaterally the stimulation had no effect or it first triggered a Hm.

Two types of eye-head movements patterns were distinguished according to the site of stimulation: (1) With low currents, saccades directed to a particulat site were obtained. The direction, amplitude and latency depended on initial eye position. At twice the threshold for evoking Ems, Hms occurred 25-50 ms after the initial saccade. This pattern was characteristic of the sites where units were identified as related to Ems. (2) The first movement evoked was a head rotation with a latency of 60-80 ms., irrespective of the stimulus intensity. Ems occurred later. This pattern was obtained by stimulating sites where Hms-related units had been recorded. These data give further support to the hypothesis that the IML is concerned with gaze control, not solely eye movements. (Supported by USPHS grant NS 04955; Dr. H. Maldonado was supported by CONACYT #16002, México).

251.5 A RETROGRADE HRP STUDY OF FRONTAL EYE FIELD INTERCONNECTIONS WITH THE MOTOR AND VESTIBULAR AREAS IN THE CAT.

R.S. Babb, R.S. Waters, A. Mori*, and H. Asanuma
The Rockefeller University, New York, N.Y. 10021

Classically the frontal eye field (FEF) has been considered to be the cortical site of voluntary eye movements. The work of Bizzi (1968), however showed that the FEF neurons became active after eye movements rendering this idea untenable. Stimulation and unit-recording have shown that eye movements and neck EMG activity are associated with FEF neuronal activity (Guitton and Mandl, 1978). With the object of uncovering the neural basis of the coordination of extraocular and neck muscle activity, we are investigating the connections between the FEF and motor cortex (MCx) using horseradish peroxidase (HRP) as a tracer.

In each brain of 12 cats, either two or three pressure injections of from 20 to 50 nl of 50% HRP (Sigma VI) in normal saline, were made over a 20 min. duration, bilaterally or unilaterally in the grey matter of the walls of the presylvian sulcus, the exact locations being confirmed later by the histology. After a survival time of two days each animal was anesthetized, perfused and 50μm (frozen) sections cut and then incubated according to the tetramethyl benzidine neurohistochemistry of Mesulam, (1976). Cortical areas were defined according to the architectonic criteria of Hassler and Muhs-Clement (1964).

The result of unilateral HRP injections into the FEF was observed to produce in the white matter a well defined fascicle of axons filled with the blue HRP reaction product. Medium-sized labelled pyramidal cell bodies (20-25μm dia),with their apices directed towards lamina I, were observed in the region of the cruciate sulcus. These neurons were found in lamina III and just outside the area containing the giant Betz cells. The projection was bilateral, unlike that of the labelled cell bodies found in the FEF after HRP injections in the ipsilateral pericruciate area. Clusters of irregularly shaped, labelled cell bodies were also found bilaterally in the coronal gyri. Unilaterally, dispersed (20-30μm dia) and small (12-20μm dia) labelled pyramidal-shaped cell bodies were observed in the anterior of the suprasylvian gyrus and buried in the ventral wall of the ansate sulcus a region that has been implicated in the reception of vestibular information by electrophysiological studies (Keminsky, 1951; Mickle and Ades, 1952 and Sana et al., 1970). From these observations it appears that interconnections do occur between the FEF and the MCx and also that the FEF receives input from a vestibular projection area of cortex. Such connections can be considered as candidates for part of the neuronal substrate underlying the coordination of eye and head movements.

(Supported by NIH grant #NS-10705)

251.6 A RELATIONSHIP BETWEEN THE NIGROTECTAL AND CROSSED TECTORETICULAR PATHWAYS IN THE GREY SQUIRREL

P. J. May and W. C. Hall. Department of Anatomy, Duke University, Durham, North Carolina 27710

The superior colliculus projects to the paramedian reticular regions concerned with controlling gaze by means of a crossed descending pathway which originates from neurons in the intermediate grey layer (SGI). We have previously shown that the addition of saponin to injections of horseradish peroxidase (HRP) into the crossed pathway produces a homogeneous backfilling of neurons in SGI. The resultant "Golgi-like" appearance of their somas and dendritic fields allows them to be characterized and distinguished from other cell groups present in SGI. Analysis of the neurons which project to the contralateral reticular formation reveals an isodendritic population of cells which vary in the size and orientation of their dendritic fields. However, the dendritic fields of these neurons are confined to a band which occupies the deeper portion of SGI and, ventrolaterally, extends into the adjacent parts of the intermediate white (SAI) and deep grey (SGP) layers. Within SGI, this band corresponds to a sublamina that can be distinguished by its relatively dense cell population and by its modest number of myelinated fibers, which are oriented primarily in a rostral-caudal direction. One important input to SGI arises in substantia nigra pars reticulata. In order to characterize this input we have filled axons anterogradely by injecting HRP with saponin into substantia nigra. Following injections into the pars reticulata a dense plexus of homogeneously filled axons can be traced to the deep sublamina of SGI. These nigrotectal axons run for long distances within the sublamina. They branch occasionally and frequently exhibit enlargements along their course; but they seldom produce sprays of terminal boutons. The plexus of nigrotectal axons also crosses into SAI and SGP in a band which overlaps precisely the ventrolateral extension of the strip of backfilled cells. This close correlation between axonal arborizations and dendritic fields suggests that a special relationship exists between a major "motor" input to the superior colliculus and the cells which give rise to the crossed descending output to pontine gaze centers (supported by NS-09623).

251.7 SUBCORTICAL AFFERENTS TO THE MONKEY SUPERIOR COLLICULUS.

J. E. Albano. Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, MD 20205.

The discharge of neurons in the intermediate layers of the superior colliculus precedes the occurrence of a saccadic eye movement, but the subcortical structures that contribute to this saccade-related activity remain unknown. Subcortical afferent connections to the superior colliculus in the Rhesus monkey were studied using the horseradish peroxidase (HRP) retrograde tracing method using a modification of the Mesulam TMB-reaction procedure. Injections were made in three awake monkeys using electrophysiological recording and stimulation to localize cells with eye movement-related activity. The large injections (0.4 ul 50% HRP, Sigma VI) in two monkeys were centered in the intermediate layers but also involved significant spread into the superficial and deep layers. In both cases numerous HRP-filled neurons were located ipsilaterally in the antero-lateral portion of the substantia nigra (pars reticulata), the parabigeminal nucleus, and in the contralateral intermediate and deep colliculus layers. In addition, both cases also contained a few labeled cells bilaterally, in the mesencephalic reticular formation and ipsilaterally, in the nucleus reticularis pontis oralis.

In addition to these structures that contained labeled cells, other structures contained cells in only one of the two cases. In one case, the injection site involved the antero-medial portion of the superior colliculus and spread into the nucleus of the posterior commissure. In this case, numerous HRP-filled cells were seen in the contralateral nucleus of the posterior commissure and in a region corresponding to the rostral interstitial nucleus of Cajal, below the fasciculus retroflexus and nucleus parafascicularis adjacent to the central gray. In the other case, with a lateral and posterior injection that spread into regions near the parabigeminal nucleus and inferior colliculus, HRP-filled cells were seen in the ventral lateral geniculate nucleus, zona incerta, and nucleus of the brachium of the inferior colliculus.

In a third monkey the injection was restricted to the superficial layers. In this case, HRP-labeled cells were not seen in either the substantia nigra or the parabigeminal nucleus.

Previous anatomical studies, in the cat, have found that numerous subcortical structures project to the superior colliculus. However, these preliminary results suggest that, in the monkey, the most prominent subcortical inputs to the colliculus arise from two midbrain structures: the substantia nigra (pars reticulata) and the parabigeminal nucleus.

251.8 ANATOMICAL CONNECTIONS OF A PORTION OF THE DORSOLATERAL MESENCEPHALIC RETICULAR FORMATION OF THE MONKEY ASSOCIATED WITH HORIZONTAL SACCADIC EYE MOVEMENTS.

B. Cohen, J. Buettner-Ennever*, D. Waitzman and M.B. Bender, Dept. of Neurology, Mount Sinai School of Medicine, New York, N.Y. 10029 and Institute of Brain Research, Zurich, Switzerland.

Anatomic connections of a region of the dorsolateral mesencephalic reticular formation (MRF) in monkeys were assessed with axonal transport techniques. This region, which roughly corresponds to nucleus cuneiformis in humans (Olszewski & Baxter, 1954), is believed to be related to generation of visually-guided and spontaneous saccadic eye movements to the contralateral side. Radioactive amino acids, ^{3}H-Leu and ^{3}H-Pro, were used to trace the efferent projections. ^{125}I wheat germ agglutinin (WGA) and HRP were used to demonstrate afferent pathways. Sites of injection were localized by recording activity of single units associated with saccadic eye movements or by electrically microstimulating the MRF to produce characteristic contralateral saccades. Efferent projections from this region go to both the ipsilateral and contralateral superior colliculus. Fibers cross to the contralateral side in the commissure of the superior colliculus. Only the deep layers of the superior colliculus contain the typical silver grain pattern indicative of axon terminals. Other structures receiving an afferent input from dorsolateral MRF include the intralaminar nuclei of the thalamus (MD pm, Olszewski, 1952), nucleus reticularis tegmenti pontis, and both medial and lateral regions of the pontine reticular formation including the raphe nuclei. Fiber projections to the contralateral pontine reticular formation cross the brainstem under rostral portions of the oculomotor nuclei. These findings in the monkey are in general agreement with those of Edwards and deOlmos (1975, 1976) in the cat.

Afferent projections to dorsolateral MRF labelled with HRP were demonstrated from discrete groups of cells in the deep layers of the ipsilateral superior colliculus. Evidence that uptake was at least in part due to incorporation of HRP by axon terminals comes from additional experiments in which ^{3}H amino acids were injected into the superior colliculus. This gave rise to a silver grain distribution typical of axon terminals in dorsolateral MRF. Double injections of HRP and WGA were made at different locations in the dorsolateral MRF of individual animals to determine if there was a differential projection of cells from superior colliculus to dorsolateral MRF.

The results show that dorsolateral MRF has the appropriate connections so that it could participate in producing saccadic eye movements.

251.9 PROJECTIONS FROM THE VESTIBULAR TO ABDUCENS NUCLEI AS REVEALED BY SPIKE TRIGGERED AVERAGING. Charles A. Scudder* and Albert F. Fuchs. Dept. of Physiology and Biophysics, University of Washington Seattle, WA 98195

Projections of cells in the monkey vestibular nucleus (VN) onto abducens motoneurons were examined with the method of spike triggered averaging. Two EMG electrodes, designed to sample from many motor units, were chronically implanted in the left lateral rectus (LR) muscle. Recordings from vestibular neurons were obtained from two alert, behaving monkeys using standard chronic recording techniques. Extracellular action potentials were used to trigger a computer of average transients to obtain post spike averages of LR-EMG activity.

Cells were identified on the basis of their firing patterns while the monkey was either (1) smoothly pursuing a spot of light (2) suppressing the VOR, or (3) fixating a spot stationary in space while undergoing head oscillation. Of 130 cells recorded in the right (contralateral) VN, only Type I Tonic-Vestibular-Pause cells (TVP) (N=25) consistently and reliably yielded averages. These cells were characterized by increased firing for right head velocity, for left eye movements, and by a pause for right saccades. Of the remaining cells which yielded averages (N=9), the majority had some left eye movement sensitivity. Units with head velocity sensitivity but no eye movement sensitivity (N=30) consistently failed to yield averages, although very weak connections might not be revealed using this technique. Nearly all the averages were of the same polarity (i.e., negative) as EMG averages triggered from left (ipsilateral) abducens motorneuron spikes, but of longer latency (1.5 as opposed to 1.0 msec), and longer duration. We conclude that Type I-TVP cells make powerfull monosynaptic excitatory connections onto contralateral abducens motorneurons and constitute the dominant crossed input from the VN.

We had very little success in averaging EMG activity triggered from TVP or any other cells in the left (ipsilateral) VN. At present we are uncertain if these negative findings reflect weaker or fewer projections from the ipsilateral VN, or whether they reflect a limitation of the technique in detecting inhibitory connections. Left burst-tonics, which might be expected to excite left abducens neurons, also failed to yield averages.

251.10 EM DEMONSTRATION OF INTRACELLULAR HRP-LABELLED ASCENDING TRACT OF DEITERS NEURONS SYNAPSING WITH MEDIAL RECTUS MOTONEURONS. C.H. Markham, N. Furuya and I.J. Bak. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

This presentation was designed to answer the question whether or not ascending tract of Deiters (ATD) unilateral termination axons are premotor neurons to ipsilateral medial rectus (MR) motoneurons. Horseradish peroxidase (HRP) was iontophoretically injected into ATD axons which were recorded in the MR motoneuron pool of the oculomotor nucleus. Criteria for the axons were:

1. They showed type I responses to horizontal rotation, monosynaptic responses on ipsilateral labyrinth, and no response on contralateral labyrinth or contralateral abducens nucleus stimulation.

2. Light microscopic examination showed the main stem axons to be in the ATD, and terminal boutons were in contact with ipsilateral identified MR motoneurons.

The electron micrographs showed the HRP-injected ATD axons have synapses on MR motoneurons which were identified by prior injection with HRP. ATD boutons made axosomatic and axodendritic synapses on MR motoneurons. The synapses showed symmetrical structure and contained numerous spherical synaptic vesicles. There were different appearances between HRP taken up retrogradely and transported to cell bodies and proximal dendrites and HRP injected directly into axons and transported anterogradely to nerve terminals. The former appeared as granules 50-500 nm in diameter while the latter appeared as fine electron dense particles precipitated in the axoplasm and sometimes adhering to vesicles and other organelles.

In conclusion, unilateral ATD neurons are premotor neurons to ipsilateral medial rectus motoneurons.

251.11 NEURONS OF THE NUCLEUS OF EDINGER-WESTPHAL ARE THE SOURCE OF ENKEPHALINERGIC AND SUBSTANCE P-CONTAINING TERMINALS IN THE AVIAN CILIARY GANGLION. Jonathan T. Erichsen, Anton Reiner, John B. Cabot and Harvey J. Karten. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, New York 11794

Substance P-like and enkephalin-like immunoreactivity have been localized to preganglionic axons and terminal endings upon both ciliary and choroid neurons in the avian ciliary ganglion (Karten et al., Neurosci., submitted). Since the nucleus of Edinger-Westphal (EW) projects to the ciliary ganglion in birds (Narayanan & Narayanan, JCN 166:101, 1976), we investigated the possibility that EW is the source of these peptidergic terminals.

Using immunohistochemical techniques with antisera directed against either substance P (SP) or leucine-enkephalin (ENK), no SP-like or ENK-like immunoreactive cells were observed in EW of the normal pigeon. When the birds were pretreated with colchicine, however, both SP- and ENK-containing cells were found. In order to determine whether these cells are the source of the immunoreactive terminals in the ciliary ganglion, an electrode (#00 insect pins, epoxy-insulated to within 100μm of the tip) was localized to EW using stimulation and stereotaxic techniques. Electrodes were considered to be optimally centered within EW when short trains of cathodal, constant current pulses (.5msec pulse duration, 25-100μa, 100Hz, .25-1.0sec train duration) elicited both pupillary constriction and increases in the accommodative state of the eye. Subsequently, discrete unilateral lesions (1ma, DC anodal current, 30msec duration) were made. Following almost total destruction of EW on one side, nearly complete elimination of SP-like and ENK-like immunoreactivity was observed in the terminal endings around both the choroid and ciliary neurons in the ipsilateral ciliary ganglion.

These results indicate that the SP- and ENK-containing neurons in EW are the source of the SP-like and ENK-like immunoreactive terminal endings in the avian ciliary ganglion. Since the neurons of EW are known to be the source of cholinergic input to the ciliary ganglion (a parasympathetic ganglion), these results suggest that a peptide (SP or ENK) may coexist with acetylcholine in some preganglionic terminal endings within the ciliary ganglion. The possible coexistence of both a peptide and an established neurotransmitter in the same terminal ending implies that SP and ENK may play an ancillary role in neurotransmission in the ciliary ganglion. 252.1 RELATION OF PUTAMEN NEURONAL DISCHARGE TO DIRECTION OF MOVEMENT OR PATTERN OF MUSCULAR ACTIVITY. M.D. Crutcher and M.R. DeLong, Depts. of Physiology and Neurology, Johns Hopkins Univ. Sch. Med., Baltimore, Md. 21205

Previous studies of the relation of neural activity to movement parameters have shown that neural activity within the basal ganglia is best correlated withdirection of movement (Georgopoulos and DeLong, Can. J. Neurol. Sci., 1979). The purpose of this study was to determine whether the activity of neurons in the putamen (the portion of the striatum receiving inputs from the motor and sensory cortices) is related to the direction of movement per se or to the underlying pattern of muscular activity.

Two rhesus monkeys were trained on a visuomotor tracking task. The arm was restrained to allow only flexion or extension movement at the elbow in the horizontal plane. Animals were required first to position and hold the arm within a center window indicated by a target light. After a variable hold time, different magnitudes of sustained flexor or extensor loads were randomly applied to the limb via a torque motor coupled to the manipulandum. After repositioning the handle within the center window and holding for a variable period against the load, the target light was instantaneously moved to the right or left. The animal was required to make a rapid elbow extension or flexion movement with assisting or opposing loads in order to realign the handle with the target light. This paradigm thus dissociated the direction of movement from the pattern of muscular activity required to perform the movement.

Most (128/134) cells in the arm area of the putamen responded to load application: 46% (59/128) of these showed short-latency "sensory" (25-50 msec) responses. 114 of 128 cells (89%) had different patterns of response to the two directions of load application. Only 46 of 138 cells (33%) showed tonic load effects as the animal maintained the arm stationary against the sustained loads and most of these static load effects were weak. During the step portion of the task 120 of 138 cells tested showed consistent changes in activity: of these 53% were primarily related to the direction of movement. The EMG's of the prime movers of the elbow, as well as more proximal muscles, showed a characteristic pattern of activity in the task. 13% (15/120) of cells in the putamen had a pattern of activity similar to that of muscles. 42 cells showed patterns of activity different from both the direction and muscle models. These results indicate that neuronal activity in the putamen is predominantly related to the direction of passive and/or active limb movement rather than to the pattern of muscular activity.

252.2 ACTIVITY OF NEURONS IN THE PUTAMEN DURING MOVEMENT AND POSTURAL FIXATION OF THE ARM AGAINST EXTERNAL LOADS. Samuel L. Liles. Department of Physiology, Louisiana State University Medical Center, New Orleans, LA. 70119.

Monkeys were trained to grasp a manipulandum attached to a torque motor and move it by flexion or extension of the elbow. The animal initiated a trial by positioning the lever in a 1 cm-wide center zone (indicated by a white light) for a variable period of 2 to 4 sec. When a red or green stimulus light appeared, the animal was required to move the lever (extend or flex the elbow, respectively) into an adjacent 1 cm-wide zone 4 cm from the initial zone. A drop of fruit juice was delivered after the animal maintained this position for 1.5 - 2.5s. The animals were trained to perform this task under 5 static load conditions: zero load and 125 g or 250 g opposing flexion or extension. Additionally, a single torque pulse 20 msec in duration (same polarity as static load) was delivered to the lever 1-2s before the light stimulus in each trial. This stimulus elicited a 20 msec-latency discharge in the triceps or biceps muscle. After training, the animals were prepared for single unit recording after the technique of Evarts (1968).

The present sample consists of 28 task-related neurons which were adequately isolated for the required testing period (20-30 min, 32-64 trials per load condition). During the most favorable loading condition 57% of the cells exhibited a phasic burst of discharges during arm movement (mean burst frequency = 25.6 Hz, range 8.4 - 64.6 Hz) and a lower stable discharge rate (mean = 11.9 Hz, range 1.5 - 38.6 Hz) during postural fixation. The sensitivity of the load relation was significantly greater for phasic discharges during movement (mean slope = 3.03 impulses $\cdot s^{-1} \cdot N^{-1}$) than tonic discharges (mean slope = 1.22 impulses $\cdot s^{-1} \cdot N^{-1}$) during postural fixation. The onset latency of phasic activity preceded the onset of force increase during movement by an average of 68.7 msec ($p < 0.01$). In 26% of the sample, the discharge rate during postural fixation gradually increased during the holding periods of the task (ramp pattern). Some of these cells also showed a phasic discharge during movement. The remaining cells (13%) showed only tonic discharge activity (no phasic increases during movement). None of the above 28 cells responded to the torque pulse stimuli, although an additional 10 cells not related to the movement or positioning tasks did respond (latency = 60-100 ms). These data suggest that some neurons in the putamen code force signals generated by central programs during movement and to a lesser extent force exerted during postural fixation of the arm, but do not receive proprioceptive inputs. (Supported by N.I.H. Grant NS 15485).

252.3 RESPONSES OF STRIATAL NEURONS IN THE BEHAVING MONKEY: INFLUENCE OF DOPAMINE. E.T.Rolls, S.J.Thorpe*, D.I.Perrett*, M.Boytim*, F.A.W.Wilson* and I.Szabo*. Dept. Exptl. Psychol, Oxford University, Oxford, U.K.

To analyse the role of dopamine in striatal function, the normal responses of single neurons in different regions of the striatum of the behaving rhesus monkey were analysed, and the effect which dopamine has on these responses was determined. In the tail of the caudate nucleus and ventral putamen, which receive projections from the inferior temporal visual cortex (ITC), visual responses with latencies of 90-140ms were found. These responses were often related to physical characteristics of the stimuli such as orientation, color or size, but unlike responses in ITC, typically habituated rapidly if the stimuli were repeated. In a part of the putamen which receives from sensorimotor cortex, neurons were found with responses which preceded lick and arm movements. By contrast, in the head of the caudate nucleus, which receives from the prefrontal cortex, few units with these types of sensory or motor response were found. However, many units (27.1% in one sample of 394 neurons) responded when environmental events occurred which were cues for the initiation of behavioral responses, in for example a visual discrimination task to obtain food.

The influence of dopamine on these normal responses was determined by micro-iontophoretic application, which ensures that any effects obtained are not due to altered behavior produced by drug administration. In two monkeys, of 179 neurons influenced by dopamine, all showed a decrease and none an increase of spontaneous firing rate when dopamine was applied. In all the 40 cases in which it was possible to determine the effect of dopamine on the normal responses of striatal neurons, it was found that the dopamine reduced not only the spontaneous activity of the neuron, but also the magnitude of its response related to a cue or movement.

Two conclusions follow. First, neurons in different regions of the striatum have responses which reflect the activity in the region of cortex from which they receive. Second, dopamine, by reducing the magnitude of these striatal responses, must influence the transmission of this information from the cortex on to output structures of the striatum such as the globus pallidus.

252.4 PALLIDAL NEURONAL ACTIVITY AND THE CONTROL OF HEAD MOVEMENT IN CATS. J.S. Schneider, J.R. Morse and T.I.Lidsky, SUNY at Stony Brook, N. Y. The disruption of eating and drinking caused by globus pallidus (GP) lesions indicates a role for the GP in oro-ingestive behaviors. In order to understand the nature of this role, an assessment was made of the relationship between GP activity and some of the sensory and motor events which are involved in ingestion.

Units were recorded from behaving cats. Animals were partially restrained in a device which allowed horizontal rotational head turning as well as jaw and tongue movements. Von Frey hairs, blunt probes and an electromechanical device (that produced events of reproducible magnitude and duration) were used to present cutaneous oro-facial stimulation.

42% of GP units (160 sampled) were affected by oro-facial stimulation. Receptive fields were typically large and bilateral (49%) or contralateral (43%). The majority of receptive fields (43%) were from areas innervated by one branch of the trigeminal nerve (in every case the maxillary) though many fields were subserved by two (22%) or all three branches (35%).

Further analysis, directed at assessing the informational content of these sensory responses, indicated that GP units have an extremely limited ability to encode stimulus force. However, stimulus location was encoded. Stimulation within peri-oral zones was more likely to evoke a GP response than was stimulation applied further from the mouth. The majority of receptive fields (75%) had components which included peri-oral tissue. Half of the units which were affected by deflection of facial hair showed enhanced responding to stimuli moving in a particular direction. Of these units, 82% responded best to stimuli moving toward the mouth.

15% of GP cells (68 sampled) changed firing rate in relation to head movements. 37% of these movement-related cells changed firing rate prior to onset of neck muscle activity. Mean lead time was 433 msec though considerable variability was seen with successive movements (standard deviation = 392). The majority of these units (55%) fired best in relation to contralaterally directed head movements. The remaining neurons showed no directional preference. Other parameters of movement (e.g. velocity, magnitude) were not reflected in GP activity. None of the 86 neurons observed during ingestive activity were related to jaw, tongue or facial movements.

These data suggest that the GP's role in ingestive processes does not involve direct control of consummatory movements. Rather, the GP seems to be concerned with the head positioning movements which enable subsequent jaw and tongue movements.

252.5 SOMATOSENSORY PROCESSING IN THE ENTOPEDUNCULAR NUCLEUS OF CATS
J. R. Morse, J. S. Schneider and T. I. Lidsky, SUNY at Stony Brook, Stony Brook, N. Y. 11794.

As part of an ongoing series of experiments investigating the sensory-motor nature of basal ganglia function, neuronal responses to sensory stimuli were recorded from the entopeduncular nucleus in awake, restrained cats. Trigeminal sensory fields were explored since the basal ganglia have been implicated in oro-facial control. Reproducible punctate stimuli were applied to the face using an electromechanical stimulator fitted with calibrated Von Frey hairs. Moving stimuli were applied using a hand held probe. Of the entopeduncular units sampled to date, 21% had facial sensory fields most of which were contralateral or bilateral. These sensory fields were generally large and 77% of them included areas innervated by at least two trigeminal divisions. Both punctate and moving stimuli evoked responses from 55% of responding neurons. The remaining 45% were activated only by stroking and most of these were directionally sensitive, responding to stimuli moving toward the mouth. Cells responsive to punctate stimulation encoded force only to a very limited extent and responses within their receptive fields were heterogeneous. This kind of sensory information could be useful in controlling a variety of movements involved in prey killing and ingestion, including locating food objects and moving them toward the mouth.

252.6 MOTOR AND SOMATIC SENSORY CORRELATES IN THE STRIATUM OF THE AWAKE RAT.
S.E. Knowles, J.K. Chapin and D.J. Woodward. Dept. of Cell Biology, Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235.

The aims of this study were to determine the distribution, degree of specificity, and degree of convergence of motor and somatic sensory properties onto single striatal cells. Single units were recorded in the striatum of awake, behaving rats at locations which previous anatomical studies have shown to receive afferents from motor and/or somatosensory cortex. Free observation, film analysis and computer techniques were used to quantify motor and somatic sensory correlates. Cells in the quietly resting rat had very low spontaneous activity (up to 60 sec interspike intervals) but generally discharged during either spontaneous movement or orientation responses elicited by novel sensory stimuli.

Motor correlates were determined by using a computer to generate peri-event histograms (PEH's) of unit activity around limb, body and neck movements seen in frame-by-frame analysis of video recordings of rats during various behaviors. Nearly all striatal units examined were correlated with gross postural movements, but many could be more specifically correlated with a discrete movement such as head rotation, sniffing or movement of a single limb. The strongest correlate observed was with neck movements especially if they resulted in a change of orientation of the body axis in space. PEH's showed increases in unit activity up to 200 msec preceding the initiation of both ipsi- and contraversive turning. The firing was inhibited at the end of movement.

Cutaneous sensory receptive fields (RF's) were analyzed for these same cells by compilation of post-stimulus time histograms (PSTH's) to natural touch with a probe or to electrical stimulation through electrodes surgically implanted in the paws. Latencies of response to such stimulation ranged from 15 to 50 msec. Nearly 2/3 of the units had discernable cutaneous RF's. About half of these covered the whole body or contralateral half body and thus could be considered relatively "nonspecific". The rest were more specific, being restricted to the contralateral fore- or hindlimb. As yet no overall somatotopic organization of these correlates has been discerned. Striatal unit responses to peripheral stimulation were greater when the animal was aroused and oriented to the stimulus. Natural touch from a probe held by the experimenter was more effective in eliciting striatal unit responses than stimulation through implanted electrodes even when the later was sufficient to elicit limb flexion.

In summary, both motor and somatic sensory properties converged on single cells in all striatal areas tested. Our initial hypothesis is that the expression of both of these properties is predominantly seen during behaviors associated with reorientation of attention. Supported by NIAAA AA-0390 and the Biological Humanics Foundation.

252.7 ATTENUATION OF SENSORY EVOKED IPSP'S IN CAUDATE FOLLOWING BILATERAL ROSTRAL CORTICAL ABLATION.
J.S. Wilson* (SPON: S. Soltysik). Mental Retardation Research Center and Brain Research Institute, School of Medicine, UCLA, Los Angeles, CA 90024.

The purpose of this research was to study the effects of rostral cortical ablation on the sensory evoked postsynaptic potentials (PSP's) in the head of caudate nucleus (Cd). All cortex (Cx) rostral of the lateral ventricles was removed bilaterally by suction. Additionally, all Cx rostral of the ansate sulcus, extending medially to the midline and ventrolaterally to the anterior rhinal sulcus, was removed to a depth of 3-5mm. Mild electrical shocks to either forepaw and "clicks" served as somatosensory (SS) and auditory (Aud) stimuli, respectively. Intracellular recordings were made in three groups of cats: intact cats (N=25), 0-9 days postlesion cats (N=6) and 28-45 days postlesion cats (N=4). In intact cats, 97% of Aud and SS stimuli evoked intracellular responses in Cd neurons. Of these responses, 84% consisted of initial excitation (E) followed by inhibition (I), i.e. an E-I response. 100% of the responses had an I component. In the 0-9 days postlesion cats, only 68% of SS and 53% of Aud stimulation trials evoked responses. Only 36% of the responses were E-I and only 45% had an I component. In the 28-45 days postlesion cats, 86% of the SS and 78% of the Aud stimulation trials evoked PSP's. 72% of the responses were E-I's. 80% of the responses had an I component. Although these data suggest a partial recovery in responsiveness in the long-term survival animals, less than 5% of responses of this group had I's with amplitudes $\geq \bar{X}$ I amplitude of intact animals. In both the long- and short-term survival groups, the $\bar{X}$ I amplitude was significantly smaller ($p < 0.001$) than the $\bar{X}$ I amplitude of intact animals. In contrast to the I's, the initial E's of the responsive neurons were not greatly different for the three groups of animals. To test whether the attenuation of the postlesion sensory evoked I's might be due to non-specific changes in the CNS, the intralaminar thalamus (a direct, intact pathway to Cd) was stimulated. Postlesion, thalamic stimulation evoked E-I response sequences with amplitudes consistent with intact animals. Our data suggest that important components of Cd's responses to SS and Aud stimuli are mediated through rostral Cx. In particular, sensory stimulation was less effective in evoking I responses when rostral Cx was ablated.

252.8 METHYLPHENIDATE (MPH): (1) ABSENCE OF READINESS POTENTIAL IN PATIENTS WITH PARKINSON'S DISEASE AND IN PATIENTS FOLLOWING LONG-TERM MPH TREATMENT.
Boop, R.*, Garcia-Rill, E., Skinner, R. D., Dykman, R.* and Peters, J.* (Spon: J. Spyker-Cranmer), Depts. of Anatomy and Psychiatry, Univ. of Arkansas, Little Rock, AR 72205.

The Readiness Potential (RP) is a negative DC shift recorded from the scalp and beginning 600-800 ms prior to an uncued, voluntary movement. This wave may be a measure of the viability of the neurological substrates involved in the preparation for movement. Others have shown that patients with Parkinsonism have no appreciable RP. These patients also are known to lack striatal dopamine (DA) and exhibit deficits in the initiation of movement. We recorded the RP in a population of Parkinson's patients and confirmed the absence of a RP. An age-matched normal population was also studied which demonstrated a reduced amplitude of the RP, confirming an age-related decrease in the amplitude of the RP in the normal population. A small group of Parkinson's patients also were studied following thalamotomy for the treatment of tremor. The RP was not restored by the surgery although tremor was reduced or eliminated.

From another line of evidence, it has been shown that long-term depletion of striatal DA may occur following amphetamine administration. Our preliminary findings indicate that Methylphenidate (MPH) administration also may lead to a reduction of striatal DA in animals (this meeting). For these reasons we recorded the RP in a population of young adults (20-23 yrs) with a history of at least 5 years of MPH treatment for "hyperactivity". A group of age-matched normal individuals also was studied. Normal young adults had a peak amplitude of 5μv compared to 3μv for the older adult group (age-matched for Parkinson's patients). No member of the Parkinsonism or the MPH-treated group exhibited a RP. Some of the latter group were not currently under MPH treatment. It has yet to be determined if children with "hyperactivity" exhibit a RP. That is, whether the absence of RP is due to the condition of "hyperactivity" itself or whether it is due to its treatment with MPH.

These data, combined with our animal studies, indicate that MPH administration can lead to a reduction in striatal DA, and suggest that MPH treatment could compromise the neurological substrates involved in the generation of the RP. If this is the case, following long-term MPH treatment, these patients may be predisposed to a Parkinson-like syndrome.

252.9 METHYLPHENIDATE (MPH): (2) REDUCTION OF STRIATAL DOPAMINE AND COPPER CONCENTRATIONS FOLLOWING MPH TREATMENT IN CATS. Skinner, R. D., Garcia-Rill, E., DeLuca, D.* and Sorenson, J.*, Depts. of Anatomy, Biochemistry and Pharmacy, Univ. of Arkansas, Little Rock, AR 72205.

Recent findings from other laboratories have described long-term decreases in the concentration of striatal dopamine (DA) in the rat and cat following administration of amphetamine. Methylphenidate (MPH) is pharmacologically similar to amphetamine but its effects on striatal DA are unknown despite widespread clinical use. Intraperitoneal injections of MPH (5 mg/Kg) were administered to two groups of cats every two days. One group received a total of three injections and the other received a total of twelve injections. Behavioral effects were very similar to those reported following amphetamine administration. Two groups of control animals were given the appropriate number of vehicle injections. Two weeks after the last injection the animals were sacrificed in two ways.

For DA analysis, the cats were barbiturate anesthetized, the brains removed, the caudate nuclei dissected and frozen in liquid nitrogen within one minute. A radioenzymatic assay was used to determine DA concentration in control and MPH-treated groups.

For copper (Cu) analysis, anesthesia was induced with halothane, then a locally anesthetized, paralyzed preparation made before perfusing with metal-free saline and metal-free formalin. Thirteen different brain regions were dissected and the samples analyzed by atomic absorption spectrophotometry in control and MPH-treated groups.

Our results indicate that MPH induced a 30% decrease in striatal DA following each type of treatment. Striatal Cu was reduced by 25% and 40% after 3 and 12 injections, respectively. Other areas of the brain also suffered significant decreases in Cu (substantia nigra 25% and 40%, respectively; thalamus 30% and 50%, respectively; etc.).

These preliminary findings indicate that short-term, high-dose MPH-treatment can induce a reduction of DA and Cu in the striatum. Current studies will determine if long-term, low-dose MPH-treatment will have the same effects. Although the dose used in this study is several times the usual clinical dose, it is within the limits of MPH abuse.

When these findings are taken together with our results demonstrating an absence of Readiness Potential in patients with a history of long-term MPH treatment (this meeting), the implication exists that long-term MPH treatment or abuse could predispose subjects to a Parkinson-like syndrome.

252.10 NEUROCHEMICAL CORRELATES OF ESTROGEN INDUCED HYPER- AND HYPO-SENSITIVITY TO DOPAMINE. K. O. Perry*, J. C. Curtin and J. H. Gordon (SPON: C. M. Combs). Dept. of Pharmacol., The Chicago Med. School, N. Chicago, IL. 60064.

The administration of high doses (100ug/kg) of estradiol benzoate (EB) for 3 days in ovariectomized (OVX) rats results in a suppression of apomorphine induced stereotypy at 24 hrs after the last dose of EB. In subsequent tests (48, 72, 96 hrs after the last dose of EB) the animals are hypersensitive to the behavioral effects of apomorphine. The experiments reported here evaluate several neurochemical parameters in both the hyposensitive (24 hrs after lase dose of EB) and the hypersensitive(72 hrs after last dose of EB) animals.

The hypersensitive animals displayed several neurochemical alterations in dopamine function and/or activity. The tyrosine hydroxylase (TH) activity in striatal homogenates was decreased by 16 % in the hypersensitive animals. The TH activity in striatal synaptosomal preparations was decreased by 36 %. The ability of apomorphine to inhibit TH activity in striatal synaptosomal preparations was also increased, EC_{50} = 0.55 + 0.06 uM for the hypersensitive animals and 0.90+0.09uM for the control animals. Coincident with the decreases in TH activity was a decrease (28 %) in glutamic acid decarboxylase (GAD) activity in the substantia nigra (SN) of the hypersensitive animals. for

The hyposensitive animals were not different from contols in either the TH activity or the efficacy of apomorphine to inhibit TH activity in synaptosomes. However the GAD activity in the SN was significantly decreased in the hyposensitive animals. The behavioral response to apomorphine and preliminary binding data utilizing ^{3}H-spiroperidol as a ligand are indicative of a decreased postsynaptic sensitivity in the hyposensitive animals. The decrease in the postsynaptic efficacy of dopamine may be responsible for the decreased GAD activity seen in these animals (i.e. a decreased activity of dopamine at postsynaptic sites could result in a compensatory release of GABA inhibitory feedback). The hypersensitive animals appear to be hypersensitive postsynaptically, as reflected by the increased GAD activity in the SN (i.e. increased negative feedback to decrease dopamine release). This compensatory increase in the GABA feedback may be reflected by the decreased TH activity and/or the increased presynaptic sensitivity (as measured by apomorphine inhibition of synaptosomal TH activity). Thus it appears that the postsynaptic supersensitivity, induced by "withdrawal" from EB, may result in a compensatory presynaptic supersensitivity. This may account for the maintenance of the hypersenitivity seen in the OVX animal. Because an increase in presynaptic sensitivity would result in a decreased dopamine release, which would decrease any down regulation of pre- or post-synaptic receptors by endogenous dopamine. (These studies were supported in part by NIMH grant MH33991).

252.11 NEUROCHEMICAL CORRELATES OF HYPOPHYSECTOMY-INDUCED STRIATAL DOPAMINE SUPERSENTIVITY AND N. ACCUMBENS HYPOSENSTIVITY. J. H. Gordon and V. L. Radice*, Dept. of Pharmacol. The Chicago Med. School, N. Chicago, IL. 60064.

Seven to 9 days post-hypophysectomy (HYPOX) female rats are hyposensitive to the locomotor and hypersensitive to the stereotypy (i.e. sniffing, licking, gnawing) effects of apomorphine (APO). At one month post-HYPOX these animals were hypersensitive to both the locomotor and the stereotypy effects of APO.

Both the tyrosine hydroxylase (TH) activity in n. accumbens (ACB) and glutamic acid decarboxylase (GAD) activity in the ventral tegmental region (VTR) were significantly increased in the 7 day post-HYPOX animals relative to sham operated controls. At 29 days post-HYPOX both the TH activity in the ACB and the GAD activity in the VTR were decreased. Thus the hyposensitivity to the locomotor effects of APO is associated with an increase in TH activity and the hypersensitivity is associated with a decrease in TH activity in the ACB. The changes seen in GAD activity do not support the proposed inhibitory nature of GABA in the VTR, because with an increased TH activity the model would predict a corrisponding decrease in GAD activity, and this is not the case for the HYPOX animals.

The TH activity in the striatum (STR) and the GAD activity in the substantia nigra (SN) were decreased at both 7 and 29 days post-HYPOX This decreased TH activity appeared to be associated with the increased sensitivity to the stereotypy effects of APO. Coincident with the decreased STR TH activity and increased APO efficacy was an increased ^{3}H-spiroperidol binding to STR membranes (38% increase in B_{max} with no change in affinity).

The behavioral and neurochemical data support the hypothesis that following HYPOX female rats will develop a transient decrease in ACB dopamine sensitivity while the STR dopamine sensitivity is increased at this time. Very few experimental manipulations offer the advantages contained in the HYPOX animal (i.e. simultaneous mesolimbic hyposensitivity and STR hypersensitivity), thus the HYPOX animal may prove beneficial in studing the roles of these two dopaminergic systems in modulating various behaviors. (These studies were supported in part by NIMH grant MH33991).

252.12 HYPOPHYSECTOMY INDUCED STRIATAL DOPAMINE SUPERSENITIVITY IN MALE RATS: ANTAGONISM BY PROLACTIN, EXACERBATION BY CHRONIC HALOPERIDOL. B. I. Diamond and J. H. Gordon Dept. Anesthes., Mt. Sinai Hosp., Chicago, Il. and Dept. Pharmacol. The Chicago Med. School, N. Chicago, IL.

Recent reports (Hruska et al., Eur. J. Pharm. 65:455-456, 1980) have suggested that hypophysectomy (HYPOX) in male rats would antagonize the development of striatal dopamine supersensitivity, induced by chronic administration and withdrawal of haloperidol (Haldol). Conversely we have reported (Perry et al., Soc. Neurosci. Abstrs. 759, 1980) that HYPOX produced striatal dopamine supersensitivity in female rats, which could be enhanced by chronic administration of Haldol. These two reports would appear to indicate a profound sexually dimorphic response to HYPOX, to test for this possibility we have repeated our studies on apomorphine-induced stereotypy in HYPOX male rats.

HYPOX or sham operated (SHAM) male rats (180-200 gm) were purchased from Hormone Assay Labs, Chicago. Groups of 8 animals were treated daily, for 16 days, with 1.0 mg/kg of Haldol, 1.0 mg/kg Haldol ± 1.0 mg/kg prolactin, or saline. Animals were then tested with a threshold dose of apomorphine (0.25 mg/kg, i.p.) and the resulting sterotypy scored on the 8th day of withdrawal. During the behavioral test the SHAM animals, treated with saline, displayed an increase in locomotor activity with very few observations of stereotyped sniffing (score = 1.0±0.1). The HYPOX animals treated with saline displayed a significant increase in stereotyped sniffing (score = 1.7±.2). Chronic Haldol treatment and withdrawal in the HYPOX animals resulted in a significant increase in gnawing relative to all other test groups (score = 3.7+.2). The HYPOX animals that received both Haldol and prolactin displayed a decrease in gnawing behavior, relative to the Haldol only animals (score = 2.6±0.2).

Because of the ability of prolactin to attenuate the development of the Haldol-induced striatal dopamine supersensitivity, the experiment was repeated using prolactin injections as the only variable The behavior tests (3 days after the last injection of prolactin or saline) were indicative of a HYPOX-induced striatal dopamine supersensitivity, while the prolactin treatment resulted in a significant decrease in stereotypy.

The data from these studies indicate that: 1. HYPOX in male male results in striatal dopamine supersensitivty; 2. That this supersensitivity can be antagonized by prolactin administration; 3. Chronic Haldol does not required the presence of the pituitary to induce striatal supersensitivity to dopamine, however the presence of a pituitary secretion, perhaps prolactin, can modulate striatal dopamine sensitivity. (These studies were supported in part by NIMH grant MH33991).

252.13 ACETAMINOPHEN METABOLISM IN CAT CAUDATE NUCLEUS MEASURED BY IN VIVO ELECTROCHEMISTRY. Curt R. Freed* and Bryan Yamamoto* (SPON: P. Molinoff). Departments of Medicine and Pharmacology, U. Colorado School of Medicine, Denver, Colorado 80262.

The in vivo electrochemical detector has been shown to be useful for measuring catecholamine release from caudate nucleus of rat and cat. We have demonstrated that acetaminophen can be used as an internal standard for in vivo electrode calibration because it is an electrochemically active compound that can be administered systemically, that penetrates into brain, and that can be seen as an electrochemical peak distinct from dopamine (Morgan and Freed, Soc. Neurosci. 6, 141, 1980). We have now seen evidence of acetaminophen metabolite formation in cat brain. Mongrel cats 3-4 kg were anesthetized with ketamine and a tracheostomy performed. Animals were then maintained on halothane/N_2O/O_2 anesthesia. A carbon paste electrode 250 μ was inserted into left caudate at stereotaxic position 15 mm anterior, 5 mm lateral, and 15 mm vertical relative to the interaural line. Data were recorded with cyclic voltammetry using a Bioanalytical Systems DCV-4 and output was processed by semidifferentiation. Under these conditions, dopamine oxidized at 0.2-0.3 volts relative to an Ag/AgCl electrode also implanted in brain. After signal stabilization, acetaminophen 75 mg/kg i.p. was injected. The expected peak at 0.4 volts corresponding to acetaminophen rose rapidly, reached a peak value within 30 min, and then slowly fell with a $t_{½}$ of 160 min and 587 min in two different animals. Shortly after acetaminophen injection and peak development, a second peak appeared at an oxidation potential of 0.1-0.2 volts, lower than the catechol peak. This peak rose slowly, reaching a maximum at 120 min and 250 min in the two animals described above. The magnitude of this signal was 40 to 50% of the acetaminophen peak. Several pieces of evidence suggest this is a metabolite of acetaminophen produced in brain. First, the acetaminophen administered was chemically pure so that the early oxidizing peak was not due to contaminated drug. Second, the apparent metabolite peak appeared after acetaminophen. During the drug decay phase of acetaminophen from brain, the second peak reached a constant fraction of the decreasing acetaminophen peak (27%) suggesting that the rate of synthesis and rate of elimination of the metabolite were in equilibrium with the falling acetaminophen concentration. Attempts to isolate and identify this apparent metabolite of acetaminophen are ongoing.

252.14 ESTRADIOL SUPPRESSES THEN ENHANCES INTRACAUDATE DOPAMINE-INDUCED CONTRALATERAL DEVIATION. J.N. Joyce, R.L. Smith*, and C. Van Hartesveldt. Psychology Department, University of Florida, Gainesville, Florida 32611.

Recent research has shown that estrogen can affect behaviors elicited by drugs that act on dopaminergic systems in the brain; however, it has not been clear whether estrogen enhances the effect of dopamine at the receptor, or blocks it. Problems in interpretation of research in this area include first, the fact that dopamine (DA) agonists or antagonists have been administered systemically, and estrogen might influence the rate of their metabolism; and second, that the effects of these drugs were measured at varying times after estrogen treatment. In order to resolve these points of controversy, we tested the effects of estradiol priming on the contralateral postural deviation elicited by unilateral intracaudate injection of DA at 2 and 6 days after hormone treatment.

Male Long-Evans hooded rats weighing 300-350 g were implanted bilaterally with 21 ga stainless steel guide cannulae directed at the dorsal anterior caudate nucleus (CPU). Through 27 ga injection cannulae extending 3 mm below the guide cannulae, rats were unilaterally administered first a vehicle solution consisting of sucrose in 0.1 M phosphate buffer; and four hours later, dopamine (DA, 25 μg in 0.25 μl buffer solution). Immediately after each intracaudate injection, rats were observed for 30 min in a circular chamber. Duration of time spent in ipsilateral or contralateral postural deviation was recorded. Then, either estradiol benzoate (EB, 150 μg/animal) or its vehicle (peanut oil, 0.5 cc/kg) was administered subcutaneously, and the behavioral effects of both buffered vehicle and DA injection into dorsal CPU were again measured as above 6 days later. In another group of animals, testing was carried out both 2 and 6 days after EB or peanut oil treatment.

Consistent with previous research, unilateral injection of DA into dorsal CPU induced significantly greater durations of contralateral deviation than the vehicle. Two days after EB treatment, DA injection into the CPU elicited less contralateral deviation, and 6 days later, more contralateral deviation, than in the pre-treatment test. Animals treated with sesame oil showed no changes in DA-elicited postural deviation either after 2 or 6 days; EB had no effect on postural deviation elicited by intracaudate injection of the phosphate buffer.

Both these results and those of Gordon (1980) are consistent with the interpretation that estrogen blocks the action of DA immediately, but as it leaves the system DA receptors increase in number in the CPU, resulting in increased behavioral sensitivity to DA agonists.

252.15 RAPID AVOIDANCE BEHAVIOR DEFICITS AND MOVEMENT INITIATION IN RATS AFTER 6-HYDROXYDOPAMINE MICROINJECTIONS IN SUBSTANTIA NIGRA. W. W. Spirduso,[1] R.E. Wilcox,[2] T.J. Schallert,[3] P. Gilliam,[1] D. Vaughn,[2] and M. Upchurch.[3]*Depts. of PHE,[1] Pharm.[2] and Psy.[3] Univ. of Texas, Austin, TX 78712.

Deficits in movement initiation and conditioned avoidance behavior are known to occur following bilateral 6-hydroxydopamine (6-OHDA) induced damage to the nigrostriatal dopamine pathways. In the present study unilateral microinjections of 6-OHDA (or a sham vehicle) were placed in the medial forebrain bundle, and the results from unilaterally produced escape and avoidance latencies, neurological tests, rotation tests, and unilateral striatal [^{3}H]-dopamine uptake, [^{3}H]-spiroperidol, and [^{3}H]-apomorphine receptor binding were analyzed in terms of being ipsilateral or contralateral to the lesion. These results were also compared to the behavior of control animals.

One week post-operatively, escape and avoidance movement initiation capacity was determined by measuring, over a seven day acquisition schedule, the latency (msec) to release a lever which terminated shock. A special jacket restrained either the left or right forelimb, providing simple reactive capacity latencies for each paw independently. Ipsilateral and contralateral neurological tests included tests to assess sensorimotor deficits (e.g. neglect), lateral hopping/bracing reactions, and spontaneous/apomorphine-induced movement asymmetries (e.g. rotations, slant grid performance).

The results were that unilateral 6-OHDA microinjections induced DA system damage that was associated with sensorimotor deficits, movement asymmetries, and drug-induced rotation. Movement initiation latencies, percent successful avoidance, and avoidance acquisition curves were also severely affected by the unilateral lesions.

Supported in part by grants NIA,AG 02071 to Spirduso; NINCDS NS-12259 to Wilcox; NIH 17673 to Schallert.

252.16 SYNTHESIS OF GABA IN CAUDATE-PUTAMEN AND SUBSTANTIA NIGRA IN VIVO: ALTERATIONS INDUCED BY DESTRUCTION OF NIGROSTRIATAL DOPAMINE NEURONS. M. Casu* and K. Gale (SPON: K. Dretchen). Department of Pharmacology, Georgetown University, Schools of Medicine and Dentistry, Washington, D.C. 20007.

The synthesis of GABA in vivo in caudate-putamen (CP) and substantia nigra (SN) was evaluated by examining the rate of accumulation of GABA after irreversible inhibition of GABA-transaminase (GABA-T) by gamma-vinyl-GABA (GVG). GVG was microinjected directly into SN (5ug in 0.5ul saline over 5 min) or into CP (20ug in 1.0ul saline over 10 min), and the rats were killed 1.5 and 3.0 hr after GVG. We have previously demonstrated that after intracerebral microinjection of GVG, GABA-T is rapidly inhibited (less than 5% remaining at 10 min) and GABA levels increase linearly for at least 3 hr; a significant proportion of this GABA elevation was found to be associated with nerve terminals. In rats which had received unilateral 6-hydroxydopamine (6-OHDA) lesions in the medial forebrain bundle 4 weeks before, tyrosine hydroxylase was <5% of control and the rate of accumulation of GABA was significantly greater in the CP from the 6-OHDA lesioned hemisphere than in control CP (0.40 nmol/mg prot/min vs. 0.26 nmol/mg prot/min). On the other hand, the rate of accumulation of GABA in the SN of the lesioned hemisphere was significantly reduced as compared to controls (0.41 nmol/mg prot/min vs. 0.67 nmol/mg prot/min). Since steady-state levels of GABA in SN and CP were not significantly changed by the 6-OHDA lesions, these data suggest that the alterations in rate of GABA accumulation reflect a change in GABA turnover. It appears that destruction of dopamine projections causes an increase in GABA turnover in CP and a decrease in GABA turnover in SN. This is consistent with a model in which nigrostriatal dopamine pathways exert an inhibitory influence on striatal GABA interneurons, and a disinhibitory influence on striatonigral GABA projections.

Supported by HHS grants DA 02206 and MH 32359

252.17 AMPHETAMINE-INDUCED TURNING BEHAVIOR AND IN VIVO ELECTROCHEMICAL RECORDING FROM CAUDATE IN RATS WITH 6-HYDROXYDOPAMINE LESIONS OF SUBSTANTIA NIGRA. Michael E. Morgan* and Curt R. Freed*, (SPON: S. Roper). Depts. Med. and Pharm., U. Colo. Sch. Med., Denver,CO.

Rats injected with 6-hydroxydopamine (6-OHDA) unilaterally in substantia nigra are known to have dopamine (DA) and DOPAC depletion in caudate on the same side. Systemic administration of amphetamine (AMPHET) will cause animals to turn toward the side of the lesion, presumably as a result of the decreased DA release from that side. To evaluate the dynamic relationship between catechol release and turning behavior, we have studied 6-OHDA lesioned rats with electrochemical recording. Male Sprague-Dawley rats 150-200 gm had substantia nigra lesions made stereotaxically. After a recovery period of 2 to 4 weeks, animals had carbon paste 250 μ electrodes implanted bilaterally in caudate. An Ag/AgCl and a stainless steel electrode were also placed in brain. After overnight recovery, animals were placed in a circular drum and a 30 min recording of basal catechol release was made. Measurement was with a Bioanalytical Systems DCV-4 cyclic voltammetry apparatus with electrochemical output processed by semidifferention. Detectors on each side of brain were scanned alternately every 5 min over the range 0.0-0.8 volts with the peak at 0.2-0.3 volts defined as the catechol peak. Turns were monitored by an observer. After basal measurements, animals were injected with 1.5 mg/kg i.p. d-AMPHET and turns and catechol release assessed for 150 min thereafter. At the end of the experiment, relative electrode sensitivity was measured by injection of 75 mg/kg i.p. acetaminophen. Animals were sacrificed and caudate DA and DOPAC measured by HPLC with electrochemical detection. Results show that all animals had at least 80% DA depletion and 4/7 had greater than 95% depletion. Only 4/7 animals turned to the side of the lesion despite the marked DA depletion. In the animals turning appropriately, turning appeared within 5 min of AMPHET injection, reached maximum intensity at 20-30 min and then declined over a period of 90 min. By contrast, the electrochemical detector response on the unlesioned side rose and then plateaued by 90 min post-injection. Little fall-off in signal occurred over 150 min of observation. Turning intensity appears, therefore, to be related to the rate of change in the electrochemical signal observed in the caudate rather than its absolute magnitude. Electrochemical signals on lesioned and unlesioned sides were compared. Although tissue assays demonstrated 80% DA depletion and 60% DOPAC depletion, output from the lesioned side was never less than 50% of the unlesioned side. Higher than expected release from the lesioned side may be due to accelerated DA turnover in remaining neurons and to comeasurement of oxidizable substances like ascorbic acid.

252.18 EFFECTS ON DOPAMINE-MEDIATED CIRCLING BEHAVIOR OF GABA-ERGIC ACTIVITY AND NEUROTENSIN IN NUCLEUS ACCUMBENS. S.L. Hartgraves[4] and P.H. Kelly. Dept. Physiology and Biophysics, University of Southern California, Los Angeles, CA 90033.

Previous studies suggest that dopamine activity in the nucleus accumbens facilitates the amphetamine- and apomorphine- induced circling of rats with unilateral 6-hydroxydopamine (6OHDA)-induced lesions of the nigrostriatal pathway (Kelly and Moore, 1976). Since GABA-ergic mechanisms in the nucleus accumbens have been reported to inhibit dopamine-mediated locomotor activity, but to increase dopamine-mediated stereotyped behavior (Pycock & Horton, 1976; Scheel-Kruger, Cools & Van Wel, 1977) the present studies investigate the effects of GABA-ergic mechanisms in nucleus accumbens on dopamine-mediated circling. Neurotensin in the nucleus accumbens also antagonizes certain behavioral effects of amphetamine (Nemeroff, 1980), and has also been studied here.

Rats received unilateral 6OHDA (8μg of base) injections into the tail of the caudate nucleus. As assayed by the high-affinity uptake of 3H-dopamine into crude synaptosomal preparations of caudate nucleus and nucleus accumbens these injections destroy 70-80% of dopaminergic terminals in the ipsilateral caudate nucleus, without markedly damaging mesolimbic dopaminergic terminals. Bilateral microinjections of GABA (125-500μg in 1μl) into the nucleus accumbens via chronically-implanted cannulae resulted in a dose-dependent inhibition of the ipsiversive circling provoked by d-amphetamine (5mg/kg s.c.). Similar injections of muscimol (8-200 ng) into the nucleus accumbens also reduced amphetamine-induced circling. A dose of muscimol (40 ng) which markedly reduced amphetamine-induced circling less severely reduced (by 45%) the contraversive circling produced by apomorphine (1 mg/kg. s.c.). Bilateral injection of neurotensin (2μg in 1μl) into the nucleus accumbens did not significantly affect amphetamine-induced circling. These studies suggest that increased GABA-ergic activity in the nucleus accumbens exerts an inhibitory influence on circling provoked by asymmetry of nigrostriatal dopaminergic activity. At least in the dose used here neurotensin has no significant effect on this behavior.

252.19 INTRASTRIATAL INJECTIONS OF KAINIC ACID (KA) DISRUPT THE BLOOD BRAIN BARRIER (BBB) AND CAUSE CEREBRAL EDEMA. Peter H. Cooper[1], Larry L. Butcher[1,2] and Donald Novin[1,2]. Department of Psychology[1] and Brain Research Institute[2], University of California, Los Angeles, CA 90024.

A large literature exists demonstrating that lesions which disrupt the BBB allow for extravasation of serum proteins and for the development of cerebral edema (e.g., Olsson & Hossman, Acta Neuropath. 16:103, 1970). Horseradish Peroxidase (HRP, Sigma Type II) is one of the protein tracers commonly used to assess the extent of damage to the BBB. Because KA has been used widely in attempts to destroy cell bodies without affecting fibers of passage, the present study was undertaken to determine whether KA causes extravasation of HRP. At various times after unilateral intrastriatal injection of KA, HRP (50 mg/kg) was administered intravenously to conscious unrestrained rats through indwelling jugular cannulae. The brains were subsequently examined histologically for BBB involvement.

Two days after the injection of KA there was massive leakage of HRP into the striatum. In all animals, the tracer engulfed the fascicles of corticofugal fibers traversing this structure. In some animals there was spread of the tracer to the overlying corpus callosum and the cerebral cortex. BBB breakdown also occurred in several other sites in which the distribution of HRP was not continuous with the HRP which was extravasated into the striatum. These sites included the lateral septal nucleus, portions of the hippocampus, entorhinal and pyriform cortices as well as dorsal medial thalamic structures. However, BBB breakdown did not occur consistently in all animals at all of these sites. It is possible that this extrastriatal damage is due to the epileptogenic action of KA (e.g., Ben-Ari, et al., Brain Res., 191:79, 1980). In all structures, the amount of extravasated HRP decreased over the next several weeks suggesting repair of the BBB.

The extravasation of HRP is evidence that BBB breakdown and edema result from KA administration. Because cerebral edema may functionally impair fibers of passage, the present observations should be considered when interpreting the effects of KA on behavior and brain biochemistry. Conversely, because BBB breakdown may be involved in the regeneration of axons (Kierman and Contestabile, Acta Neuropath., 51:39, 1980), these findings may also have implications for understanding the cause of the sprouting of axons in the hippocampal formation after certain types of brain damage. (Supported by USPHS Grant NS10928 to LLB.)

252.20 REGIONAL CEREBRAL BLOOD FLOW AND BLOOD-BRAIN BARRIER IN RATS WITH SUBSTANTIA NIGRA LESIONS: EFFECTS OF APOMORPHINE AND AMPHETAMINE. D.K. Zucker and G.F. Wooten; Depts. Neurology and Pharmacol., Wash. Univ. Sch. Med., St. Louis, MO 63110

Regional cerebral glucose utilization (GU) was increased in ipsilateral globus pallidus (GP) following unilateral substantia nigra (SN) lesions with 6-hydroxydopamine (J. Neurosci. 1:285-291, 1981). Further, administration of apomorphine (Apo) 0.5mg/kg resulted in increased GU most prominently in ipsilateral striatum (ST), substantia nigra pars reticulata(SNPR), and entopeduncularis (EP). In contrast amphetamine administration (2.5mg/kg) produced relative increases in GU in contralateral ST, EP and SNPR (Neurosci. Abstr. 6:124.2, 1980).

To determine if these focal, asymmetric changes in GU were accompanied by changes in regional cerebral blood flow, we studied the distribution of ^{14}C-iodoantipyrine (IAP) autoradiographically in the same experimental paradigm. Also, to ascertain if the focal changes in GU might be accompanied by alteration of the blood brain barrier (BBB), the cerebral distribution of ^{14}C-aminoisobutyric acid (AIB) and trypan blue dye was determined in nigral-lesioned animals after administration of Apo and Amph. In rats with unilateral lesions of SN, IAP accumulation was increased by 24% in ipsilateral GP compared to contralateral. No abnormal accumulation of AIB or trypan blue was noted. Apo 0.5mg/kg S.C. resulted in increased ipsilateral IAP accumulation relative to contralateral in ST (31%), EP (18%), GP (30%) and SNPR (41%) (P at least < 0.025); while Amph 2.5mg/kg S.C. resulted in an increase in IAP accumulation only in contralateral SN (28%) (P < 0.01). Neither Apo nor Amph administration affected the normal distribution of AIB or trypan blue. Both Apo and Amph treated groups had significant increases in cerebral blood flow throughout both hemispheres compared to untreated controls.

These results suggest that measurement of regional cerebral GU is a more sensitive and specific index of regional brain metabolic activity than is regional cerebral blood flow as assayed by IAP distribution. Further, focal changes in basal ganglia GU after SN lesion and treatment with Apo and Amph do not appear to be the consequence of an alterred blood-brain barrier as estimated by cerebral distribution of AIB and trypan blue.

253.1 IMPORTANCE OF THE IMMUNOLOGICAL STATUS OF AMYOTROPHIC LATERAL SCLEROSIS PATIENTS. Fred Westall and Charles Jablecki*. Autoimmune and Neoplastic Disease Lab., Salk Institute for Biol. Studies, San Diego, CA 92138 and Department of Neurosciences, Univ. Calif., San Diego, San Diego, CA 92093.

The immunological status of 63 amyotrophic lateral sclerosis (ALS) patients has been assessed over a three year period. Seven of these patients possessed exceptional high serum IgA. As a group these patients had low serum IgG. All seven patients had slowly progressive clinical courses. Another group of six patients with subnormal values of serum IgA were examined. The serum IgG of these patients were also low. Clinically these patients had an intermediate rate of clinical progression. No correlation between IgA and IgM concentrations were found in either subpopulation of ALS.

The percentages of various subclasses of T and B lymphocytes were estimated. The average percentage for Tμ lymphocytes in ALS patients is 20% while the average for normals is 38% ($p<.0002$). This difference was found in all ALS patients and correlates neither with the rate of clinical progression nor with the level of neurologic disability of the patient. Suppressor T cell levels are elevated in ALS patients (38% for ALS compared to 31% for normals) and the levels correlate directly with the rate of clinical progression of the disease. This data suggests that some ALS patients have an immune disorder which predisposes to development of ALS and/or that the rate of clinical progression may be related to immunologic parameters.

253.2 ABNORMAL GANGLIOSIDE PATTERNS IN AMYOTROPHIC LATERAL SCLEROSIS BRAIN. Maurice M. Rapport, William Brunner*, Hyman Donnenfeld*, and Harry Bartfeld*. Division of Neuroscience, N.Y. State Psychiatric Institute, New York, N.Y. 10032 and ALS Center, St. Vincent's Hospital, New York, N.Y. 10011.

A ganglioside pattern comprising 12 ganglioside species (GM1, GM2, GM3, GM4, GD1a, GD1b, GD2, GD3, GT1a, GT1b, GQ1b, Gx) has been determined in cortex from 4 regions of post-mortem brain (middle frontal gyrus, middle temporal gyrus, motor, parahippocampal gyrus) representing 16 cases of ALS and 11 non-ALS controls. The ALS group (11 M/5 F, 63±16 years) were diagnosed on the basis of a combination of upper and lower motor neuron findings. The control group (6 M/5 F, 65±21 years) was comprised of 6 non-neurological cases and 5 with neurological involvment (2 multiple sclerosis, 1 multiple infarct, 1 infarct of brain stem, 1 progressive multifocal leukoencephalopathy). The ganglioside pattern in ALS showed marked abnormalities: three species were low (GD1b, GT1b, GQ1b) and two were high (GM2, GD3), with the differences highly significant ($p< .01$) for some regions. For example, the values for frontal cortex (as % of total sialic acid determined by high performance TLC and densitometry) were 7.98 vs. 17.60 (GD1b), 8.74 vs. 17.91 (GT1b), 1.11 vs. 3.16 (GQ1b), 8.25 vs. 2.01 (GM2), and 16.19 vs. 7.40 (GD3). Several ganglioside species did not show marked alterations: GM1, GD2, and GT1a were normal; GD1a was slightly low ($p<.05$). Other ganglioside species (GM3, GM4, Gx) were not detectable or present only in traces in 6 or more of the ALS cases and in most of the control group. Abnormal patterns were similar in frontal cortex, motor cortex and temporal cortex, but much less pronounced in cortex of parahippocampal gyrus. These findings indicate that the disease process in ALS is not limited to motor neurons. The low values of GD1b, GT1b, and GQ1b indicate a metabolic disturbance in the 1b biosynthetic sequence (GD2→GD1b→GT1b→GQ1b) that is not apparent in the 1a biosynthetic sequence (GM1→GD1a→GT1a). Since the value of GD2 is normal, a partial metabolic block is indicated in the conversion of GD2 to GD1b. Since the total ganglioside sialic acid in these 4 cortical regions in ALS was only slightly decreased from that in the controls (7± 5%), it is unlikely that the abnormal pattern results from cellular loss. We conclude that in ALS there may be an abnormality in neuronal and/or glial cell membranes and that this abnormality may be due to a metabolic disturbance in ganglioside biosynthesis.

253.3 ALTERATIONS IN THE CENTRAL CATECHOLAMINE SYSTEMS OF THE RAT MUTANT DYSTONIC (dt). Joan F. Lorden, Gary A. Oltmans, Mitchell Beales,* Henry J. Baker,* Nancy Cox,* Steven U. Walkley, and Mary Martin.* Depts. of Psych. and Comp. Med., Univ. of Alabama in Birmingham, Birmingham, AL 35294; Dept. Pharmacol., Chicago Med. Sch., No. Chicago, IL 60064; and Dept. Neurosci., Albert Einstein Coll. Med., Bronx, N.Y. 10461.

An animal model of human torsion dystonia was discovered in Sprague-Dawley rats in 1978 by Baker and Cox. At about 10 days of age, affected pups display clinical signs which include a stiff paddling gait and falling to the side. As the disorder progresses, mutants display a lack of coordinated movement, rolling left or right, self-clasping of limbs, hyperflexion and rigidity. Pedigree analyses indicate that both sexes are affected and that the ratio of diseased to normal pups is 1:4. Histopathological examination of the brain and spinal cord of dt rats has not revealed any morphological changes at the light microscopic level.

Neurochemical and pharmacological observations were made on pups 16-25 days of age provided with supplemental hand feeding. Litter size was also reduced to improve the nutritional status of mutants. Cerebellar norepinephrine (NE) levels were elevated by 42% in mutants in comparison with normal littermates. This increase occurred in the absence of a reliable difference in tissue weights. No significant differences in NE levels were found in cortex or hippocampus. Decreased β-adrenergic receptor numbers were also noted in cerebellar tissue of dt rats. A small increase in dopamine (DA) receptor number but no difference in DA levels was found in the striatum of dt rats. Changes in receptor binding appeared selective, as no differences between normal and dt rats were noted in quinunclidinyl benzilate binding in the striatum or spiroperidol binding in the nucleus accumbens.

The effects of intraperitoneal injections of haloperidol (.5-10 mg/kg), amphetamine (5 mg/kg), apomorphine (1-3 mg/kg) and scopolamine (1 mg/kg) were examined. No drug, including doses of haloperidol which produced profound catalepsy in normal rats, inhibited all dystonic movements. Apomorphine decreased the incidence of torticollis and scopolamine, of paw clasps in dt rats. The frequency of stereotyped movements such as gnawing, licking and sniffing in response to apomorphine was markedly reduced in comparison with controls. Since these behaviors are seen in dt rats in response to appropriate food stimuli, this difference probably reflects an insensitivity to the drug.

The differences observed between normal and dt rats suggest biochemical abnormalities in the motor systems of the mutants. Further study will be needed to relate the specific changes observed to dystonic movements.

253.4 INDUCTION OF AN EXPERIMENTAL NEUROPATHY IN THE MONKEY BY PASSIVE TRANSFER OF HUMAN GUILLAIN-BARRE SYNDROME (GBS) WITH IMMUNOGLOBULINS. K. Heininger+, H.-G. Ross, K.V. Toyka+, S. Cleveland+, U.A. Besinger+, A.P. Anzil+, Neurolog. Klinik and Neurophysiol. Inst., Univ. Düsseldorf; Neurolog. Klinik, Techn. Univ. München; Max-Planck-Inst. f. Psychiatrie, München; Federal Republic of Germany

Recently, the possible role of humoral factors in the pathogenesis of the GBS-type neuropathy has been proposed on the indirect evidence that patients with the disease may benefit from plasma exchange treatment. Using plasma from a patient with chronic GBS who had responded dramatically and reproducibly to plasma exchange (Toyka et al., Ann. Neurol. 8: 205, 1980), we have studied the potential pathogenetic role of immunoglobulins (Ig) by adapting the passive transfer model of myasthenia gravis (Toyka et al., Science 190: 397, 1975) to the marmoset monkey. The animals were injected i.m. with multiple doses of crude or purified IgG from the patient or from healthy human controls for 3 weeks. Serial measurements of motor nerve conduction velocities were carried out at the sciatic and tail nerves using standard techniques. In the 2 monkeys treated with GBS-IgG nerve conduction velocity gradually slowed from 60 m/s to 35 m/s; none of the controls showed slowing of nerve conduction velocity. In subsequent acute experiments under nembutal anesthesia, ventral and dorsal roots of the lumbar spinal cord were cut following laminectomy, and the afferent and efferent conduction velocities and refractory periods were determined. This procedure revealed a predominant involvement of efferent fibers. Reconstruction of the "fiber spectrum" according to Smith (J. neurol. Sci. 48: 191, 1980) also confirmed a greater effect of the GBS-IgG on α motor fibers. Preliminary light and electronmicroscopic analysis of excised nerve tissue revealed only mild lesions.

Our results suggest that typical features of the human neuropathy may be reproduced by the passive transfer of human IgG to monkeys.

253.5 SENSORY PROCESSING DEFICIT IN AN INHERITED MOVEMENT DISORDER: DECREASED VISUAL CONTRAST SENSITIVITY IN DYSTONIA MUSCULORUM DEFORMANS. Joy Hirsch* and Donald Kay Riker (SPON:W.F. Riker, Jr.). Depts. Opthal. & Visual Sci. & Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510 & West Haven V.A. Med. Ctr., West Haven, CT 06516.

Movement disorders occupy an important position in neurology since they exemplify how discrete dysfunction of human neurotransmitter systems can alter behavior. Sensory deficits are not widely recognized pathognomic features of movement disorders since, if they occur, they may be subtle and superfluous to diagnosis. For example, Parkinson's disease is distinguished by the triad of tremor, rigidity, and akinesia; nevertheless, latent sensory signs are manifest findings in many patients (Snider et al, Neurology 26:423, 1976), and increased latencies in visual evoked potentials have been reported (Bodis-Wollner & Yahr, Brain 101:661, 1978). Nigrocollicular pathways are suspected in visual and oculomotor deficits in basal ganglia disease. Dystonia musculorum deformans (DMD) is an inherited disorder marked by powerful, slow contractions of muscles of the extremities, trunk, and neck. Sensory (including visual) deficits have not previously been reported in DMD.

Visual sensitivity to contrast of spatial frequency gratings (alternating vertical light and dark bars) of six patients with DMD was compared to that of a well parent or sibling. All observers were free of eye disease and were corrected for normal vision. Comparisons of threshold data across observers was achieved by use of a signal detection theory parameter (d') to correct for differences in response bias. In each paired comparison the affected family member showed significant loss of contrast sensitivity (approximately 0.25 log unit) over the range of spatial frequencies (bar sizes) tested.

Categorization of inherited neurologic disorder simply by overt clinical signs may not direct attention to the true extent of biochemical lesions. Neurologists suspect that DMD is a basal ganglia disorder. These data suggest that, in addition to motor output, sensory processing may also be affected. (Supported by The Dystonia Medical Research Foundation, Beverly Hills, CA; NEI grants EY00785 and EY00167-01; and Research to Prevent Blindness).

253.6 PLASMA ACETYLCHOLINESTERASE ACTIVITY - A POTENTIAL MARKER OF 2,5-HEXANEDIOL NEUROTOXICITY. Barbara F. Bass* and Alan M. Goldberg. Division of Toxicology, Dept. of Environmental Health Sciences, The Johns Hopkins University, Baltimore, MD 21205.

Neuromuscular disorders such as muscular dystrophy (Lyles, J.M., et al. J. Neurochem. 34:978, 1980) and amyotrophic lateral sclerosis (Festoff, B.W., et al. Neurochem. Abstr., #83, 1980) have been associated with increases in plasma acetylcholinesterase (AChE) activity. Muscle AChE activity is also known to undergo changes in response to neuromuscular damage. The present study was undertaken to examine whether a known neurotoxic agent, 2,5-hexanediol, would produce alterations in plasma or muscle cholinesterase activity and if so, would these changes preceed the development of overt toxicity. Female Sprague-Dawley rats were exposed to 0.5% 2,5-hexanediol via their drinking water for up to 9 weeks at which time treatment was terminated and the animals were given tap water. At weeks 2,4,6,8,10, 12 and 15, control and treated rats were killed and plasma and muscle samples obtained. Plasma was assayed for both acetylcholinesterase (AChE) and butyrylcholinesterase (BChE) activities. ^{14}C -ACh was used as the substrate in both assays with BW284C51 and iso-OMPA used as selective inhibitors of AChE and BChE respectively. By week 6, 12% of the animals exhibited signs of the neuropathy and by week 8, all treated animals had developed peripheral motor disturbances. Once exposure to the hexacarbon was terminated, recovery slowly occurred over the next several months. Plasma AChE activity was found to differ significantly between control and treated groups ($P < .01$). At week 4, plasma AChE activity in the treated group was elevated. This upward trend continued, reaching significance at week 10 ($P < .01$). This was one week after exposure to 2,5-hexanediol had been stopped. By week 12, AChE activity had returned to control levels. It should be noted that AChE activity increased in the experimental group prior to any overt manifestations of a neuropathy. No changes were observed in plasma BChE activity over the 15 weeks. In muscle no significant differences were seen in total AChE activity per muscle. However, total protein content per muscle decreased as compared to controls after week 8 and remained so throughout the rest of the experiment (week 15). Therefore, the activity of AChE per mg protein showed an increase during this time period.

In conclusion, the present study is further evidence that plasma AChE activity is a potential marker of neuromuscular disorders, whether chemically induced or naturally occurring, and that it may be useful as an early indicator of the hexacarbon induced neuropathy.

253.7 PRESENCE OF "SLOW" MYOSIN IN FAST-TWITCH MUSCLES OF THE DYSTROPHIC MOUSE. D.J. Parry* (Spon: K.C. Marshall). Dept. of Physiology, Univ. Ottawa, Ottawa Ont. Canada K1N 9A9

The fast-twitch anterior tibialis (AT) and extensor digitorum longus (EDL) muscles of normal mice contain few, if any, type I fibres as demonstrated by myofibrillar ATPase histochemistry. This has been confirmed by showing the almost complete absence of fibres which react with anti-myosin raised against myosin extracted from the slow-twitch cat soleus. (N.B. The anti-myosin was prepared by Dr. Anthea Rowlerson). AT and EDL of the dystrophic mouse, C57 BL dy^{2J}/dy^{2J} aged 6-8 months exhibit significantly slower isometric twitches than their control counterparts. Time to peak tension (CT) and half relaxation time (1/2 RT) were both significantly prolonged. In addition EDL also shows post-tetanic and cooling potentiation effects characteristic of slow-twitch muscle. With ATPase histochemistry a large number of fibres with intermediate staining intensity are seen in dystrophic hind-limb muscles. Using the "sandwich" technique for myosin immunohistochemistry it may be seen that a much higher proportion of fibres in both AT and EDL of dystrophic mice contain "slow" myosin. Many of the fibres containing "slow" myosin were atrophic. Forearm muscles did not show such a pronounced increase in "slow" myosin content. The isometric twitch of extensor carpi radialis longus (ECRL) was prolonged, but this was almost entirely due to an increase in half-relaxation time. 1/2 RT in dy^{2J} ECRL was 21.1±3.5 msec compared with control values of 10.4±2.5 msec. CT in the dystrophic forearm muscle was 10.9±0.8 msec and in control mice was 9.0±0.6 msec. It is well known that the hind limb muscles of dystrophic mice undergo spontaneous twitching, a phenomenon not observed in fore-limb muscles. It is suggested that synthesis of "slow" myosin in dystrophic hind limb muscles may be a result of the altered activity pattern and not of the dystrophic process per se.

253.8 ALTERATIONS IN SKELETAL MUSCLE AChE AND PLASMA CPK OF HENS WITH TOCP-INDUCED DELAYED NEUROTOXICITY. C. Michael Cisson[1] and Barry W. Wilson, Department of Avian Sciences, University of California, Davis, California 95616.

Degenerative changes in chicken skeletal muscle following surgical denervation have been previously studied in this laboratory. Most notably, acetylcholinesterase (AChE, E.C. 3.1.1.7) activity increased eight times that of normal innervated muscle, sarcoplasmic enzyme activity appeared outside the region of the motor endplate, and the 20S AChE molecular form virtually disappeared. In addition, plasma creatine phosphokinase (CPK, E.C. 2.7.3.2) significantly increased following denervation. Axons within the sciatic nerve of hens with a delayed neurotoxicity induced by TOCP (tri-ortho-cresyl phosphate) are known to become swollen and undergo fragmentation, and motor control of the legs is lost. The muscles of hens treated with TOCP (500 mg/kg s.c.) were observed for degenerative changes following the development of this neuropathy. Mean muscle weight and fiber diameter of the M. gastrocnemius, a muscle innervated by a branch of the sciatic nerve, were significantly decreased. The muscle fibers were also rounded, and high AChE activity appeared in the muscle fiber sarcoplasm in regions where there were no apparent motor endplates Biochemical studies showed the concentration of AChE and nonspecific cholinesterase (ChE, E.C. 3.1.1.8) activities were twice that of control, and sedimentation of the AChE molecular forms on sucrose density gradients showed a 57% decrease in the 20S form. Plasma CPK activity was four times normal after the onset of delayed neurotoxicity, and there was a concurrent 56% decrease in the CPK activity of the M. gastrocnemius. Degenerative changes were not observed in muscles of birds treated with parathion (O,O-diethyl-p-nitrophenyl phosphorothioate), the negative control for these studies, which suggested the alterations were directly related to delayed neurotoxicity. (Supported by NIEHS grant ES 00202 and a grant from the University of California cooperative Extension Western Regional Pesticide Impact Assessment Program.)

253.9 EFFECTS OF PRECENTRAL CORTICAL LESIONS ON GLUCOSE UTILIZATION IN THE DEEP CEREBELLAR AND RELATED NUCLEI IN THE MONKEY. S. Gilman, G. Dauth, K. Frey*and J. Penney, Department of Neurology, The University of Michigan, Ann Arbor, MI 48109

In humans and infrahuman primates damage to precentral cortex results in a contralateral hemiparesis, initially hypotonic, and later hypertonic. The neurological events following such a lesion are largely unknown. In particular it is not known which structures are important in the development of hypertonia.

The primate model with unilateral 4 & 6 cortical lesions and the [^{14}C]-2-deoxyglucose ([^{14}C-2-DG]) quantitative autoradiographic technique were used to evaluate changes in motor system structures following the lesions. The [^{14}C]-2-DG technique as described by Sokoloff et al. (1977) was used to determine rates of glucose utilization. One group of animals was sacrificed 1 week after surgery during the hypotonic phase and another group at 8 weeks when the animals were clearly hypertonic.

An analysis of glucose utilization rates reveals that there are asymmetries in glucose utilization in the red nuclei, pontine nuclei and inferior olivary nuclei both at 1 and 8 weeks after the lesion. The structures ipsilateral to the lesion had lower glucose utilization rates than those contralateral to the lesion. The asymmetries in these structures were similar at both 1 & 8 weeks. Analysis of the deep cerebellar and vestibular nuclei revealed that there were no consistent left-right asymmetries in glucose utilization at either 1 or 8 weeks after a unilateral 4 & 6 lesion.

These findings suggest that the red, pontine and olivary nuclei may be important in hemiparesis but not important for the development of hypertonia. The lack of asymmetries in the deep cerebellar and vestibular nuclei suggest that alteration of neural activity in these structures may not be of primary importance for the hemiparesis which follows cerebral injury.

253.10 ACUTE EFFECTS OF THE NEUROTOXIN KAINIC ACID ON NEURONS OF THE PIGEON BASAL GANGLIA: BEHAVIORAL, ELECTROPHYSIOLOGICAL, LIGHT AND ELECTRON MICROSCOPIC OBSERVATIONS. G. K. Rieke and D. E. Bowers, Jr.* Department of Anatomy, Texas A&M Univ. College of Med., College Station, Tx 77843.

The paleostriatal complex (PC) of the pigeon is the probable avian analogue of the mammalian caudatoputamen and globus pallidus. Intracerebral injection of kainic acid (KA, 0.00053µg-1µg) into the PC resulted in marked postural problems, significantly elevated discharge rates of KA sensitive neurons, and morphological changes in neurons and neuropil. Birds anesthetized with ether and intracerebrally injected with 1µg KA/µL demonstrated postural disturbances of the head and neck. The head and neck were twisted to the side of injection and the head was characteristically inverted. There was resistance to passive movement of the head and neck away from the side of rotation. The bird also circled toward the side of injection. Kainic acid sensitive neurons, particularly the large neurons of the paleostriatum primitivum, responded to KA with elevated discharge rates (3-12 times the base line rate). The discharge rates of individual units treated with aliquots of KA (0.2µL, 1µg KA/µL) remained elevated for 1-2 hrs, after which the treated unit suddenly ceased firing. Units treated with low concentrations of KA (0.00053µg/µL) responded with elevated discharge rates that were sustained for longer periods of time, while discharge rates were not significantly elevated by treatment with aliquots of 0.9% NaCl vehicle alone. Morphological changes induced by KA appeared to involve initially the neuropil, as dilated dendritic profiles were a common feature 1 hr after the injection of 1µg KA. The morphological changes became more intense and by 4 hrs both dendrites and soma showed marked pathology. There appeared to be a relationship between tissue response and the dose of the toxin. The larger the dose the more rapid the destruction of neurons. In addition, there was a dose-survival time correlation as KA is a persistent toxin and small doses ultimately have the same destructive effect on neurons over a longer period of time. The close correlation between cessation of cell discharge, metabolic alterations and morphological changes suggests that KA sensitive neurons do not recover from the influence of the toxin. The mechanisms by which KA destroys neurons are not clearly understood; however, our observations support, in part, the excitotoxin hypothesis as one means for the toxicity of KA. The pigeon may be a useful model to study both movement disorders and the actions of KA or KA-like substances on sensitive neurons that appear to play a role in the regulation of movement and maintenance of posture. Supported by Office of Univ. Res., Grant #15707.

253.11 WHICH IS THE MAIN SUBSTANTIA NIGRA RETICULATA (SNR) EFFERENT INVOLVED IN TURNING BEHAVIOUR? M. Garcia-Munoz*, P. Patino*, and A. Zainos*. (SPON: R. Salceda). Centro de Investigaciones en Fisiología Celular, Universidad Nacional Autónoma de México, Apartado Postal 70-600, México 20, D.F., México.

The administration of dopaminergic (DA) agonists to rats with unilateral destruction of striatal DA nerve terminals induces circling behaviour. This alteration in the motor system has been used to test different drugs interacting with the DA receptor and has led to a tendency to explain turning only in terms of the degree of receptor activation. Little is known about the structures involved. Recent studies propose that the activation of a gabaergic system projecting from SNR may be involved as an output system for nigro-striatal motor responses. Gabaergic agonists induce turning, and the administration of GABA-receptor blockers ipsilateral to a 6-OHDA lesion antagonizes the turning produced by DA agonists. Efferents from SNR are to thalamus (VMT), superior colliculus (SC) and the reticular formation of the ponds (RFP). To clarify the possible participation of these areas in turning we made kainic acid lesions (1.25 ug/0.25ul). Rats with unilateral lesions of VMT turned 160.7+75 times/30 min (apomorphine 2.5 mg/kg). This same lesion performed 10 days after a 6-OHDA injection in the medial forebrain bundle reduced the number of turns by 60% if compared against turning before the TVM lesion and by 81% if compared against a 6-OHDA lesioned group operated once but tested twice as the double lesioned animals, (apomorphine 0.25 mg/kg). Rats with a bilateral lesion in VMT after a 6-OHDA injection also reduced the number of turns by 66% compared against themselves and by 79% compared against the 6-OHDA lesioned group. A unilateral lesion of RFP produced 59+37 turns/30 min and a unilateral lesion of SC produced 28.5 turns+17 turns/30, (apomorphine 2.5 mg/kg). Animals with lesions in these areas after a previous 6-OHDA injection did not alter significantly their turning. Bilateral TVM lesions decrease the number of turns providing the lesion is symetric and made with kainic acid. It is possible that some fibers lesioned electrolitically may also participate. We propose that the main efferent from SNR mediating this behaviour produced by striatal DA nerve terminal degeneration is to VMT.

253.12 THE EFFECTS OF STIMULATION OF THE DORSAL SPINAL CORD ON THE STRETCH REFLEX IN THE DECEREBRATE CAT. C.E. Chapman* and M. Wiesendanger (SPON: V.B. Brooks). Institut de Physiologie, Universite de Fribourg, CH-1700 Fribourg, Switzerland.

It has been reported that stimulation of the dorsal spinal cord may, by an unknown mechanism, produce a dramatic and long-lasting reduction in spasticity. The effects of dorsal cord stimulation (DCS) on stretch reflex activity in triceps brachii and triceps surae were investigated in 10 intercollicular decerebrate cats and 2 decorticate cats. During stimulation (0.2 ms, 50 Hz, 80-150 µA for 1-20 min. at the C_1 level) the tonic stretch reflex (TSR) and the phasic, monosynaptic reflex (MSR) of triceps brachii were inhibited in both the decerebrate and the decorticate cat. After cessation of stimulation, the MSR always recovered quickly whereas the TSR often remained depressed for up to 5-20 min. Stimulation at more caudal levels (T_2) had weaker inhibitory effects on the triceps brachii TSR. DCS (T_8 level) had similar, but less marked, inhibitory effects on the triceps surae TSR, in the decerebrate cat. The corresponding MSR was either weakly inhibited or unchanged. Dorsal column section (T_{10}) exaggerated the effects of stimulation rostral to the lesion. Stimulation caudal to the lesion failed to elicit any inhibition, suggesting that the inhibitory effects were mediated by dorsal column afferent activation of more rostral structures.

Thus, the present results indicate that DCS produces a marked inhibition of stretch reflex activity. In forebrain-lesioned cats, the inhibitory effects did not, however, outlast the period of stimulation for hours as found in spastic man.

254.1 SODIUM ION EFFECTS ON THE RESPIRATION PROPERTIES OF ASTROCYTES FROM PRIMARY CULTURE. James E. Olson and David Holtzman. Depts. of Pediatrics and Neurology, Stanford University School of Medicine, Stanford, CA 94305.

In a previous study, we reported that oligomycin-insensitive, or phosphorylation-independent, respiration increases with increasing NaCl concentration in cerebral astrocytes from primary culture (Olson and Holtzman, Trans. Soc. Neurosci. 186.1, 1980). This increase did not occur in sucrose media of the same osmolarity. We have investigated further the ionic dependence of and effects of metabolic inhibitors on astrocyte respiration in vitro.

Primary cultures of astrocytes were prepared from 3 day old rat cerebral cortex. Respiration was measured polarographically as previously described (Olson and Holtzman, J Neurosci Res. 5(6):497, 1980). Phosphorylation-independent respiration was measured using a maximally inhibiting concentration of oligomycin (5 μM). This respiratory rate increased as the osmolarity increased from 274 to 1096 mOsm with NaCl or Na acetate but not with choline Cl or sucrose as the osmotic agent. Amiloride, known to block passive movement of Na^+ across the plasma membrane of other cell types, produced a dose-dependent decrease in phosphorylation-independent respiration in astrocytes suspended in the 1096 mOsm NaCl medium. A 43% inhibition was obtained with 1.5 mM amiloride. No effect of amiloride was observed on the phosphorylation-independent respiration of cells suspended in 1096 mOsm sucrose medium.

Ouabain (1 mM), an inhibitor of Na-K ATPase, was found to inhibit the basal respiration of astrocytes by 31% and 27% in 274 and 1096 mOsm NaCl medium respectively. Addition of amiloride (1 mM) to ouabain-inhibited cells produced no change in the respiratory rate in 274 mOsm NaCl, but further inhibited respiration in cells suspended in 1096 mOsm NaCl by 13%. This same concentration of amiloride added to cells without the prior addition of ouabain produced a 23% inhibition at each osmolarity.

Measurements of the volume of astrocytes in media of increased osmolarity were the same with NaCl or sucrose as the osmotic agent. In hypo-osmotic solutions, cells swelled more in NaCl compared to sucrose solutions.

These results suggest that, in the astrocyte, there exists a respiratory component, responsive to extracellular Na^+, which is not coupled to oxidative phosphorylation. This respiratory component may be important in the astrocyte's proposed function as a buffer of extracellular ion and water activities.

This study was supported by NIH grants ES 02571 and NS 16256 and a Stanford University Dean's Post-doctoral Fellowship.

254.2 OXIDO-REDUCTION OF FLAVINE ADENINE DINUCLEOTIDE IN THE RESPIRATORY CHAIN OF NEURON SOMAS OF FROG DORSAL ROOT GANGLION. Carlos Rodríguez-Estrada. Cátedra de Fisiología. I.M.E. Fac. Medicina, U.C.V., Caracas, Venezuela.

It has been reported (Rodríguez-Estrada Soc. Neuroscience Abst.#300,p91,1979) that an increase of carbon dioxide partial pressure produced a decrease of reduced nicotinamide adenine dinucleotide, i.e. oxidation of respiratory chain in neuron somas of dorsal root ganglion in vitro preparation. This change could be due to a new equilibrium constant pH dependent (E. Racker J.Biol.Chem. 184:313,1950). It has been accepted that reduced nicotinamide adenine dinucleotide in the neuron somas is located in their mitochondrias and that this hydrogen carrier is a link in the respiratory chain between substrate donor and flavoproteins of the respiratory chain. Therefore, an oxidation of NADH could be achieved in either direction (toward flavoproteins or substrate) by lowering the pH with carbon dioxide but in fully reduced state of NAD the flavine adenine dinucleotide also is fully reduced. Hence the hydrogen acceptor is the substrate and oxidation of $FADH_2$ also could be observed. Dorsal root ganglion preparation were used with a temperature controled at 25°C, alternating fluorometric determinations of NADH and FAD were done. NADH determinations were performed as previously describe. FAD fluorescence emission was recorded with 5200 angstroms interference filter. Light excitation of 4350 angstroms was used. The oxido-reduction level determined in O_2 atmosphere was taken as reference level. When replacing the O_2 for N_2 there is an increase of $FADH_2$. In fully reduced state replacing this N_2 atmosphere for one containing N_2 97.5% and CO_2 2.5% there is a decreased of the reduction level, both NADH and $FADH_2$, i.e. an oxidation was observed. After incubating the preparation with Amytal (5-30 minutes) the reduction in N_2 atmosphere was not seen, and the oxidation with N_2-CO_2 mixture was not observed. The Amytal produced a partial block, the oxidation in the N_2-CO_2 mixture was also observed, but a smaller reduction than was expected. The results indicated that the oxidation recorded by the increase of carbon dioxide is a chemical reaction change only occurring in the respiratory chain.

254.3 INFLUENCE OF CEREBRAL POTASSIUM EFFLUX ON CYTOCHROME a,a_3 REDOX STATE DURING ISCHEMIA IN THE RAT. T.J. Sick, R.B. Duckrow, J.C. LaManna and M. Rosenthal. Dept. of Neurol., Univ. of Miami Sch. of Med., Miami, FL. 33101.

Cerebral ischemia is accompanied by an increase in the ratio of reduced/oxidized cytochrome c oxidase (cyt a,a_3) in brain. The initial period of ischemia is characterized by fast reduction of cyt a,a_3. This is followed by a period when cyt a,a_3 reaches a plateau or even becomes transiently oxidised, and finally by a period of further reduction of cyt a,a_3. The multiphasic nature of this response was evaluated, in the present study, by comparing the timecourse of changes in cerebral oxygen availability and extracellular potassium ion activity (K^+ o). The redox state of cyt a,a_3, tissue oxygen tension and K^+ o were monitored continuously in male and female Wistar rats made ischemic by coagulation of the vertebral arteries and subsequent occlusion of the carotid arteries. Cyt a,a_3 was monitored by dual wavelength spectrophotometry while tissue oxygen tension and extracellular potassium ion activity were monitored respectively with oxygen and potassium sensitive microelectrodes.

Carotid ligation resulted in decreased brain oxygen tension, reduction of cyt a,a_3, elevation of K^+ o from 2-4 mM to 6-8 mM and ECoG silence. During this period, cyt a,a_3 reached a plateau and in many cases then became transiently oxidized. This period often was characterized by partial reoxygenation of the brain. K^+ o eventually underwent rapid elevation to levels in excess of 50 mM. This rise in K^+ o was accompanied by further reduction of cyt a,a_3. Release of the carotid clamps resulted in rapid re-oxygenation of the brain, re-oxidation of cyt a,a_3, a later return of K^+ o to control levels and sometime thereafter a resumption of EcoG activity. Recovery was dependent upon the duration of cerebral ischemia which was varied from 5 to 30 min.

The multiphasic changes in cyt a,a_3, tissue oxygen tension, K^+ o and ECoG during initial phases of ischemia may reflect attempted compensation in brain to overcome the imbalance between energy production and energy utilization when blood flow is limited. Such conpensation, reflected by slowed reduction or partial re-oxidation of cyt a,a_3, may reflect partial tissue re-oxygenation, decreased energy utilization reflected by ECoG depression, and/or limitation of substrate availability. 254.4 MICROREGIONAL PO_2 AND ACTION POTENTIAL MEASUREMENT IN THE GERBIL CORTEX. R.M. Martin and J.H. Halsey. Dept. of Neurology and the Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

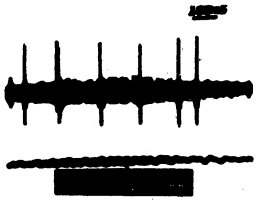
Simultaneous PO_2 and action potential recordings were made from a recessed oxygen microelectrode (tip diameter = 1 μM, current = 10^{-11} amp) utilizing a feedback current amplifier that maintained a constant polarization voltage (see Kunke et al., J. Appl. Physiol., 32:436, 1972). This capacity afforded an opportunity to analyze the spike frequency for selected neuron populations within the gerbil cerebral cortex during normoxia and hypoxia (nitrogen breathing) to observe the disappearance of spikes with falling PO_2 and reappearance upon reoxygenation. We observed a number of responses to this brief hypoxic insult ranging from total recovery with no apparent permanent effects to a massive discharge of spikes followed by no recovery of activity. This technique was used to approach a basic question. Namely, can it be demonstrated that as a group neurons normally exposed to a high resting PO_2 lose function sooner and/or regain it later than neurons which exist at much lower PO_2. If this selective vulnerability can be shown, further experiments are planned to attempt to determine if this vulnerability derives from a higher oxygen demand. Supported in part by NS 08802 and NS 07123.



254.5 CEREBRAL OXYGENATION DURING RECURRENT SEIZURES: ROLE OF CHANGES IN ARTERIAL PO_2. N. Kreisman, H. Follis*, A. Light*, M. Rosenthal, J. LaManna and T. Sick. Dept. of Physiol., Tulane U. Sch. Med., New Orleans, LA 70112 and Depts. of Neurology and Physiol. Biophys., U. of Miami Sch. Med., Miami, FL 33101.

Changes in systemic physiology secondary to recurrent seizures can have profound effects on cerebral O_2 supply and may be involved in the development of neuronal damage following status epilepticus. We have reported that initial seizures in a series elicited in rats with pentylenetetrazol (PTZ) were accompanied by increases in cerebral PO_2 and oxidation of cytochrome a,a_3 (cerebral O_2 sufficiency). Subsequent seizures, however, were accompanied by decreases in cerebral PO_2 and shifts of cytochrome a,a_3 toward reduction (cerebral O_2 insufficiency) (Kreisman et al, Brain Res., in press). This transition was accompanied by failure of arterial blood pressure (aBP) or cerebral blood volume (cBV) to increase or by hypotension, separately or in combination, in association with succeeding seizures. In some cases, prolonged increases in aBP occurred immediately preceding transition.

Two hypotheses were tested in the present study. First, that cerebral O_2 insufficiency during later seizures may be the result of decreases in arterial PO_2 (PaO_2). Second, that increasing the fraction of inspired O_2 (FiO_2) can prevent the transition from occurring.

Rats were anesthetized, paralyzed and artificially ventilated with 30% O_2/70% N_2. Measurements were made of cerebral PO_2, cytochrome a,a_3 redox levels and cBV from cerebral cortex during PTZ or bicuculline seizures. Decreases in mean PaO_2 from 124.8± 9.6 to 60.5±5.0 occurred in association with the prolonged increases in aBP. This hypoxemia was accompanied by a decrease in cerebral PO_2, reduction of cytochrome a,a_3 and an increase in cBV. Respiring other rats continuously with increased FiO_2 delayed, but did not prevent, the onset of transition. Raising FiO_2 from 30% to 100% after transition temporarily reversed seizure-induced cerebral PO_2 decreases and cytochrome a,a_3 reductive shifts back to the normal cerebral PO_2 increases and cytochrome a,a_3 oxidative shifts observed prior to transition. Conversely, transition could be precipitated on occasion by lowering FiO_2 from 30% to 21%.

The results indicate that systemic hypoxemia is one potential factor causing cerebral O_2 insufficiency during recurrent seizures. They suggest also that increasing FiO_2 may have some benefit in temporarily ameliorating this cerebral O_2 insufficiency.

254.6 DIRECT ELECTRICAL STIMULATION OF THE CEREBRAL CORTEX SUGGESTS THAT VASCULAR AS WELL AS METABOLIC FACTORS DETERMINE THE OXIDATIVE RESPONSE. R.B. Duckrow, J.C. LaManna and M. Rosenthal. Department of Neurology, University of Miami School of Medicine, Miami, Fl. 33101.

Direct electrical stimulation of the cerebral cortex produces an increase in extracellular potassium activity and transient oxidations of all respiratory enzymes, including cytochrome a,a_3. The magnitude of these transient oxidations is proportional to the magnitude of the potassium increase and the corresponding shift of the cortical steady potential (SP shift). To test the hypothesis that vascular mechanisms might play a role in the response of cytochrome a,a_3 to increases in cortical "work" induced by direct stimulation, the amplitude of the transient oxidative response of cytochrome a,a_3 was measured by dual-wavelength spectrophotometry after electrical stimulation delivered at various pulse widths and frequencies. Male Wistar rats were anesthetized with pentobarbital, paralyzed with curare, and mechanically respired. Arterial blood pressure, arterial blood gas tensions, arterial pH, and rectal temperature were monitored and maintained within normal limits. After left parietal craniectomy, the intact dura in the center of the optical field was stimulated by a bipolar stainless steel electrode with 0.5 mm tip separation. Monophasic square wave pulses were delivered in stimulus trains of 2 sec duration. Pulse width was varied from 0.05 to 5 msec and pulse frequency varied from 3 to 300 Hz. The evoked SP shift was measured with a single Ag-AgCl wire 1 mm from the stimulating electrodes with an indifferent reference. Stimulus voltage was varied to obtain a range of SP shifts not greater than 4 mV. The slope of the linear relation between the magnitude of the SP shift and the evoked cytochrome a,a_3 oxidation was used as an index of cytochrome a,a_3 oxidation for a constant metabolic demand. The amplitude of the transient oxidation of cytochrome a,a_3 for a given SP shift was maximal for a pulse duration of 0.5 msec and a stimulus frequency of 50 Hz. The myogenic and neurogenic components of vascular responses to direct stimulation vary with stimulus pulse width, frequency, and duration. If the cytochrome response were solely determined by the metabolic demand imposed by increased extracellular potassium, one would expect invariance of the slope of this response over the range of stimuli presented. The variance observed in this study suggests that there is a vascular contribution to the transient oxidative response of cytochrome a,a_3 to direct cortical stimulation, and that there may be a relative surplus of oxygen supplied to cortex under the "active" condition imposed by this stimulation. (Supported by NIH NS14325, NS14319, NS00399 and the AHA of Greater Miami.)

254.7 CALCIUM-DEPENDENT INCREASE IN AXONAL ATP DURING REPETITIVE ACTION POTENTIAL DISCHARGE. D.O. Smith and C.T. Gibson* Department of Physiology, University of Wisconsin, Madison, WI 53706.

Levels of ATP were measured in the terminal region of the excitor axon innervating the opener muscle of the crayfish walking leg. In each experiment, about 16 preparations were placed in a well-oxygenated physiologic saline at 23°C. In half of the preparations, the axon was stimulated at 50 impulses/s while the other half served as unstimulated bath controls. The tissue was quickly frozen in liquid nitrogen and then lyophilized at ≤ -80°C to prevent hydrolysis of ATP. Axon collaterals, weighing less than 1.0 µg dry weight, were dissected free and subsequently assayed for ATP content using the luciferin-luciferase method.

Following 1 min of stimulation, the average (± S.E.; n=8) ATP content rose from 10.7 ± 0.7 nmol/mg dry wt to 21.8 ± 1.3 nmol/mg dry wt. This increase is significant at the 0.05 level. Smaller increases in ATP levels were observed following longer stimulation times. After ≥ 10 min of stimulation, the ATP levels were not significantly higher than in the bath controls.

The increase in ATP was directly related to the concentration of extracellular Ca^{2+}. When $[Ca^{2+}]_e$ was raised to 40 mM (3x normal), ATP levels increased to 32.4 nmol/mg dry wt following 1 min of stimulation at 50 impulses/s; this is 2.5 times the amount of ATP in the corresponding bath controls. However, when $[Ca^{2+}]_e$ was 0.01 mM, there was no change in ATP level following stimulation. Addition of 10 mM $CoCl_2$, which blocks Ca^{2+} currents in this preparation, also prevented a rise in ATP.

It is doubtful that the increased ATP is due entirely to enhanced mitochondrial activity. ATP was still found to increase during stimulation in the presence of 10^{-4}M atractyloside, which should block the transport of ATP to the cytosol via the ATP-ADP antiport system. In related experiments, addition of ruthenium red (10 µM) led to an increase of ATP levels to 15.5 ± 1.5 and 13.9 ± 3.6 nmol/mg dry wt in the stimulated and the nonstimulated tissue, respectively. After incubating the tissue in the Ca^{2+} ionophore A23187 (50 µg/ml), the ATP level dropped from 11.1 ± 1.7 to 8.9 ± 1.3 nmol/mg dry wt in the nonstimulated and the stimulated axons, respectively. The Ca^{2+}-dependent rise in ATP may be due to a change in intracellular pH during action potential activity which causes a shift in the arginine kinase reaction $ArgP + ADP + H^+ \rightleftharpoons ATP + Arg$.

Supported by NIH grants NS13600 and NS00380 and the Alfred P. Sloan Foundation.

254.8 THE EFFECT OF ACUTE OR REPEATED ADMINISTRATION OF DESMETHYLIMIPRAMINE ON THE REGIONAL CEREBRAL METABOLIC RATE OF GLUCOSE. J.C. Gerber, III, J. Choki*, M. Reivich and D.J. Brunswick*. Depts. of Psychiatry and Neurology, University of Pennsylvania, School of Medicine, and V.A. Hospital, Philadelphia, Pa. 19104.

It has become clear that the acute pharmacological effects of tricyclic antidepressants (TCA's) can be very different from the effects they produce after repeated administration. To determine whether differences in the functional activity of brain neurons occur after the administration TCA's we treated rats with desmethylimipramine (DMI) either acutely (10mg/kg, 1 hour before experiment) or repeatedly (10mg/kg twice a day for 7 days) and measured glucose utilization in 30 regions of rat brain with the quantitative ^{14}C 2-deoxyglucose technique. This technique is a potentially powerful method for studying the effects of centrally acting drugs in vivo and since little is established on the mechanism of antidepressant action of TCA's this method was applied to determine the effect of these drugs on local cerebral energy metabolism.

Neither an acute dose nor repeated administration of DMI had a statistically significant effect on the metabolic rate of glucose in any of the 30 brain regions studied. These findings indicate that a single dose or 7 days of dosing with DMI may not result in a significant functional alteration in basal CNS activity in rats. Administration of DMI for longer than 7 days may be necessary to achieve significant changes in glucose utilization. Alternatively, use of the ^3H 2-deoxyglucose technique, which would enable changes in glucose utilization on a cellular level to be measured, may shed more light on this matter. (Supported by funds from MH-14654 and NS-10939-09)

254.9 BEHAVIORAL CONTROL OF ERYTHROCYTE GLYCOLYSIS. R. Jevning*. Dept. of Medicine, Univ. of Calif., Irvine, Irvine, CA. 92717.

Several behavioral states, including states of stress and anxiety, have been correlated with altered blood lactate concentrations; however, the underlying cause of the blood lactate changes is little understood. The mental technique known as "Transcendental Meditation" (TM) is associated with acute decline (within 30 minutes) of blood lactate concentrations, and therefore can serve as an ideal behavioral tool for in depth investigation of the changes in metabolism underlying a behavioral state and in particular of the mechanism and cellular origin of the noted change of blood lactate metabolism.

We now report rapid decline of erythrocyte metabolism during TM. Blood samples were drawn every 15 minutes during 45 minutes of this behavior and for 30 minutes after cessation of practice in 25 normal adults who had been regularly eliciting this state twice daily for at least 7 years.

Blood samples were incubated at 37 and 25 and rate of lactate generation measured. Subsequent measurement was made of rate of glycolysis in blood samples from which white cells were removed. Both sets showed rapid decrease (30%) of glycolytic rate in the samples drawn during the practice period. Therefore, since blood plasma has no glycolytic capacity, the decline of blood glycolytic rate is attributed to erythrocytes.

Since concomitant measurement of blood pH, pCO_2, pO_2, and hematocrit showed no change of these parameters, the effect is not an epiphenomenon of respiratory changes.

This acute effect of behavior on red cell glycolysis constitutes a unique and possibly important finding for many fields of research in behavior, since this cell is believed to typify the membrane, the metabolism and the metabolic control of more advanced tissue such as nerve and muscle. Also the factor(s) responsible may affect metabolism in general since oxygen delivery to tissues is affected by status of red blood cell metabolism.

254.10 BINDING AND RELEASE OF ZINC IN HOMOGENATES AND SLICES OF RAT HIPPOCAMPUS. N.F. Harris and I.L. Crawford. Depts. of Pharmacology and Neurology, UTHSCD and VAMC, Dallas, Texas.

The high concentration of zinc (Zn) in the hippocampus relative to other brain regions may be attributed in part to the presence of the metal in mossy fiber terminals. Zinc in the paleocortex is present in several compartments: free ions, and bound with varying affinities to protein and metalloenzymes. Some of this Zn may be available for release in response to certain stimuli. A series of experiments were designed to determine the extent of binding and release of Zn in the hippocampus. Flame atomic absorption (AA) was used to assay Zn. Although flameless AA is more sensitive and requires a smaller sample, the technique was more variable and gave erroneous absolute values.

For determination of relative quantities of free and bound Zn, whole hippocampi were dissected from brains after decapitation. Homogenates of tissue (10% w/v) were made in deionized double-distilled water buffered to pH 7.4 with sodium bicarbonate. Samples were spun at 7000 x g and filtered through regenerated cellulose membranes with 0.2 µm pores. The final supernatant not retained by the membrane contained 48% of total Zn. Zinc concentrations measured in homogenates dialyzed (molecular wt. cutoff was 12,000 daltons) 18 hrs against "Zn-free" artificial cerebrospinal fluid (CSF) showed only a 16% decline from initial homogenate values (17.1 $\pm$ 1.2 µg/g wet wt. $\pm$ SEM).

In another set of experiments slices of hippocampus (500 µm) were depolarized with potassium (K) in artificial CSF. No significant changes of endogenous Zn were noted between fresh slices (18.5 $\pm$ 0.7), and those incubated in 6 mM K (17.8 $\pm$ 1.6) and 60 mM K (16.5 $\pm$ 0.8). Problems in reporting values in brain slices on a wet wt. basis may be due to tissue swelling. Values for Zn in hippocampus varied depending on the basis used to express concentration. A comparison of slice wts. gave the following results: dry wt. = 12% of wet wt; ashed wt. = 8% of wet wt.

Binding studies suggest Zn exists in several pools: chelated or structurally bound to large molecules; associated with smaller molecules or colloids which can pass through membrane pores, but are not dialyzable; and freely dialyzable Zn. In slices, release of a free fraction of endogenous Zn was not detectable by AA methods.

254.11 THE EFFECT OF ANDROGEN RECEPTORS AND ITS INTERACTION WITH HEAVY METALS ON THE METABOLISM OF MOTOR NEURONS IN TISSUE CULTURE. R.C. Yu, and B.G.W. Arnason. Department of Neurology and Brain Research Institute, University of Chicago, Chicago, Ill. 60637.

Androgen is preferentially taken up by motor neurons both those of the cranial nerves and those of the spinal cord. Little androgen is found in the nuclei of sensory nerves. Sensory neurons have been demonstrated to take up estrogen predominantly (Biochem 7:1163). The topographic distribution of androgen receptors in motor neurons differs between regions and coincides with those neurons involved or spared in patients with amyotrophic lateral sclerosis(ALS)(Ann.Neurol. 4:245). Notable in this regard is the fact that motor neurons of the III,IV,VI and X cranial nerves takes up little androgen and are spared in ALS. The pathological finding of Bunina body inclusions in the Perikarya of motor neurons is consistent with a disorder in protein metabolism in ALS. Epidemiological data has suggested that heavy metals may be associated with the development of motor neuron disease, although the point is controversial.

We used organotypic cultures developed from 14-day-old rat embryonic spinal cord to examine the role of androgen receptors and heavy metals in relation to motor neuron metabolism as reflected by the enzymatic activity of choline acetyltranferase (CAT). Heavy metals Zn^{++}, Hg^{++}, Pb^{++} dissolved in water and cyproterone(α-MPD), a potent anti-androgen-receptor drug in ethanol as supplements to regular tissue culture medium at final concentrations of 10^{-5}M. Water or ethanol alone was added in medium for control. Selected well developed spinal cord cultures were incubated with one of these media for one week before being homogenized and assayed blind for CAT activity. Cultures incubated with Hg^{++} showed an effect of general toxicity as reflected by a substantial reduction of total protein content below the level of the control group. In each of the experimental groups, CAT was calculated based on the total amount of protein measured (CPM/mg). There was a significant decrease of CAT activity both in cultures treated with α-MPD ($P<0.05$) and with lead ($P<0.01$) as compared with the controls. Zinc in contrast had no effect.

Certain bivalent metals are known to alter the androgen receptor complex and prevent it from entering into the nucleus. These results lead us to conclude that intrinsic androgen receptors may play an important role in regulating cellular metabolism which dictates motor neuron survival.

Supported by a grant from the Amyotrophic Lateral Sclerosis Society of America.

254.12 KINETIC CONSTANTS OF BLOOD-BRAIN BARRIER NEUTRAL AMINO ACID TRANSPORT: COMPARISON OF NEWBORN RABBIT AND ADULT RAT. L.J. Mietus* and W.M. Pardridge (SPON: A. Yuwiler). UCLA School of Medicine, Los Angeles, CA 90024.

Amino acid availability in brain regulates a number of pathways of cerebral amino acid metabolism (Fernstrom and Wurtman, 1977). Amino acid supply in brain is a function of (i) plasma amino acid levels and (ii) the K_m, V_{max}, and K_D of blood-brain barrier (BBB) transport. The newborn period is associated with a level of plasma aminoacidemia that would nearly fully saturate the neutral amino acid carrier in the adult rat. Therefore, the present studies were designed to determine the kinetics of neutral amino acid transport through the BBB of the newborn rabbit using a nonlinear regression analysis of brain uptake index (BUI) data obtained with the carotid injection technique.

Amino acid	K_m (mM)		V_m (nmol $min^{-1}g^{-1}$)		K_D (ml $min^{-1}g^{-1}$)	
	Rat	Rab	Rat	Rab	Rat	Rab
Phenylalanine	0.12±0.02	0.41±0.15	36± 7	101±53	0.015	0.027
Leucine	0.12±0.01	0.41±0.06	30± 3	56±13	0.019	0.032
Tyrosine	0.15±0.01	0.52±0.13	42± 5	64±25	0.016	0.050
Tryptophan	0.19±0.01	0.52±0.08	35± 3	75±19	0.002	0.019
Isoleucine	0.29±0.05	0.69±0.21	53±12	70±30	0.005	0.042
Methionine	0.20±0.08	0.93±0.42	31±15	94±58	0.022	0.031
Histidine	0.27±0.03	1.43±0.07	37± 6	101±18	0.011	0.040
Valine	0.54±0.06	1.29±0.33	40± 6	96±36	0.003	0.016

A 67% solution of newborn rabbit serum resulted in a 45% inhibition of tryptophan transport, and bound 43 $\pm$ 3% of serum tryptophan in vitro at 37°C. However, dialyzed newborn rabbit serum or commercial defatted bovine albumin, which actively bound tryptophan in vitro with a dissociation constant (K_D) of 138 $\pm$ 7 µM, exerted no inhibition of tryptophan transport in vivo. The extraction of alanine, 16 $\pm$ 1%, and glutamine, 19 $\pm$ 2%, by the newborn rabbit brain was higher than the adult rat. However, alanine or glutamine transport was not inhibited by 25 mM N-methylaminoisobutyric acid, a model amino acid specific for the alanine preferring or A-system. Conclusions: (i) K_m and V_{max} values obtained for the adult rat with a nonlinear regression analysis are not statistically different from our previously reported values obtained with a linear transformation. (ii) Newborn BBB transport of amino acids is characterized by a lower affinity and higher capacity relative to the adult rat and this change in the newborn accomodates the hyperaminoacidemia of the neonatal period. (iii) Albumin of newborn rabbit serum binds tryptophan in vitro, but exerts no inhibition of tryptophan transport in vivo, owing to the high capacity of tryptophan binding by the brain capillary neutral amino acid carrier.

254.13 A METHOD FOR THE MEASUREMENT OF LOCAL BRAIN PROTEIN SYNTHESIS.
B. E. Dwyer*, P. Donatoni* and C. G. Wasterlain* (SPON: R. Nishimura). Epilepsy Research Laboratory, V.A.M.C. Sepulveda, CA 91343 and the Department of Neurology and the Brain Research Institute, UCLA, Los Angeles, CA.

We have developed a method for measuring local brain protein synthesis. It combines the intraperitoneal injection of a large amount of L-(1-^{14}C) amino acid of low specific activity (Dunlop et al. J. Neurochem., 24:337, 1975)and the use of an internal standard with quantitative autoradiography. Four day old rats were injected with L-(1-^{14}C)valine (150mM) (10μmole/g; 0.5μCi/μmole)and were decapitated at varying time intervals up to two hours. Some brains were frozen in cryo-embedding media, cut into 20μm sections and exposed with ^{14}C standards to single layer X-ray film for autoradiography. In some animals,one half the forebrain was acid precipitated and delipidated and the rate of valine incorporation into protein was measured directly. The other half forebrain was mechanically dispersed to form a homogeneous brain "mix". The "mix" was frozen, cut in 20 μm sections and used for autoradiography. Film darkening was related to the rate of ^{14}C-valine incorporation measured directly in the other half of the same brain. Stable ^{14}C standards were calibrated with the brain "mix" and included with every exposure. Film darkening in various brain regions was related to rates of amino acid incorporation via the standard brain "mix" curve. Rates of protein synthesis (% per hour) can be calculated for individual brain regions if two other parameters are known: 1) a factor relating the regional protein concentration to that of the brain "mix" standard and 2) the regional valine content of the acid precipitated and delipidated protein extract. Both must be calculated for each experimental condition. Smith et al. (Trans. Amer. Soc. Neurochem., 11:94, 1980) described a method for measuring local brain protein synthesis in adult rat after i.v. injection of L-(1-^{14}C) leucine. Our method avoids the stress of surgery and anesthesia. It is advantages for small animals where arterial and venous catheterization is impractical and in behavioral experiments where immobilization is undesireable. Since flooding amounts of amino acid are used, the problem of estimating the specific activity of the precursor pool under pathological conditions is minimised. The use of an internal standard should correct for problems such as self absorption of radiation, which could vary in pathological tissue.

This work was supported by grant # 13515 from NINCDS and by the research service of the Veterans Administration.

255.1 THE CORTICAL LOCALIZATION AND CHARACTERIZATION OF SEROTONERGIC FIBERS IN THE PRIMATE BRAIN. E.C.Azmitia, P.J.Gannon*, C.Clewans*, Dept. of Anatomy, Mt.Sinai Sch. of Med., N.Y., N.Y. 10029.

Serotonergic fibers were reported to be uniformly distributed in the cortex of humans and monkeys. However, boutons labeled by high-affinity reuptake of ^{3}H-5HT shows a varied cortical distribution.

The brains of Macaca fascicularis(2.5-3Kgm female) were quickly removed for analysis. These were prepared either for synaptosomal uptake measurements of radioautographic localization of ^{3}H-5HT uptake into slices (Azmitia & Marovitz, J.Histochem Cytochem, 28:636, 1980). Kinetic studies showed that subcortical and cortical regions had similar uptake mechanisms (Km 1.5x10^{-7}M; (^{3}H-5HT)=0.15-2.00x10^{-7}M, NEN). Comparisons between regions were made at 5x10^{-8}M ^{3}H-5HT. The dorsal raphe (650 pmole/gm/8 min), Amygdala (445±125, n=5), Hypothalamus (470±131, n=4) were among the highest, and the lateral thalamus (142±12, n=3), and the lateral geniculate (82±36, n=3) among the lowest in uptake. The cortical distribution was highest in temporal lobe and lowest in the frontal lobe. The highest uptake occurred in the Sup and Inf Ctx (342±65, n=4; 373±107, n=40, Enthorhinal Ctx (360±95, n=4) and the calcarine Ctx (224±5, n=2) while the sup frontal ctx (165±3, n=2), nonstriate occipital ctx (103±50, n=4) and Precentral ctx (98±36, n=4) were the lowest. The uptake in the hippocampus (214±75, n=7) was highest in the dentate gyrus (288±107, n=4) and lowest in the CA fields (119±48, n=7). Studies to measure the distribution of tryptophan hydroxylase activity are now in progress.

Radioautography showed a dense accumulation of silver grains at high-affinity uptake sites. These were identified as neuronal boutons at the EM level. The density in subcortical areas paralleled the uptake measurements, and the pattern was strikingly similar to that seen in subprimates. In the cortex these sites were seen in all layers, but were usually heaviest in layer IV. In cingulate cortex a heavy band was seen in layer V and in the calcarine cortex the sites occurred in the upper part of layer IV. These findings suggest the serotonergic fibers may have a special relationship with granule cells.

255.2 THE ONTOGENY OF CENTRAL SEROTONERGIC SYSTEMS IN THE CHICK EMBRYO: AN IMMUNOCYTOCHEMICAL STUDY. J.A. Wallace, M.T. Libber* and J.M. Lauder. Department of Anatomy, Univ. of North Carolina, School of Medicine, Chapel Hill, NC, 27514.

Although mammalian species have frequently been used in morphological studies of monoaminergic neuronal development in the central nervous system, no previous reports have dealt with the ontogeny of monoamine containing neuronal systems in the chick embryo. Because of the advantages of using the chick embryo as an experimental model for developmental studies, we have begun an investigation of the initial phases of the embryogenesis of central serotonergic systems in this species, employing immunocytochemical techniques. Antibodies against serotonin (5-HT) have been used to detect 5-HT -containing cells in serially sectioned paraffin-embedded material utilizing the peroxidase anti-peroxidase staining method. Preliminary results have been obtained from embryos taken at 3,4,5,7 and 9 days of incubation.

Small bilateral groups of 5-HT -containing cells were first observed at the mesencephalic-metencephalic border on day 4 (E4). These lightly stained cells were located adjacent to the floor plate of the neural tube, at the outer boundary of the ventricular zone and contained little if any staining in neuronal processes. By E5, however, a marked increase was observed not only in the number of cells stained, but also in the elaboration and projection of their processes. Large continuous groups of cells were found caudally from the rostral border of the metencephalon extending through myelencephalic regions into the upper cervical spinal cord. Migration and reaggregation of various components of the serotonergic system were already apparent at E5, as well as extensive ascending and descending fiber bundles. Large, intensely stained processes were observed entering the diencephalon at E5, which became more numerous and highly branched throughout the diencephalon at E7, and penetrated ventral portions of the telencephalon by E9.

One especially significant finding was the observation of a small group of cells situated bilaterally in the posterior wall of the presumptive hypothalamus, which appeared to transiently stain for 5-HT, beginning on E5, but could no longer be detected on E7 or E9, although this region was heavily innervated by 5-HT axons at these ages.

These initial studies form the basis for an extensive ontogenic analysis of the serotonergic systems in the chick embryo.

255.3 IMMUNOCYTOCHEMICAL LOCALIZATION OF SEROTONIN CONTAINING CELL BODIES AND FIBERS IN THE RAT HYPOTHALAMUS. M.Frankfurt*, J.M.Lauder, V.G.Daniels*, E.C. Azmitia, Dept.of Anatomy, Mt.Sinai Sch.Med.NY, NY 10029.

The serotonergic innervation of the rat hypothalamus has been studied by radioautographic, biochemical and immunocytochemical techniques. In this report the rat hypothalamus was studied using a specific antiserum to serotonin. Sections of hypothalamus (50um) were cut on a vibratome and incubated with serotonin antiserum (1/2000) or serotonin antiserum preabsorbed with 10^{-3}M serotonin (18h at 4 C). After incubation with the primary antiserum sections were processed by an immunoperoxidase technique.

Moderate to heavy staining of fibers was seen throughout the entire hypothalamus. In normal, pargyline (200mg/Kg) pretreated and pargyline (200mg/Kg) and L-tryptophan (200mg/Kg) pretreated rats the heaviest staining of fibers was seen in the lateral hypothalamus, the suprachiasmatic nucleus and the periventricular areas. Fibers were seen in the median eminence in both the inner and outer layers, however no labelling of tanycytes was observed. In rats that had received colchicine pretreatment (50 or 100ug) fibers were seen in the arcuate, dorsomedial and ventromedial area.

In addition to the fiber staining a group of neuronal cell bodies immunostained for serotonin in the dorsomedial hypothalamus of rats pretreated with both pargyline and L-tryptophan. These cells were located adjacent to the third ventricle, primarily in the dorsomedial nucleus. The cells measured approximately 9um and extended over a rostro-caudal distance of 900um. No serotonin containing cell bodies were detected in any other areas of the hypothalamus.

These cells corresponded to those described by (Beaudet and Descarries, Brain Research, 160:231-243, 1979). Studies involving lesions of the dorsomedial hypothalamus with 5,7 dihydroxytryptamine, are currently in progress to further establish whether these cells constitute an additional serotonergic cell group, B-10. 255.4 THE RAPHE NUCLEI OF THE RAT BRAIN STEM, A COMBINED CYTOARCHITECTONIC AND IMMUNOHISTOCHEMICAL STUDY. H.W.M. Steinbusch and R. Nieuwenhuys[x], Dept. of Anatomy and Embryology, Univ. of Nijmegen, Nijmegen, The Netherlands.

Specific antibodies to serotonin(5-HT) were applied to visualize immunohistochemically cell bodies with their dendrites in 50 and 100 µm thick vibratome sections of the rat brain. The aim of this study was to elucidate the localization of 5-HT immunoreactive neurons within and beyond the raphe nuclei. To this end 1) the seven raphe nuclei were subjected to a detailed cytoarchitectonic analysis, 2) the 5-HT positive cell bodies present in the brain stem were plotted and 3) the dendritic pattern of the 5-HT containing neurons were investigated. The cytoarchitectonic analysis was based on a) counterstaining the 50 µm thick vibratome sections mentioned above with cresyl violet to delineate each raphe nucleus and b) Nissl- or Klüver-Barrera stained paraffin material to analyse the cell types. This survey revealed that within the confines of each raphe nucleus two to four cell types are present: small, medium, large and very large. No specific cytoarchitectonic similarities were found among the various raphe nuclei. Cells in all of the four categories may contain 5-HT, but most of the serotoninergic elements belong to the categories medium-sized and large. The cell-type small, present in the four rhombencephalic raphe nuclei, did not contain serotonin. The category very large was only present in the nucleus raphe dorsalis. The investigation of the dendritic pattern of the 5-HT positive neurons showed that they have in general three to five dendrites with relatively few branches. The length and orientation of these processes vary among the different nuclei. The 5-HT immunoreactive cells are not equally distributed within the raphe nuclei and moreover, they form, except for the nucleus raphe dorsalis, only a minority of the total cell population in these centers. Studies in our own and in other laboratories have revealed that in the raphe nuclei, apart from serotoninergic cells, elements containing eight other neuroactive principles occur (see table, in which our own results are indicated with an x).

255.5 SEROTONIN AND THE ULTRASTRUCTURAL ORGANIZATION OF THE RAPHE NUCLEI IN THE MONKEY: AN IMMUNOHISTOCHEMICAL STUDY. N. C. de Lanerolle, S. Kapadia* and C. LaMotte, Sections of Neurosurgery, Neuroanatomy and Gross Anatomy, Yale Univ. Sch. of Med. New Haven, CT 06510.

The distribution of serotonin in the brainstem of Macaca fascicularis was examined with an antibody to a 5HT-BSA conjugate, and the indirect antibody peroxidase-antiperoxidase method of Sternberger. Perikarya with serotonin-like immunoreactivity were located in the nuclei raphe dorsalis, centralis superior, raphe magnus, pallidus and obscurus, the lateral reticular formation, and the lateral reticular nucleus. Electron microscopic examination of the nu. centralis superior and raphe magnus areas revealed the presence of large, medium and small neuronal perikarya, and a neuropil exhibiting a variety of synaptic formations. The immunoreactive perikarya were of medium size (15-30 microns). They are characterized by spherical or oval shaped cell-bodies, which are devoid of somatic spines. They contain a spherical and indented nucleus, and the cytoplasm has a variety of organells. The rough, granular endoplasmic reticulum appears as clumps and laminar stacks. Within the area were also immunoreactive terminal like profiles of two types-- those containing dense-core vesicles in addition to small round vesicles, and those having only small round vesicles. They formed predominantly asymmetrical type junctions. The immunoreactive terminals formed junctions onto both immunoreactive soma and dendrites, as well as onto the soma of small unlabelled perikarya and unlabelled dendrites of a variety of sizes. Unlabelled terminal profiles (those containing dense core vesicles, and those with round agranular vesicles alone) also formed junctions with immunoreactive soma and dendrites. Occasionally, small unlabelled cells formed junctions onto immunoreactive soma, and immunoreactive terminals formed junctions with unlabelled terminals. Glial cells in close aposition to immunoreactive soma were also observed. Further, immunoreactive myelinated axons were seen within the neuropil of these areas.

The observed ultrastructural features of serotonin containing processes provides the probable morphological basis for physiological observations such as autoregulatory modulation of serotonin neurons, correlative firing of serotonin and non-serotonin neurons, and short latency activation of spinal neurons upon raphe stimulation. (Supported by NIH grant NS13335)

255.6 COLLATERALIZATION OF SINGLE NORADRENERGIC NEURONS TO CEREBRAL CORTEX AND SPINAL CORD. K.N. Westlund, R.M. Bowker*, M.G. Ziegler, and J.D. Coulter. Depts. Psychiat. and Physiol. and Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX. 77550, and Dept. of Medicine, Univ. of California Med. Center, San Diego, CA. 92103.

Individual neurons in the nucleus locus coeruleus have been suggested by a number of studies to have divergent axons which project to two or more different regions of the brain. Until only recently, suitable techniques were not available for demonstrating simultaneously both the collateralizations and chemical identification of neurons in the brain. In this study cells have been labeled from cerebral cortex and spinal cord utilizing retrograde axonal transport techniques and immunocytochemistry with an antibody to dopamine-β-hydroxylase (DβH). In anesthetized rats, HRP was injected into the cortex while antiserum to DβH was injected into the spinal cord. While both HRP and DβH antiserum are known to be retrogradely transported to the cell body, the DβH antiserum is specifically taken up and retrogradely transported by noradrenergic neurons (Silver and Jacobowitz, Brain Res., 1979). Following a 24-48 hour survival period, animals were routinely perfused with 3.8% paraformaldehyde. Frozen tissue sections were first reacted for the retrogradely transported HRP using $CoCl_2$ and diaminobenzidine as the chromagen. The sections were then processed immunocytochemically using rabbit anti-goat IgG and goat peroxidase-antiperoxidase to visualize the cells of origins of spinally projecting noradrenergic neurons. Cells retrogradely labeled with HRP contained black punctate reaction product within a relatively clear to grey tinted cytoplasm. Neurons projecting to forebrain structures were located dorsally in the nucleus locus coeruleus. Locus coeruleus neurons specifically labeled with DβH antiserum from the spinal cord contained small brown granules against the light brown staining of the cytoplasm and proximal dendrites. Noradrenergic spinally projecting cells were located ventrally and caudally in the locus coeruleus in agreement with other studies. In addition to cells labeled with one or the other of the retrograde markers, a population of cells was identified which had black granules within a light brown stained cytoplasm, indicating that these cells contained both HRP and DβH immunoreactivity. Using this technique, it is possible to simultaneously visualize chemically specified, descending noradrenergic neurons and neurons projecting to other areas of the brain. We have also clearly demonstrated that single noradrenergic neurons collateralize and project to widely divergent areas of the brain and spinal cord.

255.7 THE ONTOGENY OF NE AND THALAMIC PROJECTIONS TO MURINE NEOCORTEX: A SPATIAL SUBSTRATE FOR SEQUENTIAL INNERVATION. Barry E. Kosofsky* and Mark E. Molliver. Depts. of Cell Biology & Anatomy and Neuroscience, J.H.U. Sch. of Med., Baltimore, Md. 21205.

Early in development, monoamine (MA) neurons in the brainstem project widely to the cerebral cortex; there are conflicting reports as to whether they exert a trophic influence upon the maturation of cortical circuitry. We have studied - in fetal mouse - the development of cortical MA afferents in order to characterize the early temporal and spatial relationships of these axons of brainstem origin with respect to other (e.g., thalamic) projections to cortex and to the cellular compartments of immature cortex which they reach. In the mouse telencephalon at E16, five zones constitute the full thickness of the pallium: (1) a proliferative zone nearest the ventricular surface; (2) a migratory intermediate zone that later becomes the subcortical white matter; (3) a subplate zone that is composed of the most mature neurons; (4) the cell dense cortical plate; (5) The molecular layer, a cell-sparse superficial zone.

Noradrenergic (NE) axons in fetal cortex were visualized by histofluorescence enhanced by intrauterine administration of timed fetuses with α-methyl-norepinephrine. Cerebra from littermates were prepared for Nissl and axon stains as well as for serotonin immunocytochemistry (in conjunction with H. Lidov). The NE axons establish an organized and characteristic pattern, well seen at E16: thin, varicose fibers form a tangentially continuous, bilaminar plexus above and below the cortical plate, most dense rostrally with more caudal sites displaying progressively decreased axon density. Fiber bundles reaching the ventral limit of the telencephalon were seen to divide and encase the developing cortical plate. Fluorescent axons, extending longitudinally through the marginal and subplate zones, are not visualized within the cortical plate or in the intermediate zone of the pallium. At these fetal stages, thalamo-cortical axons reach only as far as the intermediate zone, hence restricting their influence upon those most immature neurons migrating outward to the cortical plate. The early presence of brainstem fibers in the subplate zone along with relatively mature neurons, combined with the previous report that this zone is the major site of early cortical synaptogenesis (Kostovic & Molliver, Anat. Rec. 178 (1974) 395), suggest that MA-cortical interactions occur in this location. The spatial segregation of thalamic and MA axons to the intermediate and subplate zones, respectively, provides an anatomic substrate in the form of a spatial template for temporally sequential interaction of these afferents with cortical neurons. (Support NIH Grant NS08153 and GM07309).

255.8 DIFFERENTIAL REGULATION OF TYROSINE HYDROXYLASE IN INDIVIDUAL NORADRENERGIC AND DOPAMINERGIC NEURONS OF RAT BRAIN AS DEMONSTRATED BY COMPUTER ASSISTED QUANTITATIVE IMMUNOCYTOCHEMISTRY. R.H. Benno, L.W. Tucker*, T.H. Joh and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

We used a computer assisted quantitative immunocytochemical technique to examine at the cellular level the differential regulation of tyrosine hydroxylase (TH) in individual noradrenergic (NE) neurons of the locus ceruleus (LC) and dopaminergic (DA) neurons of the substantia nigra (SN). Three groups of six rats were studied. One received reserpine (10 mg/kg, 3d survival), a drug which increases the amount and activity of TH in LC but not SN homogenates by increasing accumulation of enzyme protein (induction) (JPET:193:775, 1975). A second received oxotremorine (dose 1.5 mg/kg), a cholinergic agonist which increases activity but not amount of TH in homogenates of LC but not in SN (JPET:200 :523,1977). The third group was untreated. Sagittal sections of 5u were taken through LC and SN and immunostained for TH using reaction conditions necessary to produce linearity of the staining intensity. Density was measured by a video based image analysis system and expressed as units of average optical density (A.O.D. x 10^{-3} ± SEM), a measure of concentration of TH per unit of tissue. Two regions of LC were examined: the central core with neurons with less TH than in the rim (including subceruleus). These were compared with neurons in SN. Cellular analysis was made at 40X; regional analysis (for neurons and neuropil) at 6.3X. The results of the cellular analysis of 1168 neurons are shown in the Table.

	LOCUS CERULEUS			SUBSTANTIA NIGRA		
	Core	Rim	Rim/Core	SN	SN/Core	SN/Rim
Control	108±9.4	140±7.3	1.30**	133±11.4	1.23*	0.95 NS
Oxotrem	111±9.0	137±8.7	1.23*	141±12.2	1.27*	1.03 NS
Ox/Cont	1.03 NS	0.98 NS	-	1.06 NS	-	-
Reserp	133±7.8	160±5.7	1.20**	132±9.4	0.99 NS	0.83**
Res/Cont	1.23*	1.17*	-	0.99 NS	-	-

*=P<.05 **=P<.01 NS= Not Significant

Reserpine but not oxotremorine increased TH for the entire LC 1.8 fold (P<.01). We conclude: (a) The amount of TH/neuron is similar in the LC rim and SN, thus some NE and DA neurons contain equal amounts of TH; (b) Oxotremorine fails to increase the immunoreactivity of TH; (c) Reserpine increases TH in all classes of LC neurons but not in any cells in the SN , the increase being primarily in neuropil. The close parallelism between the biochemical and cytochemical results demonstrates that quantitative cytochemistry can be used to detect changes in neurotransmitter enzyme protein at the cellular level.

255.9 LAMINAR AND REGIONAL DISTRIBUTION OF NOREPINEPHRINE FIBERS IN SQUIRREL MONKEY NEOCORTEX AS REVEALED BY IMMUNOHISTOCHEMISTRY. S. L. Foote, J. H. Morrison, F. E. Bloom and D. O'Connor*. Salk Institute and (*) UCSD School of Medicine, La Jolla, CA 92037.

The purpose of these studies was to analyze the laminar and regional distribution of norepinephrine(NE) fibers in primate neocortex and to determine the major intracortical trajectories utilized by these fibers as they extend into and permeate various cortical regions. We have utilized an antibody to human dopamine-beta-hydroxylase(DBH), visualized by peroxidase immunohistochemistry, to provide detailed, permanent, bright-field visualization of NE fibers in squirrel monkey neocortex.

Adult squirrel monkeys were perfused with cold phosphate buffer followed by cold 4% paraformaldehyde in phosphate buffer. The brain was then removed, cut into blocks, and post-fixed for 1.5 hours. The blocks were then placed in an 18% sucrose solution overnight. Sections were cut on either a cryostat or sliding microtome and incubated either freely floating or slide-mounted. The primary antibody was raised in rabbit and directed against DBH purified from human pheochromocytoma cells. Sections were incubated overnight in a 1:2000 solution of anti-DBH, washed, then incubated in peroxidase-conjugated goat anti-rabbit IgG and treated with diaminobenzidine in order to visualize the antibody complex.

The laminar pattern of NE cortical innervation in the squirrel monkey is similar to that described previously for the rat (Morrison, et al.,JCN,1978): NE fibers in layers I and VI are predominantly tangential to the cortical surface while fibers in layers II and III are typically radial. The pattern of NE innervation in layers IV and V is more heterogeneous, being characterized by: a) long tangential fibers, b) short, tortuous axon segments of diverse orientations, and c) occassional pericellular swirls. This laminar pattern was similar in several cytoarchitectonic regions. The effects of cortical and subcortical lesions on NE cortical innervation are being studied in order to determine the trajectories of NE fibers as they enter and distribute themselves over the cortical mantle. In preliminary experiments, aspiration lesions within the frontal lobe produced a dramatic reduction in the density of NE innervation in distant cortical regions caudal to the lesion. This result suggests that in primate, as in rat (Morrison,et al.,Neuroscience,1981), a large group of NE fibers enters the neocortex at the frontal pole and proceeds caudally through the deep layers of dorsolateral cortex. Supported by USPHS Grants NS 16209, AA 03504, and AA 07273.

255.10 PEPTIDE-MONOAMINE INTERACTIONS AT THE LEVEL OF BRAIN STEM CATECHOLAMINE GROUPS. J.R. Sladek, Jr. and J. Schöler*. Dept. Anatomy and Center for Brain Research, Univ. Rochester Sch. Med. & Dent., Rochester, NY 14642.

Brain stem catecholamine (CA) groups which comprise the ventral noradrenergic pathway contribute a dense innervation pattern to hypothalamic neurosecretory neurons of the paraventricular (PVN) and supraoptic (SON) nuclei. Simultaneous analysis of monoamine histofluorescence and peptide immunohistochemistry indicates that the noradrenergic innervation patterns favor vasopressin over oxytocin target neurons by about a 3.5:1 ratio in rat (Sladek et al., Peptides 1, supp.1:141, 1980); a similar pattern, although as yet unquantified, is seen in monkey. The PVN is known to be the site of origin of descending projections which reach caudal brain stem and spinal cord. Many of these fibers reach the A2 region of the medulla (Nilaver et al., Neuroendo.30: 150, 1980) which raises the possibility of a reciprocal-type innervation existing between vasopressin and/or oxytocin fibers and CA-containing perikarya. The present study addressed this concept in 3 month old, male Fischer 344 rats by the application of a combined histofluorescence-immunohistochemical approach. Analyses were made from sections which had been prepared for formaldehyde-induced fluorescence of monoamines. Tissue samples were freeze-dried, treated with formaldehyde vapor at 80°C, paraffin embedded, and serially sectioned. Catecholamine perikarya were identified in brain stem groups A1, A2, A5 and A7 with fluorescence microscopy. Adjacent sections were stained for rat neurophysin (courtesy of Alan Robinson) and were analyzed in concert with histofluorescence sections in a comparator bridge microscope. Neurophysin-positive fibers were found within each CA group; moreover neurophysin fibers were seen in apposition to several CA-containing perikarya in each group. This phenomenon was especially prominent in the A1 group of the lateral reticular formation wherein the intensely fluorescent, multipolar, CA neurons often appeared rimmed with neurophysin-positive fibers along their perikaryon and proximal dendrites. Pertinent to this is the recent observation (Sawchenko & Swanson, Anat. Rec. 199: 225A, 1981) that the A1 group contributes the main source of CA fibers to the PVN. Together, these findings suggest a possible morphological link between hormone-specific neurosecretory neurons of the hypothalamus and CA neurons of the brain stem which could serve as a reciprocal feedback circuit for the mediation and/or monitoring of neuroendocrine activity. Supported by USPHS Grants NS 15816 and AG 00847 to JRS.

256.1 INTERACTION BETWEEN SEROTONERGIC AND BETA ADRENERGIC RECEPTORS IN THE NICTITATING MEMBRANE OF THE CAT. E. Adler-Graschinsky * (SPON:
Inst. Invest. Farmacol., CONICET, Junín 956, 5º Piso, Buenos Aires 1113, ARGENTINA.

It has been proposed that presynaptic serotonergic and β-adrenergic receptors of the rat cerebral cortex participate, through a common site of action, in a positive feedback regulation of norepinephrine (NE) release by nerve stimulation (Adler-Graschinsky and Martínez, Adv. Biosci. 18: 299, 1979). The aim of this communication has been to study whether such interaction was also present at the level of the peripheral neuroeffector synapses.

In the experimental model selected, the isolated nictitating membrane of the cat, two consecutive frequency-response curves to nerve stimulation were applied. The frequency of stimulation that produced 50% of the maximal contractile response (EF 50), expressed as the log (100 x EF 50) was 2.15 ± 0.12 in the first and 2.01 ± 0.08 in the second control curve (n = 6).

The frequency-response curve to nerve stimulation was shifted to the left in the presence of 0.1 μM serotonin. The log (100 x EF 50) was 2.08 ± 0.07 for the first control curve and 1.82 ± 0.06, $p < 0.025$, for the second curve in the presence of serotonin . This displacement was prevented both by β-adrenoceptor antagonists (0.1 μM propranolol) and by serotonergic antagonists (0.1 μM methysergide, 0.1 μM pizotifen and 0.1 μM morphine).

The effect of serotonin is not likely to be related to changes in the sensitivity to the neurotransmitter released by the stimulation since it did not modify the concentration-response curve to exogenous NE (pD_2=5.31 ± 0.05 in a first control curve and 5.16 ± 0.07, n=6, in a second curve in the presence of 0.1 μM serotonin). With the exception of morphine, that produced a slight shift to the right in the concentration-response curve to NE, the sensitivity to the exogenous neurotransmitter was not modified by the antagonists employed.

The present results suggest that the potentiation of the responses to nerve stimulation produced by serotonin may result from an increase in the amount of NE released by the stimulation. In addition, the data presented are compatible with the hypothesis that an interaction between presynaptic serotonergic and β-adrenergic receptors, similar to that described for the central nervous system,is also present at the level of the peripheral sympathetic fibers.

Supported by grants from CONICET, ARGENTINA.

256.2 IONTOPHORETICALLY APPLIED BENZODIAZEPINES INHIBIT LOCUS COERULEUS UNIT ACTIVITY. Howard K. Strahlendorf and Jean C. Strahlendorf. Departments of Medical and Surgical Neurology and Physiology, Texas Tech University Health Sciences Center, Lubbock, Texas, 79430.

Benzodiazepines (BDZ) represent the most widely used class of anxiolytics. These compounds also possess skeletal muscle relaxant effects, anticonvulsant properties and are useful in suppressing motor and autonomic symptoms of withdrawal from opiates and ethanol. BDZ presumably enhance the synaptic efficacy of GABA at central nervous system synapses. Neurons of the locus coeruleus (LC) have membrane receptors for GABA and iontophoretically applied GABA profoundly inhibits LC unit firing. The LC by virtue of its efferent connections to the spinal cord, cerebellum, cerebral cortex and limbic system may represent an important substrate for many BDZ actions e.g., anxiolytic, sedative, skeletal muscle relaxant. We are studying the effects of BDZ on LC neurons applied by microiontophoresis.

Chloral hydrate anesthetized male rats were used in all experiments. Conventional 5 or 7 barrel micropipettes containing 2M NaCl saturated with fast green in the center recording barrel were employed to record single LC unit activity. Drug barrels contained 0.2M GABA, 0.1M flurazepam di-HCl (FLU), 0.1M chlordiazepoxide HCl (CDP), 0.1M glycine (all in distilled water) and 0.01M clonidine HCl in 165mM NaCl. The current balance barrel contained 4M NaCl. LC neurons were identified by characteristic electrophysiologic criteria at the time of recording and histologically at the end of each experiment. Both CDP and FLU markedly suppressed LC firing when applied iontophoretically in pulses 30 sec. long at currents ranging from 5nA to 30nA. Higher currents often produced membrane effects. Percent inhibition of discharge rate ranged from 5% to 82% (n=20 cells) and appeared to be dose related for a given set of neurons tested with the same pipette. FLU was more active than CDP. With a 40 sec. off time between ejection pulses no cumulative effects were seen. Occasionally (n=3 cells), tolerance appeared to repeated test applications and a rebound excitation also occurred. Interaction with GABA-elicited inhibition will also be presented. These data demonstrate that BDZ can profoundly inhibit LC unit activity and provide preliminary evidence that the LC may be an important site for some BDZ actions.

256.3 DOPAMINERGIC MEDIATION OF EFFECTS OF APOMORPHINE ON MIDBRAIN RAPHE NEURONS. E.H-Y. Lee* , and M.A. Geyer. Dept. of Neurosciences and Psychiatry, Univ. of California at San Diego, Sch. of Med., La Jolla, CA 92093.

In an effort to assess the functional inter-relationships between monoaminergic systems in brain, we have used quantitative cytofluorimetry to measure changes in cellular serotonin (5-HT) produced by the dopaminergic agonist apomorphine. A measure of fluorescence fading using a computerized microspectrofluorimeter enables us to discriminate changes in 5-HT from changes in catecholamines and to discriminate intracellular from extracellular amines.(Geyer et al.,1978.J. Pharm. Expl. Ther. 207 :650-667) Thirty minutes after intraperitoneal injections of saline or various doses of apomorphine, male rats(125-150gms) were sacrificed, the midbrain raphe area was removed, freeze-dried, treated with formaldehyde, and embedded in paraffin. Microscopic measures were made in both the dorsal and median raphe nuclei in 8 micron sections. The results showed that 0.1,1,3 and 10 mg/kg apomorphine all increased intracellular 5-HT content in the dorsal raphe significantly without affecting the median raphe. On the other hand, 20 mg/kg apomorphine significantly decreased intracellular 5-HT level in both nuclei. Thus, this high dose of apomorphine may cause a non-specific pharmacological action. Extraperikaryal 5-HT levels were also elevated in the dorsal raphe by 3,10 and 20 mg/kg apomorphine, suggesting some alteration in 5-HT release and/or turnover rate within this nucleus. The dorsal raphe nucleus can be divided into the following five subdivisions: the dorsomedial, dorsolateral,ventrolateral and ventromedial, which is further divided into the dorsal and ventral parts. Regional mapping experiments revealed that apomorphine slightly increased intracellular 5-HT level in each of these subdivisions but this effect was most pronounced in the dorsal part of the ventromedial subdivision.

To examine the time-course of apomorphine's effect, additional animals were sacrificed at various times (10 min to 80 min) after 0.1 mg/kg apomorphine. Apomorphine increased the intracellular 5-HT fading measure in the dorsal raphe as soon as 20 min after injection, with the maximal effect occurring at 1 hr.

Haloperidol, a dopaminergic antagonist, decreased 5-HT levels in cells of the dorsal raphe at a dose of 0.8 mg/kg. A lower dose of haloperidol (0.4 mg/kg), which had no significant effect by itself, completely blocked the effect of 1 mg/kg apomorphine in the dorsal raphe. This result supports the hypothesis that the effects of apomorphine on 5-HT neurons are secondary to dopamine receptor stimulation. Further studies are in progress to clarify the changes in catecholamines within the raphe nuclei and to determine the anatomical pathway and mechanism responsible.

256.4 NE AND 5-HT LESIONS DIFFERENTIALLY ALTER BASAL ACTIVITY AND RESPONSIVENESS TO SENSORY STIMULI OF TYPE A AND B SUBSTANTIA NIGRA DA CELLS. L.A. Chiodo, A.R. Caggiula and S.M. Antelman*. Psychobiology Program, Depts. of Psychology and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260.

We have recently demonstrated the existence of two functional subclasses of dopamine (DA) cells in the zona compacta of the substantia nigra (Chiodo et al., Brain Res. 189:544, 1980): type A cells which increase, and type B cells which decrease their discharge rate in response to sensory stimuli. Since other work has shown that both NE and 5-HT systems also modulate DA cell activity, in the present study we examined the influence of NE and 5-HT lesions, both alone and in combination, on both basal firing and the responsiveness of A and B cells to sensory stimuli.

The basal discharge rate of verified DA cells and their response to mild tail pressure and light flashes were determined in male rats which were either unoperated or given one of the following lesions 3-4 weeks beforehand: 1) 5-HT; an intraventricular injection of 5,7-DHT (225 ug free base) 30 min. after DMI (30 mg/kg i.p.), 2) NE; intraventricular 6-OHDA (250 ug free base) 30 min. after buproprion hydrochloride (50 mg/kg i.p.), 3) combined 5-HT and NE lesions, 4) sham lesions.

Basal discharge rates of type A and B neurons were significantly increased by NE lesions (151% and 197% of control respectively) and by combined NE and 5-HT lesions (140% and 165%). On the other hand, selective 5-HT destruction increased the activity of type B cells (159%) but had no effect on type A neurons.

Similar to our previous reports, tail pressure increased type A activity (135% of baseline) and decreased that of B cells (72%) in controls. Light flash increased the activity of both cells (130%). The responsiveness of type A and B neurons to sensory stimuli was totally abolished by 5-HT lesions and by combined 5-HT and NE lesions. By contrast, selective NE lesions significantly enhanced the effects of sensory stimuli on type A cells while having no influence on the type B response.

Our results indicate that the responsiveness of nigral DA neurons to sensory stimuli is critically dependent on the integrity of 5-HT but not of NE-containing neurons. However NE does appear to exert an influence, at least for the type A cell. Further, this study provides no evidence that either 5-HT or NE is responsible for the divergent effects of sensory stimuli on A and B cells. These data, together with additional observations that A and B neurons respond identically to the iontophoretic application of GABA and that kanic acid lesions of striatonigral feedback loops also fail to abolish A/B differences, suggest the possibility that the organization of local intranigral circuitry may underlie these effects.

256.5 SEROTONIN'S POTENTIATION OF ACETYLCHOLINE INDUCED CONTRACTIONS IN THE LEECH PENILE ENVERSION MUSCLE. E. K. McGlade*, W. J. Higgins* and B. Zipser. (SPON: C. R. Creveling). Dept. of Zoology, Univ. of Maryland, College Park, Maryland 20742.

Cholinergic and serotinergic neurons are found in the vicinity of the leech (Heamopis marmorata) penile enversion muscle (LPEM). Contractures of the LPEM induced by either acetylcholine (ACh) or electric field stimulation are potentiated by low doses of serotonin (5HT; threshold = 5×10^{-9}M). In addition 5HT accelerates relaxation. However, 5HT by itself at any concentration does not measurably alter the resting tension. Other biogenic amines investigated (norepinephrine, epinephrine, octopamine, and dopamine) only nonspecifically (threshold = 10^{-4} or 10^{-3}M) alter the resting tension of the ACh induced response.

The current investigation will ultimately determine the mechanism of 5HT potentiation of the ACh and electric field stimulated contractions. This information will characterize the role of 5HT in regulation of LPEM contractility and perhaps clarify the modulatory role which amines play in intercellular communication.

While several conventional cholinergic blocking agents (d-tubocurarine, hexamethonium, or atropine) fail to inhibit the ACh response; however, benzoquinonium (Bzq) is a potent ACh antagonist in this system ($I_{50} = 10^{-7}$M). In experiments utilizing Bzq, 5HT continued to potentiate the contractions elicited by electric field stimulation and accelerated relaxation. These data suggest that 5HT acts on the muscle but do not exclude the possibility that 5HT also acts presynaptically at the cholinergic motor neuron.

Future work will investigate the actions of 5HT on the electrical properties of the LPEM.

256.6 SOCIAL ISOLATION IN RATS ALTERS FIRING RATES OF SINGLE DOPAMINERGIC AND SEROTONERGIC NEURONS AND AFFECTS THEIR RESPONSIVENESS TO CLONIDINE. G. R. Christoph*, R. J. Leonzio*, L. G. Davis and M. D. Dibner. Central Research and Development Department, E. I. du Pont de Nemours and Co., Wilmington, DE 19898.

Conventional single-neuron recording techniques were used to record the spontaneous firing rate of presumed dopamine-containing neurons in the substantia nigra pars compacta and serotonin-containing neurons in the dorsal raphe nucleus of chloral hydrate anesthetized rats. For one to eight days prior to the recording session, the rats were housed 2-3/cage (GROUP) or 1/cage (SINGLE). Presumed dopamine-containing neurons fired significantly slower in GROUP rats (3.6 ± 0.35 spikes/sec, N=17) than in SINGLE rats (5.0 ± 0.33 spikes/sec, N=10). Administration of clonidine (0.01-0.04 mg/kg, i.v.) significantly increased the firing rate in GROUP rats (to 4.9 spikes/sec), whereas clonidine had no effect in SINGLE rats. When SINGLE rats were converted to the GROUP condition for two days the electrophysiological and clonidine responses of nigral cells were the same as those for rats that only had GROUP housing. Unlike dopaminergic cells, presumed serotonin-containing neurons in the dorsal raphe nucleus fired significantly faster in GROUP rats (1.01 ± 0.11 spikes/sec, N=10) than in SINGLE rats (0.66 ± 0.05 spikes/sec, N=17). Clonidine administration reduced the firing rate of serotonergic neurons for both SINGLE and GROUP rats but was more effective in SINGLE rats ($ID_{50} = 0.003$ mg/kg, i.v.) than in GROUP rats ($ID_{50} = 0.006$ mg/kg, i.v.). Manipulation of ambient temperature of SINGLE rats (37°C, 3 hr) prior to recording dopaminergic and serotonergic neurons produced a pattern of results (baseline rates and clonidine effects) similar to that observed for normal GROUP-housed rats. Another physiological measure, systolic blood pressure, was significantly higher in GROUP rats (131 mm Hg) than in SINGLE rats (118 mm Hg). Scatchard analysis of receptor binding experiments with α_2 (^{3}H-p-aminoclonidine) and α_1 (^{3}H-WB4101) ligands in rat cerebral cortex and thalamus showed no detectable receptor differences between GROUP and SINGLE rats. The present work demonstrates that relatively brief manipulations of a rat's environment alters monoaminergic neuronal activity, responsiveness to clonidine, and blood pressure. These physiological changes apparently are not due to changes in α-adrenergic receptor properties.

256.7 DOPAMINE CAN MODULATE THE INHIBITORY EFFECTS OF GABA ON SUBSTANTIA NIGRA PARS RETICULATA NEURONS. B.L. Waszczak and J.R. Walters. NINCDS, NIH, Bethesda, MD 20205.

The presence of dopamine (DA) in dendrites of substantia nigra (SN) pars compacta DA neurons raises the possibility that dendritic release of the transmitter might exert local effects on adjacent non-dopaminergic SN pars reticulata neurons. These cells, which project largely to motor-related areas such as the thalamus and superior colliculus, are markedly sensitive to inhibition by iontophoresed GABA and likely to receive a GABAergic input. It was of interest to assess whether DA could influence non-dopaminergic nigral output pathways either by 1) directly altering reticulata cell firing, or 2) modifying the effects of GABA on these cells.

Extracellular, single unit activity of pars reticulata neurons was monitored in chloral hydrate-anesthetized male rats, 250-300g. Attempts were made to antidromically activate the cells from the ventromedial nucleus of the thalamus (VMT). For each cell, repeated 30 sec iontophoretic pulses of GABA (0.001 M in 0.2 M NaCl) and glycine (GLY; 0.1 M), separated by 30 sec baseline periods, were applied before and during simultaneous iontophoresis of DA (0.2 M, 10 nA ejection current). Ejection currents were selected for GABA and GLY which could inhibit firing by more than 50%, but not totally. Under these condtions, iontophoresed DA caused increases in reticulata cell firing to an average of 27% over baseline ($n=20$, $p<.001$). In addition to the increase in rate, DA consistently and markedly attenuated the inhibitory responses of cells to GABA. The degree of this attenuation was not correlated with nor dependent upon the increase in firing. Both the absolute inhibition, in numbers of spikes, as well as the percent inhibition by GABA were significantly reduced by applied DA ($n=18$, $p<.001$). In contrast to its attenuation of GABA responses, DA did not consistently alter responses of cells to iontophoresed GLY ($n=15$).

To assess the specificity of these actions of DA on reticulata neurons, studies were conducted in which an equimolar solution of norepineprhine (NE; 10 nA ejection current) was substituted for DA. While NE caused similar average increases in firing to 30% over baseline ($n=16$, $p<.01$), it did not consistently or significantly alter, over all cells tested, the absolute amount of inhibition elicited either by GABA ($n=15$) or GLY ($n=12$). In both NE and DA experiments, approximately 60% of reticulata cells tested could be antidromically activated from the ipsilateral VMT.

These results indicate that DA, released from dendrites within the nigra, could potentially modulate the actions of GABA on SN pars reticulata cells projecting to motor areas, including the VMT. The increased firing elicited by DA alone may reflect either a direct excitatory action and/or its ability to modulate inhibitory influences provided by GABAergic inputs these cells receive.

256.8 PROLACTIN STIMULATES DOPAMINE RELEASE FROM RAT STRIATAL TISSUE SUPERFUSED IN VITRO. Yiu-Fai Chen* and V. D. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana Illinois 61801 (SPON: E. J. Roy)

Spontaneous and induced release of dopamine from fragments of male rat striatal tissue superfused in vitro was examined in the present experiments. Adult male Holtzman rats were killed by decapitation at 1000-1100 h (during a 0500-1900 h light schecule). Striatal tissues were quickly dissected and placed in ice cold Krebs Ringer Phosphate buffer (pH 7.4) containing glucose(10 mM), bovine serum albumin(0.1%), ascorbic acid(0.1%), and pargyline (3.5×10^{-4}M). This same buffer was also used for superfusion of the tissue. The equivalent of 2 rat striatal fragments were used in each experimental chamber. The superfusion chamber was positioned in a constant 37° C water bath. The volume held in the chamber was 500 ul. The medium was pumped through the chamber at a 100 ul/min flow rate. Following a 40 minute stabilization period, effluent samples were collected on ice in 0.1 N $HClO_4$(final concentration) at 4 minute intervals. Dopamine was determined by a specific radioenzymatic assay with a sensitivity of 31 to 62 pg. The enzymatic reaction for this assay involved transfering a tritium labeled methyl group from S-adenosyl-L-methionine to the catecholamines. The methylated products were extracted and finally separated on Dowex-50-W-X-4 cation exchange columns. The spontaneous release of dopamine from striatal tissue was relatively stable. The basal release rate over a 76 minutes period (19 intervals) was 22.5 ± 1.2 pg/mg/min. Augmented release in response to a depolarizing pulse injection of 60 mM K^+ verified tissue viability at the end of superfusion.

In experimental chambers, prolactin infused for 24 minutes significantly increased dopamine release from pre-infusion basal levels of 17.9 ± 1.6 to 34.0 ± 4.1 pg/mg/min during infusion ($n = 4$ experiments). Within 8 - 12 minutes after the removal of prolactin the release of dopamine returned to basal levels (18.1 ± 2.9 pg/mg/min). Infusion with heat-denatured prolactin (boiled for 30 minutes) had no effect on dopamine release (24.3 ± 4.1 pg/mg/min, $n = 4$ experiments). Furthermore, thyrotropin-releasing-hormone (TRH, 10 ng/ml infused for 24 minutes) had no effect on dopamine release from striatal tissue (16.7 ± 1.7 pg/mg/min, $n = 4$ experiments). These results demonstrate that prolactin has a stimulatory effect on dopamine release from striatal fragments of male rats in vitro. The absence of a response to heat-denatured prolactin and TRH demonstrates the specificity of this response and suggests that the basal ganglia may constitute a target tissue for prolactin. (Supported by a NIH grant HD 14625 to VDR.)

256.9 AMPHETAMINE INCREASES ACETYLCHOLINE RELEASE FROM THE PHRENIC NERVE: EVIDENCE FOR A NORADRENERGIC-MEDIATED RESPONSE. R. Michael Snider and Michael C. Gerald, Division of Pharmacology, College of Pharmacy, The Ohio State University, Columbus, Ohio 43210.

(+)-Amphetamine (AMPH) increases physical performance and endurance in humans and animals. A similar stimulatory effect has been demonstrated in the isolated mammalian nerve-skeletal muscle preparation, suggesting the increase in performance may be due, in part, to a peripheral component. Experiments were conducted to examine the mechanism by which AMPH stimulates neuromuscular function employed the rat phrenic nerve-diaphragm preparation. Using indirect methods, the results of previous studies in this laboratory suggest that AMPH may be capable of increasing acetylcholine (ACh) release from motor nerves: (1) AMPH increased MEPP frequency and EPP amplitude (Snider and Gerald, Pharmacologist 22:165, 1980); and (2) in the incannulated diaphragm AMPH enhanced contractions elicited by nerve stimulation but not by ACh injection (Gerald and Snider, Fed. Proc. 40:278, 1981).

In the present studies ACh release from the vascular perfused rat phrenic nerve-diaphragm preparation was directly measured radioenzymatically (Bierkamper and Goldberg, JEPT 6:40, 1978). AMPH (30-300 μM) produced a 45-478% increase in ACh release. To investigate the mechanism responsible for this stimulatory effect, rats were pretreated with reserpine (5 mg/kg, 18 hr) or α-methyl-p-tyrosine (α-MT) (250 mg/kg, 18 hr) and the AMPH-induced release of ACh measured. AMPH (100 μM) alone produced a 315% increase in ACh release. α-MT pretreatment completely blocked this stimulatory effect, whereas reserpine pretreatment decreased the AMPH-induced enhancement of ACh release to 108%. These results, suggesting catecholamine involvement in AMPH-induced ACh release, are supported by the result that norepinephrine (5×10^{-6}M) also increased ACh release (99%).

AMPH (135-270 μM) produced a significant 10-30% increase in nerve-stimulated muscle contractions. This stimulatory effect was completely blocked by tissue preincubation with phentolamine (3×10^{-5}M). Similarly, phentolamine attenuated the AMPH-induced (100 μM) increase in ACh release to 30%.

These studies demonstrate that AMPH increases ACh release. Results presented are consistent with the hypothesis that this effect is mediated by catecholamines which in turn stimulate ACh release via a presynaptic alpha-adrenergic mechanism. (Supported by NIDA grant DA-01477).

256.10 CORTICAL MODULATION OF STRIATAL CHOLINERGIC ACTIVITY. J.R. Simon. Inst. of Psych. Res., Depts. of Psychiat. & Biochem., Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The striatum receives a substantial innervation from the cerebral cortex, and this is believed to be, in large part, glutamatergic in nature. Thus, destruction of the frontal cortex results in decreased uptake and content of glutamate in the striatum. The interactions of this cortico-striatal system with other neuronal systems in the striatum is of considerable interest. This study focuses on the possibility of a glutamatergic-cholinergic interaction. To examine potential alterations in striatal cholinergic activity, use was made of the ability of the high affinity choline uptake (HAChU) system to change in response to varying states of activity of cholinergic neurons. In the present study, the effect of selective ablation of the frontal cortex on striatal HAChU was investigated. Two weeks after cortical ablation, the levels of glutamate were decreased approximately 30% in synaptosomes prepared from the ipsilateral striatum. In these same tissue samples, glutamate uptake and HAChU were also decreased by approximately 40% and 50%, respectively, whereas GABA uptake was unaffected. In acute experiments (1 hr. post cortical ablation), HAChU was again found to be significantly reduced, while in the same samples, glutamate and GABA uptake were unchanged relative to sham operated animals. This observation of decreased choline uptake 1 hr. after decortication suggests the existence of an excitatory (perhaps glutamatergic) influence of cortical origin on striatal cholinergic neurons. To further investigate this possibility, 10 nmoles of kainic acid (KA) was locally injected into the striatum 1 hr. after removal of the ipsilateral frontal cortex, and the animals were sacrificed 2 minutes after injection. This was done in an attempt to restore the excitatory input to the striatum which was presumably removed by the cortical ablation. KA injection into the striatum of control animals (acute; 2 min) resulted in a significant increase (30%) in HAChU compared to uptake in the contralateral striatum. KA injection into the striatum of decorticate animals also resulted in increased HAChU of similar magnitude (25%) compared to the contralateral striatum. When compared to uptake in the striatum from the lesioned side, this increase amounted to approximately 70% owing to the significantly reduced uptake due to the lesion. Thus, KA injection into the striatum of decorticate animals appeared to reverse the effect of the lesion on HAChU. These observations suggest that cortical afferents to the striatum, which may use glutamate as the transmitter, influence the activity of striatal cholinergic neurons. Whether this cortical modulation of cholinergic activity is mediated via direct or indirect interactions remains to be examined. (PHS NS 15951).

256.11 FFFECT OF MORPHINE ON HIGH-AFFINITY CHOLINE UPTAKE IN THREE REGIONS OF THE RAT BRAIN. M. L. Arceneaux* and S. F. Atweh (SPON: R. J. Dinerstein). Dept. of Neurology, University of Chicago, Chicago, IL 60637.

Sodium-dependent High-Affinity choline uptake (HACU) in synaptosomal preparations is associated with cholinergic terminals in rat brain. Recent evidence suggests that HACU may be the rate limiting step in the synthesis of acetylcholine (Ach). Changes in the rate of HACU correlate well with cholinergic activity in rat brain (Atweh et. al., Life Sci, 17:1535, 1975), thus making it feasible to use synaptosomal HACU as a measure of Ach turnover. Morphine inhibits the release of Ach in the guinea-pig intestine and rat occipital cortex. Opiate receptors and endogenous opioids are also enriched in certain brain regions which are rich in cholinergic markers. We investigated the effect of morphine on HACU in three brain regions where interactions between opiate receptors and Ach may take place.

Rats were injected with varying doses of morphine or saline and sacrificed 30 minutes later by decapitation. Brains were quickly removed and dissected in cold saline. Crude synaptosomal fractions of brain homogenate were prepared from frontal cortex, hippocampus and striatum. HACU was measured by incubating the synaptosoms with ^{3}H-Choline in normal and Na-free Kreb's. HACU showed a 35% decrease in Vmax in hippocami of morphine treated rats as compared to controls ($P < 0.05$), but not in striatum or cortex. This decrease was dose dependent, but statistically significant only at high sedating doses of morphine (30-50 mg/kg). Naloxone by itself did not affect hippocampal HACU, but reversed the morphine effect. In vitro morphine did not affect HACU in all brain regions tested. Preincubation of synaptosomes in high-K^+ (62meq) solution resulted in a Ca^{++}-dependent stimulation of HACU in both striatal (+34%) and hippocampal (+92%) synaptosomes. The presence of 10μm Morphine in the high-K^+ solution did not affect this increase in either brain region.

This data suggest that high dose morphine treatment decreases cholinergic activity in the hippocampus. This effect is not due to presynaptic inhibition of Ach release in hippocampal terminals, since morphine has no effect on K^+-stimulated release, but is probably due to the sedating effect of high doses of morphine and inhibition of the septal-hippocampal neurons, as is seen with other sedatives such as barbiturates and general anesthetics. Although the striatum is rich in opiate receptors, these results do not suggest a significant interaction of opiate receptors with cholinergic neurons in the striatum.

256.12 NALOXONE POTENTIATION OF APOMORPHINE STEREOTYPY AND INFLUENCE OF PRETREATMENT WITH μ-, σ- AND κ-OPIATE DRUGS. Raymond M. Quock. Div. Pharmacology, Marquette Univ., Milwaukee, WI 53233.

The dopaminergic agonist apomorphine (APO) evokes stereotypic climbing activity in mice (Protais, Costentin & Schwartz, Psychopharmacol. 50:1, 1976). Previous studies in our laboratory have shown that prior treatment with the narcotic antagonist naloxone (NX) significantly potentiates APO climbing (Quock & Lucas, Life Sciences 28:1421, 1981). We have speculated that the enhanced dopaminergic drug effect might result from NX blockade of presynaptic opiate receptors that are located on dopaminergic nerve terminals. The purpose of this investigation was to ascertain whether the opiate receptor species involved in this interaction might be identified. This was accomplished through treatment of animals with morphine, SKF 10,047 (N-allylnorphenazocine) and ketocyclazocine which compete with NX for binding to μ-, σ- and κ-opiate receptors, respectively. Male ICR mice were used in this investigation. In control experiments, NX (1.0 and 5.0 mg/kg) administered 5 min prior to the APO (2.0 mg/kg) challenge produced significant potentiation of APO climbing activity which was scored 10 and 20 min following the challenge. In one series of tests, mice were pretreated with varying doses of one of the three opiate drugs 10 min prior to APO challenge to ascertain the influence of these drugs upon APO climbing. In another series of tests, mice were pretreated with varying doses of one of the three opiate drugs 5 min prior to NX treatment and 10 min prior to APO challenge to ascertain whether these drugs might competitively reverse the potentiating influence of NX upon APO climbing. Doses of morphine between 1.0 and 5.0 mg/kg exerted no behavioral suppressant effect upon APO climbing; yet these same doses did effectively reverse the potentiating influence of NX upon APO climbing. Doses of SKF 10,047 between 1.0 and 5.0 mg/kg also exerted no behavioral suppressant effect upon APO climbing; yet these same doses did likewise effectively reverse the potentiating influence of NX upon APO climbing. Doses of ketocyclazocine between 1.0 and 10.0 mg/kg did significantly reduce APO climbing; however, these same doses failed to reverse the potentiating influence of NX upon APO climbing. Based upon these experimental findings, we conclude that: (1) potentiation of APO climbing activity in mice by NX may involve NX blockade of μ- and/or σ-opiate receptor types; and (2) κ-opiate receptor types appear not to be involved in the NX/APO drug interaction. (This research was supported in part by a research grant from the American Parkinson Disease Association and also in part by a Faculty Development Award from the Marquette University Graduate School.)

256.13 Neuroleptic-like Actions of Cholecystokinin. Steven L. Cohen,* Carol A. Tamminga, Martha Knight, Thomas N. Chase. NINCDS, NIH, Bethesda, Md., 20205; Maryland Psychiatric Research Center, Baltimore, Maryland 21228.

Cholecystokinin octapeptide (CCK-8) has been localized within the mammalian central nervous system and is thought to function there as a neurotransmitter. It has been identified within cell bodies and terminals of certain dopamine (DA)-containing neurons of the A10 (mesolimbic) DA cell group. Since this sytem has been implicated in mediating the antispychotic effect of neuroleptic drugs, we tested the neuroleptic potential of CCK-8 by performing a group of behavioral, biochemical, and endocrinologic experments. All CCK-8 was tested for purity prior to use and dose dilutions were verified by HPLC after experiments. Classic behavioral effects of neuroleptic drugs in laboratory animals include a reduction in learned conditioned-avoidance behavior, a blockade of apomorphine induced stereotypy, and the production of catalepsy. A conditioned-avoidance paradigm was employed, utililizing a signaled-avoidance task with a tone and light conditioned stimulus, a shuttle box, and a 0.7 ma shock. The effects of CCK-8 (.02-3.8 mg/kg i.p.), haloperidol (100 µg/kg i.p.) and saline were compared in different groups of 3-day trained animals on learned conditioned-avoidance behaviors. Both those groups receiving CCK-8 and Haloperidol evidenced significant reductions in avoidance behavior. Additionally, CCK-8 potentiated the effect of haloperidol on the avoidance task and facilitated extinction of the previously learned avoidance response. Stereotypy induced by apomorphine was diminished by CCK-8. CCK-8 did not induce catalepsy at doses up to 1.28 mg/kg i.p. Biochemical studies focused on elucidating the effect of CCK-8 on DA turnover using the AMPT-induced inhibition of DA synthesis. Male rats pretreated with either AMPT (350 mg/kg) or saline were given CCK-8 in varying doses or placebo by subcutaneous and intraventricular route. Dissections were made of the medial striatum, olfactory tubercle, nucleus accumbens, and median eminence (ME). Tissues for analysis of DA levels were sonicated in 0.4 N perchloric acid, purified over an alumina column, and analyzed with an electrochemical detector on a high pressure liquid chromatography system. Results suggest that CCK-8 decreases the turnover of DA in the ME. Additionally, CCK-8 increases plasma prolactin levels in the unanesthetized male rat. These behavioral and biochemical results suggest that exogenously administered CCK-8 may modify certain functions mediated by central DA systems.

256.14 NEUROENDOCRINE, NEUROANATOMICAL AND NEUROPHARMACOLOGICAL STUDIES OF A PUTATIVE VENTRAL TEGMENTAL AREA/N. TRACTUS DIAGONALIS NEURONAL SYSTEM. E. A. Muth* and D. M. Jacobowitz (SPON: J. A. Moyer). Lab. Clin. Sci., NIMH, Bethesda, MD 20205 and Dept. of Pharmacology, George Washington Univ., Wash., DC 20037.

The central effects of muscarinic and nicotinic cholinergic pharmacological agents on luteinizing hormone (LH) secretion, ovulation, and sexual behavior in the rat have suggested the participation of central cholinergic neurons in the feedback effets of gonadal hormones. In a previous study, both the n. tractus diagonalis (td), a cholinergic cell body area, and the ventral tegmental area (avt), the location of the A10 dopaminergic cell bodies, showed changes in cholinergic activity in male and female rats after gonadal hormone manipulations which altered LH secretion (Muth, Crowley, and Jacobowitz, Neuroendo. 30: 329-336, 1980). These results suggested (a) that these two brain areas may be anatomically related, and (b) that such a system may participate in the feedback control of LH secretion. Subsequent neuroanatomical studies revealed a direct mesolimbic dopaminergic projection from the avt to the td, several limbic cholinergic projections from the td, as well as a direct non-cholinergic projection from the td to the avt. In further neuroendocrine experiments, neither stimulation nor ablation of the avt or the td had any effect on LH secretion. Furthermore, implantation of testosterone directly in the td had no effect on the choline acetyltransferase activity in that nucleus nor in several of its projection areas. In addition, it was shown that hypophysectomy blocks the castration-induced alteration in the choline acetyltransferase activity of the td. Thus, despite its apparent involvement in gonadal hormone feedback effects, the avt/td system was shown to respond to, rather than participate in, the neuroendocrine control of gonadotropin secretion.

The neuropharmacological relationship of the td and the avt was explored in another series of experiments. Acute stimulation of the avt resulted in reduced acetylcholine concentration in the hippocampus, a well-known td cholinergic projection area. In addition, both destruction of afferent catecholamine terminals in the td by 6-hydroxydopamine, and also chronic treatment with the dopamine receptor antagonist, haloperidol, caused alterations in choline acetyltransferase and acetylcholine concentration, respectively, in the avt. These results suggest the presence of a feedback-type functional relationship between the td and the avt which may be pertinent to the cholinergic and dopaminergic neurotransmitter-mediated effects of hormones and psychoactive drugs on behavior.

256.15 PROLONGED TRICYCLIC ANTIDEPRESSANT TREATMENT REDUCES SENSITIVITY OF GABA FACILITATION BY NE IN CEREBELLAR PURKINJE CELLS. H.H. Yeh, H.C. Moises, B.D. Waterhouse and D.J. Woodward, Dept. Cell Biology, Univ. Texas Health Science Ctr., Dallas, TX 75235

Chronic treatment of rats with desipramine (DMI) has been reported to result in a decreased β-adrenoceptor density. The question considered here is whether such biochemical measures are reflected in experimentally demonstrable physiological processes. We have demonstrated previously that the enhancement of GABA-induced Purkinje cell (PC) inhibition by NE can be mimicked by isopreterenol but not phenylephrine and antagonized by sotalol, indicative of a β-receptor mediation. In this iontophoretic study, we examined the possibilty that the sensitivity of GABA facilitation by NE in PC's of normal and DMI rats might reveal a physiological correlate of the proposed alteration in the β-receptor population.

Adult albino rats were pretreated for 11 days with DMI (10 mg /kg. body wt.; i.p.; twice daily). All electrophysiological experiments were performed on the 12th. day. Multibarrel micropipets were used to apply drugs and record extracellular PC unit responses. Inhibitory responses to iontophoretic pulses of GABA were examined before, during and after NE iontophoresis using computer-generated drug response histograms.

PC's of DMI rats fired spntaneously at a mean rate of 23.4 spikes/sec (S.E. +.6, N=80), 1/3 slower than that of normal rats (32.5 spikes/sec, S.E. +1.1, N=91). Interspike interval histograms reveal a marked increase in the frequency of long pauses without significant changes in the number of climbing fiber bursts.

An initial indication that PC's of DMI rats are subsensitive to NE was the finding of a higher mean iontophoretic current needed to induce threshold depressions of spontaneous discharge. Thirty-two PC's from DMI rats were tested for interaction between NE and GABA-induced inhibitions. NE exerted little or no effect in 12 cells and enhanced GABA inhibitions in only 4 cases. A striking finding was that, although PC responsivity to GABA was similar in both groups, GABA inhibitions were effectively antagonized by concurrent NE application in 16 cells.

In summary, the results provide evidence for a major alteration in the response characteristics of β-receptors mediating the facilitating action of NE on GABA. DMI appears to induce a form of subsensitivity involving β-receptor mediated heterosynaptic interactions. These electrophysiological data support the hypothesis of an adaptive down-regulation of β-receptors as one possible mode of action of antidepressant drugs. (Supported by NIDA DA-02338, NSF BNS77-01174 to D.J.W. and the Biological Humanics Foundation.)

256.16 BROMOCRIPTINE INHIBITS PHOSPHORYLATION OF TWO SPECIFIC PROTEINS IN RAT BRAIN. C. A. Stratford* and T. Ueda (SPON: J. H. Woods). Mental Health Research Institute, Depts. of Psychiat. & Pharmacol., Univ. of Michigan, Ann Arbor, MI 48109.

Bromocriptine is an effective agent in the treatment of hyperprolactinemia and parkinsonism, and is believed to achieve its therapeutic effects by a mechanism involving the D-2 dopamine receptor which is not coupled to adenylate cyclase. In an effort to understand some of the biochemical actions of bromocriptine in the central nervous system, crude synaptosome preparations from neostriatum, cerebral cortex and other regions of the rat brain were examined for the effect of the ergot compound on phosphorylation of specific proteins. Bromocriptine was found to inhibit specifically the phosphorylation of 50,000 and 60,000 dalton proteins (BrC-P_{50} and BrC-P_{60}). The bromocriptine-inhibitable phosphorylation was shown to occur on a threonine residue of both proteins. The concentration of the ergot required to cause a 50% inhibition was 8 µM. This inhibitory effect was not observed when dopamine, norepinephrine, isoproterenol, histamine, carbachol, serotonin, GABA, and adenosine were tested at concentrations up to 50 M. However, other ergots, particularly those which have a peptide moiety, such as α-ergocriptine, dihydroergocriptine, and ergotamine, mimicked the inhibitory effect of bromocriptine. Among these ergopeptines, bromocriptine was the most potent and ergotamine was the least potent. Those ergots which lack a peptide moiety, such as ergonovine and methysergide, showed the inhibitory effect only at much higher concentrations. The selective D-2 dopamine receptor antagonists metoclopramide and sulpiride did not block or mimic the inhibitory action of bromocriptine. The dopaminergic ergot lergotrile and the α-adrenergic antagonists phentolamine and yohimbine showed the inhibitory effect at high concentrations; these agents were less potent than ergotamine but more potent than ergonovine. The bromocriptine-sensitive phosphorylation of BrC-P_{50} and BrC-P_{60} was not detected in the anterior pituitary, which contains D-2 receptors but is devoid of D-1 receptors, nor in the goldfish retina, which contains D-1 receptors but is devoid of D-2 receptors. The bromocriptine-sensitive phosphorylation system was found in many regions of the brain but was not detected in the heart, lung, liver or kidney. These observations suggest that the bromocriptine-sensitive phosphorylation system does not represent specific dopaminergic, α-adrenergic, or serotonergic receptors, and raise the possibility that there may be a unique receptor for ergopeptines in the central nervous sytem.

257.1 Endorphin-related Peptides in the Cerebrospinal Fluid of the Rat and Their Responses to Immobilization Stress. R. Sanford Kiser, Sue Jackson*, Roger Smith*, Lesley H. Rees*, P.J. Lowry*, and G. M. Besser*. Department of Chemical Endocrinology, Pituitary Hormone Laboratory, and Department of Endocrinology. St. Bartholomew's Hospital, London, England EC1A 7BE.

Endorphin-related peptides are found in both plasma and cerebrospinal fluid (CSF). Plasma levels of adrenocorticotropic hormone (ACTH) and β-endorphin rise in response to certain forms of stress, while met-enkephalin levels remain unchanged. Much less is known about the nature or physiology of these peptides in the CSF. The goal of this study was to characterize these peptides in the CSF of the rat and to examine their responses to immobilization stress.

Male albino rats were implanted with chronic cisterna magna cannulas. After the animals had been habituated to handling, daily samples of blood-free CSF were taken and pooled for chromatography on a Sephadex G-75 column. ACTH immunoreactivity was examined utilizing an antiserum with no cross-reactivity with non-ACTH portions of the pro-opiocortin molecule. ACTH immunoreactive peaks were present at the expected positions of the 31K ACTH precursor molecule, the 23K ACTH biosynthetic intermediate, the 14K, glycosylated form of ACTH, and 4.5K ACTH. The major peak was at the position of 14K ACTH. Beta-endorphin immunoreactivity was tested with an antiserum having cross-reactivity with β-lipotrophin but none with ACTH or met-enkephalin. Beta-endorphin-immunoreactive peaks occurred at the expected positions of the 31K precursor molecule, β-lipotrophin, and β-endorphin. The largest peak occurred at the β-endorphin position. Met-enkephalin levels, measured via the specific met-enkephalin assay developed by Clement-Jones et al. (J. Endocr. 86:231-243, 1980), were 48.5 pg/ml.

We then examined the effects of immobilization stress upon the total levels of ACTH, β-endorphin, and met-enkephalin immunoreactivities. CSF samples were taken after one hour of immobilization and compared to baseline samples. No significant changes in ACTH or β-endorphin immunoreactivities were observed (ACTH: baseline = 115 ± 8.8 pg/ml; post-stress = 122 pg/ml; β-endorphin: baseline = 127 ± 15.2 pg/ml, post-stress = 148 pg/ml). Met-enkephalin levels fell slightly to 35 pg/ml.

These results suggest that the CSF of the rat contains β-endorphin, ACTH, and their previously described precursor molecules. Significant levels of met-enkephalin are also present. Immobilization stress produced a slight fall in met-enkephalin levels but had no significant effect upon the immunoreactive levels of β-endorphin or ACTH.

257.2 DISSOCIATION OF BLOOD AND CEREBROSPINAL FLUID β-ENDORPHIN RESPONSES IN THE RAT. M.C. Pian*, M.A. Arnold*, and J.B. Martin. Department of Neurology, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

The effects of various stimuli on β-endorphin (β-E) release into blood and cerebrospinal fluid (CSF) were studied in the rat. Using camel β-E for the RIA standard the assay could detect 2-3 pg/tube; the antibody recognized human β-E and human β-lipotropin on an equimolar basis. The antibody showed negligible cross-reactivity with the enkephalins or with α-endorphin or γ-endorphin. With the use of chronically implanted blood (right atrial) and CSF (cisterna magna) cannulae, blood and CSF samples were withdrawn from unanesthetized, non-stressed male rats for periods of several hours. Gel permeation chromatography of 10 ml rat CSF indicates that 69.4% of the β-endorphin immunoreactivity co-migrates with synthetic β-E. A similar analysis of talc-extracted rat plasma indicates that about 90% of the β-endorphin immunoreactivity co-migrates with synthetic β-E. Immobilization of rats for 30 minutes results in a large increase in mean plasma β-E levels measured over a 1.5 h period (801.1 ± 264.0 in immobilized group vs. 169.4 ± 39.0 pg/ml in control group; mean ± S.E.). CSF β-E levels obtained 10 and 70 minutes after immobilization (147.9 ± 34.7 and 114.2 ± 14.1 pg/ml, respectively) did not differ from pre-immobilization CSF peptide levels (112.9 ± 27.9 pg/ml). Similarily, the iv administration of caffeine (20 mg/kg) more than doubled mean plasma β-E levels measured over a 3 hour period but did not affect CSF β-E 30 and 90 minutes after injection (30 min, 144.4 ± 14.2; 90 min, 178.9 + 23.4 pg/ml) as compared to control levels (-30 min, 147.9 + 17.0 pg/ml). These results indicate that blood and CSF β-E levels are independently regulated in the rat.

257.3 RISE IN PLASMA BETA ENDORPHIN IMMUNOREACTIVITY DURING SURGICAL STRESS, MODIFIED BY EXOGENOUS OPIATES M. Dubois*, D. Pickar*, M. Cohen*, P. Gadde*, T.E. Macnamara* and W.E. Bunney (SPON: R. Coppola). Anesthesia Section, NIH; and Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

Beta endorphin seems to play a definite role in the biological response to stress (Rossier, J., et al, Nature, 270: 618, 1977) and in the endogenous mechanism of pain perception (Hosobuchi, Y., et al, Science, 203, 279, 1979). Exogenously administered opiates during surgery decrease or even supress the activation of the "stress hormones" (i.e. ACTH, Cortisol, etc.) (George, J.M., et al, J. Clin. Endocrinol. Metab., 38:736,1974).

In the present study, a standard general anesthetic technique using no opiates was administered to a first group of nine patients undergoing a staging laparotomy. All patients were medication-free prior to the surgery. In the postoperative period, they were given morphine sulfate for pain relief. In a second comparable group of six patients, selected by the same criteria and undergoing the same type of surgery, fentanyl was administered as main anesthetic drug. In both groups, multiple blood samples were collected prior to, during and after the surgery, following the same time protocol. Plasma beta endorphin immunoreactivity (B-Eir) and plasma cortisol were determined by radio immunoassay. Intra assay variation for plasma cortisol was 6% and for B-Eir 3.5%.

Induction of anesthesia did not raise significantly B-Eir in both groups. Surgery in the first (=no opiate) group was associated with important increases in B-Eir (ANOVA with repeated measures: F=11.2, df=2,14,p=0.001). When morphine was administered in the postoperative period, a significant concomitant decrease in B-Eir was observed (from 74.9±29 pmole/liter after wakening, to 16.6±0.8 pmole/liter, after start of morphine treatment; mean ± SEM). Levels of plasma cortisol followed the same trend in all cases and were significantly related to plasma B-Eir (r=0.61, p<0.01). When fentanyl was given as main anesthetic, plasma B-Eir did not rise during surgery and most levels were undetectable for 90-120 minutes following the injection of the opiate. In three cases, a substantial increase in plasma B-Eir was observed, while the analgesic effect of the drug was disappearing, as monitored by cardiovascular changes during anesthesia or pain on awakening.

In subjects receiving no opiates, surgical stress appears to activate the endorphin system, as it is already known to activate the hypothalamic-pituitary-adrenal axis. On the other hand, the administration of opiates (morphine for postoperative pain relief, and fentanyl during surgery) supresses this activation consistently.

257.4 OPIATE INVOLVEMENT IN ETHANOL INDUCED EFFECTS ON THE CENTRAL NERVOUS SYSTEM IN THE RAT. J.P. Allen, A.K.S. Ho*, T.A. Kepic, L. Biesecker*, A. Mizera*, and B. Hofreiter*. Dept. of Neurosciences and Basic Science, Peoria School of Med., Peoria, IL 61605.

The mechanism through which ethanol effects central nervous system function is incompletely understood. Recent advances in opiate research prompted investigating the role of acute ethanol administration on plasma β-endorphin and ACTH concentrations in the rat. To test whether the opiates are involved in the effects of ethanol on the central nervous system, groups of 200 gm adult male Sprague-Dawley rats were treated with morphine (10 mg/kg, i.p.); ethanol (2g/kg, i.p.); naloxone (0.4 mg/kg, i.p.); morphine (10 mb/kg, i.p.) and naloxone (0.4 mg/kg, i.p.); ethanol (2 g/kg, i.p.) and naloxone (0.4 mg/kg, i.p.); and normal saline (1 cc, i.p.). Naloxone or saline was administered at 0830 and fifteen minutes later the remaining drugs or saline were injected. Sixty minutes after the initial naloxone or saline injection, the rats were decapitated and trunk blood collected for later analysis of β-endorphin and ACTH by radioimmunoassay. There was a significant increase in mean plasma β-endorphin concentration following morphine ($p < 0.001$) or ethanol ($p < 0.01$) compared with controls. This increase induced by either alcohol or morphine was significantly antagonized by naloxone pretreatment ($p < 0.01$). There was no significant difference in the mean plasma β-endorphin concentration between the naloxone and the saline treated controls. In contrast the mean plasma ACTH concentration showed no significant difference between the various treatment groups. We conclude from our data that the central nervous system effects of ethanol may in part be mediated through endogenous opioids and their receptors.

257.5 ENDOTOXIC SHOCK IS ACCOMPANIED BY A NALOXONE-SENSITIVE INCREASE IN NOCICEPTIVE LATENCIES. Gregory Lucas Belenky, Barry A. Ruvio* and John W. Holaday. Dept. Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20012.

In earlier work it was shown that endotoxin shock hypotension was rapidly reversed by the opiate antagonist, naloxone (Holaday and Faden, Nature 275, 450, 1978). From this, it was suggested that endotoxemia resulted in the activation of endogenous opiates which contributed to the cardiovascular pathophysiology of shock. The purpose of the present study was to determine if the apparent functional activation of endogenous opiates by endotoxin also resulted in an opiate-like elevation in nociceptive latencies. Male Sprague-Dawley rats (250-300g) were surgically prepared with external jugular-vein cannulae. On the following day, these now-conscious rats were repeatedly exposed to a 52°C hot plate until consistent escape latencies were obtained. Tail-flick latencies and colonic temperatures were also measured. Endotoxemia was produced by the intravenous (iv) injection of 15 mg/kg E. coli lipopolysaccharide endotoxin in rats pretreated 10 min earlier with 10 mg/kg naloxone or saline iv. In saline pretreated rats, a gradual elevation of hot-plate escape latencies was observed over the first 40 min post-endotoxin injection. By contrast, naloxone-pretreated rats showed a decline in escape latencies over this same 40 min interval [ANOVA, $F(3,54)=3.16$, $p=0.032$, n=10 rats/group]. Tail-flick latencies and colonic temperatures were relatively unaffected by endotoxin or drug pretreatment. This dose of endotoxin was 100% lethal in both groups 24 hrs post-injection. The elevation of nociceptive latencies produced by endotoxin, combined with the lack of such effect in naloxone pretreated rats, indicates that endogenous opiate systems may be functionally activated by endotoxins to result in antinociception. Whether this is a direct effect upon endogenous opiate release or an indirect consequence of stress cannot be determined by these experiments. Nonetheless, it appears possible that endotoxemia results in a generalized activation of endogenous opiates to result not only in shock hypotension, but antinociception as well.

257.6 ANALGESIA AND INCREASES IN BRAIN NOREPINEPHRINE METABOLISM PRODUCED BY PERIAQUEDUCTAL GRAY INJECTIONS OF OPIATES. T. G. Reigle. Dept. of Pharmacology, Univ. of Georgia Sch. of Pharmacy, Athens, GA 30602.

Previous work in our laboratory (LoPachin and Reigle J.P.E.T. 207:151, 1978) has demonstrated the ability of systemic opiate injections to produce receptor-specific increases in brain levels of the major norepinephrine (NE) metabolite, 3-methoxy-4-hydroxyphenylethylene glycol sulfate (MOPEG-SO_4) in rats. The present study examined the ability of periaqueductal gray (PAG) injections of morphine (M) and levorphanol (L) to increase limbic and cortical MOPEG-SO_4 and attempted to correlate changes in MOPEG-SO_4 with the analgesic effects of PAG opiates in the same experimental animals. Isotonic solutions of opiates were bilaterally injected into the ventral PAG through permanent cannulae in male Sprague-Dawley rats. Analgesia was determined 30 minutes after opiate injection by measuring changes in tail-flick latency to a fixed heat stimulus and animals were sacrificed immediately after analgesic testing for the determination of brain MOPEG-SO_4. At 30 minutes, bilateral PAG injections of morphine (0.5-5 µg, base) and levorphanol (10-20 µg, base) produced a dose-dependent analgesic effect accompanied by dose-dependent increases in limbic and cortical MOPEG-SO_4. The bilateral injection of an identical volume of saline (1.0 µl) resulted in tail-flick latencies and MOPEG-SO_4 concentrations which were not significantly different from those obtained in untreated controls subjected to analgesic testing. Analgesia and the increases in MOPEG-SO_4 produced by PAG opiates were antagonized by 10 minute pretreatment with systemic naloxone (1 mg/kg, i.p.) and significant correlations were obtained between the degree of analgesia produced by PAG opiates and limbic and cortical concentrations of MOPEG-SO_4 ($r=0.94$ and 0.85, respectively). These findings indicate that analgesia and increases in brain norepinephrine metabolism in two brain regions are mediated by the specific activation of opiate receptors in the PAG and thus provide further evidence for the involvement of brain noradrenergic systems in opiate analgesia. Supported by NIDA Grant no. 02869.

257.7 4-AMINOPYRIDINE REVERSAL OF MORPHINE ANALGESIA. A.S. Tung, M.D* and B.W. Brandom, M.D*. (SPON: J. Roppolo, Ph.D.) Univ. of Pgh. Sch. of Med., Dept. of Anesthesiology, Pgh., PA 15261.

4-Aminopyridine(4AP) reversal of morphine analgesia was assessed because while morphine sulfate(MS) inhibits the release of neurotransmitters involved with pain transmission[1], 4AP enhances calcium-dependent neurotransmitter release[2]. 4AP has been used clinically to reverse non-depolarizing muscle relaxants[3] and ketamine-diazepam anesthesia. The usefulness of 4AP in these circumstances may be due to an ability to block potassium conductance, create a regenerative calcium current and thus enhance neurotransmitter release. These events may also diminish morphine induced analgesia.

Analgesia was measured by tail flick and hot plate tests. The response latencies in these tests were converted to maximal possible effect (%MPE) .MPE = (Postinjection latency - baseline) / (cutoff time - baseline). All drugs were given i.p.

$\bar{X} \pm$ SEM	MS-10	4AP-2	MS & Saline	MS & 4AP-0.5	MS & 4AP-1.0	MS & 4AP-2.0
%MPE TPL	88±10	3±6	65±12	48±32	10±8	22±16
%MPE HPL	36±17	59±14	34±18	48±21	55±21	100±0

Statistically significant ($P<.05$) results are as follows. MS 10 mg/kg elevated both the tail flick (TFL) and hot plate (HPL) latencies. 4AP alone did not affect the TFL but increased the HPL. In addition, all three doses of 4AP caused a significant reduction of the MS induced increase in TFL. On the other hand, 4AP at 2mg/kg resulted in a potentiation of the MS effect on HPL.

As indicated by the results of the TFL (a nociceptive spinal reflex) 4AP did reverse MS analgesia. Analgesia reversal was not demonstrated by the HPL because the end point of the hot plate test was indicated by the animal's ability to lick or tap its hind paw. This behavior would require multisynaptic supraspinal function which was affected by the central excitatory action of 4AP. A clinical implication of these results is that while attempting to antagonize muscle relaxant or anesthetic effects in postoperative patients with 4AP, incidental reversal of much needed narcotic analgesia may occur.

257.8 CONTINUOUS NALOXONE INFUSION INDUCES ABSTINENCE-LIKE SYNDROME. D.H. Malin, M.A. Reagan*, J.G. Leavell*, and C.A. Westmoreland*. Univ. of Houston at Clear Lake City, Houston, Texas 77058.

Continuous blockade of endorphin receptors by subcutaneous naloxone infusion produced behavioral symptoms resembling opiate abstinence syndrome within 28 hours. Rats were implanted subcutaneously (under ether anesthesia) with two Alzet osmotic minipumps delivering a total of 0.625 mg naloxone/hour/kg, or with two control minipumps delivering distilled water only. They were observed for ten minutes under blind conditions at 16 and 28 hours post-implant. After 16 hours, the naloxone-infused rats showed significantly more abdominal writhes than controls (means of 1.17 vs. 0.17, $p<.05$). At 28 hours, the naloxone animals showed significantly more abdominal writhes than controls (means of 1.67 vs. 0.0, $p<.02$), as well as more wet-dog shakes than controls (means of 5.83 vs. 0.83, $p<.05$) and less weight gain since implant than controls (means of 23.3g vs. 30.0g, $p<.005$).

One interpretation of these results is that rats under normal circumstances need at least some daily exposure to endorphergic stimulation in order to maintain a state of comfort or behavioral normality. Another interpretation is that rats suffering from implantation discomfort need endorphinergic stimulation to suppress symptoms of irritation resulting from implantation. In the latter case, severe symptoms should appear in rats implanted with two H_2O containing minipumps, if they are acutely deprived of endorphinergic stimulation at 28 hours post implant by a high dose naloxone injection (3 mg/kg s.c.). However, this treatment produced virtually no wet-dog shakes or abdominal writhes in a group of six rats. A control group of six unimplanted rats also failed to demonstrate these symptoms in response to acute naloxone.

Supported by a University of Houston at Clear Lake City Organized Research Grant.

257.9 MORPHINE DEPENDENCE AND NALOXONE CONTRACTIONS IN ISOLATED GUINEA-PIG ILEUM. R.F. Mucha*, L.E. Robson* and H.W. Kosterlitz. Unit for Research on Addictive Drugs, University of Aberdeen, Marischal College, Aberdeen, Scotland, AB9 1AS.

In morphine-withdrawn ileum isolated from guinea-pigs implanted for 3 days with 2 morphine pellets, the inhibitory effects of the presynaptic α-adrenoceptor agonist clonidine on electrically-induced twitches were much reduced and the dose response (DR) curve was flat. Addition of morphine to the bath restored the inhibitory effect (Gillan et al., Br. J. Pharmac. 1979, 66, 601-608). We used naloxone to produce the morphine-withdrawn state and studied the relation of flattening of the clonidine DR curve to the well-known ability of naloxone to produce contractions in ilea treated with morphine.

Ilea exposed to one of three different treatment conditions were used. Procedures for setting up were described by Gillan et al. (0.5 ms, 0.1 Hz, maximal voltage). The first kind of tissue was removed from guinea-pigs implanted with 2x75 mg morphine pellets for 12, 24, or 48 h. Ilea were set up in Krebs solution containing 1600 nM morphine. The second was tissue removed from naive guinea-pigs and preincubated in Krebs containing 10 μM morphine at room temperature for 24 h. These ilea were then set up in Krebs containing 1600 nM morphine. The third kind of tissue was removed from naive guinea-pigs and set up in normal Krebs. After stabilization, morphine (1600 nM) was added to the Krebs and the tissue was incubated for 3 h.

Segments of whole gut from each of the conditions underwent contractions of few minutes duration on addition of naloxone (400 nM) to the bath fluid. In the tissue treated with pellet implants the mean peak contraction produced by naloxone was not greater than that seen in tissue from the other two treatment conditions. Yet, in the tissue treated with pellet implants, the clonidine DR curve measured in the presence of naloxone was flat, whereas in tissue preincubated for 24 h at room temperature in 10 μM morphine the curve was less flat; in tissue incubated for 3 h in the tissue bath in 1600 nM morphine, the clonidine curve was almost unaltered. Longitudinal muscle strips with the myenteric plexus were also studied. Naloxone contractions were only observed in ilea treated with pellet implants, but at the duration of implantation studied (12 and 24 h), clonidine sensitivity was similar in the presence and absence of naloxone.

The naloxone contraction has generally been considered a manifestation of tolerance produced by morphine treatment. However, it is clear that naloxone contractions are not related in a simple way to tolerance to clonidine seen in the morphine-withdrawn gut. (Supported by the United Kingdom M.R.C. and by NIDA grant DA 00662. R.F.M. is a M.R.C. of Canada fellow)

257.10 DEPRESSION OF THERMOREGULATORY BEHAVIOR AFTER CENTRAL INJECTION OF OPIOIDS IN THE CAT. G.L. Bernardini* and W.G. Clark. Dept. of Pharmacology, Univ. of Texas Hlth Sci. Ctr. at Dallas, TX 75235.

Changes in thermoregulatory activity produced by a drug can be assessed by determining the pattern of changes in core body temperature (Tb) induced over a range of environmental temperatures. The value of this approach is enhanced if the changes in thermoregulatory effector activities which cause or accompany the change in Tb are also noted. Behavioral changes can contribute to the overall determination of drug actions on thermoregulation. The usual pattern is that (1) if a drug alters the level about which Tb is regulated, behavioral activity facilitates the Tb change whereas (2) if the drug depresses thermoregulation or alters thermoregulatory effector activity, behavioral changes tend to oppose the change in Tb. Changes in Tb and behavior produced by morphine, D-Ala^2-Met-enkephalinamide (DAME) and pentazocine (PTZ) were determined in unrestrained cats in which a cannula was implanted for injections into the third cerebral ventricle. Tb was recorded automatically from a thermocouple implanted in the retroperitoneal space. For the behavioral tests each animal was placed in a cold room (4°C) in a cage above which was a battery of infrared lamps. They were trained either (1) to hold down a lever to turn the lamps on and to keep them on as long as the lever was depressed (heat-reinforcement, HR) or (2) to press the lever to turn the lamps off, etc. (heat-escape, HE). The height of the lamps was adjusted for each cat so that it depressed the lever 40-60% of the time after vehicle administration. Data from previous studies were used to select doses of morphine (20 μg) and DAME (25 μg) that increase the level about which Tb is regulated, thereby raising Tb in the cold, and a dose of PTZ (1 mg) which initially depresses thermoregulation, thereby decreasing Tb in the cold. Hence the predicted behavioral responses after all three agents would be enhanced HR activity or decreased HE activity. Contrary to the former expectation, these agents greatly decreased HR activity. On the other hand, in animals tested so far, morphine and DAME either did not change or only slightly decreased HE activity. This indicates that the cats could still sense the heat from the lamps and retained adequate motor capability. Thus these opioids did not evoke the predicted overall pattern of behavioral changes but instead tended to depress thermoregulatory behavior. This decrease in responding, which apparently occurred without associated motor or sensory impairment, may reflect the general ability of opioids to decrease reactions to various sensations such as pain, etc. (Supported by National Institute on Drug Abuse Research Grant # DA02188.)

257.11 BODY TEMPERATURE RESPONSES TO MICROINJECTIONS OF MORPHINE IN BRAIN SITES CONTAINING OPIATE RECEPTORS. J.A.P. Teasdale*, M.A. Bozarth, J. Stewart (SPON: R.B. Malmo) Dept. of Psychology, Concordia University, Montreal, Canada H3G 1M8.

High doses of morphine administered systemically have been shown to produce a biphasic effect on temperature in rats. The first phase of this response is hypothermia followed by hyperthermia. To determine the central sites of action for these morphine effects, rats were given microinjections of morphine in various brain regions.

Male hooded rats were unilaterally implanted with 22 gauge cannulae in one of the following sites: central caudate nucleus (CN), periventricular gray substance (PVG), medial preoptic area of the hypothalamus (MPO), lateral hypothalamic area (LH), or ventral tegmental area of Tsai (VTA). Morphine sulfate was infused through a 28 gauge injection cannula that extended 1 mm beyond the indwelling guide cannula. A 2.5 μg dose of morphine sulfate was dissolved in 0.5 μl of Ringer's solution and delivered over a 28 sec period with an additional 30 sec allowed for diffusion (Bozarth, M.A. & Wise, R.A. J. Neurosci. Meth. 2, 273, 1980). Core temperatures were recorded with a rectal telethermometer 15 min before and 15, 45, 105, and 165 min after the infusion of morphine. Core temperatures following the infusion of morphine were compared with temperatures previously obtained following the infusion of Ringer's solution.

At this dose morphine did not produce hypothermia at any of the brain sites tested. There were no significant temperature increases in response to morphine infusions directed to the CN, PVG, LH or VTA. However a significant temperature rise with fast onset was observed from animals implanted in the MPO. These results suggest, as have other studies, that the MPO is involved in the mediation of morphine's thermic effects. The LH and the CN which contain opiate binding sites have failed to produce any thermal effects to morphine infusions in our study. The PVG which has been implicated in the analgesic effects as well as in physical dependence to morphine also failed to show any mediational role in the thermic effects of morphine. The VTA which has been shown to sustain self-administration of morphine, equally did not show any temperature effects in response to morphine at the dose employed in this study.

From these data it would seem that different responses to morphine such as the ones mentioned above are anatomically separate from the temperature response. (Supported by grants from Medical Research Council of Canada (MA-6678) and from NIDA (DA-02285).)

257.12 MODIFICATION OF OPIOID PEPTIDES LEVEL IN THE HYPOTHALAMUS BY CHRONIC TREATMENT WITH d-FENFLURAMINE. L. G. Harsing, Jr.*, H.-Y. T. Yang*, S. Govoni* and E. Costa. (SPON: I. K. Ho). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

The content of met^5-enkephalin (ME) was measured by radioimmunoassay in various brain structures of rats treated repeatedly with d-fenfluramine (15 mg/kg/day). Groups of animals were killed by exposing the head to microwave irradiation on the 5th, 10th and 15th day of treatment. The hypothalamic ME content was elevated from 6.2±1.0 ng/mg protein to 12.9±0.9, 10.3±1.1 and 9.6±0.7 ng/mg protein (n=8-9, $p<0.02$) on the 5th, 10th and 15th day of d-fenfluramine treatment. The increase of ME content in the hypothalamus was associated with a marked decrease of body weight. The striatal ME content was increased from 12.2±1.1 to 18.2±2.1 ng/mg protein (n=9, $p<0.02$) on the 5th day of d-fenfluramine treatment then returned to the control values. In the frontal cortex, hippocampus, brainstem and pituitary the ME content remained unchanged during the treatment with d-fenfluramine. The content of β-endorphin immunoreactive material (β-E-IR) of hypothalamus was increased from 4.4±0.8 to 9.3±1.8 and 7.0±0.8 ng/mg protein (n=8-10, $p<0.05$) on the 5th and 10th day of d-fenfluramine treatment whereas no change was detected in cortical and hypothalamic content of cholecystokinin like immunoreactive material after 5 days d-fenfluramine treatment. An acute injection of d-fenfluramine (15 mg/kg) or d-amphetamine (3mg/kg) failed to affect the ME content in the frontal cortex, striatum, hypothalamus and brainstem or the β-E-IR in the hypothalamus. Five days treatment with d-amphetamine (3 mg/kg) did not modify the ME content in the frontal cortex, striatum, hypothalamus or brainstem. From these experiments one can infer that an accumulation of hypothalamic ME and β-endorphin may be operative in mediating the anorectic action of d-fenfluramine but not that of d-amphetamine. The present experiments do not allow us to differentiate whether this accumulation is due to an increase of synthesis or a decrease utilization. However since naloxone decreases appetite we are investigating whether the anorectic action is mediated by a decreased utilization of ME and β-endorphin.

257.13 THE RELEASE OF ANTERIOR PITUITARY HORMONES BY WIN 44,441-3; A REPORTED KAPPA OPIATE RECEPTOR ANTAGONIST R. Pechnick*, R. George* and R. Poland* (SPON: D. Janowsky). Dept. of Pharmacology, UCLA and Dept. of Psychiatry, Harbor General Hospital, Los Angeles, CA 90024.

Win 44,441-3 has been reported to be a pure antagonist with antagonist activity at the kappa opiate receptor. This compound is unique in that antagonist activity is usually associated with alkyl substitutions of the N-methyl group. Few compounds that retain the N-methyl group demonstrate antagonist activity. This compound has a saturated ketone side chain attached to position 9 of the metazocine ring. The changes in pattern of release of anterior pituitary hormones following administration of this compound should give an indication of whether the kappa receptor activity can be distinguished from mu receptor activity.

Male, Sprague-Dawley rats were housed in the experimental room under 12/12 hour light dark cycle for eight days prior to the experimental day. Three days prior to the experimental day the subjects were handled and given s.c. saline injections to habituate them to the experimental procedure. On the day of the experiment rats 48 days old with a mean weight of 239.9±2.2 g were randomly assigned to control and treatment groups. Win 44,441-3 was dissolved in 8.5% lactate, the pH brought up to 3.8 by the addition of 0.1 N NaOH and normal saline used to dilute to volume. The control subjects received the vehicle adjusted to a pH of 3.8. The treatment groups received Win 44,441-3 in doses equimolar to 5.0, 10.0 and 20.0 mg/kg of morphine base (equivalent to 13.1, 26.2 and 52.4 μMoles/kg respectively). All injections were given s.c. with a volume of 1.0 ml/kg. 30 minutes following injection trunk blood was obtained for measurement of corticosterone, growth hormone, prolactin, luteinizing hormone and thyroid stimulating hormone via RIA. Statistical analysis was performed on the log transformed data. Analysis of variance was first performed followed by Dunnett's test when initial significant differences were found.

There were no gross behavioral changes seen following the administration of Win 44,441-3. No significant changes were seen in the release of corticosterone, growth hormone or thyroid stimulating hormone. A highly significant increase in the level of luteinizing hormone was seen as well as a significant decrease in the prolactin level was found. These results demonstrate a similar profile to that seen following the administration of naloxone with the exception of no fall in growth hormone levels as reported by several investigators following naloxone administration. 257.14 IN VIVO RELEASE OF ENKEPHALIN FROM THE GLOBUS PALLIDUS IS TONICALLY INHIBITED BY ENDOGENOUS GABA. A. Bayon, R. Drucker-Colin, L. Lugo*. Centro de Investigactiones en Fisiologia Celular. U.N.A.M., Apartado Postal 70-600, Mexico 20, D.F., and W.J. Shoemaker, R. Azad*, and F.E. Bloom. The Salk Institute, P.O. Box 85800, San Diego, CA 92138.

Previous studies demonstrated that endogenous immunoreactive-enkephalin is released in vivo from the globus pallidus; this release is enhanced during local or caudate nucleus stimulation (Bayon et al. Neurosci. Letters. Vol. 23, 1981). Since the globus pallidus is one of the brain regions richest in glutamate decarboxylase, we have investigated the relationship between the GABA-containing system and the enkephalin release in this area. Methodological details of the push-pull perfusion technique used in these experiments have already been reported (Bayon et al., ibid): Cats were chronically implanted under pentobarbital anesthesia with guide-cannulae to allow the stereotaxical placement of concentric perfusion cannulae in the globus pallidus one week later. At that time the fully awake-unrestrained animals were perfused with a modified Krebs-Ringer solution containing BSA (0.1%) and bacitracin (30 μg/ml), to which drugs were added when indicated. The flow rate was held constant at 23 μl/min and perfusates were collected every 15 min. Fractions were assayed by a Leu-enkephalin RIA (3% cross reactivity with Met-enkephalin). As already reported, local perfusion with medium containing Veratrine (60 μg/ml) enhanced the enkephalin release. Exogenous GABA (10^{-4}M) did not elicit a measurable change in resting enkephalin release but significantly inhibited that stimulated by Veratrine. Picrotoxin (5×10^{-4} M), a GABA receptor antagonist, increased the resting enkephalin release (about 3-fold) both in the presence and in the absence of exogenous GABA. This observation suggests that endogenously released GABA may exert a tonic inhibition upon pallidal release of enkephalin. In this context, it is noteworthy that a substantial release of immunoreactive enkephalin (about one half of the tissue stores in 40 min) occurs during resting perfusion of pallidal slices (Bayon et al, PNAS USA, 75, 3503, 1978). Based on our present hypothesis, this massive enkephalin release could be due to the lack in this isolated preparation of the GABA input originating from extrapallidal structures.

257.15 ENHANCEMENT OF LYMPHOCYTE PROLIFERATIVE RESPONSES BY β-ENDORPHIN. Steven C. Gilman*, Jeffrey M. Schwartz*, Robert J. Milner*, Floyd E. Bloom, and Joseph D. Feldman*. Scripps Clinic and Research Foundation and the A.V. Davis Center at the Salk Institute, La Jolla, CA 92037.

The effects of α and β endorphin on rat lymphocytes were studied using an in vitro culture system. Spleen cells from 3-4 month old Lewis rats were cultured in the presence or absence of purified synthetic α and β-endorphin at final concentrations of 10^{-12} M to 10^{-14}M. Cellular proliferation, measured by the uptake of ^{3}H-thymidine (^{3}H-Tdr), was assessed after 72 hours of culture. α and β endorphin alone had no effect on the proliferation of unstimulated spleen cells. However, the β-endorphin enhanced the proliferative response of spleen cells to the T cell mitogen Concanavalin A (Con A). ^{3}H-Tdr uptake of Con A stimulated cells was increased 2-4 fold in cultures containing 10^{-12}M β-endorphin, compared to uptake in cultures given Con A alone. The enhancing effect of β-endorphin was dose-dependent and was most pronounced when a sub-optimal dose of Con A was used. In contrast, α-endorphin had no effect on Con A responses at any concentration tested. The enhancement of Con A induced ^{3}H-Tdr uptake by β-endorphin was inhibited by naloxone (10^{-5}M). These results suggest that endogenous opiates such as β-endorphin may modulate immune responsiveness and open the possibility of an association between the neuroendocrine and immune systems. Furthermore, given the recent demonstration in rats of immunoreactive β-endorphin secretion in response to stress (Guillemin et al., Science, 1977), the results obtained using this in vitro culture system may reflect cellular mechanisms underlying the psycho-somatic interactions proposed to explain demonstrated modifications of immune function by psychosocial processes (M. Stein et al., Science, 1976). Supported by USPHS Grants AI 7007, MH 07899.

258.1 CORRESPONDENCE OF MELANIN-PIGMENTED NEURONS IN HUMAN BRAIN TO A1-A14 CATECHOLAMINE CELL GROUPS. C.K.Petito and C.B. Saper, Depts. of Neurology and Pathology, New York Hosp.-Cornell Univ. Med. Ctr., New York, NY 10021.

The distribution of catecholaminergic neurons has been plotted in detail for many species, but never for the adult human brain. We report that the adult human brain contains melanin-pigmented and therefore presumably catecholaminergic neurons in a distribution which closely parallels that of the A1-A14 catecholamine cell groups in other species.

Three brainstems and basal forebrains from 56-80 year old people dying of non-neurological causes were obtained at autopsy. After 4-26 weeks formalin fixation the brains were frozen sectioned at 50 u and every tenth section mounted and lightly stained with thionin. Alternate series of sections were stained with PAS; with oil red O; for iron; and with Fontana-Masson stain both with and without hydrogen peroxide bleaching.

The A1 and A2 cell groups, with similar cytological features, were easily distinguished at the level of the dorsal motor vagal nucleus, but no distinct A3 cell group was found. The neurons of the A5 group, near the superior olivary nucleus, the A4 and the A6 groups in the cerebellum and subjacent dorsolateral pons and the A7 cell group in the lateral pontine tegmentum were all larger and tended to be more densely pigmented than the A1 and A2 neurons. The A8, A9 and A10 cell groups, in the substantia nigra pars compacta and associated dorsolateral and medial midbrain tegmentum, also contained primarily larger, densely pigmented and staining neurons. In contrast, the A12, A13 and A14 cell groups in the arcuate and periventricular nuclei of the hypothalamus consisted of much smaller and less densely pigmented neurons. A few similar cells were seen in the posterior hypothalamic area in a cluster which may be homologous to the A11 cell group.

Stains for iron and lipofuscin were not taken up by the pigmentation, but a Fontana-Masson stain for melanin was positive. The pigmentation was bleached, as is appropriate for melanin, with hydrogen peroxide.

These results indicate that in the adult human brain melanin-pigmented neurons are found not only in the locus coeruleus, substantia nigra and dorsal motor vagal nucleus, but more widely in a distribution identical to that of the A1-A14 catecholamine cell groups in other species. As brain melanin is a byproduct of catecholamine synthesis, it appears that melanin may be used as a natural marker in neuropathological assessment of the entire human catecholamine neuron system in post-mortem material.

258.2 TOPOGRAPHICAL ORDERING OF LOCUS COERULEUS PROJECTION TO THE TELENCEPHALON OF THE RAT. J.M. Cedarbaum and C.B. Saper. (SPON: H.P. Davis). Dept. of Neurology, New York Hospital-Cornell Univ. Med. Ctr., New York, NY 10021.

The noradrenergic neurons of the locus coeruleus (LC) are known to project widely throughout the CNS, including the spinal cord, cerebellum, thalamus, limbic system and neocortex. Single LC neurons may send axon collaterals to multiple terminal fields. Nevertheless, retrograde tracer studies have demonstrated a degree of topographical ordering within the system. Several studies suggest that projections to the spinal cord and the hypothalamus arise from the ventral part of LC, projections to the hippocampus arise from its rostrodorsal portion and that the cortical projection arises diffusely from all portions of the nucleus. No topographical ordering to the LC projection to the cerebral cortex has, however, been described. Using a retrograde transport method employing wheat germ agglutinin conjugated to horseradish peroxidase developed with TMB, we have been able to distinguish a crude topographical ordering within the telencephalic projection of LC.

Labeled neurons were seen in LC both ipsilateral and contralateral to the injection sites (in a ratio of about 10-20:1)in all areas studied. The labeled neurons often appeared to be arranged in clusters or in bands, frequently in relation to small blood vessels. By superimposing results from several experiments with similar injection sites, however, a topographic pattern of labeling emerged. In agreement with previous studies, injections into the septum, the infralimbic cortex and the hippocampus retrogradely labeled neurons in the rostrodorsal LC. A similar pattern was seen after olfactory tubercle, piriform or entorhinal cortex injections. A crude topographical pattern was seen within the LC projection to the neocortex. Medial frontal injections labeled primarily cells in the rostral medial part of LC, whereas lateral hemispheric injections labeled mainly cells in the lateral part of LC and more posterior injections labeled a more caudal population of neurons. More diffuse retrograde labeling within LC was seen following injections into the cingulate cortex presumably due to uptake of label by axons passing through the cingulate bundle. This rough topographic mapping of the LC projection to the cortical surface may provide an anatomical substrate for noradrenergic modulation to be employed differentially in various cortical areas.

258.3 REGION-SPECIFIC CATECHOLAMINE INNERVATION OF PRIMATE CEREBRAL CORTEX. P.Levitt, P. Rakic and P.S. Goldman-Rakic. Sec. of Neuroanatomy, Yale University Sch. of Med., New Haven, Ct. 06510

The distribution of norepinephrine(NE)-and dopamine(DA)- containing afferents of the cerebral cortex in the adult rhesus monkey was examined using the sensitive SPG fluorescence histochemical method of de la Torre. The density and laminar distribution of catecholamine (CA)-containing axons exhibits remarkable regional specificity that correlates closely with endogenous transmitter levels measured biochemically in the same cortical areas of the rhesus monkey (Brown, Crane & Goldman, Brain Res. 168 '79). In primary sensory areas such as S1 somatosensory, auditory and visual cortices, NE-type axons are distributed primarily in layers II, III and VI. Surprisingly, fluorescent axons are virtually absent in layer I which is usually densely innervated in rodent neocortex. Within secondary sensory cortical areas, CA fibers are similarly distributed, but less dense. In contrast to the sensory areas, motor cortex (Brodmann areas 4,6) contains adrenergic axons in all layers: layers II, V and VI are profusely innervated by NE-type axons, while layers II and III contain both DA- and NE-type axons. Fluorescent fibers are particularly dense medially in the distal hindlimb region as well as more laterally in the distal forelimb and face area. CA-containing axons exhibit a still different pattern of distribution in frontal and parietal association cortex. In these regions, layers II and III are most heavily innervated, and except in Brodmann's area 9 surrounding the principal sulcus, layer I contains few CA fibers. Both NE and DA-type axons are present in anterior cingulate, dorsolateral and orbital cortex of the frontal lobe. Insular cortex has a unique CA fiber distribution, expressed as an extremely dense and homogeneous input to all layers except layer I. Also, unlike other cortical fields, the fluorescent axons in the insula course in only one direction, predominantly dorsoventrally. Additional, more general features of the CA fiber distribution in primate cerebral cortex include a) the presence of a network of long preterminal axons coursing in both anteroposterior and mediolateral directions through the deep strata of layer VI and within the subcortical white matter, b) frequent localization of terminal NE-type axons around interstitial neurons situated within subcortical white matter and c) the more prominent accumulation of CA axons around sulcal invaginations, particularly in more superficial layers.

These general features and the regionally specific patterns and density of NE- and DA-containing afferents in primate cerebral cortex differ substantially from that in rodent. These findings indicate that in the primate, this class of cortical afferents may have specialized functions within each individual cortical field. (Supported by grants NS16666, NS14841 and F32NS06143.)

258.4 SELECTIVE INCREASE OF LOCUS COERULEUS AXONS IN A DEFINED SINGLE GENE MUTATION. Jeffrey L.Noebels and Pat Levitt, Sect. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, Ct. 06510.

The mutant gene tottering (tg, autosomal recessive, chromosome 8) expresses in the mouse a reproducible alteration in CNS physiology characterized by a delayed developmental appearance of ataxia, spontaneous cortical spike-wave discharges, and focal motor seizures. No disturbances of neuronal organization, regional brain morphology or size have previously been recognized. To further define the cellular expression of the tg allele, the central catecholamine (CA) neuron system of C57Bl/6J tg/tg mice was examined using fluorescence histochemistry and biochemical analysis of CA content. Glyoxylic acid histofluorescence studies revealed 2-3 fold increases in the number of noradrenergic axons within all terminal fields innervated by the nucleus locus coeruleus (LC), including neocortex,hippocampus, cerebellum, and dorsal lateral geniculate nucleus, when compared with age-matched wild type (+/+) mice. This increase was seen uniformly at the time of the earliest behavioral expression of the tg neurological syndrome (4 weeks postnatal) and persisted into adulthood. Concomitant elevations of 100-200% in norepinephrine (NE) levels were detected by high performance liquid chromatography in these terminal regions. In contrast, CA fibers and transmitter content within target areas innervated by a second major NE axon system arising from brainstem lateral tegmental neurons were unaltered. Nuclei receiving a dense dopaminergic innervation were also unchanged in terminal axon number and transmitter content. Despite the striking hypertrophy of the LC axonal plexus, the number and size of LC somata were identical in both tg/tg and +/+ mice, as were the dimensions and cellular organization of all target nuclei. Based on the anatomical segregation of central CA terminal projections, these results show that a single locus mutation can selectively alter the locus coeruleus NE neuronal system while sparing other cell groups sharing the same class of neurotransmitter. The increased number of LC axons in the tg/tg brain differs from the atrophic changes of specific cell types often observed in other neurological gene mutations. This unusual growth may be related to the capacity of central CA neurons for fiber plasticity in developing and adult animals. Unlike sprouting following experimental injury, the inherited lesion displays a generalized proliferation throughout the entire LC axonal arbor, indicating that the expression of a terminal field of defined proportions can be directed by a single gene. The findings described are consistant with a specific gene-linked alteration of developmental events controlling the number of axons produced by a single neuronal population in the mammalian brain. Supported by grant F32NS06143.

258.5 COLLATERALIZATION OF MONOAMINE NEURON PROJECTIONS TO FOREBRAIN
Sandra E. Loughlin,* Sally O. Issacs* and James H. Fallon.
Dept. of Anatomy, Univ. of Calif. Irvine, Irvine, CA 92717

The monoamine (MA) cell groups projecting to the forebrain consist of dopamine cells in the ventral tegmental area (VTA) and substantia nigra (SN), serotonergic cells in the raphe nuclei, and norepinephrine cells in the locus coeruleus (LC). The efferent targets of these cells have been characterized and the topographical organization of these projections have been the subject of our previous work. These studies suggested that at least some cells in each nucleus could collateralize to innervate more than one structure. The recent development of the fluorescent retrograde tracer techniques has allowed us to address the question of whether individual cells in these nuclei might collateralize to innervate more than one cortical region, or both cortical and subcortical sites. In the present study nuclear yellow, granular blue, true blue, and propidium iodide were injected into MA forebrain fields in the albino rat. The results suggest that each of these MA cell groups differ with respect to their principles of collateralization. VTA cells are rarely double labeled, suggesting that each cell projects to one, or only a few, target areas. SN cells, however, are frequently observed to be double labeled and one cell may project to limbic, striatal, and cortical sites. They are, however, highly organized with respect to this collateralization and only certain combinations of injections result in double labeling. For instance, whereas one cell might project to pregenual and supragenual cortex, one cell does not appear to innervate supragenual and suprarhinal cortex simultaneously. The other MA cell groups, raphe and LC, are highly collateralized. One cell can be observed to innervate cortical and subcortical sites. The innervation of cortex by these groups, however, may be governed by very different organizational principles than those of the DA cell groups. That is, spatial rather than cytoarchitectonic subdivisions may be important. Although one cell may innervate medial pre-frontal and occipital cortex, the same cell is not observed to innervate more lateral regions. The principles governing the collateralization of these projections will be discussed.

258.6 PROJECTIONS OF THE A1 AND A2 NOREPINEPHRINE CELL GROUPS TO THE SEPTUM OF THE RAT.
Edward W. Akeyson* and Reinhard Grzanna.
Departments of Cell Biology & Anatomy and Neuroscience, Johns Hopkins University, School of Medicine, Baltimore, Md. 21205.

The septum of the rat receives a noradrenergic (NA) innervation from the locus coeruleus and from cells in the medulla. We have made use of the highly selective uptake and retrograde transport of antibodies against dopamine-β-hydroxylase (DBH) by NA axons to determine which of the two medullary NA cell groups (A1 and A2) gives rise to NA fibres in the septum. Rats received a stereotaxic injection of 0.05-0.2 µl guinea pig anti-rat DBH antiserum into the lateral septal nucleus. Antibodies were delivered through a glass micropipette over a period of 40 min. To control for specificity, guinea pig globulins were injected in place of anti-DBH antiserum. After 18 h rats were perfused and 60 µ sections were cut on a Vibratome. Sections were stained with HRP labeled antibodies to visualize retrogradely transported anti-DBH antibodies. Every third section was processed for immunocytochemical staining of DBH.

At the injection site staining for anti-DBH extended from the midportion of the lateral septal nucleus into the medial septal nucleus and the dorsal portion of the interstitial nucleus of the stria terminalis. Positive retrograde labeling of NA cells was indicated by the presence of immunoreactive granules in the cytoplasm and dendrites of NA cells. Strong labeling was observed in a small number of A1 cells bilaterally in the ventrolateral portion of the medulla rostral to the obex; in contrast, very few of the more caudally located A1 cells were labeled. None of the presumably epinephrine containing cells in the rostral medulla contained retrogradely transported anti-DBH antibodies. Numerous labeled A2 cells were found bilaterally at the level of the area postrema but none at the level of the nucleus gracilis. In the pons, a considerable number of labeled cells were present in the rostral and dorsal part of the locus coeruleus. No retrogradely transported anti-DBH was detectable in cells of the A5 and A7 group.

The data indicate that the septal area receives NA fibres from the locus coeruleus and from a restricted portion of the A1 and A2 cell groups. The existence of a NA projection arising from A2 cells, which are embedded in the nucleus of the solitary tract, provides evidence for a direct NA link between this visceral afferent nucleus and the septal area. Support: USPHS NS 16654.

258.7 THE NORADRENERGIC INNERVATION OF PERIAQUEDUCTAL GREY MATTER AS VISUALIZED BY HIGH RESOLUTION RADIOAUTOGRAPHY.
K.C. Watkins* and L. Descarries, Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada H3C 3T8.

To examine noradrenergic axon terminals in the periaqueductal grey matter (SGP), light and electron microscope radioautographs were prepared after prolonged (3 h) latero-ventricular instillation of 10^{-4} M tritiated noradrenaline (^{3}H-NA, DL-7-^{3}H-noradrenaline hydrochloride, 200 µCi) in adult rats pretreated with a monoamine oxidase inhibitor. Semi-thin and thin sections taken at various levels across the caudal half of the midbrain displayed labeled axonal varicosities almost exclusively within a distance of 0.5 mm from the ependyma; for example, few were detected inside the nucleus raphe dorsalis proper. A tissue block, centered on the midline and grazing the aqueduct of Sylvius dorsally, was selected for detailed topometric analysis. Radioautographs of serial thin sections were exposed for 6 months, developed with paraphenylenediamine, and all aggregates of silver grains comprising three or more filaments were charted and photographed in a ribbon of 4 sections. Moreover, every axonal process thus recognized as labeled was photographed in each of the sections where it was visible. The region surveyed in this manner measured approximately 0.7 mm^2 and showed 280 different labeled sites. Of these, 57 (20%) could be identified as intervaricose segments belonging to thin unmyelinated axons (mean diameter: 0.3 µm), and 213 (76%) as axonal varicosities, i.e. enlargements containing clustered synaptic vesicles (mean diameter:1 µm). When expressed per unit area, the number of labeled varicosities diminished linearly with increasing distance from the ependyma ($r = -0.96$). A close correlation was also found for the frequency with which the labeling was detected in each section across varicosities seen more than once ($r = -.90$). Only 16 (6%) of the labeled varicosities exhibited a membranous differentiation of synaptic junction, which was invariably axo-dendritic. The junctional profiles were slightly larger (mean diameter: 1.2 µm) than their non-junctional counterparts and appeared randomly distributed with respect to their distance from the ependyma. These data emphasize the restricted penetration of ^{3}H-NA in brain tissue after intraventricular administration. In SGP, the gradient of diffusion actually precluded complete identification of all noradrenergic axon terminals. Nevertheless, topometric analysis of serial thin sections allows the conclusion that the noradrenergic innervation of the SGP is largely non-junctional. (Supported by MRC grant MT-3544).

258.8 AXOPHORESIS OF [^{3}H]DA AND [^{3}H]NA BY CENTRAL CATECHOLAMINERGIC NEURONS IN RAT BRAIN: RADIOAUTOGRAPHIC DEMONSTRATION.
L. Descarries, F. Berthelet* and S. Garcia* (SPON: A. Beaudet). Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada.

To visualize an eventual axonal transport of tritiated dopamine ([^{3}H]DA) or noradrenaline ([^{3}H]NA) in CNS, one or the other tracer (25 µCi/0.5 µl for 10 min) was injected immediately above the substantia nigra (SN) or inside the nucleus caudate-putamen (CP) of adult rats pretreated or not with a monoamine oxidase inhibitor. After 1-24 h survival, the entire brain was radioautographed by exposure of frozen sections on film (LKB) or following perfusion-fixation with glutaraldehyde, paraffin embedding and dipping in liquid emulsion. Labeling at a distance was detected only after pretreatment with monoamine oxidase inhibitor and predominated 3-24 h after the injections, reaching its maximum at 6 and 12 h. The same structures showed labeling with both tracers. 1) After supra-SN injections: rostrally, ipsilateral neostriatum and nucleus accumbens; caudally, ipsilateral fibers in the brainstem tegmentum and nerve cell bodies in the locus coeruleus and in the bulbar groups A-1, A-2 and A-3. A few labeled cell bodies were also seen in the contralateral locus coeruleus. 2) After CP injections: ipsilateral fibers of the nigro-striatal system and nerve cell bodies in the SN, zona compacta, and ventral tegmental area. In addition, a small number of labeled neuronal somata were visible bilaterally, near the midline, in nuclei linearis caudalis and raphe dorsalis; the cells in raphe dorsalis occupied only the rostralmost portion of its medial subgroup (ventral more than dorsal cluster). Concomitant administration of non radioactive serotonin at a concentration 10 times higher than that of [^{3}H]DA had no apparent effect on these patterns of labeling. In rats subjected 15 days earlier to unilateral injection of 6-hydroxydopamine in the zona compacta of SN (8 µg/4 µl), labeling of the nigro-striatal dopaminergic system was almost completely suppressed, which was also the case for the retrograde nerve cell body reactions associated with supra-SN injections. The latter reactions persisted when the rats had been treated with 6-hydroxydopamine after a single dose of desipramine (25 mg/kg i.p., 1 h antea). Two conclusions were drawn: 1) that anterograde and retrograde axophoresis of [^{3}H]-DA or [^{3}H]NA occurs exclusively in catecholaminergic neurons; 2) that the recently described "non-serotoninergic" projection from nucleus raphe dorsalis (and linearis caudalis) to CP in the rat (Steinbusch et al., 1980) is most probably dopaminergic. (Supported by MRC Grant MT-3544).

258.9 UPTAKE OF [^{3}H]ADRENALINE BY CENTRAL MONOAMINERGIC NEURONS. O. Bosler* and L. Descarries (SPON: H.H. Jasper). Département de Neurobiologie Cellulaire, CNRS, BP 71, 13277-Marseille, France, and Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Qué., Canada.

Neuronal sites of accumulation of adrenaline (A) were investigated with light and electron microscope radioautography after lateroventricular instillation of 10^{-4} M [^{3}H]A (DL [7-^{3}H]adrenaline hydrochloride, specific activity: 11.6-17.3 Ci/mM, 60-350 µCi, for 10 min - 3 h) in adult rats pretreated with a monoamine oxidase inhibitor. Following glutaraldehyde perfusion and osmium postfixation by immersion, there were no aggregates of silver grains suggestive of neuronal uptake and retention of the tracer. In contrast, selective labeling was detected in brains which had been rapidly fixed and postfixed by successive vascular perfusion of the glutaraldehyde and osmium solutions (Nature 284: 620-622, 1980). [^{3}H]A-labeled nerve cell bodies were seen in various regions, all known to contain a catecholaminergic population, wherein they were distributed according to the topographic patterns expected from these elements: preoptic area, periventricular hypothalamus and dorsal thalamus, ventral tegmental area, zona compacta of substantia nigra, locus coeruleus, A-1 (C-1) and A-2 (C-2) areas of the medulla. [^{3}H]A-labeled axonal varicosities were prominent in the caudate-putamen, nucleus accumbens, lateral septum, juxta-ventricular and basal hypothalamus, inner layer of the median eminence, periventricular gray matter, and within the subcommissural organ and above the ependymal lining of several portions of the ventricles. The addition of 10^{-3} M non radioactive serotonin to the [^{3}H]A solution markedly diminished the labeling in the subcommissural organ and the supra-ependymal plexus, but had no apparent effect elsewhere in brain. Prior unilateral injection of 6-hydroxydopamine in the pars compacta of substantia nigra (8 µg/4 µl, 15 days earlier) eradicated the axonal labeling in the ipsilateral neostriatum, but spared that in the nucleus accumbens which receives its dopaminergic innervation mainly from the ventral tegmental area. It was concluded that serotonin-containing axon terminals of the subcommissural organ and the supra-ependymal plexus, as well as dopamine and norepinephrine neurons throughout the neuraxis can take up adrenaline, for which they probably have a lesser affinity than toward their own transmitter. Further work will be needed to distinguish presumptive central adrenergic neurons from their dopaminergic and noradrenergic congeners on the basis of such properties. (Supported by MRC grant MT-3544).

258.10 REGIONAL DISTRIBUTION OF CATECHOLAMINE SYSTEMS IN THE RAT MEDULLA A COMBINED NEUROCHEMICAL AND FLUORESCENCE HISTOCHEMICAL STUDY. M.A. Rea, S.K. Jackson,* D.L. Felten and M.H. Aprison, Inst. of Psychiatric Res., Depts. of Psychiatry, Anatomy and Biochemistry Ind. Univ. Sch. of Med., Indianapolis, IN 46223

Specific catecholamine innervation of medullary nuclei in Wistar rats was carried out with combined neurochemical and histofluorescence methods in an attempt to further characterize adrenergic influences on vagal nuclei. The localization of catecholamine cell bodies and varicosities was achieved with both formaldehyde and glyoxylic acid histofluorescence. For comparative biochemical studies, rats were killed by immersion in liquid N_2 for 30 seconds. The frozen brains were removed in a -30°C cryostat; 300 µm thick coronal sections of brain stem were prepared. Tissue samples containing the descending nucleus of V (DNV), inferior olivary nucleus (ION), medullary Raphe nuclei, hypoglossal nucleus, dorsal motor nucleus of X + nucleus of the solitary tract (DMN+NTS), dorsomedial reticular formation (DMR), ventromedial reticular formation (VMR) and ventrolateral reticular formation including the nucleus ambiguus and vagal preganglionic cell bodies innervating the heart (VLR+NA) were isolated from 6 frozen coronal sections (900 µm caudal to the obex through 900 µm rostral to the obex) with an 18G micropunch. The levels of norepinephrine (NE), epinephrine (Ep) and dopamine (DA) were determined by HPLC with electrochemical detection. Tissue NE levels varied 8-fold among the medullary regions and, in general, correlated well with the density of NE terminals detected by fluorescence histochemistry. The high level of NE in the DMN+NTS (218+10 pmol/mg protein (P)) is consistent with the presence of NE cell bodies of the A_2 catecholamine cell group and the high density of NE varicosities projecting from brain stem cell groups to the DMN of X. Moderately high levels of NE were detected in regions containing DMR (99±5 pmol/mg P), ION (94±4 pmol/mg P) and VLR+NA (80±5pmol/mg P). The DNV, characterized by sparse NE innervation, was found to contain the lowest level of NE (28±1 pmol/mg P). In the VLR+NA punch, cell bodies of the A_1 cell group were found around the lateral reticular nucleus and a moderate density of fluorescent varicosities was found around and dorsomedial to the NA. The current combined neurochemical-histofluorescence observations suggest that the preganglionic parasympathetic cell bodies in the DMN of X are more densely innervated by NE varicosities than the preganglionic cardioinhibitory cell bodies around NA. Although Ep levels did not vary greatly, levels were highest in the DMN+NTS (4.8±0.8 pmol/mg P) providing additional evidence for Ep as a putative transmitter in cell group A_2. DA levels were also highest in DMN+NTS (31±6 pmol/mg P). Supported in part by N.I.H. grant Rol NS 16205.

258.11 BIOCHEMICAL IDENTIFICATION OF A NIGRO-CEREBELLAR PATHWAY. Melvin H. Van Woert, Eunyong Chung Hwang, Mark J. Perlow and Melvin D. Yahr. Dept. of Neurology & Pharmacology, Mount Sinai School of Medicine, New York, N.Y. 10029.

Neuronal connections between the basal ganglia and cerebellum have been suggested, however, the neurotransmitters involved and the precise mechanisms by which they interact to control motor activity is not known. In order to examine for a possible nigro-cerebellar pathway and its neurotransmitter, we lesioned the substantia nigra (SN) and examined high affinity uptake of several neurotransmitters in the cerebellum.

Male Sprague-Dawley rats (150 g) were anesthetized with chloropent and electrothermic lesions of both SN (AP = 2.5 mm, L = ± 2.0 mm and V = 6.8 mm from dura according to Konig and Klippel Atlas) were made with a Grass LM4 lesion maker. 14 days following the lesion, the cerebellum was removed and high affinity (2.5 x 10^{-9}M to 1 x 10^{-7}M) synaptosomal uptake of neurotransmitters was carried out:

Cerebellar Synaptosomal Uptake
(cpm/15 mg/15 min)

Neurotransmitter	Control	SN Lesioned
^{3}H-Norepinephrine (^{3}H-NE)	3810 ± 296	2507 ± 335*
^{3}H-Dopamine (^{3}H-DA)	1158 ± 78	875 ± 182*
^{3}H-Glutamate	2159 ± 186	2106 ± 257
^{3}H-GABA	4646 ± 409	4446 ± 292
^{3}H-Choline	385 ± 88	339 ± 22

* $p < 0.05$ compared to control by t-test.

Cerebellar ^{3}H-NE and ^{3}H-DA uptakes in SN lesioned rats were significantly lower than the controls, while uptake of the other neurotransmitters examined were not significantly different from control.

In order to investigate whether this is a dopaminergic or noradrenergic pathway, we injected 6-hydroxydopamine (6-HODA) into the same region of the SN after pretreatment with desmethylimipramine (DMI) (25 mg/kg ip) which specifically blocks the uptake of 6-HODA into noradrenergic neurons. 6-HODA lesions of the SN produced similar reductions in cerebellar synaptosomal uptakes of ^{3}H-NE and ^{3}H-DA as electrothermic lesions. DMI pretreatment had no effect on the reductions of ^{3}H-NE and ^{3}H-DA uptakes in the cerebellum.

In summary, our results suggest that there is a nigro-cerebellar pathway which appears to be dopaminergic. (Supported by USPHS grant NS 71631).

258.12 BRANCHED COERULEOCEREBRAL-COERULEOCEREBELLAR PROJECTIONS: A DOUBLE RETROGRADE AXONAL TRACING STUDY USING ^{3}H-N-ACETYL WHEAT GERM AGGLUTININ AND HORSERADISH PEROXIDASE. Dennis A. Steindler* (SPON: J. Zacks). Dept. of Anatomy, Michigan State University, East Lansing, Michigan 48824.

The existence of a noradrenergic innervation of the neuraxis and cortical structures arising from neurons of the pontine nucleus locus coeruleus has been well documented in numerous studies. Despite the presupposition that cells in locus coeruleus give rise to collateralized axonal projections, there has been a lack of direct evidence that substantiates the presence of significant numbers of branched neurons within this nucleus. The present double retrograde axonal tracing study was undertaken in order to resolve the existence of collateralized efferent projections of locus coeruleus neurons to both forebrain and cerebellar cortical structures. Injections of horseradish peroxidase (HRP) or ^{3}H-N-acetyl wheat germ agglutinin (^{3}H-acetyl WGA, New England Nuclear, 1.97mCi/mg) were placed within portions of the cerebral cortex, neostriatum, hippocampus and cerebellar cortex of adult Spb;HA(ICR) white mice. Following survival times of 24-36 hr. and aldehyde fixation, sections were processed for combined histochemistry and autoradiography (exposure times varying from 9 days to 4 months) and examined using bright- and darkfield microscopy. The distribution of retrograde labeled neurons within locus coeruleus observed after forebrain and cerebellar cortical injections of the tracers was compared to the distribution of noradrenergic neurons observed in sections treated for aldehyde-induced catecholamine fluorescence. The following observations were made: 1)Bidirectional axonal transport of both tracers was discerned in several structures (e.g. thalamus, substantia nigra, deep cerebellar and precerebellar nuclei). 2) The boundaries of fluorescent noradrenergic locus coeruleus neurons and those revealed by retrograde labeling were strictly coincidental. 3) The distribution of coeruleocerebral and coeruleocerebellar neurons was found to be similar, and the number of retrograde labeled locus coeruleus neurons appeared to be related to the amount of cortical tissue encompassed by the injected material. 4)Injections of both tracers anywhere in the forebrain and cerebellum in the same animal invariably produced double labeling of neurons scattered throughout the ipsilateral locus coeruleus, and of the neurons that were found to be retrogradely labeled from a cerebellar injection, over 50% were also labeled from the forebrain injection of the other tracer. Thus, noradrenergic locus coeruleus neurons achieve a wide spread innervation of the forebrain and cerebellar cortices at least in part through axonal collateralization. (Supported by NIH Grant NS 15931).

259.1 BIOCHEMICAL PROPERTIES OF HUMAN PLATELET IMIPRAMINE RECOGNITION SITES. L.R. Meyerson, B. Beer and L.P. Wennogle*. Dept. of CNS Research, Medical Research Division, American Cyanamid Company, Lederle Laboratories, Pearl River, New York 10965.

The high affinity specific binding of ^{3}H-Imipramine (^{3}H-IMI) has been demonstrated in both neuronal and platelet sources. Suggestions have been advanced relating this recognition site to serotonin reuptake systems, while others have stated that the modulation of this platelet site may represent a biochemical index of depressive illness. Thus, in light of these theoretical constructs we now provide preliminary biochemical evidence and possible metabolic control mechanisms which may influence the expression of this platelet ^{3}H-IMI site. Platelet membrane fractions were prepared by standard procedures either with NaCl-Tris buffers or with similar buffers supplemented with a variety of enzyme inhibitors including antiproteases and EDTA. In the presence of enzyme inhibitors, consistently higher (1.5x) densities of binding sites (Bmax) were observed while Kd values remained unchanged. Experiments were performed in order to assess the contribution of proteins and lipids to this variation. Trypsin and pronase at concentrations of 0.2 and 0.3 mg/ml, respectively, were sufficient to reduce the number of ^{3}H-IMI recognition sites on isolated platelets to 50% of their original value. In contrast, phospholipase A_2 concentrations of only 2 µg/ml were required to reduce the density of IMI sites by 50%. These observations indicate that the IMI site is particularily susceptable to phospholipid perturbations while being fairly resistant to protease degradation. Further studies demonstrated that a calcium activated metabolic process maybe involved in the stability of the ^{3}H-IMI site. Receptor deterioration (75% reduction) is observed in the presence of 3 mM calcium when exposed at 37°C for 20 hours compared to matched controls (-20°C). This loss is further potentiated by the addition of the calcium-ionophore A-23187. Interestingly, this calcium-mediated degradation can be blocked by chelating agents such as EDTA and EGTA. Thermal denaturation of the ^{3}H-IMI site occurs in the same range expected for a typical membraneous entity with a temperature for 50% inactivation ($T_{½}$) of 62°C. The effect of ultrasonic disruption on intact platelet membranes resulted in a negligible loss of total binding sites. However, the specific binding values/mg protein of the resuspended membrane fragments increased probably due to loss of occluded soluble proteins. The results presented herein provide further characterization of the platelet IMI binding site and how possible metabolic processes mediated by divalent cations such as calcium may play an important role in the preservation and maintenance of proteanaceous recognition sites labeled by ^{3}H-IMI.

259.2 GLUCOSE-INDEPENDENT BRAIN RESPIRATORY RESPONSES. J.T. Cummins, M. Juarez* and E. Keller*. Addiction Research Lab., V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. of Psychiatry, UCLA.

The degree of glucose dependency during depolarized respiratory responses was studied in slices from rat brain cortex. The slices, incubated in Krebs-Ringer bicarbonate with and without glucose, were depolarized with electrical pulses (100Hz, 10V, 30 sec.) and the redox responses of the respiratory intermediates, pyridine nucleotides (NADH) and cytochrome a-a_3, were measured by dual wavelength spectrophotometry. Our results demonstrate that certain components of the depolarized respiratory responses do not depend on exogenous glucose. Following electrical depolarization, the reduction of cytochrome a-a_3 is the same with and without glucose, whereas the NADH response increases three-fold from a basal (no glucose present) response in the presence of glucose. Interestingly, depolarized reduction of NAD^+ and cytochrome a-a_3, enhanced by the ß-adrenergic agonist isoproterenol, is not dependent on glucose. These data have suggested that there are several redox responses following depolarization, some possibly using endogenous compounds rather than exogenous glucose to reduce the respiratory intermediates. One of the endogenous redox responses appears to occur in a biochemical compartment high in mitochondrial activity and activated by an adrenergic agent. This differentiation of several brain redox reactions that occur following depolarization may be used to further study the respective brain biochemical compartmentation.

259.3 CHARACTERIZATION OF A HYDROPHOBIC, DIMERIC FORM OF ACETYLCHOLINESTERASE (AchE) FROM TORPEDO ELECTRIC ORGANS. S.L. Lee*, S.J. Camp* and P. Taylor* (Spon: C.E. Spooner). Div. of Pharmacology, University of California at San Diego, La Jolla, CA 92093.

Prior to this study, the native molecular species of Torpedo and Electrophorus AchE which had been purified and characterized were the dimensionally asymmetric, high ionic strength soluble forms of the enzyme. These asymmetric forms of AchE contained a filamentous unit of partial collagen-like composition, which appears responsible for the localization and apparent association of the enzymes with the basal lamina found in the synapse between nerve and muscle cells. This laboratory has reported (Fed. Proc. 39:179, 1980) that following DTT reduction of the asymmetric Torpedo AchE the subunit components consist of the catalytic unit monomer (68K), a partially collagenous subunit (55K), and a relatively protease-sensitive structural subunit (100K). In the absence of DTT, the dimer of catalytic subunits (131K) and an array of 8-12 evenly spaced bands from 405-750K MW are found.

In this presentation, we describe a stable hydrophobic species of AchE which is composed of a dimer of disulfide-linked subunits purified to apparent homogeneity from Torpedo californica electric organs. The enzyme is soluble at low ionic strength in the absence of detergent, but exists as an aggregate. Non-ionic detergent dissociates the complex into a discrete 5.6S species. Although the hydrophobic dimer [5.6S] and the asymmetric forms of AchE [(17+13)S] show immunologic cross-reactivity, a similar carbohydrate content, and neither contains lipids, there are distinct differences between the catalytic subunits. The 5.6S AchE contains a higher content of hydrophobic amino acid residues and a unique peptide map. On SDS gels, ideal migration behavior is observed for the 5.6S dimeric species, while the dimer of the (17+13)S AchE shows atypical migration when mobility is plotted against acrylamide concentration. Since the (17+13)S monomer (68K) and the slightly smaller 5.6S monomer (66K) both show ideal behavior following DTT reduction, the disparate non-reduced migration behavior is likely due to a difference in secondary structure. Hence it is unlikely that the hydrophobic 5.6S and asymmetric (17+13)s AchE species are precursors or products for each other in situ. Rather, they exist as discrete entities with different dispositions within the synapse. Its comparatively hydrophobic amino acid composition and properties of self-association in the absence of detergent suggest that the 5.6S AchE is loosely associated with plasma membrane through hydrophobic interactions. (Supported by GM 18360 and the Muscular Dystrophy Association.)

259.4 ACETYLCHOLINE RECEPTOR SYNTHESIS OF CHICK SKELETAL MUSCLE CELLS IN CULTURE IS ALTERED BY RYANODINE. Leo Pezzementi and Jakob Schmidt. Dept. of Biochemistry, SUNY at Stony Brook, NY 11794

Synthesis of acetylcholine receptor (AcChR) of muscle cells in culture is regulated by the activity of the muscle fibers. We have investigated the effect of ryanodine on AcChR metabolism. Ryanodine is a plant alkaloid which at micromolar concentrations causes contraction of skeletal muscle due to depletion of calcium from the sarcoplasmic reticulum (SR), and at millimolar concentrations stimulates efflux of calcium from the muscle cell. We found that, after a 48-hour exposure of chick myofiber cultures, micromolar concentrations of ryanodine decreased AcChR to approximately 60% of control levels, while millimolar concentrations increased AcChR to over 200% of control. This appears to be a specific effect on the synthesis of the receptor since appearance rates but not degradation rates of AcChR are altered by the drug. Intracellular transport of AcChR is not affected as both surface and total AcChR content are changed in parallel. The differences in receptor levels do not reflect a general alteration of muscle cell metabolism since protein levels, protein synthetic rate, creatine phosphokinase activity, myosin heavy chain levels, and cell surface acetylcholinesterase are not similarly affected. Additionally, after 48 hours total cellular acetylcholinesterase is unchanged from control levels, although there is a transient (ca. 30%) decrease after 24 hours.

The decrease in receptor seen with micromolar concentrations of ryanodine is not affected by either TTX (which blocks sodium channels) or D-600 (a calcium channel blocker), but is inhibited by Dantrolene Sodium (which blocks release of calcium from the SR). Millimolar concentrations of ryanodine overcome the decrease in AcChR elicited by micromolar concentrations of the drug and by caffeine (which releases calcium from the SR), but this effect is blocked by veratridine (a sodium channel activator). These observations lead us to believe that elevated cytoplasmic calcium, released from the SR by micromolar concentrations of ryanodine, acts to shut off receptor synthesis. We also conclude that ryanodine at millimolar concentrations increases AcChR synthesis by causing a decrease in cytoplasmic calcium, through increased calcium efflux from the cell, thus counteracting the effects of micromolar ryanodine and of caffeine, which increase cytoplasmic calcium. Veratridine, by activating sodium channels, allows reentry of calcium into the muscle cell thus inhibiting the increase in receptor synthesis normally seen with high concentrations of ryanodine. (Supported by a grant from the Muscular Dystrophy Association.)

259.5 MODULATION OF ACETYLCHOLINESTERASE ACTIVITY AND ACETYLCHOLINE RECEPTOR NUMBER IN AN ANDROGEN SENSITIVE NEUROMUSCULAR SYSTEM.
W.V. Bleisch and V.N. Luine. Rockefeller University, New York, N.Y. 10021.

The syrinx of the songbird may provide a novel system in which to study the regulation of synaptic machinery in a physiologically relevant context. The syrinx is highly sensitive to androgens, and syringeal weight, protein, acetylcholinesterase (AChE) activity and acetylcholine receptor (AChR) number all decrease following castration of adult males and increase following testosterone (T) treatment of adult females (Luine et al., 1980, Brain Res. 192:89; Harrelson et al., this volume). We now report that T stimulates the syrinx within days and that the effect of castration occurs much more slowly.

Syrinxes were homogenized in buffered 1.5% Triton X-100 and AChE activity was assayed as described in Luine et al. above. For determinations of AChR number, homogenates were incubated at 30° C for 1 hour and spun at high speed. These extracts were then diluted to equal protein concentration and assayed for binding of I-125 α-bungarotoxin (400pM incubated for 3 hours). Bound and free toxin were separated by the method of Kohanski et al. (1977, Anal. Biochem. 80:531). Nonspecific binding was measured by competing with 500 nM gallamine. This assay proved to be sensitive and linear between 0 and 40 fmoles of AChR. Affinity curves for toxin binding to AChR from male and female zebra finch syrinxes were superimposable, indicating no difference in the kinetics of toxin binding.

In order to study the time course of the effects of T, adult female zebra finches were implanted with T (5mm silastic capsules, as in Luine et al. above) at 11, 6, 5, 3, 2 and 1 days before sacrifice. AChR number was significantly elevated 1 day after implantation ($p < .05$) and protein also rose rapidly. In contrast, AChE activity increased little in the first 2 days after implantation, then rose rapidly between 2 and 5 days. Protein, AChR number and AChE activity all appeared to reach a plateau by 5 days.

In contrast to these rapid changes after T stimulation, the effect of castration appeared much more gradually. Adult male zebra finches were castrated at 59, 23 and 11 days before sacrifice. Syringeal weight, protein, AChR number and AChE activity all decreased gradually from 0 to 23 days, after which they appeared to reach a plateau. Half-times for these losses were calculated from a first order model and found to be 6.6 days for total protein, 15.8 days for AChE activity and 12.5 days for AChR number. This last value is consistent with published turnover rates for adult junctional AChR (see Fambrough, 1979, Physiol. Rev. 59:165).

260.1 A NEW CLASS OF NEUROACTIVE COMPOUNDS, THE AVERMECTINS; EFFECTS ON PERMEABILITY PROPERTIES OF THE LOBSTER INHIBITORY NEUROMUSCULAR JUNCTION. T. N. Mellin, R. D. Busch and C. C. Wang. Dept. of Biochemistry, Merck Institute for Therapeutic Research, Rahway, NJ 07065

The avermectins are a new family of anthelmintic macrocylic lactones which paralyze nematodes and insects. One highly potent constituent, avermectin-B_{1a} (AVM), blocks postsynaptic potentials at the lobster nmj by reducing membrane resistance, (Fritz et al., PNAS, 76: 2062, 1979). It also blocks transmission between interneurons and excitatory motorneurons in the ventral cord of the parasitic nematode, Ascaris (Kass et al., PNAS, 77: 6211, 1980).

Our studies with AVM (5 µg/ml), in lobster opener and stretcher muscle, have confirmed earlier observations which showed that AVM caused a rapid disappearance of IPSP's. EPSP amplitude and input membrane resistance were found to decline at a slower rate, with a common time course. A 3-4 mV membrane hyperpolarization was also observed. These effects were not reversed by extensive washing. EPSP amplitude was partially restored by picrotoxin (20 µM). Both GABA (50 µM) and AVM (5 µg/ml) decreased the slope of I/V curves in stretcher muscle, reflecting an increase in membrane conductance. Bicuculline (50 µM) or picrotoxin (20 µM) reduced the conductance changes caused by GABA or AVM. Increases in membrane conductance, induced by various concentrations of GABA, AVM, or avermectin analogs, were determined from changes in resistance. Dose-response curves showed AVM and a 22,23-dihydroavermectin-B_{1b} analog to produce greater conductance increases than GABA. The magnitude of membrane conductance changes induced by avermectin analogs generally paralleled the degree of stimulation of ^{3}H-GABA release from rat brain synaptosomes and paralysis of the free-living nematode, C. elegans (Pong et al., J. Neurochem. 34: 351, 1980). Replacement of 50% of the Cl^- in lobster saline, with equimolar isethionate, resulted in a depolarization of membrane potential by AVM and GABA, rather than the hyperpolarization normally observed. Cl^- replacement did not alter I/V responses to GABA and AVM. Some fibers of the cockroach extensor tibiae muscle lack GABA inervation. Studies on these fibers revealed no effect of AVM on EPSP amplitude.

Our results thus support earlier suggestions that AVM acts to increase Cl^- permeability of the lobster inhibitory nmj.

260.2 INTERACTIONS OF LINCOSAMIDE ANTIBIOTICS WITH IONIC CHANNELS OF NICOTINIC RECEPTORS. S.R. Ikeda*, J.E. Warnick and E.X. Albuquerque. Dept. of Pharmacol. & Exp. Ther., Univ. of Maryland School of Medicine, Baltimore, MD 21201.

The effects of the lincosamide antibiotics clindamycin (CLIN) and lincomycin (LIN) were studied on the frog sciatic-sartorius and cutaneous pectoris muscles using voltage clamp and fluctuation analysis techniques. Both agents interact primarily with the open conformational state of the ionic channel of the nicotinic ACh receptor. CLIN produced a concentration-dependent depression of peak endplate current (EPC) at 25-1000 µM. Nonlinearity of the current/voltage (I/V) relationship was evident at concentrations above 250 µM. EPC decay in the presence of CLIN was single exponential at all concentrations tested with progressive shortening of the time constant of EPC decay (τ_{EPC}) with increasing drug concentration. At concentrations above 250 µM the normal voltage dependence of τ_{EPC} was abolished. The effect of CLIN on miniature EPC (MEPC) peak amplitude and decay (τ_{MEPC}) was similar to that of EPCs. Noise analysis of EPC fluctuations in response to iontophoretically applied ACh revealed a concentration-dependent decrease in mean channel lifetime and single channel conductance. Power spectra at all concentrations of CLIN could be adequately fitted to a single Lorentzian component. In contrast, LIN produced a progressive lengthening of τ_{EPC} above 250 µM. In addition, a second fast component was evident in τ_{EPC} with higher concentrations (400-1200 µM) of LIN and hyperpolarized membrane potentials (-90 to -160 mV). EPC peak amplitudes in the presence of LIN were depressed in a dose-dependent manner with significant nonlinearity of the I/V relationship evident at concentrations above 100 µM. Studies on τ_{MEPC} revealed two components at concentrations of LIN greater that 50 µM and at all membrane potentials tested (-60 to -120 mV). The fast component of τ was relatively insensitive to drug concentration and membrane potential while the slow component of τ increased with hyperpolarization and drug concentration. The amplitudes of the fast and slow components were insensitive to both drug concentration and membrane potential. Noise analysis in the presence of 50 µM LIN or greater produced spectra consistent with two kinetic components. These results suggest that LIN and CLIN react primarily at the ionic channel in the open conformation and may explain the inability of Ca^{++} and anticholinesterase agents to reverse lincosamide-induced neuromuscular blockade. Furthermore, studies with LIN may provide information about factors controlling τ_{EPC} and τ_{MEPC}. (Supported in part by a grant from The Upjohn Co. and USPHS grant NS-12063.)

260.3 BIOCHEMICAL CHARACTERIZATION OF KETAMINE INTERACTIONS WITH THE NICOTINIC RECEPTOR-ION CHANNEL COMPLEX. Latha Narayanan* and Robert S. Aronstam (SPON: J.J.Buccafusco). Department of Pharmacology, Medical College of Georgia, Augusta, GA 30912.

The interactions of ketamine with the nicotinic receptor-ion channel complex in Torpedo electric organ membranes were investigated using radiolabelled probes for sites associated with the receptor and the ion channel. Receptor binding was measured with 0.1 µM [^{3}H]acetylcholine ([^{3}H]ACh) and [^{3}H]d-tubocurarine ([^{3}H]d-TC) using equilibrium dialysis techniques. "Ion channel" binding was measured with [^{3}H]perhydrohistrionicotoxin ([^{3}H]$_{12}$-HTX) and [^{3}H]phencyclidine ([^{3}H]PCP) using a filtration assay. Ketamine depressed the binding of 2 nM [^{3}H]PCP and 1 nM [^{3}H]H_{12}-HTX to the channel in a dose-dependent fashion; IC50 values ranged from 3 to 8 µM. The ability of ketamine to inhibit the binding of either ligand was enhanced 2 to 3 fold in the presence of 1 µM acetylcholine. Ketamine was equally effective in depressing [^{3}H]PCP and [^{3}H[H_{12}-HTX binding. The inhibition was reversed upon removing the ketamine by centrifugation.

In contrast, ketamine at concentrations up to 1 mM did not depress the binding of 0.1 µM [^{3}H]acetylcholine or [^{3}H]d-tubocurarine to the acetylcholine receptor. This binding was measured using equilibrium dialysis techniques. This suggests that the interference of ketamine with neuromuscular transmission detected in biophysical studies (Alkadhi et al., Fedn. Proc. 40:263, 1981) reflects interactions of the drug with sites removed from the receptor itself.

Probe	Concentration, nM	Ketamine IC50, µM
[^{3}H]ACh	100	>1000
[^{3}H]d-TC	100	>1000
[^{3}H]H_{12}-HTX	1	6.2
[^{3}H]H_{12}HTX/ACh	1	3.1
[^{3}H]PCP	2	7.9
[^{3}H]PCP/ACh	2	3.2

*In these cases binidng was measured in the presence of 1 µM ACh.

Supported by NIH grant DA-02834.

260.4 THE SYNERGISTIC INTERACTION OF 4-AMINOPYRIDINE AND NEOSTIGMINE AT THE NEUROMUSCULAR JUNCTION. Peter C. Tierney*, Yong I. Kim* and T.R. Johns. Department of Neurology, University of Virginia School of Medicine and the University of Virginia Jerry Lewis Neuromuscular Center, Charlottesville, Virginia 22908.

4-Aminopyridine (4-AP) facilitates nicotinic neuromuscular transmission by an increase in the release of acetylcholine (ACh) from motor nerve terminals. Clinical trials of this compound indicate that it is a potent antagonist of the actions of non-depolarizing neuromuscular blocking drugs and that it produces an improvement in muscle strength and neuromuscular transmission in patients with Eaton-Lambert syndrome or myasthenia gravis. Using intracellular microelectrode recording techniques, we investigated the interaction between 4-AP and neostigmine at the rat neuromuscular junction. Our results demonstrate a synergistic increase in neuromuscular facilitatory action when the two drugs were used simultaneously in vitro.

End-plate potentials (EPPs) were measured from forearm flexor digitorum longus muscles exposed to a physiological buffer containing 1.2 µg/ml of d-tubocurarine chloride (TC). Control measurements of EPPs from 15 different end-plates were followed by a one hour perfusion with a solution containing either 4-AP, neostigmine or both. EPPs were recorded again from 15 different end-plates following perfusion. The drug concentrations used were 0.5, 1 and 2 µM 4-AP and 2 and 8 nM neostigmine.

The increase in EPP amplitude when 0.5 µM 4-AP was combined with either 2 or 8 nM neostigmine was equal to or slightly greater than the summation of their individual effects when applied separately. When 1 µM 4-AP was combined with 2 or 8 nM neostigmine, a 20% greater than additive increase in EPP amplitude was seen. An effect 50% greater than additive was produced when 2 µM 4-AP was used with either neostigmine concentration.

This study suggests that a significant portion of the synergism between 4-AP and neostigmine on facilitating neuromuscular transmission occurs at the junction and that this synergism is concentration dependent. Future investigations will attempt to further determine the site of interaction between the two drugs.

260.5 THE EFFECTS OF PROCAINAMIDE ON NEUROMUSCULAR TRANSMISSION. David C. Lee*, Yong I. Kim* and T.R. Johns (SPON: G.R. Hanna). Department of Neurology, University of Virginia School of Medicine and the University of Virginia Jerry Lewis Neuromuscular Center, Charlottesville, Virginia 22908.

Procainamide has been shown to produce clinical exacerbations in patients with myasthenia gravis when utilized for the control of cardiac arrhythmia. We wished to characterize the neuromuscular effects of procainamide at therapeutic doses on the rat flexor digitorum longus muscle.

Using intracellular microelectrode recording techniques, control measurements were made for spontaneously occurring miniature end-plate potentials (MEPPs) from 15 end-plates and then from 15 end-plates after perfusion with procainamide. This was performed at 1, 2, 4, 6 and 8 times the maximum therapeutic level (MTL-16 mg/l). Similar measurements were made for neurally evoked end-plate potentials (EPPs) on muscles treated with 0.6 µg/ml of d-turbocurarine chloride at 1, 4 and 8 MTL.

MEPP amplitude decreased in a dose dependent manner with no detectable MEPPs at 8 MTL. MEPP frequency was reduced significantly only at 6 MTL. The resting membrane potential (RMP) was stable. EPP amplitude was decreased to a comparable degree with that of MEPP with no significant effect on RMP. The half-decay time demonstrated a marked prolongation, while the rise time was slightly reduced. MEPP and EPP measurements made at 4 MTL on single end-plates revealed a reduction in amplitude similar to that of the multiple puncture studies. The effects on both MEPPs and EPPs were reversible with washing with control solution.

Direct quantal analysis was performed using a physiologic buffer containing a high magnesium concentration (10 mM Mg^{++}). Single junction studies were made for 1 and 4 MTL and a decrease in both EPP and MEPP amplitudes was demonstrated. The EPP reduction was greater than that of the MEPP and thus there was a reduction in the number of ACh quanta released from the motor nerve terminals. Both pre- and postjunctional blockades produced by the drug were reversed with a control buffer wash.

This study demonstrates that procainamide decreases postjunctional sensitivity to ACh as well as reduces the quantal content of ACh at clinically significant doses. This direct inhibitory action of procainamide at the junction may account for the clinical exacerbations produced by this drug.
(Supported in part by a center grant from the Muscular Dystrophy Association).

260.6 EVIDENCE FOR GENERATION OF THE SLOW IPSP BY THE DIRECT MUSCARINIC HYPERPOLARIZING ACTION OF ACETYLCHOLINE IN BULLFROG SYMPATHETIC GANGLIA. Peter A. Smith and Forrest F. Weight, Department of Pharmacology, University of Alberta, Edmonton, Alberta, TGG 2H7 Canada and Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852

The synaptic pathway and the neurotransmitter mediating the slow IPSP in bullfrog sympathetic ganglia has been controversial for several years. To study the slow IPSP, the nicotinic fast EPSP must be reduced or blocked with antagonists such as nicotine or d-tubocurarine (dTC). Weight & Padjen (Brain Res. 55, 225, 1973) found in nicotine blocked bullfrog ganglia, that the muscarinic hyperpolarizing action of ACh was present in a low Ca/high Mg Ringer; they proposed that the slow IPSP is generated by a direct muscarinic hyperpolarizing action of ACh released from the cholinergic preganglionic fibers that synapse on C neurons. Libet & Kobayashi (J. Neurophysiol. 37, 805, 1974) confirmed that observation, but reported that in curarized ganglia low Ca/high Mg abolished the hyperpolarizing response to ACh or methacholine (MCh); they concluded that the slow IPSP in curarized ganglia involves an adrenergic interneuron. We have re-examined the generation of the slow IPSP and the effect inhibiting transmitter release on the MCh-hyperpolarization (MCh_H) in curarized ganglia. The experiments were performed on the IXth or Xth paravertebral sympathetic ganglion of the bullfrog in the presence of 70 uM dTC. With intracellular recording, stimulation of the VIIIth spinal nerve generated a slow IPSP that could be recorded intracellularly from C neurons; the iontophoretic administration of ACh to C neurons elicited a slow hyperpolarizing response in those neurons. In sucrose gap experiments, Ringer's solutions containing the following were used to inhibit transmitter release: (i) tetrodotoxin (10^{-5} M); (ii) 4 mM cobalt; (iii) Ca-free (no Ca^{2+} added); (iv) Ca-free with 10^{-4} M EGTA; or (v) Ca-free with 10 mM Mg^{2+}. Although each of these treatments effectively inhibited synaptic transmission, none blocked the MCh_H. In fact, the MCh_H was increased in amplitude by Ca-free Ringer with 10^{-4} M EGTA. If an interneuron is involved in the generation of the slow IPSP, the MCh_H should be abolished by conditions that prevent neurotransmitter release. On the basis of the observations reported here, the MCh_H appears to be a direct muscarinic postsynaptic response in curarized, as well as nicotinized ganglia. This suggests that the slow IPSP results from a direct muscarinic hyperpolarizing action of ACh released from cholinergic preganglionic fibers that synapse on C neurons, regardless of the nicotinic antagonist.

260.7 EFFECT OF PHENTOLAMINE ON SYNAPTIC TRANSMISSION IN BULLFROG SYMPATHETIC GANGLIA. Parviz Yavari* and Forrest F. Weight, Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852

The neurotransmitter and pathway mediating the slow IPSP in the sympathetic ganglia of bullfrog has been controversial for several years. One hypothesis proposes that the slow IPSP is mediated by a direct muscarinic action of acetylcholine released from cholinergic preganglionic fibers (Weight & Padjen, Brain Res., 55:225, 1973). A second hypothesis proposes that the slow IPSP is mediated by a catecholamine released from an adrenergic interneuron (Libet & Kobayashi, J. Neurophysiol., 37:805, 1974). The latter hypothesis is based, in part, upon the observation that the alpha-adrenergic antagonist phentolamine in a concentration of 40 and 200 µM partially depresses the slow IPSP. We have used the sucrose-gap recording method to study the effect of phentolamine on synaptic transmission in the IXth or Xth paravertebral sympathetic ganglia of bullfrogs. Preganglionic B fibers were stimulated in the sympathetic chain between the VIth and VIIth ganglion, and preganglionic C fibers were stimulated in the VIIIth spinal nerve. In a concentration of 1 or 10 µM, phentolamine did not have any appreciable effect on the amplitude of the transmitted action potential of either the B or the C fiber pathway. However, when the concentration of phentolamine was increased to 40 µM, the amplitude of both the B and the C volley was consistently reduced. Phentolamine in a concentration of 40 µM for 30 min. reduced the B action potential 13 ± 2% (mean ± SEM; n = 8) and the C spike 12 ± 3% (n = 4). In other experiments, when 40 µM phentolamine was perfused for 60 min, the reductions were 23 ± 5% for B (n = 4) and 20 ± 7% for C spikes (n = 3). At a concentration of 200 µM, phentolamine produced a 38 ± 6% (n = 3) reduction in the height of the B volley when it was perfused for 30 min. Since synaptic transmission in bullfrog ganglia is mediated by a nicotinic cholinergic mechanism, the results indicate that in concentrations greater than 10 µM, the alpha-adrenergic antagonist phentolamine can have non-specific depressant effects on synaptic transmission.

260.8 EFFECTS OF ACIDIC AMINO ACID DERIVATIVES ON PERFORANT PATH EVOKED RESPONSES. Eric W. Harris, James F. Koerner* and Carl W. Cotman. Department of Psychobiology, Univ. Calif. Irvine, Irvine, CA 92717 and Department of Biochemistry, Medical School, Univ. Minn. Minneapolis, MN 55455.

Acidic amino acids, in particular L-glutamate, have been proposed as candidates for neurotransmitters in the central nervous system. There is especially strong supportive evidence that glutamate is the transmitter for the entorhinal cortical projection to the dentate gyrus (the perforant path). Using the isolated hippocampal slice preparation, we investigated the effects of superfusion with several putative glutamate antagonists and found a very potent anatgonism by the L-stereoisomer of 2-amino-4-phosphonobutyric acid (L-APB). Micromolar L-APB antagonized the evoked response in the outer-most portions of the dentate dendritic field (Koerner and Cotman, Brain Res., in press). The input to this region arises from the more lateral portions of the entorhinal cortex. The projection from more medial entorhinal cortex, terminating in the middle part of the dentate dendritic field, is is less sensitive and exhibits a compound inhibition by L-APB. The L-APB-sensitive lateral component was less sensitive to the D-stereoisomer of APB and to the two homologues D,L-2-amino-3-phosphonopropionic acid and D,L-2-amino-5-phosphonovaleric acid.

To further characterize the receptors activated by the perforant path, we have examined the effects of D-α-aminoadipic acid (DαAA) and glutamic acid diethyl ester (GDEE), which block the classes of receptors activated by N-methyl-D-aspartic acid and quisqualic acid, respectively (see Evans and Watkins, Life Sci., 28, 1303-1308, 1981). Evoked responses along the lateral component of the perforant path were much less sensitive to antagonism by DαAA than by APB. The perforant path appears to be uniformly sensitive to antagonism by DαAA, and is relatively insensitive to the L-stereoisomer of αAA, or to GDEE which produced significant reduction in the evoked response size only at very high concentrations (>4mM). At concentrations of either APB or DαAA which yielded assymptotic levels of antagonism, addition of the other compound produced a further response decrement, suggesting that the compounds act on non-identical populations of receptors.

Our results indicate that transmission at the perforant path to granule cell synapse involves a novel type of receptor, that, for the lateral component, is sensitive to L-APB, and that does not fit the prevailing acidic amino acid receptor classification scheme.

260.9 PHARMACOLOGICAL CHARACTERIZATION OF THE ELECTROPHYSIOLOGICAL AND BEHAVIORAL EFFECTS OF ADENOSINE AGONISTS. Thomas V. Dunwiddie and Thomas Worth*. Dept. of Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262

Biochemical experiments have suggested that adenosine may interact with at least two different types of receptors in brain tissue (Bruns et al.,PNAS 77:5547,1980). We have characterized physiological responses to adenosine analogs in order to compare their pharmacological actions to their relative affinities for adenosine receptors.

Adenosine, related purines, and analogs of adenosine were examined in terms of their effects on synaptic transmission and anticonvulsant activity in vitro, and for sedative, anticonvulsant, and hypothermic actions in vivo. Several non-metabolizable analogs of adenosine were found to be extremely potent in antagonizing synaptic transmission, and in inhibiting the rate of interictal discharge in the hippocampus in vitro, with EC50's in the low nanomolar range.

In vivo, these same analogs exhibited sedative, hypothermic, and anticonvulsant activity in both mice and rats. Several results suggest that these adenosine analogs do not act via a homogeneous population of receptors to produce these effects in the intact animal. First, the potency of a given agonist in producing sedative effects could be as much as an order of magnitude greater than its potency as an anticonvulsant. Secondly, some agonists were relatively better anticonvulsants, while others were more potent as sedatives. Finally, when the anticonvulsant actions of adenosine agonists were examined with respect to a variety of convulsants, some dissimilarities between different agonists were readily apparent. Cyclohexyladenosine and 2-chloroadenosine appeared quite similar, being very potent in antagonizing picrotoxin-induced seizures, and relatively weak as anticonvulsants of pentylenetetrazol-induced convulsions. Conversely, L-phenyl-isopropyladenosine was effective against a range of different convulsants including pentylenetetrazol. If all adenosine analogs acted on a single population of receptors to produce their effects one would expect that, although some might be weaker agonists than others, all would show the same general profile of relative potency when tested in various ways. This clearly was not the case.

The results from both in vitro and in vivo experiments suggest that the receptors mediating these responses are similar to those tentatively characterized as A1 receptors. However, the heterogeneity of the responses seen in vivo suggests that other types of receptors may be implicated as well.

260.10 BUSPIRONE'S EFFECTS ON FELINE SPINAL REFLEXES. G. Keith Matheson. Indiana University, School of Medicine, Evansville, IN 47732.

This study was undertaken in order to determine the acute effects of buspirone on the monosynaptic reflex (MR) and on modulatory mechanisms regulating the MR. Buspirone HCl is a nonbenzodiazepine anti-anxiety agent with a markedly different psychopharmacologic profile from other known antianxiety agents. Unlike the benzodiazepines, buspirone has no anticonvulsant activity, interacts minimally with CNS depressants, does not cause muscle relaxation and lacks abuse potential. In this study random source cats of either sex were anesthetized with alpha-chloralose (60mg/kg, i.p.), intubated, and catheterized. A paraffin boat was formed around the lumbar region of the exposed spinal cord. Some of the dorsal roots between L-6 and S-1 were attached to Pt bipolar stimulating electrodes. Platinum recording electrodes were fixed to ventral rootlets at L-7 and/or S-1 and to some dorsal rootlets at L-7. The animals were artificially ventilated and paralyzed with gallamine triethiodide. Stimulus rates were not allowed to exceed 0.5 pulses per second. Control MR potentials were collected at thirty minute intervals for 1 to 2 hours. Buspirone increased the amplitude of the MR and the dorsal root reflex by 100 percent or more. The effect peaked after the third hour and returned to pre-drug levels by the sixth hour. A dual pulse condition--test stimulation technique was used to examine the effects of buspirone on spinal excitatory and inhibitory mechanisms. During the excitatory phase the amplitude of the MR was neither enhanced nor diminished, indicating the test pulse may already be eliciting a maximal excitatory response from the neuron pool. During the post-synaptic inhibitory phase the inhibitory effect was increased nearly one-fold, attenuating the MR to approximately fifty percent of control levels. During the pre-synaptic inhibitory phase the MR was not significantly attenuated suggesting that this inhibitory mechanism was almost totally supressed by buspirone. These findings suggest that buspirone may affect spinal reflex activity by supressing pre-synaptic inhibitory mechanisms, thereby allowing maximal activity in post-synaptic excitatory and inhibitory pathways impinging on the spinal alpha-motor neuron.

260.11 PROTECTIVE EFFECTS OF L-LYSINE ON PENTYLENETETRAZOL-INDUCED SEIZURES AND DEATH. N.R.Myslinski, B.Soohoo‡ K.Thuang‡ and Y.Chang‡ Depts. of Physiology and Biochemistry, University of Maryland Dental School, Baltimore, Md. 21201.

Recent evidence indicates that certain lysine metabolites significantly influence synaptic transmission of gamma-aminobutyric acid (GABA) in the brain. Since GABA is involved in the mechanism of action of many anticonvulsant agents we studied the effects of L-lysine and its metabolites on pentylenetetrazol(PTZ) induced seizures. Male Swiss-Webster mice weighing between 15 and 29 g were used. PTZ was administered IP at 80 mg/kg, after which the animals were observed for 15 min and then sacrificed. Significance of most data was determined by the Mann-Whitney U test.

In double blind experiments using saline controls L-lysine (1M,0.01 ml/g of mouse) significantly prolonged the latency of seizures when administered either as a single dose 15 min before PTZ ($P<0.002$), or in 5 doses during the preceeding 3 days ($P<0.006$). When administered intraventricularly (ICV)(0.5 ul/g of mouse) at 1,2,5, or 10 min before PTZ, L-lysine prolonged seizure latency at both 0.2M ($P<0.05$) and 1.0M ($P<0.05$) with the greatest effect occurring when lysine was given 5 min before. The most profound effect of ICV lysine was its prevention of death. Seventy-three percent of the saline pretreated mice died, but only 21% of the L-lysine pretreated mice died as a result of the PTZ-induced seizures. Piperidine (ICV at 0.2 M), a metabolite of L-lysine, also prolonged the latency of seizures ($P<0.05$) when given 5 min before PTZ. It also reduced the death rate to 44%. Two other metabolites of L-lysine were administered ICV 5 min before but had opposite effects. L-pipecolate (0.2M) shortened the seizure latency ($P<0.02$) and increased the death rate to 90%. L -α- aminoadipic acid (0.2M) shortened the seizure latency ($P<0.05$) and increased the death rate to 100%.

260.12 BRAIN PERFUSATE DRUG KINETICS. H. D. Christensen, Berhane Gherezghiher* and Tseggai Gherezghiher*. Dept. of Pharmacology, Univ. of Oklahoma Health Sciences Center, Coll. of Medicine, McGee Institute and V.A. Medical Center, Oklahoma City, OK 73190.

One of our laboratory goals is to correlate pharmacological or behavioral responses of CNS active drugs with their pharmacokinetic parameters and modification of endogenous neurochemicals. The use of push-pull perfusion of selected brain regions, liquid chromatographic separation and multiplexing of detectors offer some advantages over more traditional approaches. Adequate serial samples can be collected for appropriate disposition kinetics, and repeated evaluations can be made in the same animal under various conditions.

If moderate concentrations of caffeine (10 mg/kg) are administered to an alert non-restrained cat, then the cortex perfusate concentrations of caffeine are eliminated slightly slower than in the plasma confirming the apparent difference observed after sacrifice of the animals. This also indicated that the brain perfusate concentrations will probably give no better correlates than the plasma caffeine concentrations to either cue discrimination or neuronal activity. By separating the compounds in the perfusate by means of a liquid chromatography column with both UV and electrochemical detectors, it was determined that the amines fluctuated slightly but adenosine showed a consistent transient increase. A very preliminary study would indicate that cyclic AMP levels, as measured by RIA, decreases in the cortex perfusate after caffeine administration.

A modification of the conceptual model for synaptic transmission in the oculomotor nucleus occurred when the mechanism of αmethyldopa (MD) induced mydriasis was investigated by analysis of oculomotor perfusate concentrations of MD and its metabolites. When MD is administered i.v. to the pentobarbital anesthetized cat, it rapidly penetrates into the brain and is eliminated from a single compartment with an elimination rate constant of 0.015 min^{-1} and volume of distribution of 1.84 L/kg. MNE is formed in the neuron with rate of conversion-synaptic vesicle transport of 0.018 min^{-1} and released into synaptic cleft at a rate of 0.007 min^{-1}. The elimination from the perfusate space is 0.003 min^{-1}. The MD induced mydriasis could be correlated ($r=0.94$) with the MNE perfusate concentrations which were dependent upon the kinetic constants and initial dose of MD. The reuptake mechanism is non-functional for αmethylated compounds in these neurons. Thus MNE cannot return to the neuron; its compartment space is about 30% of that of MD, the same as for 3-O-methyl-α-MD. This property plus the direct contact of neurons with capillaries offer an explanation of why some drugs with no intrinsic receptor activity can be ineffective given directly to brain area but are very effective when administered intravenously.

260.13 FOOD DYES ALTER SPONTANEOUS RELEASE OF NEUROTRANSMITTER FROM FROG NEUROMUSCULAR JUNCTION: A STRUCTURE-ACTIVITY STUDY. K. C. Wadhwani* and H. Levitan. Department of Zoology, University of Maryland, College Park, Maryland 20742.

The widely used food dye erythrosin B (FD&C Red No. 3) has previously been shown to alter the release of transmitter from the frog neuromuscular junction (Science 207:1489(1980)). In an attempt to better understand the basis for the ability of this xanthene dye to enhance the frequency of release, and to determine whether other food dyes commonly used in the U.S. have similar effects on transmitter release, we have examined the effects of several azo, triphenylmethane and other fluorescein dyes on the spontaneous release of transmitter from nerve terminals innervating cutaneous pectoris muscle. In experiments carried out in the dark (i.e. at light intensities at least six orders of magnitude less than ambient room light) analogs of fluorescein increased mepp frequency exponentially with time at a rate which was dependent upon the particular dye and the concentration applied. The dye concentrations producing a 10-fold increase in mepp frequency within 120 min were(in micromoles/l):Rose Bengal=1;Phloxine B=3; Erythrosin B=20;Eosin B=25; Eosin Y=80; Fluorescein=1300. The more lipid soluble the dye the more potent it was. The effects of the dyes appeared to be reversible in the dark in contrast to the effects of erythrosin B examined previously in normal ambient light. The mepp frequency also increased exponentially with time on exposure to the triphenylmethane dye FD&C Green No. 1. The azo dyes Alura Red AC(FD&C Red No.40) and Tartrazine (FD&C Yellow No.5) increased the mepp frequency only when applied in millimolar concentrations. In these azo dyes the frequency increased very rapidly to a steady-state level which was dependent upon the dye concentration applied, and remained at that level for at least as long as an hour. Upon washing out the dye the mepp frequency rapidly returned to control levels. We conclude that the xanthene and triphenylmethane dyes interact with hydrophobic regions of the nerve terminal to enhance release while the azo dyes augment release by an osmotic mechanism.

261.1 ABNORMAL KINASE ACTIVITY AND DEFICIENT ENDOGENOUS PHOSPHORYLATION IN BRAINS OF EPILEPTIC FOWL. J.M. Tuchek*, D.D. Johnson, S. Polvi* and R.D. Crawford*. Dept. of Pharmacology, Univ. of Saskatchewan, Saskatoon, Sask. S7N 0W0 Canada.

We have previously reported an abnormality of endogenous phosphorylation in epileptic fowl. The high seizure susceptibility in this model of epilepsy is due to an autosomal recessive mutation. Homozygotes (epileptics) undergo spontaneous seizures and convulse in response to photic stimulation whereas heterozygotes (non-epileptics) do not develop seizures. Three proteins with approximate molecular weights of 72, 60 and $16x10^3$ in brain homogenates from epileptics incorporated less ^{32}P from radiolabelled ATP than did the same proteins isolated from their non-epileptic hatchmates. Subfractionation of the homogenates indicated that the low molecular weight protein was associated with the myelin fraction whereas the two higher molecular weight bands were present in the 100,000xg supernatant fraction indicating a cytosolic origin. Tissue culture studies of neuronal and glial cells revealed that the proteins were of neuronal origin.

Protein kinase activity was assayed in the 100,000xg brain supernatants according to the method of Witt and Roskoski, Analytical Biochem. 66: 253 (1975). Kinase activities in the brain fractions obtained from epileptics were lower than the enzyme activities in non-epileptic brain homogenates. When assayed in the presence of 100 µM EGTA, the protein kinase could be stimulated by adding Ca^{++}, with optimal activities being achieved in the presence of 150-200 µM added Ca^{++}. This Ca^{++} stimulatory effect was diminished by the addition of $5x10^{-5}$ M cAMP. Autoradiographic data on the 72,000 and 60,000 molecular weight cytosolic proteins which were phosphorylated in vitro at 30°C for 30 seconds with endogenous kinases, confirmed the Ca^{++} stimulatory effect and the antagonism of this effect by cAMP that was seen in the protein kinase assays where histone was used as the receptor protein.

261.2 A MECHANISM OF BARBITURATE ENHANCEMENT OF SPIKE FREQUENCY ADAPTATION. G. Evans*, J.R. Huguenard*, W.A. Wilson*, D.V. Lewis* (SPON: T. Slotkin). VA Epilepsy Center and Depts. of Pharmacology and Medicine, Duke Univ., Durham, NC 27710

Barbiturates are widely used as anticonvulsants. We have shown that the anticonvulsant barbiturates phenobarbital and pentobarbital enhance the process of spike frequency adaptation (SFA), the decremental change in neuronal firing rate in response to a prolonged constant depolarization. Zbicz and Wilson (JPET, 217:222-227, 1981) demonstrated that in Aplysia neurons R2 and LP1, SFA has a fast (<10sec) and slow phase. The fast phase is a pronounced decrement in firing rate during the first 10 sec of depolarization; the slow phase is a gradual decrement in firing that continues for tens of seconds. Barbiturates do not alter the fast phase of SFA but dramatically potentiate slow SFA.

The currents underlying SFA may be elucidated by voltage clamping. Aplysia neurons (LP1 and R2) were clamped to -50mV (near resting potential) and then step depolarized to -30mV (near spike threshold) for 60 seconds. During the depolarization, a K^+ dependent slow outward current (SOC) develops which can be increased by 50-200µM pentobarbital. Upon repolarization to -50mV, tail currents that represent the exponential decay of the SOC are observed.

The kinetic parameters of the tails were examined with a curve peeling technique (compartmental analysis). Analyses consistently derived two first order decay processes for tail currents. In normal sea water half-lives for these two processes are approximately 10 and 50 seconds; the fast component having an amplitude 4 to 5 times larger than that of the slow component. However, in 100µM pentobarbital the amplitude of the slow component is markedly increased with little effect on the amplitude of the fast component or the kinetics of either component. The net result is a major contribution by the slow component to the total amplitude of the tail current. This is not unexpected since the barbiturates potentiate the slow phase of SFA in these neurons.

Compartmental analysis of tail currents thus appears to be an appropriate means of analyzing and quantitating the effect of barbiturates on SFA mechanisms.

261.3 REGIONAL ELECTRICAL EFFECTS OF TOPICALLY ADMINISTERED GAMMA-HYDROXYBUTYRIC ACID. W. O. Haggard*, L. J. Bearden, E. M. Wilson*, and O. C. Snead. Departments of Biomedical Engineering, Neurology, Pediatrics, and the Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

There is considerable evidence that the endogenous compound gamma-hydroxybutyric acid (GHB) provides an appropriate model for the study of petit mal epilepsy. Experiments have shown that the behavioral and electrical effects produced by GHB are very similar to the abnormalities observed during petit mal seizures. It has also been found that these effects are suppressed or aborted by anticonvulsants which are clinically successful against seizures of petit mal epilepsy. Other studies have found that the peptides leucine enkephalin, methionine enkephalin, and beta-endorphin also produce behavioral and electrical effects like those observed during petit mal seizures, and that these effects can be blocked by naloxone (Urca et al., Science 197:83, 1977; Frenk et al., Brain Research 147:327, 1978; Henriksen et al., Proc. Natl. Acad. Sci. U.S.A. 75:5221, 1978). Work from our laboratory has further shown that naloxone blocks the behavioral and electrical effects of GHB (Snead and Bearden, Neurology 30:832, 1980), and that the petit mal anticonvulsants (ethosuximide, trimethadione, valproic acid) effectively block the convulsive effects of leucine enkephalin. Therefore, there are significant similarities between the seizure-like effects of gamma-hydroxybutyric acid and those of the opiate peptides. We have pursued these studies further by examining the electrical effects of GHB and leucine enkephalin following injections of these compounds into discrete areas of the brain.

Adult male rats (250-350 g) were stereotaxically implanted with epoxylite insulated tungsten macroelectrodes to permit recording of the EEG from the cortex, hippocampus, thalamus, and caudate-putamen of the brain. Following recovery from surgery, animals were anesthetized with chloral hydrate, repositioned in a stereotaxic apparatus, and control EEG was recorded from the indicated sites. Subsequently, stereotaxically placed injections of GHB or leucine enkephalin were made into the brain. These injections were made via a glass micropipet, and were accomplished by means of a pressure microinjection system. Such experiments have shown that the electrical effects of both GHB and leucine enkephalin are variable between selected regions of the brain.

261.4 FOLATES MIMIC DISTINCTIVE FEATURES OF KAINATE (BUT NOT GLUTAMATE) NEUROTOXICITY. J.W. Olney, T.A. Fuller, T. deGubareff*, and J. Labruyere*, Washington Univ. Sch. Med., St. Louis, MO.

Prompted by the report of Ruck et al. (Nature 287, 852, 1980), that methyltetrahydrofolate (MTHF) competes strongly for kainic acid (KA) binding sites on neural membranes and exerts KA-like depolarizing action on frog spinal neurons, we compared a series of folic acid (pteroyl-L-glutamic acid, PGA) derivatives, including MTHF, with several glutamic acid (Glu) analogs, including KA, for their neurotoxic properties when administered by various routes, including direct injection into several brain regions. Consistent with prior observations, Glu and its linear analogs, such as DL-homocysteate (HCA) and N-methyl-aspartate (NMA), when injected directly into brain (e.g., striatum or amygdala), reproduced the local brain damaging action of KA (NMA >HCA >Glu) without inducing the sustained seizures and distant disseminated lesions that characteristically accompany direct injection of KA into brain. Conversely, folates effectively reproduced the convulsant and distant brain damaging actions of KA without damaging neurons at local brain injection sites, e.g., high intrastriatal doses did not injure striatal neurons but destroyed many neurons in extrastriatal regions typically damaged by intrastriatal KA. Diazepam (sc) protected against the entire pattern of folate-induced damage (Fuller et al.,Neurosci.Abst. 1981). PGA and folinic acid (N-5-formyltetrahydrofolate) were the most powerful folates tested, whereas MTHF and dihydrofolate were the weakest (minimal effective intra-amygdala dose for inducing a seizure-brain damage syndrome = 5-10 nmoles for the former two agents and 100-300 nmols for the latter two). When injected into the lateral ventricle, PGA tended to give an all or none response (either rapidly lethal seizures or no effect); although intra-amygdala injection of PGA (>50 nmoles) sometimes induced a typical KA pattern of hippocampal damage, intra-hippocampal PGA (50 nmoles) caused rapidly lethal seizures without appreciable hippocampal damage. When administered systemically, PGA did not reproduce the Glu type of neurotoxic action in circumventricular organs, even at doses that induced lethal convulsions. We propose that KA neurotoxicity may have a compound mechanism, one component (seizure-mediated distant damage) involving folate-sensitive receptors and another (local neuron-necrotizing action) involving folate insensitive receptors. Since PGA is readily available, inexpensive and powerfully mimics seizure-related features of KA neurotoxicity but not seizure-unrelated features, it may be at least as useful as KA for studying mechanisms of epilepsy and epileptic brain damage. Moreover, since folates are present in foods and stored in the body, including the CNS, it warrants consideration that they might play a pathogenic role in human epilepsy or epileptic brain damage. Supported by USPHS grants NS 09156-DA 00259, RSA MH38894(JWO)&MH 00330 (TAF).

261.5 DIAZEPAM MARKEDLY ATTENUATES THE NEUROTOXICITY OF FOLIC ACID. T.A. Fuller, J.W. Olney and V.T. Conboy*, Washington Univ., Sch. Med., Dept. Psychiatry, St. Louis, MO.

Kainic acid (KA), a cyclic glutamate (Glu) analog, is a powerful convulsant and neurotoxin which, when injected directly into the striatum or amygdala, destroys neurons both locally and in several remote regions of brain. Ben-Ari et al. (Br Res 165,632, 1979) have attributed the remote disseminated lesions to a seizure mechanism since the anti-convulsant, diazepam (DZ) protects against these lesions but not the local neuron-necrotizing action of KA. Folic acid (pteroyl-L-glutamic acid, PGA), also a cyclic Glu analog, was recently shown (Olney et al., Neurosci Abst,1981) to induce KA-like seizures and a KA-like disseminated pattern of brain damage when injected into various brain regions, but did not appear to exert local neurotoxic action. If PGA reproduces only the seizure-related disseminated component of KA neurotoxicity, one might expect DZ to protect against the entire PGA pattern of damage; the experiments described here were undertaken to test this hypothesis. Sixteen adult male rats were injected unilaterally with 50 nmole PGA into either the striatum or amygdala under halothane anesthesia. Half of each group received PGA only and the other half received DZ (15-20 mg/kg sc) 20 min prior to and 1 hr after PGA. The animals were perfused transcardially 24 hrs after PGA for histopathological evaluation of their brains. All rats (n=8) that received only PGA manifested repetitive seizures and moderately to extremely severe brain damage. Regions most consistently and severely damaged by either striatal or amygdala PGA were the ipsilateral amygdaloid complex, claustrum, piriform cortex and fronto-parietal cortex. The most severe local damage, after intra-amygdala injection, was not concentric about the injection site (as is the usual pattern with KA injections) but rather was often more severe at a variable distance from the injection. Following intra-striatal injection, there was no damage at or near the injection site but subacute degenerative changes were noted at the lateral margin of the striatum in those brains displaying severe lesions in the superjacent cerebral cortex. In DZ/PGA-treated rats, 1 of 8 had seizures and a very mild focus of tissue pathology (swollen dendritic processes) in the neocortex, and another, in the absence of seizures, had a questionable focus of dark cell degeneration in the piriform cortex. Our findings support the conclusion that PGA reproduces one component (seizure-related disseminated damage) of KA neurotoxicity. Further studies comparing the properties of folates with those of KA seem warranted for the light they may shed on excitatory neurotoxic phenomena and on mechanisms of epilepsy and epileptic brain damage.

261.6 SODIUM CHANNEL BLOCKING ACTION OF PHENYTOIN IN MAMMALIAN NEURONS IN TISSUE CULTURES. N. Matsuki*, F.N. Quandt*, J.Z. Yeh* and R. Ten Eick* (SPON: C.H. Wu). Dept. of Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Three mechanisms have been proposed to explain the anticonvulsant action of phenytoin (DPH): direct actions on membrane ionic channels, on synaptic membranes, and on metabolic processes. Using cultured neuroblastoma cells (NIE105) we investigated the effects of DPH on the Na channel. The single suction pipette method developed by Lee et al. (1978) for snail neurons was adapted for voltage clamping neuroblastoma cells. This technique also provides for an exchange of the internal milieu. Na currents were isolated from the other ionic currents by replacing internal and external K ions with Cs ions.

DPH (25-100 μM) applied externally produced a dose-dependent resting (background) block of Na current which depended on the level of holding potential. When held at -60 mV, in the control state, 50% of the Na channels were available for opening in response to depolarizing pulses; whereas at the same holding potential when exposed to 75 μM DPH only 10% were available. This was a reflection of a hyperpolarizing shift in the slow inactivation curve which resulted in inactivation of most of the Na channels at normal levels of resting potential. However, when holding potential was -100 mV, no resting block was observed. During repetitive pulsing the block produced by DPH was enhanced. The additional block is termed "conditioned block". The extent of conditioned block was augmented by increasing pulse rate, duration, amplitude and number and by decreasing interpulse interval and potential. For example, during 30 conditioning pulses from -80 to +10 mV for 40 msec with an interpulse interval of 500 msec DPH produced an additional 25% decrease from control in Na current. In contrast, when the holding potential was increased to -100 mV the same pulse protocol produced less than a 5% decrease.

Recovery from the conditioned block was faster at -100 mV than at -80 mV suggesting that at -100 mV the decreased effectiveness of DPH to produce conditioned block is due to the more rapid disappearance of block. It was also found that a single long pulse was more effective than several shorter pulses. Since the duration of the open state of Na channels is much shorter than the duration of the pulses used to produce conditioned block, we conclude DPH binds primarily to inactivated channels.

In summary, DPH's Na channel blocking action can be enhanced by (1) lowering the membrane potential and (2) stimulating the neuron at high frequency. Both actions are thought to be related to anticonvulsant efficacy because seizures are associated with high frequency firing and depolarization of the neuronal membranes. (Supported by Epilepsy Foundation of America).

261.7 REDUCTION OF SEIZURE THRESHOLD BY INDOMETHACIN. T. W. Lysz, P. Needleman* and J. A. Ferrendelli. Div. of Clinical Neuropharmacology, Depts. of Pharmacology and Neurology. Washington Univ. School of Medicine, St. Louis, MO 63110.

Previous studies have suggested that prostaglandins in CNS may be involved in pathophysiological mechanisms of seizures. In an attempt to define the relationship(s) between prostaglandins and seizures the effects of indomethacin a cyclooxygenase inhibitor, on pentylenetetrazol-induced seizures in adult, Swiss-Webster mice was studied. Pretreatment of animals with 10 mg/kg of indomethacin one hour prior to the administration of pentylenetetrazol consistently reduced the CD_{50} for tonic convulsion from 75 to 64 mg/kg but had no effect on clonic seizure threshold. Dose response studies revealed that indomethacin concentrations of 1 mg/kg or greater were capable of reducing tonic seizure threshold.

Measurement of cyclooxygenase activity in brain microsomes revealed that tissue from animals systemically treated with 10 mg/kg of indomethacin had a decrease in prostaglandin synthesis. This is consistent with the report of Steinhauer et al. (Naunyn-Schmiedeberg's Arch. Pharmacol. 310, 53-58 (1979)) demonstrating that PGE_2, $PGF_{2\alpha}$ and TxB_2 synthesis in mouse brain, in vivo, is markedly decreased by treatment of the animals with 1 or 10 mg/kg indomethacin.

The present data in conjuction with reported results demonstrate that indomethacin reduces seizure threshold at the same concentration that it inhibits prostaglandin synthesis in brain. This suggests that prostaglandin or some other product of arachidonic acid metabolism has an anticonvulsant action in mammalian brain. Support in part by NIH grants NS-14834, HL-14397 and HL-20787.

261.7 INTERACTIONS BETWEEN VASOPRESSIN- AND PENTYLENETETRAZOL-INDUCED CONVULSIONS IN RATS. D.M. Burnard, Q.J. Pittman and W.L. Veale. Dept. of Medical Physiology and Pharmacology, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

Arginine vasopressin (AVP) has been shown recently to cause convulsions when administered into the lateral cerebral ventricles (ICV) of rats. This occurs via a sensitization process, whereby AVP initially causes short periods of immobility and staring, but the same dose causes myoclonic-myotonic convulsions upon the second injection two days later. Pentylenetetrazol (PTZ)-induced clonic convulsions can also be produced over several days by repeated administration of initially subconvulsive doses. The present work was designed to determine if AVP would alter the typical response to a threshold dose of the convulsant PTZ, and to establish whether or not a generalized PTZ-induced convulsion would result in sensitization of the brain to the seizure-inducing effect of AVP.

Male Long Evans rats were implanted stereotaxically with a guide cannula directed towards a lateral cerebral ventricle. Following recovery, rats were divided into two groups, the first of which was given 1.0 μg AVP ICV, followed by PTZ intraperitoneally two days later. The first administration of AVP resulted in staring and immobility, as expected, followed by burrowing behavior. Subsequent to a threshold dose of PTZ on Day 3, behaviors such as rearing, myoclonic jerks of the head and forelimbs, twitching of facial musculature and/or long periods of locomotor immobility were observed. Only the last two behaviors were observed in the controls.

A second group of rats received a dose of PTZ (40.0 mg/kg) on the first day which induced myoclonic jerks of the head and body, followed by immobility, staring and a loss of postural equilibrium in some rats. Two days later, after administration of 1.0μg AVP ICV, some rats exhibited stereotyped behaviors such as burrowing, periods of immobility and staring, abnormal, exaggerated scratching, and/or locomotor difficulties. We had not previously observed the last two behaviors following a single AVP injection.

These observations suggest that AVP may be acting within the CNS to alter or modify the typical response to a threshold dose of the convulsant PTZ, and that a previous PTZ-induced convulsion modifies the typical response to a first ICV injection of AVP. Whether or not PTZ and AVP are acting to lower the convulsive threshold and potentiate the response to other such agents is yet unclear, and awaits further investigation.

261.9 EFFECTS OF BICUCULLINE ON THE SENSORY RESPONSES OF NEURONS IN BRAINSTEM RETICULAR FORMATION AND PERICRUCIATE CORTEX. C.L. Faingold and W.E. Hoffmann*. Department of Pharmacology, Southern Illinois Univ. Sch. Med., Springfield, IL 62702.

Our previous studies indicate that the sensory responses of brainstem reticular formation (RF) neurons are greatly enhanced following subconvulsant doses of pentylenetetrazol, strychnine, bemegride, or physostigmine. The responses of most lateral geniculate and hippocampal neurons are not greatly affected. RF neuronal response enhancement correlates with convulsant-mediated increases in the amplitude of RF sensory-evoked field potentials (SEPs), but SEPs in non-primary sensory cortex are also extensively enhanced (see Faingold, C.L., Prog. NeuroPsychopharm., 2, 401, 1978).

This study examined the effects of bicuculline (BIC) on the neuronal responses to sensory stimuli in RF and pericruciate cortex. BIC was infused (.025-.06 mg/kg/min i.v.) or applied iontophoretically (onto RF neurons) in locally anesthetized, paralyzed and respired cats or rats (Sprague-Dawley); and ketamine anesthetized rats. Neuronal responsiveness to visual, auditory, and somatosensory stimuli was analyzed using peristimulus time histograms (PrSTHs). Most mesencephalic (93%) and medullary (84%) RF neuronal responses were extensively enhanced in at least one sensory modality following iontophoretic or systemic BIC. RF neurons which were unresponsive before drug became quite responsive after subconvulsant doses of BIC. Pericruciate neurons (71%) showed sensory response enhancement in many cases simultaneous with RF enhancement. The degree of cortical enhancement was somewhat less extensive than that seen in MRF, and the latencies of response peaks in cortical PrSTHs were considerably longer. Drug-induced inhibition without response enhancement was observed in 10% of cortical neurons but was rarely seen in RF neurons.

Our iontophoretic findings in the RF and the previous finding that the receptive fields of neurons in visual cortex are enhanced after BIC iontophoresis (Tsumoto, T. et al., Exp. Brain Res., 34, 352, 1979) suggest that effects on RF and cortex can be mediated directly. However, RF neurons almost invariably respond to the same stimulus with a shorter latency than cortical neurons, conduction from the RF is implicated in the generation of secondary components of cortical SEPs, and a direct influence of the RF on the pericruciate neurons has been observed (Spehlmann, R. and Daniels, J.C., Brain Res., 48, 320, 1972). These findings suggest the possibility that enhanced RF neuronal responsiveness may play a role in the changes observed in cortical neurons following systemic administration of convulsant drugs, but resolution of this question requires further experimentation. These data further support the hypothesis that enhanced neuronal responsiveness to sensory stimuli in certain non-primary sensory brain regions is a general action of convulsant drugs. Since sensory stimuli can often trigger seizure generalization after subconvulsant doses of convulsant drugs, this neuronal effect may reveal information about the mechanisms of seizure initiation under these conditions. (Supported in part by CRC funds, SIU Foundation and NIH Grant NS 13849).

261.10 EVIDENCE FOR THE NEOCORTICAL MICROCIRCUITRY INVOLVED IN EPILEPTOGENESIS. A.B. Chatt and J.S. Ebersole. Dept. of Neurology, Yale Univ. School of Medicine, New Haven, CT 06510 and VA Epilepsy Center, West Haven, CT 06516.

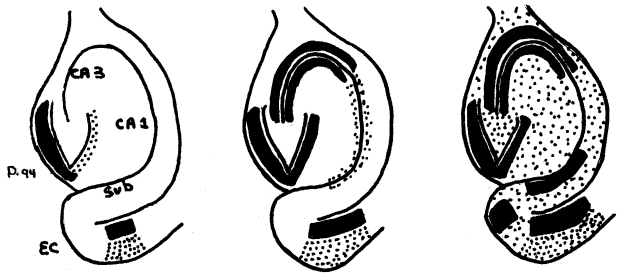
A developmental laminar analysis was conducted of interictal epileptiform potentials, induced by microinjection of nanoliter volumes of 47 mM penicillin (NaPen) at various depths in cat visual cortex and evoked by field-specific photic stimulation. Recordings were obtained from triple-barrel microelectrodes with longitudinal tip separations which permitted recording from two cortical layers while injecting in one. In several animals, ^{14}C NaPen was used and tissue excised following the development of epileptic abnormalities. The tissue was processed for diffusable-substance autoradiography and the results of NaPen spread compared to focal epileptic development in different cortical layers.

Inter-laminar induction of NaPen related abnormalities was most effective in cortical layer 4. These abnormalities included an initial enhancement of the primary latency evoked response(EPR) followed by the development of longer latency, negative epileptiform potentials. Similar negative potentials could also be induced in layers 2-3 and 5-6, but more NaPen was required and development was slower. Epileptiform potentials were not evoked from these superficial and deep cortical foci without diffusion of NaPen into layer 4 as manifest by an enhancement of the primary potential recorded there and corresponding autoradiograms. Added responsivity within layer 4 to the geniculo-cortical afferents and a corresponding enhanced output to layers 2-3 and 5-6 appears to be required to elicit epileptiform potentials from these layers even in the presence of NaPen. Evolution of epileptiform abnormalities in layer 4, however, proceeds rapidly enough to exclude a significant diffusion of NaPen into adjacent layers as requisite for epileptogenesis there(also confirmed by corresponding autoradiograms). The cellular interconnections, then, within layer 4 are apparently sufficient to elaborate an EPR into an epileptiform abnormality.

Inter-laminar projection of epileptic potentials appears to follow anatomically established pathways upwards(Gilbert and Wiesel, Nature, 1979). Abnormalities induced in layer 4 are simultaneously recorded in magnified form in superficial layers 2-3 probably reflecting the collateral afferent output from spiny stellate cells to layer 2-3 pyramidal cells. The positive "mirror" potential recorded deep to laminar epileptic foci in 4 probably reflects a current source for the epileptiform potential sink in 4. This current may be carried by layer 5-6 pyramidal apical dendrites which extend up to layer 1. An abnormal utilization of normal cortical serial processing, then, appears to underlie this enhancement of focal epileptic abnormalities initiated in layer 4.

261.11 FUNCTIONAL ANATOMY OF FOCAL LIMBIC SEIZURES IN RAT Robert G. Tearse*, Robert C. Collins, and Eric W. Lothman Neurology, Wash. Univ. Med. Sch., St. Louis, MO 63110

Relationships between site and intensity of seizure discharges, anatomical spread, and changes in behavior are not well known for limbic systems. We have studied focal seizures in entorhinal cortex (EC) in three groups of albino rats. One group (n=8) was given Na penicillin (250 units/µl) through a 33 ga recording cannula into EC at 0.1 µl/hr. A second group (n=8) was infused with picrotoxin (0.3 µg/µl), and a third group (n= 5) received bipolar tetanic stimuli. The dose of convulsant and stimulation intensity were varied to cause seizures of increasing severity judged by focal and dorsal hippocampal (HC) electrodes. Rats were studied by quantitative deoxyglucose (DG) autoradiography during local, mild, and strong seizure states.



Local (ipsilateral) | Mild (ipsi > contra) | Severe (ipsi = contral)

Hippocampal Pattern of DG Use During Focal Seizures of Entorhinal Cortex

Local seizures (<10 spikes/min) confined to EC caused no behavioral change and only a 30 to 50% increase in DG in EC and ipsilateral dentate gyrus (infra > supra). Mild seizures (>20 spikes/min) were associated with normal behavior or mild staring spells. DG metabolism was increased in EC, HC, and lateral septum. Strong seizures (prolonged afterdischarges) were associated with staring, sniffing, facial twitching, wet dog shakes, and occasional rearing. DG was markedly increased bilaterally (100-300%) in EC, HC, septum, amygdala, and substantia nigra.

These studies indicate that prolonged focal afterdischarges are necessary for seizure spread to contralateral limbic and subcortical extralimbic sites and the expression of behavioral convulsions.

261.12 FACILITATION OF KINDLING BY CONVULSIONS PRODUCED BY COCAINE OR LIDOCAINE BUT NOT PENTYLENETETRAZOL. Jeffrey S. Stripling and Curtis Hendricks*. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

Convulsions induced by cocaine have been reported to facilitate subsequent kindling in rats (Kilbey et al., Exp. Neurol., 64: 306-314, 1979). The purpose of the experiments reported here was to determine whether this effect is a general property of convulsive agents or is related to a specific pharmacological action of cocaine. Male Long-Evans rats chronically implanted with an intravenous catheter and an electrode in the olfactory bulb were convulsed by an intravenous infusion of cocaine, lidocaine, or pentylenetetrazol (PTZ), or received a control infusion of saline. Beginning eight days later each animal received daily electrical stimulation of the olfactory bulb until fully kindled seizures occurred. Animals which had been convulsed by cocaine or lidocaine kindled significantly faster than saline controls. PTZ-convulsed animals did not differ significantly from controls. A second experiment was conducted to determine if an effect of PTZ on kindling could be obtained with repeated convulsions. Animals received three convulsions produced by cocaine or PTZ, spaced three days apart, or control infusions of saline. Kindling by daily stimulation of the olfactory bulb was begun on the eighth day following the last drug treatment. Cocaine-convulsed animals again kindled significantly faster than saline controls, while PTZ-convulsed animals did not. This effect was a substantial one, with two of the cocaine-treated animals exhibiting clonus on the first day of electrical stimulation. Furthermore, the facilitation of kindling was not transitory: cocaine-treated animals still exhibited a fully kindled response when stimulated 21 days after the kindling criterion was reached. These results indicate that the facilitating effect of cocaine-induced convulsions on kindling is not a general property of all convulsive agents but is a more specific effect which is apparently shared by other local anesthetics. This effect persists for at least eight days after a convulsion is produced by cocaine, and may represent not merely a modulation of the kindling process, but a form of kindling by the drug convulsion itself, since some of the cocaine-convulsed animals exhibited a well-kindled response on the first day of electrical stimulation. In this regard it is interesting to note that previous studies have provided indirect evidence that local anesthetic convulsions may be generated within the olfactory forebrain.

261.13 CONVULSANT AND ANTICONVULSANT PROPERTIES OF ALKYL-SUBSTITUTED γ-BUTYROLACTONES. W.E. Klunk*, D.F. Covey* and J.A. Ferrendelli. Div. of Clinical Neuropharmacology, Depts. of Pharmacology and Neurology, Washington University School of Medicine, St. Louis, MO 63110.

Gamma-butyrolactone (GBL) is a naturally occurring substance in mammalian brain and when administered systemically to experimental animals produces seizures which resemble petit mal absences in humans. In an effort to define the mechanism of action of GBL we have synthesized several alkyl substituted gamma-butyrolactones and have tested their convulsant and anticonvulsant properties in mice and guinea pigs.

Addition of an ethyl and a methyl group on the β-carbon of GBL (β-EMGBL) produces a convulsant agent that causes clonic and tonic convulsions which resemble pentylenetetrazol-induced seizures and are behaviorally different from those produced by GBL. β-dimethyl GBL has effects similar to those of β-EMGBL but is less potent. Seizures induced by these compounds are prevented by ethosuximide but not by phenytoin. In contrast, ethyl-methyl or dimethyl substitution at the α-carbon produces a highly effective anticonvulsant that prevents pentylenetetrazol-, β-EMGBL-, and picrotoxin-induced seizures but has no effect against maximal electroshock. Gamma-ethyl-γ-methyl GBL is also anticonvulsant but is much less potent than α-EMGBL. Alkyl substitution at both the α and β positions produces compounds with convulsant activity. These are more potent than β-substituted compounds if the α substituent is hydrophobic and less potent if it is hydrophilic. Structure activity analyses lead to the suggestion that alkyl-substituted gamma-butyrolactones act at the same site as picrotoxin which contains a β-alkyl-γ-butyrolactone that is essential for activity.

The present data demonstrate a new class of convulsant and anticonvulsant compounds which may be useful in the investigation of mechanisms of seizures and actions of antiepileptic drugs.

261.14 EFFECTS OF PROSTAGLANDIN SYNTHESIS INHIBITORS ON ANIMAL MODELS OF EPILEPSY. M.C. Wallenstein and E.A. Mauss* Dept. Physiology, New York Univ., New York, NY 10010.

Even though agents of widely divergent physical and chemical properties can induce epileptiform activity in animals, the resulting bioelectric alterations underlying the epileptogenic process tend to be very similar. It is possible that a final common pathway such as an autocoid, is involved. Prostaglandins (PGs), are autocoids and have a role in modulating neuronal activity. An investigation of the effects of pretreatment with PG synthesis inhibitors on convulsions and electrocortical seizures induced by epileptogenic agents, was undertaken. In the first study, convulsant and postural responses were scored and timed. Both paracetamol (150-300 mg/kg) and indomethacin (10-20 mg/kg) tended to reduce the convulsive effects of strychnine or picrotoxin. However, the data were not always replicable. In the second study, the electrocorticogram (ECoG) was recorded from chronically implanted supradural electrodes. Behavior was observed via video monitor. Pretreatment with indomethacin (10 mg/kg) significantly attenuated electrocortical seizure activity induced by picrotoxin but not that induced by pentylenetetrazol. Pretreatment with paracetamol (400 mg/kg) attenuated seizure activity induced by picrotoxin and by penicillin but not that induced by pentylenetetrazol. These preliminary experiments suggest that PGs may have a role in the epileptogenic process. Furthermore, the specificity of interaction of class of PG synthesis inhibitor with the particular epileptic model may help to localize the site of PG action.

261.15 *ZINC BINDING BY VALPROIC ACID.* R.W. Hurd*, B.J. Wilder, J.J. Street* and G.L. Sciscent* Dept. Neuroscience, Univ. of Fla., Neurology Section, VA Medical Research Center and Dept. of Soil Science, IFAS, Univ. of Fla., Gainesville, FL 32610.

Valproic acid (VPA) is an anticonvulsant with a broad spectrum of activity against generalized seizures including absence, generalized tonic-clonic and myoclonus. Recent incidences however, of drug related hepatic damage and deaths have concerned physicians. As of Jan. 1981 a total of 43 deaths have occurred with VPA usage.

In reviewing the side effects of VPA, we noted a striking similarity of these with symptoms of zinc deficiency. Side effects produced by VPA which are also found with zinc deficiency or the zinc responsive disease of acrodermatis enteropathica include gastrointestinal disturbance, drowsiness, hair loss, anorexia, tremor, skin rash, bad taste, decreased platelet count, hyperammonemia, pancreatitis and hepatic dysfunction. Two other symptoms of zinc deficiency, decreased thymus weight and testicular atrophy have been produced in animals on high dosage VPA. Since other 5 carbon fatty acids shown to bind zinc (Martel & Smith, Critical Stability Constants, Vol. 3) we investigated the zinc binding of VPA using differential pulse polarography. Initial results indicate significant binding of zinc by VPA.

Zinc has a concentration of 1 μg/ml in plasma while therapeutic levels of VPA range between 50-100 μg/ml indicating that even with a small binding efficacy, VPA might compete favorably with other zinc binders which are present at much lower concentration.

Phenytoin has previously been shown to bind zinc (J. Invest. Dermal. 71:396, 1978) although no overt signs of zinc deficiency are evident with this anticonvulsant. Zinc levels are currently being determined in patients and animals receiving VPA. At present, we do not know if actual zinc deficiency occurs with VPA usage contributing to the above symptomatology.

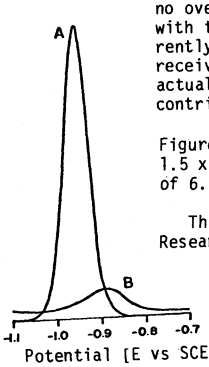

Figure: Differential Pulse Polarography of 1.5×10^{-5} Zn^{++} alone (A) and in the presence of 6.9×10^{-6}M VPA (B).

261.16 THYROTROPIN RELEASING HORMONE (TRH) INCREASES SEIZURE SUSCEPTIBILITY AND AROUSAL BEHAVIORS IN THE MONGOLIAN GERBIL. J.G. Bajorek*, R. Lee* and P. Lomax. Department of Pharmacology, School of Medicine and the Brain Research Institute, UCLA, Los Angeles, CA 90024.

Seizure sensitive Mongolian gerbils from our breeding colony at UCLA exhibit characteristic motor and EEG seizures upon exposure to novel environments or upon handling stress. As part of a series of studies examining the role of neuroendocrine agents released by stress as endogenous modulators of seizure susceptibility in the gerbil, we injected TRH (1-50 μg) intraventricularly (i.c.v.) and observed the effects on seizures and behavior. Compared to control injections of artificial cerebrospinal fluid (ACSF) (2 μl), injections of TRH (10 μg) produced a 50% increase in the incidence of seizures, a 78% increase in the severity of the seizures, and a 10.7 fold increase in seizure duration. Behavioral observations noted that a specific arousal response, 2/sec foot stomping by the rear legs, was present in 90% of the animals following the TRH injection. In some animals this behavior continued over 60 min (after TRH injection the mean duration of foot stomping behavior is 47 fold greater than in control injected animals). It was associated with EEG desynchrony and appears similar to a previous report of foot stomping in the gerbil after self stimulation or foot shock (Routtenberg, 1967). In our colony foot stomping is sometimes noted after handling, and seldom lasts over 10 sec. Higher doses of TRH (50 μg) produce toxic reactions including tremor, paw and chewing automatisms, and abnormal EEG spiking. At these higher doses foot stomping is markedly reduced to below control levels. The significance of this behavior and of the effects of TRH in the pathogenesis of the seizures are yet to be elucidated. However, our previous reports on the anticonvulsant properties of β-endorphin in these animals and the existence of foot stomping behavior under normal conditions suggests that 1) foot stomping may be an endogenous TRH mediated response, while 2) the proconvulsant effects of TRH may have a function in the partial modulatory control of seizure susceptibility in concert with β-endorphin. Routtenberg, A. and Kramis, R.C. Nature 214:173-174 (1967). (This work supported by grant ONR N00014-75-C0506).

261.17 CHANGES IN CONVULSIVE SUSCEPTIBILITY AND SEVERITY AND ANTICONVULSANT DRUG EFFECTS IN ADULT RATS ADMINISTERED 6-HYDROXYDOPAMINE OR 5,7-DIHYDROXYTRYPTAMINE DURING POSTNATAL DEVELOPMENT. Gary G. Buterbaugh and Steven B. Waller*. Dept. of Pharmacology and Toxicology, Univ. of Maryland Sch. of Pharmacy, Baltimore, MD 21201.

Marked monoaminergic involvement in electroshock convulsive thresholds and patterns has been demonstrated in neonate rats during the first three postnatal weeks (London, E.D. and Buterbaugh, G.G., J. Pharmacol. Exp. Ther. 206:81, 1978) when convulsive thresholds and patterns and central monoaminergic systems are undergoing maturation. To determine if disruption of monoaminergic systems in neonate rats would cause long-lasting changes in convulsive behavior and anticonvulsant drug action in adult rats, rats were injected intracisternally with the selective neurotoxins 6-hydroxydopamine (6-OHDA) or 5,7-dihydroxytryptamine (5,7-DHT) during two age periods in the maturation of electroshock thresholds and patterns: the first postnatal week (early, slow maturation) and the third postnatal week (rapid maturation). The rats were tested when 26 weeks old and compared to rats treated with the neurotoxins when 25 weeks old. The doses of the neurotoxins were selected to produce equivalent monoamine reduction in all three age groups at 26 weeks: 6-OHDA caused an average 49% and 33% reduction of brain norepinephrine and dopamine, respectively, with no change in serotonin; 5,7-DHT caused an average 45% reduction in brain serotonin with no change in catecholamines. The tonic electroshock convulsive threshold was significantly decreased by the same amount in rats injected with 5,7-DHT at all three ages: 6-OHDA had no effect on the threshold. The severity of the tonic convulsive pattern in all three age groups receiving 5,7-DHT was only slightly increased. In contrast, although 6-OHDA significantly increased convulsive severity in all groups, the effect was greatest (45% increase) in rats injected during the first postnatal week. The ability of phenytoin or phenobarbital to protect against electroshock tonic convulsions was competitively antagonized by both 6-OHDA and 5,7-DHT. This effect was greatest in rats injected with 6-OHDA during the first postnatal week or with 5,7-DHT when 25 weeks old. Kindled convulsions were produced by daily injections of lidocaine, 65 mg/kg, to 26 week old rats injected with the neurotoxins during the first postnatal week. The rate of kindling was accelerated by 6-OHDA but not by 5,7-DHT which caused a delayed reduction in the severity of the kindled convulsions. In summary, disruption of central monoaminergic systems in neonate rats was associated with changes in convulsive thresholds and severity in adult rats. These changes were sometimes related to the age at disruption, suggesting possible critical periods in the maturation of the interaction between monoamines and convulsive behavior.

261.18 INCREASED CONVULSIVE THRESHOLD IN INFANT RATS ASSOCIATED WITH CHRONIC ADMINISTRATION OF PENTYLENETETRAZOL. James A. McCaughran Jr.* and Nisson Schechter. (SPON: I. Fand). Department of Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, New York 11794.

Starting at 5 days of age, groups of rat pups were administered 20, 50, or 90 mg/kg of pentylenetetrazol (PTZ). Drug injections were administered subcutaneously according to a number of regimens: once daily, on alternate days, or every fifth day. An additional group of infants were administered an ascending series of doses starting from 50 mg/kg and ending with 90 mg/kg in increments of 10 mg/kg/day.

Infants that received 20 mg/kg PTZ daily failed to develop any signs of convulsive behavior over the course of the study. In the group that received 50 mg/kg daily, 40% displayed convulsions at 5 days of age but 0% by 9 days of age. Administration of 90 mg/kg daily elicited convulsions from 100% of the group at 5 days of age but from only 25% of the group by 9 days of age. Littermates of these two groups were administered a single dose of 50 or 90 mg/kg at 9, 14, or 19 days of age. At 50 mg/kg, the incidence of convulsions was 40, 33, and 38% respectively (in contrast to 0, 8, and 0% in the daily PTZ group). At 90 mg/kg, the incidence of convulsions was 100% at 9 and 14 days of age (in contrast to 25 and 19% in the daily PTZ group). In the group that was administered 90 mg.kg on alternate days, the incidence of convulsions remained at 100%. In addition, there was a high mortality rate associated with this regimen. The administration of an ascending series of doses was associated with an increasing incidence of convulsions. The incidence rose from 40% (50 mg/kg at 5 days of age) to 90% (90 mg/kg at 9 days of age). When the dose of 90 mg/kg was maintained, the incidence of convulsions on subsequent days declined to 20%.

The results of this study indicate that in the infant rat the chronic administration of convulsive doses of PTZ is associated with a transient increase in the threshold to subsequent convulsions. This elevation is evident at 24 hrs but not at 48 hrs. Age-related changes in the dose response curve (Vernadakis and Woodbury; Epilepsia, 10, 1969) could be ruled out since convulsions were effectively elicited when PTZ was administered on alternate days or every fifth day. The present results are in marked contrast to the progressive increase in seizure susceptibility that chronic administration of PTZ evokes in the adult rat.

261.19 CONTRASTING EFFECTS OF CARBAMAZEPINE, PHENYTOIN, AND CLONAZEPAM ON FOCAL AD THRESHOLDS IN AMYGDALA AND CORTEX. Penny Albright*, K.E. Livingston, and W.M. Burnham. Dept. of Pharmacology, University of Toronto, Can.

Traditionally carbamazepine and phenytoin are believed to act by blocking seizure spread whereas the benzodiazepines and drugs used in absence epilepsy are thought to elevate seizure threshold (1). The present study examined the effects of anticonvulsants from both these categories on focal AD threshold. Due to reported differences in drug action on cortical and amygdala foci (2), drug effects on thresholds from both areas were measured.

Seventy-two rats were implanted with electrodes in either the amygdala (36 rats) or the anterior neocortex (36 rats). Multiple doses of carbamazepine, phenytoin, or clonazepam were given to each cortical and amygdala group (12 rats each) and thresholds were measured under each dose. Drug thresholds were compared to baseline measures taken 3 days before and after each dose. In the cortex, all drugs produced significant elevations in seizure threshold. Carbamazepine was the most potent in this respect and phenytoin and clonazepam were slightly less effective. All drugs were less active in raising AD thresholds in the amygdala than in the cortex. Carbamazepine was the most effective here and phenytoin was somewhat less useful. Clonazepam did not elevate amygdala thresholds significantly at any dose.

These results indicate that in contrast to the classical view, carbamazepine and phenytoin are very effective in raising seizure thresholds in this study. Clonazepam, which theoretically should be the most effective, is the least potent of the 3 drugs. These data suggest a re-appraisal of the accepted mechanism of action of these drugs. Moreover these results support the proposed use of the amygdala focal seizure as a model of complex partial epilepsy (2). Like the clinical condition, the amygdala threshold is resistant to anticonvulsants but is more sensitive to the standard therapeutic agents (phenytoin and carbamazepine).

261.20 LONGTERM DEFICITS IN LEARNING FOLLOWING EXPERIMENTAL FEBRILE CONVULSIONS. Corinne Manetto*, James A. McCaughran, Jr.*, and Nisson Schechter. (SPON: T. I. Lidsky) Departments of Psychology, Psychiatry, and Long Island Research Institute, SUNY at Stony Brook, New York 11794.

In a previous study we reported that hyperthermia convulsions (HC) in the infant rat can produce longterm increases in seizure susceptibility. Although the human infant can be similarly affected by febrile convulsions, prolonged or recurrent seizures in the human infant are also associated with later deficits in learning. In the present study, the longterm effects on learning following experimental febrile convulsions during infancy in the rat were assessed in order to clarify this issue.

Infant rats were subjected to either a single hyperthermia convulsion at 5, 10, 15, or 20 days of age or to a series of HCs, at the average rate of 1/2days, starting from 5 days of age and ending at 20 days of age. Litter-mate control rats comprised two groups: one group was subjected to hyperthermia alone and not allowed to have a convulsion; the other group was subjected to handling. At 50 days of age, the ability of each rat to acquire a step-down passive avoidance response was assessed.

Rats subjected to a single convulsion at 10, 15, or 20 days of age required significantly more trials to acquire the passive avoidance response (4.1, 4.4, and 4.7 trials to criterion, respectively) than their respective hyperthermia controls (3.2, 3.0, and 2.8 trials to criterion) - or handled controls (2.8, 2.5, and 2.6 trials to criterion). Rats subjected to a single HC at 5 days of age did not differ from their respective controls (2.8 vs 2.6 and 2.6 trials to criterion). However, rats subjected to multiple HCs were not only slower than rats subjected to single HCs at 10, 15, or 20 days of age (5.1 vs 4.1, 4.4, and 4.7 trials to criterion, respectively) but also show the greatest deficits compared to their respective hyperthermia and handled control groups (2.7 and 2.4 trials to criterion).

The results of this study indicate that experimental infantile febrile convulsions can have longterm effects on the ability of rats to acquire a simple learning task. In addition, the observation that rats subjected to a single HC at 5 days of age fail to display this deficit suggests that the substrate(s) necessary for the development of passive avoidance responding have either not developed at 5 days of age (and therefore have been spared) or have been affected, but show a recovery of function. The increased deficits in responding that were observed following multiple HCs are consistent with the clinical data which indicate that infants who experience recurrent febrile convulsions have a higher incidence of neurological sequelae.

261.21 BRAIN VASCULATURE AND INDUCED ISCHEMIA IN SEIZURE PRONE AND NON-SEIZURE PRONE GERBILS. M. Donadio*, P. Kozlowski*, H. Kaplan, H.M. Wisniewski*, and J. Majkowski*. N.Y.S. Institute for Basic Research in Developmental Disabilities, Staten Island, N.Y. 10314

The relationship of seizure propensity to the morphology of the anterior cerebral arteries and to stroke induced by unilateral ligation of the common carotid artery was investigated using seizure prone (SP) and nonseizure prone (NSP) gerbils. Subjects were selected from the well-differentiated IBR colony, which regularly undergoes standard seizure tests and is now in the 10th to 12th generation of sib-sib matings. Twenty SP and 20 NSP gerbils were perfused with a latex dye and the vascular patterns of the anterior cerebral artery were analyzed. In addition, 30 SP and 30 NSP gerbils underwent unilateral ligation of the common carotid artery and the number developing stroke (determined both by clinical observation and by microscopic examination of the brains) was recorded. In all 40 gerbils, the 2 anterior cerebral arteries joined to form one central vessel that vascularized the olfactory bulbs.They also gave rise to two large lateral vessels (rostral arteries) that vascularized a previously undescribed nasal plexus. There was, however, much variability in the anatomical arrangement of these vessels, which were grouped into 5 patterns. Four of these were 'stroke-prone' patterns, i.e. there was either no or insufficient communication between right and left anterior cerebral arteries. We found no significant relationship between the anatomical pattern of the anterior cerebral arteries and seizure propensity in the gerbil. While 12 SP and only 7 NSP gerbils had stroke-prone patterns, this difference was not significant. There was also no significant difference in the number of SP and NSP gerbils developing stroke after common carotid artery ligation (9 NSP and 13 SP). Thus, in conflict with the report of Schonfeld and Glick (Brain Res. 1979, 173: 147), we found no statistically significant relationship between seizure propensity, the vascular anatomy of the anterior part of the brain and the occurrence of stroke induced by unilateral ligation of the common carotid artery. The evidence indicates, rather, that the mechanism responsible for naturally occurring seizures in the gerbil, and thet responsible for stroke susceptibility are not identical.

261.22 VARIETIES OF ANTICONVULSANT BLOCKING ACTIONS ON NA CHANNELS IN SKELETAL MUSCLE. K. R. Courtney and E. F. Etter.* Palo Alto Medical Foundation, Palo Alto, CA 94301.

Several anticonvulsants were studied for their effects on skeletal muscle Na currents of bullfrog, these Na currents being easier to measure than similar Na currents in myelinated nerve. The single cell, Vaseline gap, voltage-clamp procedure was utilized. Five anticonvulsants have been looked at (table) and they all depress sodium currents. Half-effective blocking concentrations (D50, infrequent depolarizations) are listed below for normal holding potentials where 35% of channels are inactivated. Proper care was taken to avoid possible channel unblocking effects of hyperpolarizing prepulses (Courtney, BBA 642:433, 1981) which are normally used to condition Na inactivation.

Three of these drugs show clear frequency-dependent changes in channel block as indicated by step-by-step changes in peak current levels after insertion or removal of hyperpolarizing prepulses before the channel opening depolarizations.

Time constants governing recovery from frequency-dependent changes in channel block differ considerably among these anticonvulsants (T in table). Such time constants help determine what action potential frequencies an excitable cell can follow, a capability of potential therapeutic significance. (Time constants could not be measured for ethotoin and diazepam which showed no frequency-dependent blocking at pulse rates of up to 10 Hz.)

Finally there appeared to be an "inactivation shift" produced by all drugs except phenytoin. The inactivation parameter h is set near 0.65 before drug treatment and falls by the amount indicated in the table (Δh) during treatment with drug concentrations near the half-blocking dose. Such observations could indicate relatively fast channel unblocking during the hyperpolarizing prepulse (see reference above).

In summary, these five anticonvulsant drugs all block Na channels but they do so with considerably differing potencies and kinetic detail. Future investigations along these lines will hopefully reveal some new structure/activity relationships useful for design of more effective anticonvulsant drug structures.

262.2 ANTIDOTE EFFECT OF SODIUM FLUORIDE AGAINST SOMAN POISONING IN MICE. J. G. Clement*, M. G. Filbert* and Daniel L. Rickett. Biomedical Section, Defence Research Establishment Suffield, Ralston, Alberta, Canada, TOJ 2NO; and Physiology Branch, US Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

Sodium fluoride (NaF) has long been known to: (a) inhibit both acetylcholinesterase and butyrylcholinesterase reversibly (1); (b) reactivate cholinesterase inhibited by the nerve agents sarin and tabun but not by soman (2,3); facilitate the sensitivity of the motor end plate to the stimulating action of acetylcholine (4) and activate the enzyme adenylate cyclase (5).

The facilitating action of NaF on acetylcholine's stimulation of the motor end plate was recently shown by Akasu and Karczmar (6) to be due to slowing of the progress of desensitization as well as to an acceleration of recovery from desensitization. Anticholinesterase compounds result in persistence of acetylcholine and therefore accelerate the process of desensitization. The object of this study was to determine if NaF had any antidotal properties against the lethality of soman, an organophosphorus, anticholinesterase agent.

Male mice received subcutaneous injections of soman 5 minutes after an intraperitoneal injection of either atropine (17 mg/kg) alone or a mixture of atropine + NaF. Low doses of NaF (5 mg/kg and 15 mg/kg) significantly increased the LD50 of soman from a control value of 162 µg/kg to 202 µg/kg and 208 µg/kg, respectively. When 8 mg/kg NaF was combined with atropine and pyridostigmine, a carbamate cholinesterase inhibitor, the mixture given prophylactically, the LD50 of soman was increased to 540 µg/kg.

Measurement of brain cholinesterase determined that the protective action of NaF against soman lethality is not due to reactivation of centrally inhibited enzyme. The antidesensitizing effect of NaF is a reasonable hypothesis to account for the observed antidotal effect against soman. Furthermore, desensitization of cholinergic receptors may contribute significantly to the lethality of refractory nerve agents such as soman.

262.3 COMPARISON OF END-PLATE ACTIVATION AND DESENSITIZATION AT SNAKE SLOW AND TWITCH MUSCLE FIBERS. R.M.Schnitzler*, E.A. Connor*, J.F. Fiekers and R.L. Parsons. Dept. Anatomy and Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

Desensitization of the end-plate receptor-channel complex produced by sustained exposure to agonists is well documented, but the mechanism(s) responsible for the loss of chemosensitivity remains unknown. Recently, the activation kinetics of receptor-channel gating were found to differ at snake twitch and slow muscle fiber end-plates (Dionne and Parsons, J. Physiol. 310:145, 1980; Dionne, J. Physiol. 310:159, 1981). In the present study we are investigating the influence of this difference in activation kinetics on the development of desensitization in these two fiber types. The kinetics of carbachol-induced desensitization are being compared in voltage-clamped twitch and slow muscle fibers from costocutaneous muscles of the garter snake maintained in a HEPES-buffered isotonic potassium proprionate solution (mM:NaCl 159, KCl 2.15, $CaCl_2$ 1.0, $MgCl_2$ 4.0, CsCl 5.0; pH=7.2; 19-21°C).

In initial experiments we determined that slow fiber MEPC decay was significantly longer and exhibited considerably less voltage dependence than twitch fiber MEPC decay as reported previously for muscles maintained in sodium solution. With both fiber types, microperfusion of 216 µM carbachol induced a transient EPC_{carb} superimposed on the holding current which developed with a time to peak of a few seconds and then decayed slowly towards the baseline in the continued presence of agonist. The timecourse of EPC_{carb} decay is used to estimate the timecourse of desensitization onset. At twitch fiber end-plates, EPC_{carb} decay timecourse can be described by a single exponential function at all voltages; however, at slow fiber end-plates the EPC_{carb} decay at voltages more negative than -40mV often exhibits two distinct exponential components. Desensitization appears to develop more rapidly at twitch fiber end-plates than at slow fiber end-plates, but the difference is not significant at all voltages. The timecourse of desensitization onset is voltage dependent at both end-plate types; the magnitude of the voltage dependence for twitch fibers (0.0096 mV^{-1}) being comparable to that reported previously for amphibian twitch end-plates (Fiekers et al., J. Gen. Physiol. 75:51, 1980). The equilibrium level of desensitization, obtained over a wide voltage range (-80 to +50 mV) after a 3 minute exposure to 216 µM carbachol is voltage dependent in both fiber types. The voltage dependence of the equilibrium level appears to be less in slow fibers than in twitch fibers. Additional experiments are in progress to determine the concentration dependence of desensitization kinetics in both fiber types. (Supported by the MDA).

262.4 DECREMENT IN RESPONSE OF HIPPOCAMPAL PYRAMIDAL NEURONS TO LONG IONTOPHORETIC PULSES OF GABA. R. H. Thalmann and Norman Hershkowitz*Depts. of Cell Biology, Neurology and Program in Neuroscience, Baylor College of Medicine, Houston,TX 77030

We have further studied the response decrement which has been reported when GABA is continuously ejected near the somata of hippocampal neurons(Ben-Ari et al, Can. J. Physiol. Pharmacol., 1979,57,1462-1466). In addition, we have similarly studied the depolarizing response which follows GABA application near the apical dendrites of these neurons. Responses of CA1 neurons of the rat hippocampal slice were measured in terms of change in membrane conductance. When GABA was ejected near the soma for 10-60sec,conductance increased to a maximum within about 3sec,then declined to approach an asymptote which was always greater than the resting conductance. The half-decay time of this decline was typically about 5 sec. This response decrement could be demonstrated during purely hyperpolarizing responses, or during the biphasic response which occurs during more intense iontophoretic currents. In the range of ejection currents tested, greater conductance decrements were produced by higher ejection currents. The response decrement also occurred when the bathing medium contained 10^{-6}M TTX,0Ca and 2mM Mn. In contrast, the response to GABA ejected near the apical dendrites appeared to be quite different. In this case, a given iontophoretic current tended to produce a smaller peak response, and a smaller response decrement than when applied to the somatic region. In fact, in some cases, a gradual increment in conductance occurred during the initial 10-30sec. When the TTX, 0Ca, 2mM Mn medium perfused the slices, however, only decrements in the dendritic response have been observed. The decrements in GABA responses which have been reported here were not due to decreased ejection of GABA during the long GABA pulses: Control experiments with two GABA barrels showed that the initial peak of the GABA response which was elicited by one GABA barrel was reduced when it was preceeded by a 30sec GABA pulse via the second barrel. The response decrements were also probably not secondary to changes in voltage since they occurred whether the response was hyperpolarizing or depolarizing, or when the membrane potential was held at or near the reversal potential of a given response to GABA. Finally, the occurrence of such decrements did not appear to require Ca conductances, or TTX-sensitive Na conductances, since the decrements could be readily observed even following 2 hours of perfusion with the TTX,0Ca, 2mM Mn medium. Supported by NIH grant NS 11535.

262.5 ALTERATION OF ALPHA AND BETA ADRENERGIC RESPONSES OF RAT AORTA CAUSED BY WEEK-LONG EXPOSURE, VIA MINIPUMP, TO APPROPRIATE AGONISTS. C.J. Sun* and J.P. Hanig* (SPON: J. Kenimer) Division of Drug Biology, Food and Drug Administration, Washington, D.C. 20204

Decrease in adrenergic responses or receptor density can be achieved rapidly in vitro by incubation of rat aorta or brain slices with appropriate agonists. In vivo, this desensitization or downregulation phenomenon can also be elicited following a long period of administration of antidepressants or monoamine oxidase inhibitors. This is due to an indirect increase in the effective concentration of neurotransmitter at the synapse. The present study was performed to determine whether a constant 1 week exposure to either alpha or beta agonists in vivo would allow alteration or manipulation of the responses of rat aortic alpha and beta adrenergic receptors. ALZET osmotic minipumps delivering either phenylephrine (PE) or isoproterenol (ISO) for 7 days at a constant rate of 1.0 µl/hr and a dose of 4.2 and 3.2 mg/kg/day, respectively, were implanted in male Holtzman rats under halothane anesthesia. The minipumps were designed to maintain steady-state blood levels of the drugs. Seven days later, rats were killed and aortic ring preparations were set up to measure their alpha and beta adrenergic responses. In PE pretreated rats, alpha adrenergic responses, as measured by contractions induced by PE, were markedly reduced ($P < 0.05$) across a dose range from 10^{-9} to 10^{-6}M. In contrast, in these same PE pretreated preparations, the beta adrenergic responses involving ISO-induced relaxation were significantly increased across a dose range of 10^{-7} to 10^{-5}M. In a separate series of experiments, ISO pretreatment with minipumps for 7 days resulted in a significant reduction of beta adrenergic aortic relaxation, whereas the alpha adrenergic responses to PE remained unchanged compared to controls. These findings indicate that the alpha agonist-induced desensitization or downregulation of the alpha adrenergic response after in vivo pretreatment also induces reciprocal changes in the functionally related beta adrenergic apparatus. This suggests linkage between these two receptors. In contrast, the beta receptor appears to desensitize or downregulate in response to beta agonist exposure in a manner that appears to be independent of or to operate in the absence of an alteration of the alpha receptor.

262.6 DENERVATION PRODUCES α_1-ADRENOCEPTOR SUPERSENSITIVITY IN BRAIN: PHYSIOLOGICAL AND RECEPTOR BINDING STUDIES. D.B. Menkes, D.W. Gallager, J.F. Reinhard, and G.K. Aghajanian, Depts. Pharmacol. and Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508.

Noradrenergic denervation is known to enhance postsynaptic responses to α-adrenoceptor stimulation in peripheral systems (Trendelenburg et al., J. Pharmacol. Exp. Ther., 172: 91, 1970). In the brain, such denervation has been reported to increase ^{3}H-WB-4101 binding sites (U'Prichard et al., Molec. Pharmacol., 16: 47, 1979) suggesting that α-adrenoceptor supersensitivity to norepinephrine (NE) may develop under these conditions. The present study examined the development of α-adrenoceptor denervation supersensitivity in brain using both single-unit recording and receptor binding techniques.

Male albino rats (200-250 g) were given a single intracerebroventricular injection of the catecholamine neurotoxin 6-hydroxydopamine (6-OHDA, 200 µg free base). Pretreatment with fluoxetine (10 mg/kg, i.p., 1 hr before 6-OHDA) was used to protect serotonergic neurons. Control animals were treated in the same way, except vehicle without 6-OHDA was injected. Five to eight weeks later, animals were transected at the level of the caudal mesencephalon and mounted in a stereotaxic apparatus. Neurons in the dorsal lateral geniculate (LGNd) were identified and their sensitivity to iontophoretic phenylephrine, NE, and carbachol was determined as previously described (Menkes and Aghajanian, Eur. J. Pharmacol., in press).

Previous studies have indicated that the activation of LGNd neurons in response to NE or phenylephrine is mediated by a classical α_1-adrenoceptor (Rogawski and Aghajanian, Brain Res., 182: 345, 1980). Carbachol, by contrast, produces a similar activation through a muscarinic receptor. Sensitivity of LGNd cells to NE and phenylephrine was found to be enhanced more than twofold in the 6-OHDA group ($p < .01$) while responses to carbachol were unchanged.

Following recording, animals were killed by decapitation and cerebral cortices were dissected and used for biochemical determination of NE levels and for ^{3}H-prazosin binding. Liquid chromatography showed that the 6-OHDA treatment caused a profound (> 90%) depletion of NE levels. Density of ^{3}H-prazosin-labelled α_1-adrenoceptors was found to be increased 40% ($p < .01$) by denervation with no change in Kd. These results indicate that destruction of central NE systems results in physiological supersensitivity to α_1-adrenoceptor stimulation which is correlated with an increase in α_1-adrenoceptor density.

262.7 ALPHA AND BETA RECEPTOR BINDING IN RAT SPINAL CORD FOLLOWING COMPLETE CORD TRANSECTION, L.A. Hershey, D.R. Kopaniky,* R.F. Macko,* and J.S. Brodkey. Laboratory of Neurology and Neurosurgery, Case Western Reserve Sch. of Med., Cleveland, OH 44106.

Evidence is accumulating to suggest that norepinephrine (NE) is a neurotransmitter in the spinal cord. NE appears to act through alpha and beta receptors in the ventral horn to modulate stretch reflexes. It appears to inhibit pain transmission via its action on alpha receptors in the dorsal horn. Radioligand binding methods for measuring postsynaptic noradrenergic receptors in rat spinal cord have been described recently. We compared binding of ^{3}H-dihydroalprenolol (± cold propranolol) in membranes prepared from control cords to that from cords of rats surviving complete cord transection (T2-3) for 7 days. These animals could eat and drink, but they were paraplegic. We found the number of beta-adrenergic binding sites in transected cords to be nearly double that measured in controls. When ^{3}H-prazosin binding (± cold prazosin) in control cords was compared to that measured in transected cords, there was no difference to suggest a change in alpha$_1$ receptor density or affinity. There are two alternative explanations for the difference in behavior of the alpha$_1$ and beta receptors following cord transection: 1) Both types of receptors are denervated, but they respond differently to denervation. 2) The alpha$_1$ receptors are not denervated - either because the receptors are mostly located on non-neural tissue (blood vessels, etc.) or because the receptors are driven by neurons not contained in the descending bulbospinal tracts.

262.8 ROLE OF NEURONAL SIGNAL INPUT IN THE DOWN-REGULATION OF CENTRAL NORADRENERGIC RECEPTOR FUNCTION BY ANTIDEPRESSANT DRUGS. Aaron Janowsky[1], Larry R. Steranka[2], David D. Gillespie[1] and Fridolin Sulser[1], Vanderbilt University School of Medicine[1], Nashville, TN 37232, and Indiana University[2], Gary, IN 46408.

It is now well established that antidepressant drugs, if administered on a clinically relevant time basis cause sub-sensitivity of the norepinephrine (NE) receptor coupled adenylate cyclase system. To ascertain the role of NE signal input in this noradrenergic down-regulation, desipramine (DMI) and iprindole (IP) were administered for a period of two weeks (15 mg/kg/day i.p.) to animals whose right locus coeruleus had been lesioned electrolytically two weeks prior to treatment. Successful lesions caused a selective depletion of NE in the ipsilateral cortex to less than 25% of its contralateral control value. The responsiveness of the cAMP generating system to NE (100 µM) was slightly enhanced on the lesioned side. While chronic administration of the NE uptake inhibitor DMI reduced the maximal responsiveness of the cAMP generating system to NE from 44.4 ± 5.8 (controls) to 19.9 ± 3.2 (non-lesioned side) pmoles cyclic AMP/mg/protein ± SEM, the drug did not significantly alter the responsiveness to NE on the lesioned side (36.8 ± 5.4 pmoles cyclic AMP/mg/protein ± SEM). IP which does not change the availability of NE also down-regulated the NE receptor coupled adenylate cyclase system on the non-lesioned side while not significantly reducing the sensitivity to NE on the side with the locus coeruleus lesion (49.4 ± 3.9 (controls) and 43.3 ± 6.7 (IP) pmoles cyclic AMP/mg protein ± SEM). These results support the view that NE signal input and thus the formation of the NE-receptor complex is one of the pre-requisites for down-regulation by antidepressant drugs. However, since iprindole shared the effect with DMI, but unlike DMI, does not inhibit the uptake of NE, other regulatory factors (co-transmitters?) are implicated in the process of drug induced desensitization of the NE receptor coupled adenylate cyclase system in brain.

(Supported by USPHS grant MH-29228, a Fellowship from the Upjohn Company (A.J.) and by the Tennessee Department of Mental Health and Mental Retardation.)

262.9 CORTICAL DESENSITISATION TO NORADRENALINE BY OXAPROTILINE: EFFECT OF THE TWO ENANTIOMERS. H. Olpe* (SPON: G. Lynch) Ciba-Geigy Ltd., Biology Research Laboratory, Pharmaceuticals Division, 4002 Basle, Switzerland.

Oxaprotiline (CGP 49802) is a potential antidepressant which is chemically related to maprotiline (Ludiomil). It is a potent and highly selective inhibitor of noradrenaline (NA) uptake with an ED 50 of 4 to 7 mg/kg p.o. depending on the test system used. It lacks anticholinergic and 5-HT potentiating properties. Oxaprotiline is a mixture of two enantiomers, one being a potent inhibitor of noradrenaline uptake (CGP 12104), the other being devoid of this property (CGP 12103).

Chronic administration of a number of tricyclic antidepressants or of monoamine oxidase inhibitors has been reported to reduce the number of cortical β-receptors, to attenuate the adenylate cyclase response to NA and to reduce the sensitivity of cortical neurons to microiontophoretically administered noradrenaline. It has been speculated that this desensitisation is not coupled with the NA-uptake-inhibiting property since chronically administered iprindol also induced the same effect without being a blocker of NA-uptake. With the help of the two enantiomers of oxaprotiline, it was possible to test whether the phenomenon of desensitisation is coupled to the NA-uptake inhibiting property or some other properties of the tricyclic structure. Following a ten-day treatment of rats with either CGP 12104 or CGP 12103, the sensitivity of cingulate cortical neurons to microiontophoretically administered NA was compared in chronically- and acutely-treated animals. The acutely-treated rats received a single injection of either of the two enantiomers 24 hours before the start of the experiment. Rats treated chronically with CGP 12104 but not those treated with CGP 12103 showed a marked reduction in sensitivity to NA as compared to the acutely treated rats. The cell-inhibiting property of NA was reduced with respect to both the duration of firing-inhibition and the amplitude of firing-reduction. These findings indicate that the phenomenon of NA-desensitisation is coupled with the NA-uptake-inhibiting property and not with the chemical structure of tricyclics per se.

262.10 CHRONIC ANTIDEPRESSANT TREATMENT PRODUCES SUPERSENSITIVITY TO THE ELECTROPHYSIOLOGICAL RESPONSE OF HISTAMINE IN GUINEA PIG HIPPOCAMPUS WITHOUT A CHANGE IN THE SENSITIVITY OF THE HISTAMINE SENSITIVE ADENYLATE CYCLASE. M. C. Olianas*, A. P. Oliver* and N. H. Neff. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Typical and atypical antidepressant drugs have been shown to block histamine sensitive adenylate cyclase of guinea pig brain. We have previously shown that histamine, increases the excitability of guinea pig hippocampal pyramidal cells via an H_2 receptor. In this study, we compared the interactions of histamine and antidepressants on adenylate cyclase activity in a homogenate in guinea pig hippocampus and the interictal spike frequency in the region CA-3 of a perfused hippocampal slice. Imipramine, amitriptyline, iprindole and mianserin block histamine activated adenylate cyclase with an IC_{50} in the micromolar range. In the hippocampal slice, imipramine, desmethylimipramine or chlorimiincrease neuronal excitability but do not block the histamine effect while mianserin which does not have a direct effect significantly blocked the histamine response at about 1μM. After chronically treating animals with imipramine (10mg/kg i.p.) or mianserin (10mg/kg i.p.) twice a day for 14 days there is supersensitivity of the electrophysiological response to histamine with a shift of the dose-response curve to the left and an increase of the maximal response. When we tested the responsiveness of the adenylate cyclase in the hippocampal homogenate of the same animals, however, there was no change of the response to histamine. Many factors could be responsible for the different effects of the chronic antidepressant treatment on the two histamine dependent responses. Among the possibilities are that the homogenate preparation may lack an essential factor, the two systems may not be strictly related and the electrophysiological response may be indirect.

262.11 ESTROGEN MODULATION OF SEROTONIN RECEPTORS IN THE RAT BRAIN B.S. McEwen and A. Biegon* (Sponsor D.J. Micco, Jr.) The Rockefeller University, New York, NY 10021

Serotonin (5HT) receptor density fluctuates in the basal forebrain during the estrous cycle of the rat (Biegon et al., Brain Res. 187:221, 1980). The underlying hormonal mechanisms were studied in ovariectomized (OVX) rats. In each of 2-5 experiments, estradiol (E) in ethanol/saline or estradiol benzoate (EB) in oil, in doses ranging from 2 to 50μg, were injected subcutaneously into two animals; two OVX controls received the appropriate vehicle. The animals were decapitated 1-2h later and the hypothalamus, cortex or the whole forebrain were assayed for ^{3}H-5HT binding using previously described methods. A Scatchard analysis of the binding data revealed a marked crease in the density (Bmax) of 5HT receptor following these treatments: 2μg E reduced the binding by 30%; the higher doses inhibited up to 70-80%. EB at 2μg was only marginally effective, but 5μg EB produced a 30% decrease. Incubation of brain membranes with 5HT and E simultaneously resulted in a decrease in Bmax only at high (10-5M) concentration of E. However, when brain membranes were preincubated with E in polyvinyl pyrrolidone for 2h prior to assay, a 25% reduction in 5HT binding was evident with E concentrations as low as 1nM.

Delayed effects of EB injection were also studied. Ovariectomized rats were injected with 10μg/rat/day for 2 d and killed 48h after the second injection. Under these conditions, there is a selective increase in Bmax of ^{3}H-5HT binding to membranes in estrogen concentrating brain regions - 40% in the preoptic area, 28% in amygdala, and 39% in hypothalamus. No change occurs in the cortex and caudate. Progesterone, 2.5 mg, given to estrogen-primed rats 3h before sacrifice had no additional effect on 5HT binding; neither did hypophysectomy.

The time course and anatomical localization of the increase in 5HT receptors following EB treatment suggest an estrogen-receptor-mediated mechanism, while the widespread decrease 1-2h after an acute injection of E or EB, which can be mimicked under certain conditions in vitro in a preparation free of cytoplasmic E receptors, is suggestive of a direct membrane effect of the steroid. These two mechanisms may both be operating in the estrous cycle in the rat and thus help account for 40-50% fluctuation in 5HT receptor density in the basal forebrain during the cycle.

Supported by NIH Grant NS07080 (BMc), by an institutional grant from the Rockefeller Foundation (RF70095), and by a C. Weizmann postdoctoral fellowship (AB).

263.1 PARTICIPATION OF CHOLINERGIC MECHANISMS IN THE CONTROL OF ARTERIAL PRESSURE BY THE NUCLEUS TRACTUS SOLITARII OF THE RAT. L. Criscione*, W. T. Talman, and D. J. Reis. Laboratory of Neurobiology, Cornell University Medical College, N. Y., N. Y. 10021.

The nucleus tractus solitarii (NTS) is the site of termination of baro- and other cardiopulmonary receptor afferents. The presence within the NTS of acetylcholine (ACh), cholineacetyltransferase, and cholinergic (muscarinic) receptors suggests a cholinergic innervation in the region. We have thus investigated whether cholinergic mechanisms in NTS participate in regulation of arterial pressure. Rats were anesthetized with halothane or chloralose. Microinjection (0.1 µl) of carbachol (C) or ACh unilaterally in NTS produced a dose dependent fall in mean arterial pressure (MAP) and heart rate (HR). For C, the threshold dose was 4.4 pmoles and the maximal response (fall of MAP of 41 ± 6 mm Hg from a baseline of 94 ± 6 mm Hg and of HR of 19 ± 5 bpm from a baseline of 322 ± 12 bpm; n=7; $p<.005$ and $p<.05$ respectively; mean ± S.E.M.) occurred at 44 pmoles. For ACh the dose-response curve was shifted to the right and a maximal res ponse (fall of MAP of 35 ± 2.7 from a baseline of 80 ± 3.3 mm Hg and fall of HR of 10 ± 2.2 from a baseline of 341 ± 17.4 bpm; n=5; $p<.05$) occurred at 0.28 nmoles. Within the brain stem the effective sites for C were restricted to the intermediate NTS; however, high doses injected over the dorsal surface of the brain stem at the level of the calamus scriptorius transiently elevated MAP and HR. Atropine (0.12 nmoles) injected unilaterally into NTS did not affect MAP or HR but produced complete blockade of cardiovascular responses to locally injected C. The same dose did not alter the effect of the local injection of l-glutamate (0.3 nmoles). Hexamethonium (0.21 nmoles) had no effect on C. Physostigmine (1.6 nmoles) injected unilaterally did not alter MAP or HR. Atropine (0.12 nmoles) injected bilaterally into NTS increased MAP by 17 ± 2 mm Hg in rats anesthetized with chloralose and produced a 45% inhibition ($p<.05$) of the reflex fall of HR induced by raising MAP (45-50 mm Hg) with phenylephrine (2 µg/kg, i.v.). Physostigmine (1.6 nmoles) did not affect baroreceptor reflexes. We conclude that; (a) cholinergic agents microinjected into the NTS simulate baroreflexes, (b) the receptors involved are muscarinic, and (c) muscarinic blockade produces signs of arterial baroreceptor inhibition. The study suggests that muscarinic receptors on neurons in NTS play a role in the mediation of baroreflexes and control of arterial pressure. 263.2 CENTRAL NERVOUS SYSTEM CHOLINERGIC RECEPTOR SITE ACTIVITY IN THE DAHL RAT MODEL OF HYPERTENSION. R. Friedman*, E. Edwards, W. McNally*, J. McCaughran*, J. Iwai* and N. Schechter. (SPON. B. Twarog) Department of Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, N.Y. 11794.

The Dahl model of experimental hypertension consists of two lines of rats with opposite, genetically determined predispositions to hypertension. One line, the Dahl hypertension-sensitive (DS) line, rapidly and predictably develops severe hypertension when fed a high salt diet, but remains normotensive on a low salt diet. The other line, the Dahl hypertension-resistant (DR) line, exhibits no change in blood pressure when maintained on either diet. Altered central cholinergic receptor binding activity has been reported in other models of experimental hypertension and therefore, we have determined the number of cholinergic receptor sites (muscarinic and nicotinic) in cortex, medulla, and hypothalamus in DS and DR rats on both high and low salt diets.

After three weeks on their respective diets and following blood pressure determination, brain regions from DR and DS rats were homogenized and aliquots were incubated in the presence of ^{125}I-alphabungarotoxin (aButX) for nicotinic receptors and ^{3}H-quinuclidinyl benzilate (QNB) for muscarinic receptors. Non-specific binding was determined by parallel incubations with several 100-fold excess of curare or atropine respectively. All determinations were performed at saturation. A detailed method has been previously described (Brain Res., 183 (1980) 224-228).

As anticipated, the high salt diet resulted in significant elevations in blood pressure in DS rats but was without effect in DR rats. In the low salt condition, where both lines are normotensive, there was a tendency for the DS rats to have a higher number of QNB binding sites than DR rats in all brain areas studied with the most pronounced difference occurring in the cortex. The DS rats fed high salt exhibited more QNB binding sites than low salt DS rats in cortex, medulla and hypothalamus. This contrasts with the observation that high salt DR rats had slightly fewer QNB binding sites than DR rats fed low salt. There were no differences in aButX binding sites in any area examined in the four line x diet groups.

The results suggest that DS rats in the low salt condition exhibit central cholinergic receptor activity which distinguishes them from DR rats. Furthermore, when exposed to the hypertensinogenic stimulus, DR rats tend to show modest reductions in QNB binding sites while DS rats exhibited significant increases concomitantly with elevations in blood pressure.

263.3 RELEASE OF 3H-L-GLUTAMATE AND 3H-D-ASPARTATE FROM THE AREA OF THE NUCLEUS TRACTUS SOLITARIUS BY ELECTRICAL STIMULATION OF THE VAGUS NERVES. A.R. Granata*, A.F. Sved and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. College. New York, NY 10021

We have proposed that L-Glutamate (L-GLU) is a neurotransmitter released in the nucleus tractus solitarius (NTS) by excitation of baroreceptor and other primary afferent fibers of the vagus nerve (Talman et al. Science 209:815-819. 1980). Such release appears to mediate the reflex hypotension and bradycardia of the baroreflex. In the present study we sought to determine if electrical stimulation of afferent vagal fibers with stimuli sufficient to elicit hypotension and bradycardia would elicit release of labelled L-GLU or its stable analogue D-Aspartate (D-ASP) from the area of the NTS. Rats were anesthetized with urethane, paralyzed and ventilated. The cervical vagi were transected bilaterally and the central ends placed on stimulating electrodes. One ul of artificial CSF containing 3H or 14C-GLU or 3H-D-ASP was microinjected into the NTS in order to preload endogenous stores. 14C-urea, 14C-sucrose or 14C-glycine were injected along with the 3H-amino acids as markers of non-specific release. A push-pull cannula consisting of two fused pipettes 150 u each was placed in NTS. The area of NTS was then perfused with artificial CSF at 40 ul/min and samples were collected at three minute intervals thereafter. The vagi were stimulated bilaterally to elicit a maximal fall of arterial pressure (-56 ± 3mm Hg) (6 min stim train, 2 ms pulse, 5 Hz at 15 x threshold). 3H-L-GLU, 14C-L-GLU, or 3H-D-ASP but not 14C-urea, 14C-sucrose or 14C-glycine were released during vagal stimulation. The release of 3H-L-GLU, calculated as a percent of increase in radioactivity above the pre-stimulation level, was a 140 ± 24.7% (N=11) during bilateral vagal stimulation and 47.7 ± 16.4% (N=7) during unilateral stimulation and ($P<.001$). Release, was detected only when the cannula was within the NTS area, was proportional to the magnitude of the stimulus intensity (which in turn was generally related to the magnitude of reflex hypotension), and when systemic arterial pressure was acutely elevated over 50mmHg by aortic compression. Analysis of the perfusate by thin layer chromatography in experiments utilizing D-ASP indicated that greater that 90% of the radioactivity could be recovered as D-ASP. We conclude that electrical stimulation of fibers of small diameter in the vagus nerve eliciting baroreflex-like responses will release L-GLU from NTS. The results are consistent with the hypothesis that L-GLU is a neurotransmitter of neurons in the NTS mediating the baroreflex.

263.4 BLOCKADE OF FOREBRAIN GABA RECEPTORS INHIBITS BAROREFLEX-INDUCED BRADYCARDIA IN THE ANESTHETIZED CAT. J.A. DiMicco*. (SPON: M. Aprison) Department of Pharmacology, Indiana University School of Medicine, Indianapolis, Indiana 46223

The neurotransmitter γ-aminobutyric acid (GABA) appears to play an important inhibitory role in central nervous control of autonomic outflow to the cardiovascular system (Gillis et al., Brain Res. Bull. 5 [suppl. 2]: 303-315, 1980). Thus, bicuculline methiodide (BMI), a GABA antagonist, elicits contrasting but characteristic effects on basal arterial pressure and heart rate at different CNS sites in the anesthetized cat. In the medulla, BMI elicits vagal bradycardia by blockade of GABAergic inhibition at the nucleus ambiguus (DiMicco et al., Science 204: 1106-1109, 1979). In contrast, BMI elicits hypertension and tachycardia mediated by the sympathetic nervous system when this agent is restricted to the forebrain (lateral and third) ventricles (Williford et al., Neuropharmacol. 19: 245-250, 1980). Electrical stimulation of forebrain areas eliciting similar cardiovascular changes also suppresses baroreflex-induced bradycardia (Gebber and Klevans, Fed. Proc. 31: 1245-1252, 1972). The purpose of this study was to determine whether blockade of forebrain GABA receptors with BMI might similarly alter medullary cardiovascular reflex function.

Adult mongrel cats were anesthetized with chloralose/urethane (50/500 mg/kg i.p.), artificially ventilated and paralyzed with decamethonium 0.25 mg/kg i.v., supplemented as needed. Arterial pressure and heart rate were continuously monitored. Reproducible reflex bradycardia (ranging from -42 to -165 beats/min. in different preparations) was elicited by baroreceptor stimulation (phenylephrine HCl 20-100 µg i.v.). BMI (1-32 µg) injected into, and restricted to, the forebrain (lateral and third) ventricles, suppressed baroreflex bradycardia in a dose-related fashion. Maximal effect was observed within 10 minutes of injection and consisted of 30±10% reduction at 1-4 µg (n=6), 66±8% reduction at 5-10 µg (n=4), and 88±4% suppression at 16-32 µg (n=3). The highest doses also elicited transient increases in arterial pressure and heart rate. However, significant suppression of reflex bradycardia (>50%) persisted after recovery of original baseline parameters, and after administration of lower doses of BMI which failed to alter arterial pressure and heart rate by more than 3 mmHg or 5 beats/min., respectively. Forebrain administration of the GABA agonist muscimol (10 µg), which had no effect on baseline arterial pressure and heart rate or on baroreflex-evoked bradycardia in untreated cats, completely reversed the effects of BMI on these parameters.

These data suggest that blockade of forebrain GABAergic inhibition suppresses baroreflex bradycardia.

263.5 PERIPHERAL OR CENTRAL ADMINISTRATION OF THE GABA RECEPTOR AGONIST, THIP, RESULTS IN A CENTRALLY MEDIATED HYPOTENSION.
D. W. Snyder and M. J. Antonaccio. Squibb Institute for Medical Research, Princeton, N.J. 08540

Intracerebroventricular infusion of 40 µg/kg of the GABA agonist 4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol(THIP) over a 10 min period lowers blood pressure 40 ± 9% ($p < 0.05$) and heart rate 20 ± 3% ($p < 0.05$) in chloralose anesthetized cats. In contrast, the intravenous (IV) administration of THIP (40 µg/kg) failed to alter blood pressure (8 ± 4% N.S.) and heart rate (5 ± 2% N.S.). Increasing the dose of THIP to 6-8 mg/kg IV resulted in a significant fall in blood pressure (40 ± 9%, $p < 0.05$) and heart rate (20 ± 4%, $p < 0.05$). The onset of the fall in blood pressure occurred within 1 min and was maximal within 5 min after the bolus IV injection of THIP. The fall in heart rate was evident within 1 min following the injection of THIP and reached its nadir 20-30 min later. The magnitude of the fall in heart rate appeared to be related to the resting heart rate prior to THIP. In 4 cats in which THIP (8 mg/kg IV) was administered, the increase in blood pressure produced by a bolus injection of norepinephrine (0.03 - 1.0 µg/kg IV) or 1,1 dimethyl-4-phenyl piperazinium iodide (DMPP, 1-10 µg/kg IV) were not reduced by THIP. Similarly, the vasoconstrictor response evoked during a 30 sec bilateral occlusion of the carotid arteries was not altered by THIP. In 3 cats, the GABA antagonist bicuculline methiodide (B) was infused into the cerebral aqueduct (0.5 µg/kg/min) without altering blood pressure or heart rate. During the infusion of B, THIP (6 mg/kg IV) was administered as a bolus and the resultant THIP-induced fall in blood pressure was attenuated by the B infusion. The data suggest that THIP like other GABA receptor agonists acts centrally to lower blood pressure and heart rate. There is no evidence of peripheral α-receptor or ganglionic blockade by THIP. The antagonism by B suggests that the cardiovascular actions of THIP are mediated through activation of central GABA receptors, results consistent with the previously demonstrated ability of THIP to bind to GABA receptors.

263.6 BEHAVIORAL, NEURAL AND CARDIOVASCULAR INFLUENCES OF TAURINE.
James T. Garsik*, Frank W. Marcoux, Walter C. Low, Janice E. Gellis* and David Whitehorn. Dept. of Physiology, Univ. of Vermont College of Medicine, Burlington, VT 05405.

Taurine may be a neurotransmitter or modulator and has both an inhibitory effect and membrane stabilizing properties. In the adult rat the acute effects of taurine include a gradual fall in blood pressure (BP) with intraventricular application and a more rapid fall with intracisternal (IC) application. Locomotor activity (LCMA) can be decreased by intraperitoneal injections.

We examined the effects of acute taurine administration in chloralose anesthetized spontaneously hypertensive rats (SHR). Intravenous injection of 12mg/kg taurine in saline produced no change in BP over one hour. IC application of 750 micrograms taurine in 20 microliters of vehicle solution delivered over 90 seconds produced a fall in BP to 52±8% of control within two minutes. Hypotension remained for 30-60 minutes. Heart rate (HR) fell to 78±6% of control and sympathetic nerve activity (SNA), recorded from the splanchnic, was reduced to 57±15% of control at the peak of the effect. Raising pressure with phenylephrine further reduced SNA. IC injections of isoosmotic saline had no effect.

The levels of taurine in brain can be elevated chronically by providing rats with drinking water containing 3% taurine (Nara et al, Biochem. Pharm. 27:2689:78). We examined the effects of oral taurine in adult (25 week) SHR's. BP was measured repeatedly for one week prior to onset of treatment and then for 10 days during treatment. BP fell significantly by day 3 and remained reduced until day 6. By day 10, BP had returned to pretreatment levels.

Nara et al (78) report that chronic oral taurine given to SHR beginning at age 4 weeks alters the course of blood pressure development. We have measured both BP and LCMA from age 4 to 16 weeks in treated and untreated SHR. Both groups display an increase in pressure throughout the period but the rise in BP is retarded in the treated animals (Two way ANOVA $p < .001$).

LCMA was measured at 12 and 16 weeks of age using an automated activity cage. Cumulative activity during 15 minutes was significantly lower in treated animals at both ages (Two way ANOVA $p < .001$).

These data show: 1) the fall in BP with acute IC taurine injection involves a reduction in both HR and splanchnic SNA. 2) BP is reduced in adult SHR within 3 days of the onset of chronic oral taurine treatment. 3) Both BP and LCMA are reduced by chronic administration in the developing animal. (Support from HL24110 and Vermont Heart Association).

263.7 COMPARABLE DEPRESSION OF THREE CENTRAL SYMPATHETIC PATHWAYS BY CLONIDINE AND ALPHA-METHYLDOPA THROUGH ACTIVATION OF ALPHA-2 RECEPTORS.
Parley W. Madsen* and Donald N. Franz (SPON: D. M. Woodbury). Department of Pharmacology, University of Utah, Salt Lake City, Utah 84132.

Previous studies have demonstrated a dose-dependent (2.5-50 ug/kg) depression of transmission through central sympathetic pathways by clonidine (Pharmacologist 22:301, 1980). Sympathetic discharges, recorded from upper thoracic preganglionic rami, were evoked by spinal reflex (SR) or intraspinal (IS) pathways in unanesthetized spinal cats or by long spinal-bulbospinal (SBS) reflex pathways in debuffered, chloralosed cats. The SBS pathways were more sensitive to depression by clonidine than the IS pathways, but both could be depressed completely. The SR pathway was least sensitive and could not be depressed below 40% of control values even by larger doses. The depression by clonidine could be prevented or reversed by the alpha-2 receptor antagonists, yohimbine or tolazoline.

In the present study, alpha-methyldopa (MD) was tested on the same three pathways. Although 150 mg/kg of MD alone usually produced only a slight enhancement, subsequent injection of 5 mg/kg of reserpine after at least 2 hr produced a prompt depression of transmission through each pathway. Reserpine alone generally produces only a modest increase in transmission. The SBS and IS pathways were completely depressed whereas the SR pathways were depressed to only 40% of control. Depression was rapidly reversed by yohimbine (0.5 mg/kg) or tolazoline (2-5 mg/kg). Pretreatment with these antagonists also blocked the depression produced by reserpine. A minimum period of about 45 min after MD injection was necessary before reserpine could produce depression, suggesting that the action of MD requires the formation of an active metabolite, probably alpha-methylnorepinephrine which, like clonidine, has a high affinity for alpha-2 receptors. Reserpine apparently releases the intraneuronal stores of this active metabolite which is synthesized as a false transmitter.

The results indicate that both clonidine and MD act at sites in both the brainstem and spinal cord through activation of alpha-2 receptors. In the spinal cord, these receptors appear to be postsynaptic on sympathetic preganglionic neurons.

(Supported by NIH grants HL-24085 and GM-07579.)

263.8 ENHANCED TRANSMISSION TO SYMPATHETIC PREGANGLIONIC NEURONS DURING SELECTIVE INHIBITION OF EPINEPHRINE SYNTHESIS.
Chaichan Sangdee* and Donald N. Franz. Dept. of Pharmacology, University of Utah, Salt Lake City, Utah 84132.

Sympathetic preganglionic neurons (SPGNs) receive a dense innervation of norepinephrine (NE) terminals and a lesser but almost exclusive innervation of epinephrine (EPI) terminals from neurons associated with autonomic centers in the brainstem. As yet, no concensus regarding their respective functional roles has been reached.

Our own previous studies, conducted on unanesthetized spinal cats and designed to analyze sympathetic discharges recorded from upper thoracic preganglionic rami and evoked by microelectrode stimulation of descending excitatory pathways in the cervical dorsolateral funiculus, suggest that the NE pathways activate adenylate cyclase to generate cyclic AMP which appears to increase the excitability of SPGNs. Clonidine depresses SPGNs by activation of alpha-2 receptors which appear to inactivate adenylate cyclase (Neurosci. Abstr. 6:165, 1980).

Since the affinity of EPI for central alpha-2 receptors is about twice that of NE, the possibility that EPI may function as an endogenous ligand for the alpha-2 receptors on SPGNs was tested with a selective inhibitor of PNMT, LY134046 (8,9-dichloro-2,3,4,5-tetrahydro-1H-2-benzazepine HCl) which markedly depletes central EPI within a few hours (Fuller et al., Biochem. Pharmacol., 1981, in press). Within about 0.5 hr after LY134046 (20 mg/kg, i.v.), intraspinal transmission consistently increased linearly with time to an average of 220% of control values (N=5; range, 170-300%) at 4.5 hr. This dose of the inhibitor appeared to exert little blocking action on alpha-2 receptors since neither the typical depressant effect of clonidine nor its antagonism were noticably impaired.

These results support the proposal that EPI pathways to SPGNs depress their excitability by activating postsynaptic alpha-2 receptors which are negatively coupled to adenylate cyclase. Although the synaptic coupling of EPI and NE terminals may differ, this proposal also suggests a mechanism whereby excessive activity in the excitatory NE pathways could become self-limiting, by activating the alpha-2 receptors to depress adenylate cyclase and suppress cyclic AMP synthesis.

(Supported by NIH grants HL-24085 and GM-07579.)

263.9 THE EFFECT OF A NEW POTENT ANTAGONIST OF VASOPRESSIN ON THE PRESSOR RESPONSE OF INTRACEREBROVENTRICULARLY ADMINISTERED HISTAMINE IN UNANESTHETIZED FREELY MOVING RATS. P.J. Gatti* and S.B. Gertner* (SPON: G.A. Condouris). Dept. Pharmacol., N.J. Med. Sch.-CMDNJ-Newark, N.J. 07103.

Intracerebroventricular (i.c.v.) injections of histamine in conscious freely moving or anesthetized rats have been shown to produce a rise in mean arterial blood pressure (MAP). This increase in MAP has been reported to be due to an increase in sympathetic outflow from the central nervous system to the peripheral vasculature. Studies in our laboratory have shown that in the conscious rat, these reports cannot explain our experiments which have shown that hexamethonium, a ganglionic blocker, does not block the pressor effect of i.c.v. histamine. Likewise, 6-hydroxydopamine pretreatment does not attenuate the pressor response of i.c.v. histamine. Since others have shown an antidiuresis after centrally administered histamine in the rat, cat and goat, we investigated the possibility that arginine-vasopressin, released from the posterior pituitary, may play a role in the pressor response to i.c.v. histamine. Control MAP in 20 male Sprague-Dawley rats was 100±4.0 mmHg. I.c.v. injections of histamine dihydrochloride (1 µg) into the lateral ventricles produced a rise in MAP of 29±1.4 mmHg compared to controls. When rats were pretreated with 5 µg of [1-(β-mercapto-β,β-cyclopentamethyleneproprionic acid),2-(O-methyl)tyrosine] arginine-vasopressin intravenously, and then given 1 µg of histamine 5 minutes later, the rise in MAP was reduced 72% to 8±1.1 mmHg (n=8). This was significantly lower than control ($p<.05$). However, in 6 other animals also given the same dose of blocker, the response was not attenuated at all; the rise in MAP in these animals after histamine was 31±3.3 mmHg which was not different than control ($p>.05$). It appears that in this latter group, something other than arginine-vasopressin is contributing to the pressor response of i.c.v. histamine. Work is currently being done in our laboratory to investigate the factors responsible for the hypertensive response to histamine in those animals which are not blocked by the vasopressin antagonist.

263.10 REDUCTION OF THE HARMALINE CARDIOVASCULAR RESPONSES BY DIAZEPAM ADMINISTERED IN THE CEREBELLUM. K. J. Dormer. Department of Physiology and Biophysics, University of Oklahoma College of Medicine, Oklahoma City, OK 73190.

Harmaline produces cardiovascular effects in dogs in addition to the relatively minor tremorogenic effects. These effects include elevated arterial pressure and heart rate for doses 0.5-1.5 mg/kg (1.v.). Since specific interactions are reported to occur in the inferior olivary complex which gives climbing fibers to the cerebellum, including the fastigial nucleus (FN), it has been suggested by Dormer and Brown (Soc. Neurosci. Abst. 6:163, 1980) that the cardiovascular effects resulted from FN activation. Lesions in rostral FN or cerebellectomy essentially abolished the cardiovascular responses. Since, harmaline has been associated with benzodiazepine receptors, in this study diazepam was administered subdurally to the cerebellum to observe its effects on the harmaline cardiovascular responses. Mongrel dogs (12-15 kg) were chronically instrumented with a solid-state pressure transducer (Konigsberg P-4) in the descending aorta and a Doppler ultrasonic blood flow transducer on the left renal artery. Two weeks following recovery multipolar semimicro stainless steel electrodes were implanted into the rostral FN and a PE-50 cannula was placed subdurally above folium 4 on the cerebellar cortex. After 5-10 days recovery harmaline was injected (1.5 mg/kg i.v.) and the cardiovascular responses recorded. Mean arterial pressure increased 40%, heart rate increased 61% and renal arterial blood flow velocity increased 31% (all mean responses). These changes were observed within 50 seconds of infusion and were proportional to the 6-10 cycle/sec. tremors evoked. 24-48 hours later the experiment was repeated but 10 minutes following 1.5 mg diazepam administered subdurally to the cerebellum. Arterial pressure and heart rate fell initially and subsequent harmaline administration did not elevate pressure (6% decrease from control). HR was decreased 15% and renal flow velocity increased 31%. No tremors were observed. These observations suggest the harmaline may also have direct effect on the cerebellum since diazepam abolishes the cardiovascular changes which have previously been associated with the FN. Supported by NIH Young Investigators Award HL22747.

263.11 BENZODIAZEPINE AND OPIATE RECEPTOR LEVELS IN DIFFERENT BRAIN REGIONS AND THE KIDNEY OF SPONTANEOUSLY HYPERTENSIVE RATS. Leonard G. Davis and William F. Herblin. Central Research and Development Dept., E. I. du Pont de Nemours & Co., Wilmington, Delaware 19898.

Several reports exist that describe altered neurotransmitter systems in rats with spontaneous or induced hypertension. The major change appears to involve the adrenergic system yet other receptor populations are affected. Benzodiazepines have been used by physicians in the management of essential hypertension yet these drugs have only been shown to be effective in hypertensive patients reporting psychological stress. On the other hand, opiate agonists have long been known to reduce blood pressure. These clinical observations have been partially supported by in vitro animal studies: 1) Regan et al. (Life Sci 28: 991, 1981) reported that CNS benzodiazepine receptors were unaltered in deoxycorticosterone acetate (DOCA)-salt induced hypertension but they did demonstrate that the number of kidney receptors in the DOCA-treated animals was elevated. 2) Martucci and Hahn (Endocrine Res. Comm. 6: 291,1979) reported that the number of CNS opiate receptors in spontaneous hypertensive rats (SHR) was elevated without any change in their affinity for ^{3}H-naltrexone, an antagonist. We have investigated benzodiazepine and opiate receptors in various brain regions and in the kidneys of SHR and control rats.

Utilizing a pneumatic pressure sensor and a tail-cuff, we determined the systolic blood pressure of unanesthetized rats. As expected, the blood pressures of SHR and control animals were statistically different (160 ± 9 vs. 107 ± 2, respectively). The following day, these animals were sacrificed and various brain regions were dissected free while the kidney was desheathed and removed. A crude membrane fraction was prepared from each brain region and kidney by standard centrifugation procedures after hypoosmotic shock for immediate use in standard saturation binding assays with either ^{3}H-diazepam for benzodiazepine receptors or ^{3}H-etorphin, an agonist, for opiate receptors. The data were transformed for Scatchard analysis. Although the number of benzodiazepine receptors in each brain region differed, minimal differences were detected between SHR and control rat brain regions. However, the number of kidney receptors was markedly elevated in SHR when compared to controls. Opiate receptors showed less dramatic changes in all areas studied.

The significance of the profound change in peripheral benzodiazepine receptors in hypertensive rats will be further explored as well as the possible influence of altered agonist/antagonist configuations of opiate receptor populations.

263.12 CENTRAL CARDIOVASCULAR EFFECTS OF PROSTAGLANDIN E_2 and I_2. G. Feuerstein, D.M. Jacobowitz and I.J. Kopin. Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

Prostaglandins E_2 and I_2 are important modulators of the cardiovascular system through multiple sites of actions -- i.e., blood vessels, cardiac functions, platelets homeostasis, renin catecholamines and vasopressin release. Prostaglandins are also synthesized by brain tissue, but their role in central regulation of the cardiovascular system is largely unknown. The following experiments were designed to investigate further the role of vasodilator prostaglandins - PGE_2 and PGI_2 in central cardiovascular and sympathetic regulation in halothane (0.8% in oxygen) anesthetized rats.

Injections of PGE_2 (0.5-5 nmol/kg) into the lateral cerebral ventricle (i.c.v., 5µl) elicited a dose dependent increase of heart rate up to + 117 ± 14 (n=8) beats/min.; blood pressure was also elevated, up to +27 ±6 mm Hg. These effects subsided after 30 min. At time of maximal heart rate and blood pressure responses, plasma norepinephrine (NE, radioenzymatic assay) increased up to 802 ± 103 pg/ml (from 294 ± 29 pg/ml at the control period) and plasma epinephrine (EPI) increased up to 116 ± 21 pg/ml (from control level of 41 ± 6 pg/ml). The increases in plasma catecholamine levels were also dose dependent, and tapered back to control levels after 30 min. Injection of PGE_2-0.5 nmol/kg (0.5 µl) into discrete hypothalamic regions -- the dorsomedial (DMN) and posterior hypothalamic (PHN) nuclei, elicited a moderate increase in blood pressure, up to +22 ± 2 mm Hg (n=8) and a marked increase in heart rate, up to +175 ± 23 beats/min. Plasma NE, but not EPI was increased up to 533 ± 60 pg/ml (versus 186 ± 25 pg/ml at the control period) at the time of maximal cardiovascular response. Injections of PGI_2 (0.05 - 50 nmol/kg) i.c.v. resulted in a depressor and cardiac accelerating response (dose dependent). However, the i.c.v. injections of PGI_2 were 25 times less potent (ED50) than i.v. injections of the same doses of PGI_2. Injections of PGI_2 into the DMN or PHN (0.05 nmol/kg, n=7) elicited only a short lasting (10 min) increase in heart rate, up to +55 ±4 beats/min, without effect on blood pressure. Plasma EPI was slightly elevated at the peak of the heart rate response, up to 140 ±35 pg/ml (versus 41 ±10 pg/ml at the control period, but bilateral adrenalectomy did not abolish the increase in heart rate induced by intrahypothalamic injections of PGI_2. These data suggest that PG's may modulate cardiovascular functions and sympathetic activity in specific brain nuclei. Various PG's may differ both quantitatively and qualitatively in their central actions.

263.13 USE OF TWO NON-CARDIOVASCULAR MODEL SYSTEMS IN THE ANALYSIS OF CNS AUTONOMIC ACTIONS OF CLONIDINE AND SOME ANALOGS OF CLONIDINE.

M. C. Koss and M. J. Chandler*. Departments of Pharmacology and of Ophthalmology, Univ. of Oklahoma Health Sciences Center, and McGee Eye Institute, Oklahoma City, Oklahoma 73190.

The effects of intravenous administration of clonidine and five congeneric derivatives of clonidine were tested in anesthetized cats with regard to their relative ability to depress centrally and peripherally evoked electrodermal responses (EDR) as well as with regard to their ability to inhibit parasympathetic tone to the iris. With the exception of ST-91, all of the clonidine-like substances selectively reduced the amplitude of centrally (hypothalamic) evoked EDR in a dose-dependent fashion, with the order of sympatho-inhibitory potency being clonidine (ST-155) >ST-375>ST-606>ST-600>ST-608>>>ST-91. Of these agents only ST-91 exerted a peripheral inhibitory effect, indicating a CNS site of action for all of the other compounds. The same order of potency of these compounds was observed with regard to their mydriatic (parasympatho-inhibitory) effects. In some experiments the CNS inhibition of parasympathetic nerve activity was confirmed by means of direct recordings from the postganglionic ciliary nerves. In these experiments ST-91 exerted only a modest CNS effect and then only at dosage levels in excess of 300 μg/kg. This relative lack of CNS effect of ST-91 is likely due to its low lipoid solubility as it is at least as potent as clonidine in stimulating peripheral α-adrenoceptors.

Prior treatment with yohimbine hydrochloride (0.5 mg/kg, i.v.) antagonized both the CNS sympatho-inhibitory (depression of EDR) and parasympatho-inhibitory (mydriasis associated with inhibition of ciliary nerve activity) effects of all of these clonidine-like agents. The results of this study demonstrate that all of the analogs of clonidine tested (with the possible exception of ST-91) act like clonidine to depress tone and reactivity of both sympathetic and parasympathetic autonomic mechanisms, although all of the congeners of clonidine were less potent in their effects. These results also suggest that an action on a CNS adrenergic mechanism (probably via α_2-adrenoceptors) is involved in both sympathetic and parasympathetic control of these autonomic systems.

264.1 RAPID RESETTING OF AORTIC AND CAROTID SINUS BARORECEPTORS. L.B. Bell*, J.L. Seagard, F.A. Hopp*, and J.P. Kampine. Depts. of Anesthesiology and Physiology, Med. Col. of Wis. and Wood VA Med. Ctr., Milwaukee, WI 53193

Previous studies have found that the arterial baroreceptors can adapt to changes in systemic blood pressure (BP) within hours to days, resetting both threshold and saturation pressures. A recent report has indicated that carotid sinus baroreceptors can reset as soon as 15 minutes. This study was performed to: 1) simultaneously record threshold pressures for both aortic and carotid sinus baroreceptors set at systemic BP over a physiological range; and 2) determine the ability of both sets of receptors to rapidly adapt to changes in BP within 5-20 minutes, as well as the pattern in which resetting occurs.

Mongrel dogs were anesthetized (35 mg/kg pentobarbital) and placed on positive pressure ventilation with oxygen. Simultaneous multifiber nerve recordings were made from the left carotid sinus and right aortic depressor nerves during each experimental procedure. Carotid sinus and aortic arch blood pressures were measured by cannulas inserted in the lingual and femoral arteries, respectively. Systemic BP was regulated by an isobaric pressurized reservoir system connected to the animal via the brachial arteries. This system was used to maintain constant peak systolic pressures of 80, 120, or 160 mmHg. Peak systolic BP were randomly set in each animal at these experimental pressures and thresholds were determined for both sets of receptors at 5, 10, 15, and 20 minutes following each pressure change.

The threshold pressures for either set of baroreceptors were not consistently higher than those for the other set at any of the experimental pressures. Both sets of baroreceptors demonstrated an ability to rapidly reset (within 5 min) to either an increase or decrease in BP. When BP was decreased, a rapid drop in threshold was observed at 5 min followed by a gradual increase during the next 15 min to a new threshold level below that established at the higher pressure. When BP was increased, threshold rapidly increased at 5 min and continued to gradually increase over the next 15 min. This resetting of threshold for both increases and decreases in BP appears to plateau between 15-20 minutes for both sets of baroreceptors. The magnitude of the change in threshold depended on the magnitude of the pressure change. This study has demonstrated that both aortic and carotid sinus baroreceptors begin to adapt to changes in BP within 5 min. The ability of these baroreceptors to adapt was independent of pressure within a physiologic range of 80-160 mmHg. (Supported by NIH Grants HL 16511, 06511, 05882, and VA).

264.2 REFLEX EFFECTS OF SPLENIC AFFERENTS ON RENAL AND CARDIAC SYMPATHETIC EFFERENT NERVE ACTIVITY. N.L. Herman*, D.R. Kostreva, and J.P. Kampine. Depts. of Anesthesiology and Physiology, Med. Col. of Wis. and VA Med. Ctr., Wood, WI 53193.

The reflex effects of splenic low-pressure baroreceptors on renal and cardiopulmonary sympathetic efferent nerve activity were studied in mongrel dogs (15-20 kg) anesthetized with sodium pentobarbital (35 mg/kg i.v.) and placed on positive pressure ventilation. Systemic blood pressure, splenic venous and splenic arterial pressure as well as a lead II electrocardiogram were all measured and recorded using a Grass polygraph. Splenic afferent nerve activity was recorded from the cut distal end of a branch of the splenic nerve. Renal and cardiopulmonary sympathetic efferent nerve activity were recorded from the cut central ends of the renal nerves and the anterior ansa subclavian nerve respectively. Both afferent and efferent nerve activities were amplified, filtered, displayed on an oscilloscope and recorded on magnetic tape, along with the other parameters that were measured. Splenic afferent nerve activity could be elicited by increasing splenic venous pressure by manual compression of the spleen, occlusion of a splenic vein or splenic contraction induced by injection of 100 ug of epinephrine into the splenic artery. Increases in splenic afferent nerve activity are linearly related to increases in splenic venous pressure but not splenic arterial pressure. Histological sections of the nerves from which afferent recordings were obtained demonstrated that all of the afferents were non-myelinated C-fibers. Electrical stimulation of the cut central end of the splenic nerves resulted in a marked reflex increase in both renal and cardiopulmonary sympathetic efferent nerve activity that remained elevated throughout the stimulation period. The reflex increase in cardiopulmonary sympathetic efferent nerve activity was associated with an increase in right ventricular contractile force measured with a Brodie-Walton strain gauge, an increase in heart rate (5-15 beats/min) and increases in blood pressure. The physiological effects of the reflex increases in renal sympathetic efferent nerve activity were not determined in this study. This study is the first to demonstrate both the existence of low pressure baroreceptors in the spleen and that these splenic afferents can reflexly alter cardiopulmonary sympathetic efferent nerve activity, heart rate, contractile force, blood pressure and renal sympathetic efferent nerve activity. (This study was supported by NIH Young Cardiovascular Investigator Grant HL 21042 and the VA Medical Research Service).

264.3 HEMODYNAMIC VARIABLES PREDICTING FIRING OF ATRIAL B-RECEPTORS. R. L. Stornetta* and D. G. Ward. Neuroscience Program, Univ. Virginia Sch. Med. Charlottesville, VA 22908.

It is generally accepted that atrial B-receptors respond to changes in atrial filling and pressure. However, the precise interrelations of the hemodynamic parameters responsible remain obscure. To define quantitatively the relationship of right atrial filling and mean right atrial pressure to the activity of atrial B-receptors, recordings of single fibers from the right cervical vagus were obtained from 8 cats anesthetized with chloralose/urethane. Recordings were made of 7 atrial fibers with B-activity, 2 aortic baroreceptors, 5 ventricular fibers and 6 respiratory fibers classified according to the criteria of Paintal. The activity of these fibers were examined in response to 10ml/kg hemorrhage for 3 min. Blood was reinfused after each trial. Firing rate, mean right atrial pressure (MRAP), magnitude of the right atrial "V" wave measured from its beginning to its peak ("V), mean arterial pressure(MAP) and arterial pulse pressure (APP) were each averaged for sequential 15 sec periods during each hemorrhage. All measurements were normalized as a percentage of pre-hemorrhage values. The normalized firing of each fiber was plotted against the normalized value of each hemodynamic variable. Multiple linear regressions of atrial B-receptor firing with mean right atrial pressure and magnitude of the right atrial "V" wave were calculated. Analogous calculations were made of baroreceptor firing with mean arterial pressure and arterial pulse pressure. The firing of the atrial B-receptors and the firing of the baroreceptors was each correlated statistically with each of the hemodynamic variables. However, the multiple linear regressions revealed that the firing of atrial B-receptors (F_a) was best predicted by;

$$\%F_a = -135.3 + 2.7(\%\text{"V"}) - 0.46(\%\text{MRAP}) \quad (R=0.97).$$

The firing of aortic baroreceptors (F_{br}) was best predicted by;

$$\%F_{br} = -266.1 + 0.76(\%\text{APP}) + 2.96(\%\text{MAP}) \quad (R=0.96).$$

The present data suggest strongly that the firing of atrial B-receptors during hemorrhage is best predicted by the magnitude of the "V" wave (weighting factor 2.7) in linear combination with the mean right atrial pressure (weighting factor -0.46). The weighting factors indicate that the "V" wave which estimates atrial filling is the dominant factor in predicting the firing of atrial B-receptors. Mean right atrial pressure is a minor factor. However, either hemodynamic variable alone inadequately predicts the neural response.

264.4 DISTRIBUTED FUNCTIONS OF THE CENTRAL NERVOUS SYSTEM IN THE DYNAMIC CONTROL OF THE INTRAMUSCULAR VENOUS CAPACITANCE. F.J. Thompson, J.R. Wald*, G.T. Gobbel* and B.J. Yates*. Dept. of Neuroscience, University of Florida College of Medicine, Gainesville, FL 32610.

The functions of the venous system have recently been expanded to include a dynamic role in the regulation of circulation. We have been studying the sources of input from superficial veins (venous afferents), their projections, and connections in the feline CNS and contribute these findings to that concept.

Electrical stimulation of limb venous afferent produced activation of both flexor and extensor motoneurons; microstimulation of cortical neurons activated by venous afferent stimulation elicits EMG activity in the skeletal muscles in the same limb of origin of the venous afferent fibers, (Thompson et al. 1981). The present studies were done to examine the excitability of venous afferents by perfusion-distention of selected segments of forelimb and hindlimb veins, and to compare the distribution of central neural responses to those obtained by electrical stimulation.

Perfusion-distention of a segment of femoral-saphenous vein elicited potentials recorded from the dorsum of the lumbar spinal cord, with minimum perfusion pressures of 14 mm/Hg. Rostral-caudal mapping of the lumbo-sacral spinal cord revealed that maximal N_1 potentials were sharply restricted to the fifth and sixth lumbar cord segments, and overlapped precisely the distribution determined by electrial stimulation of the femoral venous afferent fibers. Perfusion-distention of a segment of cephalic vein evoked potentials in the pericruciate cerebral cortex, with minimum perfusion levels of 25 mm Hg. Short latency initially positive potentials characteristic of primary waveforms were recorded from the lateral sigmoid gyrus and were largest near the tip of the cruciate sulcus. The cortical distribution of the maximal perfusion evoked potentials overlapped the motor cortex distribution mapped by electrical stimulation of the cephalic venous afferents. Electrical and mechanical stimulation experiments have revealed topographically organized connections to motor neurons in both the spinal cord and in the cerebral cortex; the activated neurons are widely separated in the caudal-rostral extent of the central nervous system but are functionally inter-related. The authors propose that the venous afferents form a major contribution to the central integration and control of intramuscular venous capacitance through widely dispersed but functionally interconnected components of the somatomotor system. The organization of this system as a distributed system will be discussed.

264.5 EXERCISE TRAINING AFFECTS RESPONSES TO STRESSORS. E. M. Hull, S. H. Young* and M. G. Ziegler*. Univ. Tex. Med. Branch, Galveston, TX 77550.

It is well known that exercise training reduces a number of cardiovascular and hormonal responses to a fixed amount of exercise. Furthermore, situations requiring active psychological coping elicit B-adrenergically mediated cardiovascular responses similar to those of exercise. This study was undertaken to determine whether the exercise training effect would generalize to stressors which require active psychological coping and/or to passive psychological or physical stressors.

Subjects were 55 men and women between the ages of 21 and 64, who spent an average of at least 30 min per day either exercising vigorously or pursuing a sedentary hobby. Level of exercise training was defined as length of time they ran on a treadmill before exhaustion. Heart rate and blood pressure were recorded and blood was drawn from an indwelling catheter after a 20 min rest, during and 3 and 10 min after each of 4 stressors. The passive and active psychological stressors were a film of industrial accidents and the Stroop word-color task performed under distracting conditions. The passive and active physical stressors were putting a foot in ice water for 1 min and exercising on an automated treadmill to exhaustion. In addition, a psychological rating scale consisting of 7 pairs of mood adjectives was administered during baseline and after each stressor.

Diastolic blood pressure responses to the film and Stroop test were lower in exercise trained subjects 40 years of age or older than in untrained persons of the same age category. Diastolic responses to exercise were lower for the entire trained group. Exercise training was also associated with lower baseline systolic pressures for persons over 40 and with lower heart rates for the whole group at all times except during and after maximal exercise. Norepinephrine was lower in trained subjects after 9 min of exercise, but much higher after maximal exercise, reflecting the greater work done. Trained persons reported less depression and anger after the film than did untrained persons.

There was no preferential generalization of the training effect to the active psychological task. Thus, training affects more than the B-adrenergic system. The significant reduction in blood pressure responses only in trained subjects over 40 is compatible with other evidence that blood pressure is lowered by training only in older and/or hypertensive individuals. None of our subjects was hypertensive, but pressures were higher for older subjects at several times. Exercise training, by reducing labile responses to stressors, may help to avert the more dangerous and harder to treat stable hypertension.

264.6 ELECTRICAL STIMULATION OF THE AMYGDALA CENTRAL NUCLEUS IN THE AWAKE RABBIT: EFFECTS ON HEART RATE, RESPIRATION AND SOMATOMOTOR BEHAVIOR. Bruce S. Kapp, Craig D. Applegate*, Mark D. Underwood* and Carole L. McNall*. Dept. of Psychology, University of Vermont, Burlington, Vt. 05405. (SPON: F. Abraham).

We have shown that bradycardia in response to a conditioned threatening stimulus in the rabbit is attenuated by lesions of the amygdala central nucleus (ACE) and that electrical stimulation of the ACE elicits bradycardia in the anesthetized rabbit (Kapp et al., Physiol. Behav., 1979; Kapp et al., submitted). The present study was conducted to determine the extent to which ACE stimulation elicits bradycardia and concomitant somatomotor and respiratory responses in the awake rabbit.

Sixteen sites within the central nuclei of fourteen rabbits were examined under loosely restrained and unrestrained conditions using monopolar electrical stimulation (5.0 sec trains; 100 Hz; 0.5 msec pulse duration; 150 µm tip exposure). Under loosely restrained conditions and with current levels ranging from 10-100 µA, bradycardia was elicited from thirteen of these sites, tachycardia was elicited from one site, and negligible responses were elicited from two sites. The bradycardia was of short onset latency (< 1.0 sec) and was greatly attenuated or abolished by I.V. atropine methylnitrate. The median threshold current intensity to elicit a peak bradycardia response of ≥ 10% for the sites demonstrating bradycardia was 40 µA. At threshold current intensities necessary to produce ≥ 10% bradycardia, the most frequent respiratory response was one of increased rate and decreased amplitude (9 of 12), or of decreased amplitude with no change in rate (3 of 12). These respiratory changes were most prevalent during the first second of stimulation with variable responses occurring during the remainder of the stimulation period. Pupillodilatation, although not quantitatively measured, was frequently observed to occur at these threshold current intensities.

Of the thirteen sites from which bradycardia was elicited, stimulation at intensities necessary to produce ≥ 10% bradycardia invariably evoked movements of the mouth and tongue resembling chewing responses. Under unrestrained conditions stimulation at these current intensities produced an arrest of ongoing behavior to stimulus onset which varied from a momentary arrest to an arrest for the duration of the 5.0 second stimulation period.

The results suggest that stimulation of the ACE produces a variety of autonomic and somatomotor responses which may be mediated by direct ACE-brainstem projections in this species (Schwaber et al., Neuro. Lett., 1980). (Supported by USPHS Grants RO1 MH31811 and KO2 MH00118 to B.S.K.)

264.7 DESCENDING BRADYCARDIA PATHWAY(S) FROM PARABRACHIAL NUCLEUS IN RABBITS. D. Liskowsky*, H. Ellenberger*, J. Haselton*, N. Schneiderman, and R. Hamilton. Dept. of Psychology, Univ. of Miami, Coral Gables, Fl. 33124.

Electrical stimulation (10 sec; 100 pulses/sec; 0.25 msec pulse duration; 100-150 uA) elicited primary, short latency(<1.0 sec) bradycardia (N100 beats/min) from parabrachial nucleus (PBN) in ethyl carbamate anesthetized rabbits. Single pulse (0.4 pulses/sec) stimulation of PBN orthodromically activated barosensory-sensitive neurons in nucleus tractus solitarius (NTS) and cardioinhibitory vagal pre-ganglionic neurons in dorsal vagal nucleus (DVN) at a latency of 8.4 (±7.8) msec. However, because (1) extensive attempts to backfire barosensory-sensitive neurons in PBN by stimulating NTS or DVN were unsuccessful, (2) latencies and other characteristics of NTS and DVN neuronal responses to PBN suggested the presence of an oligosynaptic pathway, and (3) only sparse retrograde labeling was seen in PBN after injections of horseradish peroxidase (HRP) were made into dorsal medulla (NTS/DVN complex), attempts were made to identify alternate putative synapses in the central bradycardia pathway between PBN and cardioinhibitory motor neurons. Anterograde and retrograde labeling using HRP conjugated with wheat germ agglutinin revealed the presence of direct projections from PBN to NTS and from PBN to nucleus ambiguus (NA). Indirect projections from PBN to NA synapsed in either the A5 region or nucleus reticularis gigantocellularis (NRG). Direct projections were traced from NA to DVN, and reciprocal connections were observed between NTS and NA. (Direct projections between NTS and DVN have previously been observed using other neuroanatomical methods.) Extensive exploration of the caudal pons-rostral medulla indicated that train stimulation of the A5 region and ventral NRG elicited bradycardia responses that were similar to those elicited by stimulating PBN. These responses were eliminated by bilateral vagotomy, but not by artificial ventilation in decamethonium paralyzed animals. Bradycardia responses were also elicited at lower current intensity (∿30uA) by stimulating NTS, DVN, and NA. The results suggest that the bradycardia pathway(s) descending through PBN may have their outflow from DVN with intermediate synapse in NTS, and from NA either without intervening synapse or with intervening synapse in the A5 region or ventral NRG.

The study also showed that train electrical stimulation of the principle nucleus of V (Nvp) elicited bradycardia responses. The form and characteristics of these bradycardia responses were similar to the trigeminal depressor response described by Kumada, et al. (1979). Injection of HRP into Nvp showed that the descending trigeminal depressor response pathway is anatomically distinct from the descending PBN bradycardia pathway.

264.8 ANTERIOR HYPOTHALAMIC STIMULATION REVERSES OUABAIN-INDUCED ARRHYTHMIAS. C. Chinn* and B.H. Natelson, VA Medical Center and Dept. of Neurosciences, College of Medicine and Dentistry of New Jersey-New Jersey Medical School, East Orange NJ 07018.

Posterior hypothalamic stimulation at sub-threshold currents for arrhythmia is known to precipitate arrhythmias in the presence of otherwise sub-toxic doses of digitalis (Evans & Gillis, JPET, 195:577, 1975). The mechanism for this effect is thought to be due to increased sympathetic neural activity to the heart. Because it is known that anterior hypothalamic stimulation decreases heart rate and blood pressure due to concomitant sympatho-inhibition and parasympathetic activation in the cat, we thought that such stimulation might reverse digitalis-induced arrhythmias.

In the chloralose-anesthetized (70-80 mg/kg, IP) cat, cardiac arrhythmias were induced by bolus IV injections of ouabain (25 µg/kg every 15 min for 30 min, then 15 µg/kg every 15 min until the appearance of arrhythmias). Two min after the onset of a sustained arrhythmia, the left anterior hypothalamus was stimulated with a concentric stainless steel electrode (NE-100, Kopf) either continuously for 3-5 min (0.5 ms duration, 0.3-0.5 mA, 100 Hz) or for 2 min at 2 min intervals. In some animals, sympathetic discharge was recorded from a left renal nerve. Lead II ECG was monitored.

Ouabain produced various cardiac arrhythmias after a total dose of 65-100 µg/kg. Rhythm strips revealed runs of ventricular extrasystoles, supraventricular tachycardia or ventricular tachycardia. Sustained or intermittent anterior hypothalamic stimulation could stop ventricular extrasystoles or supraventricular tachycardia and produce normal sinus rhythm. Ventricular tachycardia could not be converted to sinus rhythm; but during stimulation, occasional normally conducted beats were seen. Anterior hypothalamic stimulation resulted in a transient decrease in integrated renal nerve activity which returned to normal within 20 sec. No consistent relation was apparent between renal nerve activity and onset or reversal of the arrhythmias.

These experiments indicate for the first time that activation of a brain locus can reverse digitalis-toxic arrhythmias. This effect is not related in time to diminution of sympathetic nerve activity. These observations suggest a possible role for the anterior hypothalamus in the control of heart rhythm as has been found earlier for heart rate and blood pressure.
(Supported by American Heart Association-New Jersey Affiliate and NIH grant #HL-24498)

264.9 THE FULMINANT HYPERTHERMIC-STRESS SYNDROME - POSSIBLE ROLE FOR NOREPINEPHRINE IN STRESS SUSCEPTIBLE PIGS. T.P. Davis*, C.W. Gehrke, Jr.*, and C.H. Williams*. (SPON: R.P. Gruener). Dept. of Pharmacology, Univ. of Arizona Health Sciences Center, Tucson, AZ. 85724 and Dept. of Biochemistry, Univ. of Missouri, Columbia, MO. 65211.

The idea that norepinephrine (NE) and other biogenic amines play a role in the development of the fulminant hyperthermia-stress syndrome has been presented on a theoretical basis and partially substantiated with catecholamine depletor, false transmitter, and alpha blocker studies. However, the crucial test of the NE hypothesis is to accurately quantitate key biogenic amines in blood plasma during the syndrome. To accomplish this we developed a sensitive, selective, pre-column derivatization method with HPLC (Davis, T.P., J. CHROM. 162, 293, 1979) to measure NE, dopamine (DA) and serotonin (5-HT) in plasma from normal and malignant hyperthermic (MH) pigs. Samples were carefully collected from control and stressed animals under halothane anesthesia. Using a simple extraction method involving pre-column derivatization with o-phthalaldehyde and ethyl acetate partitioning, the samples were chromatographed in less than 40 minutes. Norepinephrine was found to be elevated in the six hyperthermic pigs as the syndrome progressed, reaching levels of 2 to 15 ng/ml at the height of the syndrome, versus <0.5 ng/ml for the five controls. Body temperature and total peripheral resistance followed a similar pattern reaching 42.5°C and 4.3 PRU's, respectively. These experiments provide direct evidence for our hypothesis that a failure to metabolize excess NE may be one of the key metabolic defects in causing the pathophysiology of the malignant hyperthermia stress syndrome. The application of our chromatographic method in animal and human tests may provide a pattern of biogenic amine types and levels that could be diagnostic in identifying susceptible humans and carrier animals.

264.10 GASTRIC PATHOLOGY EFFECTS OF ELECTROLYTIC LESIONS OF THE DIENCEPHALON AND TELENCEPHALON IN THE RAT. J. R. Emslie* and N. I. Wiener. Department of Psychology, York University, Downsview, Ontario, M3J 1P3.

In a series of 72 rats, the pathological effects of electrolytic diencephalon and telencephalon lesions were assessed with respect to non-lesioned controls. Animals with ventromedial nucleus of the hypothalamus plus nucleus accumbens septi lesions had greatly reduced stomach pathology compared to those with ventromedial nucleus of the hypothalamus lesions alone. Similarly, the effect of lateral hypothalamic lesions was greatly reduced by the nucleus accumbens septi plus lateral hypothalamus combination. A homeostatic model is proposed which accounts for the observed brain/stomach correlations, allows predictions for novel lesion combinations and may generalize to other stress induced procedures.

264.11 THE CONTRIBUTION OF BILE TO GASTRIC MUCOSA DAMAGE IN RATS AFTER LATERAL HYPOTHALAMIC (LH) LESIONS. C. V. Grijalva, M. G. Tordoff, P. J. Geiselman and D. Novin. Dept. Psychol. and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

There is experimental and clinical evidence that the reflux of bile into the stomach may play a role in gastric ulceration and gastritis. We conducted two experiments to investigate the contribution of bile to gastric mucosal damage in rats after anodal electrolytic lesions of the LH area.

In the first experiment we tested the possibility that LH lesions produce an immediate increase in biliary secretion. Twenty-two Long-Evans male rats were divided into two groups. All rats were deprived of food but not water overnight (16 h) and then they were anesthetized with urethane. The common bile duct was cannulated and biliary secretion was collected for 1 h prior to and every hour for 5 h following either LH lesions or control operations. There were no significant differences in the amount of biliary secretion between LH rats or controls either prior to surgery or during any of the five consecutive 1-h measures following surgery.

Although LH lesions did not alter bile flow, the possibility exists that bile may contribute to the occurrence of gastric mucosal damage after the brain lesion by refluxing into the stomach. Eighteen male rats were deprived of food but not water overnight (16 h), and then they were anesthetized with sodium pentobarbital (50 mg/kg, ip). In 9 rats the bile duct was ligated 1-cm from the duodenum. In the remaining 9 rats the bile duct was exposed but not ligated (sham ligated group). Following either bile duct ligation or sham ligation both groups received bilateral LH lesions. All animals were food and water deprived for an additional 24 h and then sacrificed with an overdose of sodium pentobarbital. The stomachs were examined for gross changes in the mucosa. The results showed that ligating the bile duct just prior to LH lesions significantly reduced the occurrence of gastric ulceration. Only one out of 9 rats in the ligated group displayed any obvious gastric pathology, whereas, 7 out of 9 rats in the sham-ligated group displayed varying degrees of glandular gastric erosions and hemorrhaging.

These results indicate that the reflux of bile into the stomach significantly contributes to the ulcerative process following LH lesions. The possibility exists that bile duct ligation reduces the propensity to ulcerate by eliminating bile salts from entering the stomach or by indirectly suppressing gastric acid secretion. (Supported by NIH grant NS07687).

264.12 MODULATION OF REGIONAL CEREBRAL BLOOD FLOW BY GAMMA-AMINOBUTYRIC ACID SYSTEMS. L. J. Bearden and R. M. Martin. Departments of Biomedical Engineering, Neurology, and the Neurosciences Program, University of Alabama in Birmingham, Birmingham, Al. 35294.

An understanding of the mechanisms involved in the control of the cerebral circulation has been the object of extensive experimental effort. However, relatively little attention has been given to the potential modulatory effects on the cerebral circulation of gamma-aminobutyric acid (GABA) systems; even though there are several lines of evidence which suggest such an involvement. Bicuculline, a potent GABA antagonist, has been shown to produce an increase in both cerebral arterial pressure and cerebral venous outflow. Both of these changes were observed approximately 6 seconds after bicuculline was administered (1.2 mg/kg, i.v.), and occurred simultaneously with the onset of the convulsive electrical effects of bicuculline (Meldrum and Nilsson, Brain 99:523-542 (1976)). It has also been demonstrated that there is a regional variability in the increase in cerebral blood flow which is induced by bicuculline (Horton, et al., Brain Research 192:399-412 (1980)), and that the increased rate of blood flow can be several times greater than normal, thus greatly exceeding the concomitant increase in cerebral oxygen consumption. Alternatively, it has also been reported recently that GABA itself and known GABA agonists produce a dose-dependent dilation of isolated segments of cerebral arteries in vitro. These observed dilatory effects could be blocked by bicuculline or picrotoxin (Edvinsson, et al., Brain Research Bulletin 5(2):335-340 (1980)). Therefore the manner of involvement of GABA-ergic systems in the regulation of cerebral blood flow remains questionable.

We have examined the effects of GABA-ergic compounds on the regional cerebral blood flow of rats by means of the hydrogen clearance technique. Adult male rats (250-350 g) were implanted with epoxylite insulated Pt/Ir macroelectrodes with the uninsulated tip of the electrodes located in the cortex, hippocampus, thalamus, or caudate-putamen of the brain. After recovery from surgery, control rates of blood flow were determined for each area of the brain. Animals were then given i.v. or icv. injections of GABA, bicuculline, picrotoxin, or muscimol, and regional blood flow rates redetermined as a function of time, dosage and type of drug. Results from these experiments support an involvement of GABA-ergic systems in the modulation of regional cerebral blood flow.

264.13 MAGNESIUM DEFICIENCY CAN INDUCE CEREBRAL ARTERIAL VASOSPASM. B.T. Altura* and B.M. Altura (SPON: J.B. Ranck, Jr.). Dept. of Physiol., SUNY Downstate Med. Ctr., Brooklyn, NY 11203

Recently, evidence has been brought forth which suggests that the concentration of external magnesium ions ($[Mg^{2+}]_o$) may be an important factor in the regulation of peripheral vascular tone and reactivity. To our knowledge, there are no direct observations on the influence of $[Mg^{2+}]_o$ on cerebral arterial tone. Studies were therefore undertaken on isolated canine cerebral (basilar-BA, middle cerebral-MCA), pulmonary (intralobular), coronary (left, right, circumflex and branches), splanchnic (mesenteric, hepatic, splenic, pancreatic) and renal arteries in the presence and absence of different $[Mg^{2+}]_o$. Lowering $[Mg^{2+}]_o$ below 1.2 mM produced spasms of BA, MCA and coronary, but not renal, splanchnic or pulmonary arteries. Withdrawal of $[Mg^{2+}]_o$ produced peak cerebral arterial vasospasms within 45-90 sec. In terms of % KCl maximal contractions, MCA $>$ BA $>$ coronary arteries. In contrast, elevation in $[Mg^{2+}]_o$ above 1.2 mM (e.g., 2.4-9.6 mM) reduced basal tone in MCA, BA and coronaries (but not renal, pulmonary or splanchnic), and in addition attenuated in a concentration-dependent manner the constrictor action of KCl, serotonin and other vasoactive neurohumoral agents. Lowering of $[Mg^{2+}]_o$ below 1.2 mM potentiated the constrictor action of these neurohumoral agents. In view of such findings, it is possible that some of the neurological derangements noted in Mg-deficient states may be a consequence of a cerebral hypomagnesemia which could result in local vasoconstriction and hypoxia. (Supported in part by the PHS Grants HL-18015 and DA-02339.)

264.14 BARORECEPTOR INPUT TO NEURONS IN THE MEDULLARY RAPHE NUCLEI OF THE CAT. C-T Yen and P.S. Blum, Department of Physiology, Thomas Jefferson University, Philadelphia, PA 19107.

Activation of baroreceptor afferents produces a reflex depression of blood pressure. Studies using electrical stimulation, neural recordings, and lesions support the hypothesis that neurons in the medullary raphe nuclei (nucleus raphe magnus, nucleus raphe pallidus, nucleus raphe obscurus; MRN) participate in this systemic baroreflex. We tested this hypothesis by examining the response properties and axonal projections of single neurons recorded within the MRN. Adult cats were anesthetized with alpha-chloralose, paralyzed with gallamine, and passively ventilated. Sinus nerve was isolated laterally and verified by a cardiac rhythm and a depressor effect following electrical stimulation. Sixty units in 13 animals were identified within the MRN that responded to electrical stimulation of the sinus nerve. The distribution of the initial spike latency for these 60 neurons ranged from 5 ms to more than 80 ms (median=25 ms). Thirty-five of these units also were tested for a response following 0.2-1.0 μg norepinephrine (i.v.). Fifteen MRN neurons had a response correlated with the pressor response induced by norepinephrine. The units responding both to sinus nerve stimulation and elevation of blood pressure were defined as baroreceptor-responsive. These units had the same distribution of latency to sinus nerve stimulation compared to other neurons but baroreceptor-responsive neurons could respond at a higher frequency of sinus nerve stimulation (median=8 Hz vs 1 Hz). In the same experiment, those units with axons projecting to the spinal cord were identified by an antidromic response to spinal cord stimulation at C5 and the quadrant of the descending axons were localized using a microstimulation technique. Four of 12 baroreceptor-responsive neurons had descending axons. Two of these axons were located in the lateral funiculus of the spinal cord (conduction velocity = 6 and 40 M/sec) and the other two were located in the ventral columns (conduction velocity = 6 and 38 M/sec). These data are consistent with the hypothesis that baroreceptor-responsive MRN neurons participate in the systemic baroreflex.

265 SYMPOSIUM

REGENERATION OF NERVE FIBERS IN THE MAMMALIAN CNS. A.J. Aguayo (Chairman; McGill Univ.), A.Bjorklund*(Univ.Lund), G.E. Schneider (MIT), S. Varon (UCLA).

Effective regeneration depends on survival of neurons, sprouting and elongation of axons and, eventually, the establishment of appropriate terminal connections. The panel will review experiments that provide new insights into conditions that influence these responses in the mammalian CNS.

A. Bjorklund: Studies using intracerebral neuronal transplants indicate that:a) embryonic CNS tissues from various parts of the neuraxis survive in the brain of adult hosts;b) axons from grafted neurons grow into the recipient while those from the host brain regenerate into the transplant; c) axons from monoaminergic and cholinergic grafted cells make highly specific connections in the hippocampal formation which mimic normal patterns of innervation; d) adrenergic growth into this formation is influenced by a neurotrophic factor released on septal deafferentation.

A.Aguayo: When nerve fibers are transected in the CNS of adult mammals there is no significant elongation of axons. However, the "substitution" of central by peripheral glia using Schwann cell containing grafts results in a marked growth (up to 3.5 cm in the rat) of axons from spinal, brain stem, basal ganglia and cortical neurons. Thus, although many mechanisms are probably involved, influences arising from glia may play an important role in the success or failure of axonal elongation after injury.

G.E. Schneider: The effects of CNS injury also differ according to age. Lesions in newborn hamsters can be followed by the growth of axons over distances greater than those observed in older animals. In addition, studies of regenerative responses in the immature CNS document compensatory changes in neuronal arborization and the functional effects of inappropriate connections.

S. Varon : Macromolecular factors controlling maintenance, growth and differentiation of nerve cells in the peripheral nervous system have been investigated in vitro. Similar techniques can now be applied to study growth requirements and regulation of central neurons while new, in vivo experimental models permit the investigation of humoral factors in regenerating nerves and possibly in the central nervous system.

266 WORKSHOP

IN VIVO ELECTROCHEMISTRY: PRINCIPLES AND APPLICATIONS. R.N. Adams (Chairman; Univ. of Kansas), R.F. Lane (Univ. of Oregon), R.M. Wightman (Univ. of Indiana), J. Justice (Emory Univ.), P. Knott (Marshall Univ.), G. Rebec (Univ. of Indiana), and P.M. Plotsky (Rhode Island Hosp., Providence).

The in vivo electrochemical methods employ very small graphite electrodes which voltammetrically monitor the concentrations of electro-oxidizable species present in brain extracellular fluid. Chronic measurements in unanesthetized, unrestrained animals are most frequently made. The endogenous compounds of major interest which can be determined are the catecholamines and their metabolites, and 5-hydroxytryptamine (5-HT) and its acid metabolite. Measurements may be carried out via potential scanning (voltammetry) or by measuring current at fixed potential (chronoamperometry), and the relative merits of each measurement mode are discussed.

In theory, each electroactive compound has a distinct oxidation potential, but in practice much overlapping occurs so that, for example, dopamine (DA) and norepinephrine (NE) cannot be distinguished in vivo by electrochemical techniques alone. Furthermore, catecholamines oxidize at about the same potential as ascorbic acid (AA) which is present in high concentration in CNS extracellular fluid. At present specificity of electrochemical response depends mainly on two experimental strategies: 1) stereotaxic placement of electrodes in brain regions where one neurotransmitter predominates, and 2) pharmacological manipulations which clearly differentiate between specific systems. Considerable progress can be expected, especially via surface modification of electrodes, in differentiating between AA and the catecholamines. However, it is unrealistic at present to suggest that direct electrochemical differentiation of DA vs. NE will be possible.

Despite the specific limitations cited above, the electrochemical technique can measure dynamic chemical changes in the CNS which are directly related to neurotransmitter functioning. Thus, the actions of various drugs, neuroleptics, etc. on catecholamines and 5-HT have been followed. Chemical changes which accompany behavioral manipulations are discussed by others in this workshop. Rather subtle sensory inputs such as vibrissae stimulation in rats result in measurable chemical changes in the brain. Simultaneous electrophysiological and electrochemical signals can be recorded and are discussed in this session. Using multibarrel pipets, Millar and coworkers have measured amounts of exogenous compounds injected iontophoretically while recording the activity of nearby neurons. Although much work is yet needed to improve the selectivity and quantitative response of the electrochemical methodology, there is good reason to believe that it can be developed into a new style of "chemical neurophysiology."

267.1 MECHANISM OF β-ENDORPHIN-REGULATED CALCIUM EVENTS IN SYNAPTOSOMES. S. Lin-Liu, W. R. Adey and E. M. Helm*. Research Service, VA Hospital, Loma Linda, CA 92357.

β-endorphin-regulated calcium events in synaptosomes were studied with a continuous perfusion technique. Synaptosomes, prepared from rat cerebri with a sucrose-Ficoll gradient and preloaded with $^{45}Ca^{2+}$, were applied to Millipore filters and perfused (1 ml/min) with a Ca^{2+}-free physiological solution at 31 C. Perfusate was collected at 1 min intervals for radioactive assay. By using the Ca^{2+}-free medium, Ca^{2+}-Ca^{2+} exchange was minimized but later activated by injecting (10 µl/min, 5-10 min) $CaCl_2$ solution with or without β-endorphin into the perfusion line. Upon injection, $^{45}Ca^{2+}$ efflux was stimulated, rose to peak in the first 3 min, then fell exponentially. This $CaCl_2$-stimulated $^{45}Ca^{2+}$ efflux was absent in mechanically ruptured synaptosomes. Also, controls injected with 0.6 M choline chloride, saline or β-endorphin alone did not show increased $^{45}Ca^{2+}$ efflux. The degree of stimulation was dependent on the concentration of $CaCl_2$ injected and reached a plateau with slow injection of 0.5 M $CaCl_2$ to a final concentration of 5 mM. The rising phase of the stimulation was probably due to activation of Ca^{2+}-Ca^{2+} exchange and the falling phase to a decrease in intracellular $^{45}Ca^{2+}$ concentration. When 500 nM β-endorphin was also included in the 5 mM $CaCl_2$, no difference in the rising phase was detected but the falling phase shifted downwards. This effect of β-endorphin can be explained by a higher Ca^{2+}-Ca^{2+} or Na^{+}-Ca^{2+} exchange rate during the falling phase. (Supported by Dept. of Energy Contract No. DE-AI01-79ET29078 and Southern California Edison Company.)

267.2 EFFECT OF OPIOID PEPTIDES AND MORPHINE ON THE RELEASE OF DOPAMINE AND SEROTONIN FOLLOWING ACTIVATION OF NICOTINIC CHOLINERGIC RECEPTOR IN RAT STRIATAL SLICES. Thomas C. Westfall and Heather Grant.* Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104 U.S.A.

Activation of nicotinic cholinergic receptors in the rat striatum is known to increase the release of ^{3}H dopamine (DA) newly taken up or synthesized from tyrosine (Neuropharm. 13:693, 1974; Brain Res. 106:117, 1976). In the present studies a similar increase in the release of ^{3}H serotonin (^{3}H 5-HT) newly taken up by superfused striatal slices has also been observed. The percent stimulation induced overflow of ^{3}H 5-HT to 100, 300 and 500 µM of the nicotinic agonist, DMPP, or to 0.1 or 1.0 mM nicotine was 8.9, 13.9, 16.6, 4.0 and 8.5%, respectively. Similar concentrations of DMPP or nicotine resulted in a concentration dependent increase in the release of ^{3}H dopamine. In light of the recent report that morphine and opioid peptides might modulate the nicotine induced release of catecholamines from the adrenal medulla, we tested for such a possible interaction in the CNS. The effect of morphine, leucine enkephalin (leu-enkephalin) and methionine enkephalin (met-enkephalin) or their more stable derivatives D-ala-met-enkephalin and D-ala-leu-enkephalin on the DMPP or nicotine-induced release of ^{3}H dopamine and ^{3}H 5-HT from superfused slices was examined. Both leu-enkephalin and met-enkephalin produced a concentration dependent decrease in the release of ^{3}H 5-HT while met-enkephalin but not leu-enkephalin reduced the release of ^{3}H dopamine. Similar results were obtained with the stable derivatives of leu- and met-enkephalin. The specificity of these effects was demonstrated by the fact that neither met-enkephalin nor leu-enkephalin altered the release of these neurotransmitters when release was induced by potassium depolarization. Morphine decreased the release of both neurotransmitters but only at high concentrations (> 5 x 10^{-5}M). Due to the well-known presence of enkephalin neurons in the striatum these results suggest that one possible function of enkephalin neurons in the striatum is to modulate the release of dopamine and/or 5-HT following activation of nicotinic cholinergic receptors present on dopaminergic or serotonergic nerve terminals. (Supported in part by USPHS-NIDA 02668 and NINCDS 16215.)

267.3 BLOCKADE OF MORPHINE-INDUCED CHANGES IN STRIATAL SPIROPERIDOL BINDING BY CYCLO(LEU-GLY). J.Z. Fields, J.M. Lee* & R.F. Ritzmann, Dept. Pharmacol., Chicago Med. Sch., No. Chicago, IL. 60064 & Dept. Physiol. and Alcohol and Drug Abuse Research and Training Pgm., U. of Ill., Chicago, IL. 60612.

Neurohypophyseal hormones, their fragments and analogs appear to affect drug tolerance, physical dependence and memory. Both MIF (Pro-Leu-Gly-NH_2), the C-terminal fragment of oxytocin, and its analog, cyclo(Leu-Gly)(cLG) alter several specific biochemical and behavioral effects of chronic morphine administration. There is evidence suggesting that modulation of dopaminergic transmission is involved both in the effects of morphine and in the mechanism of action of these peptides.

To further study these drug interactions, morphine pellets (containing 75mg free base) were implanted (s.c.) 2 hrs. after an injection (s.c.) of cLG into male Swiss-Webster mice or Wistar rats. Pellets were removed 72 hrs. later, and physical dependence was assessed by the degree of hypothermia at 8 hrs. At 24 hrs. following pellet removal, animals were tested for their responses to the dopamine (DA) agonist apomorphine (APO). Measurements were made on APO-induced hypothermia, locomotion, and stereotypy. At 48 hrs. following pellet removal, (^{3}H)-spiroperidol (3H-SP) binding to DA receptors (DA-R) in homogenates of dissected striata was measured using 1uM d-(+)-butaclamol to define specific binding.

Chronic morphine treatment resulted in a statistically significant and high degree of physical dependence as measured by withdrawal hypothermia in mice (-1.3°C) and rats (-1.0°C). cLG completely inhibited the morphine-induced effect on this measure (hypothermia) of physical dependence. Simultaneously, morphine treatment resulted in increased behavioral responses to APO (in both species). The ED_{50} of APO was significantly shifted to the left in measurements of APO-induced hypothermia, locomotion and stereotypy. Paralleling the increase in stereotypy in the rat was a 50% increase in affinity (Veh Kd=20pM) of striatal DA-R for 3H-Sp binding. The number of these high affinity binding sites (26 fmol/mg tissue) did not change. Pre-treatment of the mice or rats with cLG(2mg/kg in mice and 8mg/kg in rats) prevented both the morphine-induced increases in behavioral responses to APO and the increased binding affinity of the DA-R.

These data suffest that some of the behavioral effects of morphine may be mediated by dopaminergic pathways and that the inhibition of these drug effects by neurohypophyseal peptides may be mediated by opposing neurochemical changes in these same dopaminergic systems. Supported by NIH grants (MH-33991, BSRG RR-5366).

267.4 ENDORPHIN AND CORTICOTROPIN REGULATE TRANSSYNAPTICALLY THE ACTIVITY OF SEPTO-HIPPOCAMPAL CHOLINERGIC NEURONS. L. J. Botticelli & R. J. Wurtman. M.I.T., Cambridge, MA 02139

The content of acetylcholine (ACh) in nerve terminals of the dorsal hippocampus was examined after intraventricular, intraseptal or intrahippocampal administration of a variety of endorphin/corticotropin neuropeptides. β-LPH, α-endorphin, γ-endorphin, α-MSH, β-MSH, ACTH(1-39) and ACTH(4-10) (10 ug each) did not affect ACh levels 30 min after injection into the lateral ventricle. As reported previously (Botticelli & Wurtman, Life Sci., 24: 1799 1979; Nature 289: 75, 1981) β-endorphin, administered intraventricularly (10 ug) or intraseptally (1 ug) increased hippocampal ACh levels (31% and 47%, respectively), while ACTH(1-24), injected similarly, decreased ACh levels in the hippocampus (26% and 41%, respectively). ACh concentrations remained unaffected after direct administration of β-endorphin or ACTH(1-24) (1 ug each) into the hippocampal formation.

Acute unilateral transection of the fimbria/superior fornix resulted in a time-related decrease in hippocampal ACh levels. Concentrations did not change 1 hr after transection, however levels decreased to 72% and 26% of control values 1 day and 1 wk after deafferentation, respectively. ACh levels in the contralateral hippocampus remained unaffected at all times tested. Fimbrial transection (performed 90 min before peptide administration) blocked fully both endorphin- and corticotropin-induced changes in hippocampal ACh after the neuropeptides were injected into either the lateral ventricle or septal nuclei.

Naloxone, which after subcutaneous (1 mg/kg) or intraventricular (100 ug) injection alone failed to change levels of hippocampal ACh, antagonized effects on hippocampal ACh levels produced by intraventricular or intraseptal endorphin or corticotropin.

Results suggest a site of endorphin/corticotropin-receptor interaction at the level of cholinergic cell bodies in the septal region for regulating, in part, the activity of septo-hippocampal cholinergic neurons. These observations recommend further the participation of opioid and related neuropeptides in the general synaptic organization of the mammalian limbic forebrain.

267.5 EFFECT OF MORPHINE ON CHOLINE ACETYLTRASFERASE AND ACETYLCHOLINESTERASE ACTIVITIES IN SPECIFIC RAT BRAIN AREAS. J. O. Owasoyo,* K. Gipson* and C. A. Walker. Florida A&M University, School of Pharmacy, Tallahassee, FL 32307 and University of Ibadan, Veterinary Physiology and Pharmacy, Ibadan, Nigeria.

Specific drugs affecting the central nervous system have been shown to alter the acetylcholine (ACh) levels and acetylcholinesterase (AChE) activity in the rodent brain. Morphine has been found to increase the ACh level of rat whole brain following an IP dose of 16 mg/kg. In order to further elucidate this effect of morphine in the brain, we investigated simultaneously its effects on the activities of both the synthetic enzyme (ChAT) and hydrolytic enzyme (AChE) in specific rat brain areas.

Adult, male rats (200-250 g) adapted to a 12h light - 12h dark programmed illumination cycle were used in this study. Six control animals injected IP with physiological saline and six animals injected IP previously with 16 mg/kg morphine sulfate were sacrificed by decapitation at approximately 1200h. The brain from each animal was removed and quickly dissected on ice into cerebral cortex, cerebellum, hippocampus, hypothalamus, midbrain, pons, medulla oblongata and caudate nucleus and each brain part was homogenized (1% w/v) in ice-cold phosphate buffer containing 1% Triton X-100 (Sigma). AChE and ChAT activities in the homogenate were determined spectrophotmetrically as unmole substrate per gm of tissue and nanomoles COASH produced/min. respectively. The data was analyzed using the Student's T-Test. Results of this study show that, compared with control morphine sulfate significantly increased AChE activity in the cerebral cortex, hippocampus and caudate nucleus and also significantly increased ChAT activity in the cerebral cortex, hippocampus and cerebellum. No significant effect on either the AChE or ChAT activities of the other brain areas studied was observed. From our present findings, it appears that morphine sulfate selectively alters the synthesis and hydrolysis of ACh, the cholinergic neurotransmitter, in rat brain. This study was supported in part by the National Aeronautics and Space Administration (NASA).

267.6 EFFECTS OF PRENATAL EXPOSURE TO MORPHINE ON NEUROENDOCRINE FUNCTION IN DEVELOPING FEMALE RATS. J.P. Griffin*, D.M. Hux* and J. Rabii. Department of Physiology and the Bureau of Biological Research, Rutgers University, New Brunswick, N.J. 08903.

Since it has recently become apparent that endogenous opiate receptors mediate the effects of morphine and that the endogenous opiate ligands participate in the regulation of pituitary function, we have undertaken to examine the effects of prenatal exposure to morphine sulfate (MS) on the neuroendocrine function of the offspring. MS was injected (sc) between days 5 and 12 of pregnancy. Control animals received injections of normal saline. After birth, groups of rats 5, 15 and 25 days of age were sacrificed by terminal bleeding via the abdominal aorta (under light ether anesthesia) and plasma was kept frozen for luteinizing hormone (LH) and prolactin (PRL) radioimmunoassays. Plasma LH levels of the MS treated pups were not different from those of saline treated pups at 5 and 25 days of age. At day 15, however, the MS treated group had circulating LH levels that were 45% of the saline treated animals. In the case of PRL, the 15-day-old MS group had levels that were 57% of the controls, whereas the 25-day-old MS treated animals had plasma PRL levels similar to the 25-day-old controls. In the 5-day-old MS treated rats plasma PRL was significantly higher than that of the 5-day-old saline treated. We subsequently tested the feedback sensitivity of the hypothalamic-pituitary axis to estrogen in the pups born to MS injected dams. Groups of rats were ovariectomized at 15 days of age, under light ether anesthesia. One day after ovariectomy animals were either sacrificed or injected with estradiol benzoate in sesame oil (1 µg per 100 grams of body weight). Control animals were injected with sesame oil one day after ovariectomy. All injected rats were sacrificed 4 hours after injection. Oil injected rats did not show an inhibition of LH secretion in either ovariectomized pups born to MS treated dams or those born to saline treated controls. Estradiol benzoate, on the other hand, caused a marked reduction in plasma LH levels in ovariectomized control animals but not in ovariectomized MS treated rats. These results indicate a reduction in basal hormone release as well as a drop in steroid sensitivity of the animals born to MS treated dams. (Supported by NIH Grant DA0227-01.)

268.1 ELECTRICAL SIGNS OF A SHORT-LATENCY PATH FROM RETINA TO RAT HIPPOCAMPUS. E. F. Vastola. Dept. of Neurology, Washington Univ Sch. of Med., St. Louis, MO 63110.

Observations were performed in unanesthetized rats with rostral-pons transection, bi-polar 100μ electrodes with tip separation 0.5mm, conventional amplification and averaging ≤ 256 responses to photic or optic nerve stimulation. Electrolytic lesions 0.3-0.75mm were made to interrupt the pathway at various points and mark electrode position.

The response elicited in dorsal hippocampus has approximately the same latency, amplitude and time course as in striate cortex. After optic nerve stimulation the hippocampal response exhibits an early polyphasic deflection with the last peak at 10 msec followed by a larger bi-modal major deflection with peaks at 15 and 25 msec and later, slower, bi-phasic deflections at intervals of 125 msec. The polyphasic deflection except for a portion due to optic tract activity in the subjacent thalamus is maximal in the inferior part of the hippocampus but does not reverse polarity; the other deflections reverse above and below an isoelectric point in the hilum of the dentate gyrus, a distribution attributable to depolarization in the molecular layer, perhaps also cell bodies, of the dorsal and ventral leaves of that structure, the same distribution found for spontaneous activity in the 50/s range. The bi-modal major deflection is more sensitive to changes in optic nerve stimulus strength than the responses in striate cortex and more resistant to reduction in amplitude during repetitive stimulation, following frequencies up to 50/s. The pathway between retina and hippocampus can be interrupted by small lesions in the superficial tectum or posterior cingulum. There is probably a synaptic relay in the midbrain, possibly not in the cingulum. From the cingulum the pathway has fast and slow components in the lower and upper portions respectively associated with the first and second parts respectively of the bi-modal deflection. The pathway is not interrupted by lesions in fornix, septal nuclei, anterior cingulum, anterior medial thalamus or medial midbrain ventral to the superficial tectum.

These observations suggest that the hippocampus participates in visual processing at an early stage, i.e., one or two synapses beyond the eye. Visual deficits attributed to lesions in midbrain and striate cortex may in fact have been partially determined by associated involvement of the hippocampus. Visual functions of the hippocampus were probably developed at an early date in the evolution of mammalian brain. If this pathway continues to function in primates, as suggested by earlier observations (Brazier, M.A.B. Ann. NY Acad. Sci. 112:33-59, 1964), it seems a likely candidate for an important role in the phenomena of photogenic epilesy and, perhaps, the larger class of all petit mal seizure disorders.

268.2 AN HRP STUDY OF THE PROJECTION FROM VISUAL CORTICAL AREAS TO THE SUPERIOR COLLICULUS IN THE RAT. Jaime Olavarria* and Richard C. Van Sluyters (SPON: E. Marg). Group in Neurobiology and School of Optometry, University of California, Berkeley, CA 94720.

The posterior neocortex of the rat has been shown to contain at least seven visual areas, based on the results of physiological experiments revealing multiple retinotopic maps of the visual hemifield surrounding the striate cortex (Brain Res. 53:192, 197, 1973; 151:386, 1978), and anatomical studies demonstrating reciprocal connections between the striate cortex and each of these areas using degeneration, autoradiographic and horseradish peroxidase (HRP) techniques (Brain Res. 53:202, 1973; Olavarria & Montero, in press). In the present study we have traced the projection from the visual cortex to the superior colliculus (SC) to demonstrate the relationship between this projection and the physiologically defined visual cortical areas.

The SC of gray rats was stereotaxically injected with HRP (Boehringer Grade I, 0.02-0.04μl). Coronal sections (60μm) of the brains were processed for HRP histochemistry and the brains were later serially reconstructed to study the distribution of retrogradely labeled cortical cells. Labeled pyramidal cells were observed in layer V of striate cortex and in several well-defined cortical regions beyond striate cortex. The arrangement of labeled fields for striate and peristriate cortex corresponded closely to the previously reported subdivision of visual cortex into multiple visual areas. These peristriate fields have been named according to their position relative to striate cortex. Thus, area anteromedial (AM) lies medial to the anterior part of striate cortex; areas anterolateral (AL), lateromedial (LM), posterolateral (PL) and posterior (P) are arranged anteroposteriorly in the lateral peristriate cortex with area P in the occipital pole; and area laterolateral (LL) lies lateral to area LM. With topographically different injections into SC, the position of the labeled fields in the striate and peristriate areas varied in agreement with the previously reported retinotopic organization of these areas. The study of cases with superficial SC injections and of cases with additional involvement of deep SC suggests that posterior cortical afferents to superficial layers of SC come mainly from striate and peristriate visual areas, and that other cortical areas, located lateral and anterior to visual cortex and possibly related to other sensorial modalities, have a significant input to deep SC.

In conclusion, these experiments support the hypothesis that the rat's visual cortex is divided into multiple functional areas, and they suggest that the SC receives overlapping input from each of these visual areas.

Supported by NIH Grant EY 02193.

268.3 THE PROJECTION OF THE LATERAL GENICULATE BODY TO EXTRASTRIATE CORTEX IN THE OWL MONKEY AND SQUIRREL MONKEY. D. Fitzpatrick*, K. Itoh*, M. Conley* and I.T. Diamond. Dept. of Psychology, Duke University, Durham, NC 27706.

In the present study, we present evidence that certain cells of the lateral geniculate body of the monkey project outside of striate cortex. Injections of HRP and WGA-conjugated HRP were made into extrastriate cortical regions, from area 18 to the caudal portion of the temporal lobe including the middle temporal area (owl monkey) or the posterior bank of the superior temporal sulcus (squirrel monkey). In both species, labeled cells were found primarily ventral to the parvocellular layers including the interlaminar zones, the magnocellular layers and regions ventral to layer 1 (possibly including the "S" layer). The greatest number of labeled cells were found in the interlaminar zones, with fewer in the magnocellular layers and regions ventral to layer 1. Most of the labeled neurons were small in size (in owl monkey, mean = 12.6 μm), but there were differences in the cell sizes of labeled neurons depending on their location in the lateral geniculate body. For example, following injections into the temporal lobe of owl monkey, the labeled cells within the magno-cellular layers were small; on the other hand, labeled cells in the interlaminar zones were not only small but included some cells which were larger than those labeled in the magnocellular layers.

Since the zones in the lateral geniculate body which contain labeled cells following injections into extrastriate cortex are similar to the zones which project to the most superficial layers of striate cortex in Galago, it is tempting to speculate that the same cells are projecting both to the superficial layers of striate cortex and to extrastriate regions in the monkey. This pattern may be similar to the pattern of projections of the lateral geniculate body of the cat to striate and extrastriate regions: for example, small cells in the C laminae project to the entire visual field and also project to the most superficial layers of striate cortex. The present findings provide further support for the idea that similar cell types may exist in the lateral geniculate body of carnivore and primate lines, an underlying similarity which is obscured to some extent by differences in laminar organization.

268.4 MULTIPLE MIDBRAIN INPUT ZONES WITHIN THE LATERAL PULVINAR OF MACAQUE MONKEYS WITH SPECIAL REFERENCE TO CERTAIN OF THEIR CORTICAL TARGETS. G. P. Standage and L. A. Benevento. Department of Anatomy, University of Illinois, College of Medicine, Chicago, IL. 60680.

Traditionally studies of the ascending inputs to the simian pulvinar complex have concentrated on the midbrain inputs to the inferior pulvinar. We have shown, however, that there are multiple midbrain inputs to all subdivisions of the pulvinar complex, i.e., lateral (PL), medial (PM), oral (PO) as well as inferior (PI) (e.g., Fig. 4 in JCN 160 (1975) 348; Fig. 5 in Brain Res. 127 (1977) 206). Autoradiographic (ARG) and horseradish peroxidase (HRP) tracing methods and single unit recording indicate that there are several input zones in PL, alone, which arise from the superior colliculus (SC) and, at least one from the pretectum (PT). The input zones are located chiefly at the borders of the subdivisions of the lateral pulvinar which were defined in earlier studies (e.g., Soc. Neurosci. Abst. 3 (1977) 573). Some of these zones can be described as follows: Zone 1 is located along the lateral edge of subdivisions PLβ and PLγ. Zone 2 is located in the lateral margin of PLα. Zone 3 overlaps the border between the medial pulvinar and lateral pulvinar. The PT projection zone is dorsal to and overlaps colliculus zones 1 and 3. In contrast to other reports we find that a significant portion of these inputs arise from retinorecipient regions of SC and PT. When HRP injections are made laterally in PL the superficial cell layers (upper stratum opticum and lower stratum griseum superficiale) of SC contain labelled cells. When HRP deposits are made progressively more medially in PL and PM, the deep layers of SC and retinorecipient subdivisions of PT (such as the sublentiform nucleus) contain well labelled cells. These results indicate that, in contrast to earlier notions, a significant amount of visual association cortex can be influenced by retinorecipient regions of the midbrain via pulvinar regions other than the inferior pulvinar. In contrast, focus 3 which arises from deep layers of SC is of particular interest as this region of the pulvinar complex projects ubiquitously to the portion of area 19 which forms the crowns of the dorsal and ventral preoccipital gyri, and includes visual area 4 of Zeki. Visual 4 is known for color processing but the present results would indicate that area 19, including visual 4, is involved in visuomotor functions as well. This latter position is further supported by our HRP data which show that visual 4 has extensive connections with the lower bank of the intraparietal sulcus (cf., Seltzer and Pandya, 1980). (Supported by NIH Grant EY 2940)

268.5 RECEPTIVE-FIELD PROPERTIES IN THE TECTORECIPIENT ZONE OF THE CAT'S LATERAL POSTERIOR NUCLEUS. Leo M. Chalupa, Michael J. Hughes, Robert W. Williams (SPON: R. P. Scobey). Department of Psychology. University of California, Davis CA 95616.

A major projection from the superior colliculus to the medial part of the lateral posterior nucleus (LPm) has been described in numerous anatomical studies. We have examined the visual receptive-field characteristics of single cells in the LPm of cats maintained on a 70% nitrous oxide and 30% oxygen mixture supplemented approximately every 8 hours with 20 mg/kg chloralose. In this preparation virtually all cells in LPm were responsive to visual stimulation. More than half of the neurons were binocular, about one-third responded only to stimulation of the contralateral eye, and the remainder responded to stimulation of the ipsilateral eye. A substantial proportion of the binocular cells demonstrated inter-ocular facilitation in that they responded poorly, if at all, when either eye was stimulated alone, while brisk responses were obtained with binocular activation. The size of the fields varied from 10 degrees^2 to 1000 degrees^2. Typically the cells with the largest fields were encountered in the most dorsal portion of LPm and many of these crossed into the ipsilateral hemifield by as much as 30 degrees. The centers of receptive-fields shifted from upper to lower portions of the visual field with increasing depth of penetration. Cells with the largest fields prefered large flashing spots giving transient on, on-off, or most commonly, off discharges. Neurons with smaller fields showed a preference for moving stimuli with a wide tolerance for variation in velocity. Somewhat less than half of the cells were directionally selective and these showed a preference for movement in the horizontal plane. About one fourth of the cells in LPm were orientation specific; a small number of these were also directional. The presence of orientation specific units in LPm suggests that there is intermingling of the cortical and tectal projections. Alternatively, this property may be organized intrinsically within LPm. These suggestions could be assessed by examining the effects of cryogenic blockade of the cortex or the superior colliculus on the response properties of LPm cells. (Supported by EY03491 from NEI)

268.6 A VISUAL AREA IN THE ANTERIOR ECTOSYLVIAN SULCUS OF THE CAT. C.R. Olson* and A.M. Graybiel, Dept. Psych., MIT, Cambridge, MA 02139.

We have examined the function and connections of a previously unrecognized zone of exclusive visual responsiveness in the cat's anterior ectosylvian sulcus. The ectosylvian visual area (EVA), as defined in microelectrode recording experiments, occupies approximately 20 mm^2 of sulcal cortex. Surrounded by auditory, somatosensory and nonresponsive zones, EVA is altogether isolated from the more caudal cortical district comprising all other known divisions of striate and extrastriate visual cortex.

Iontophoretic deposits of horseradish peroxidase and labeled amino acids were placed in the center of EVA under electrophysiological guidance. The resulting patterns of retrograde and anterograde labeling led to the following conclusions. (1) EVA is not directly connected to areas 17, 18 and 19. (2) EVA is related by a weak reciprocal pathway to the medial part of the Clare-Bishop complex (PMLS). (3) Strong reciprocal pathways link EVA to certain other extrastriate areas, viz. the lateral division of the Clare-Bishop complex (PLLS) and parts of the posterior suprasylvian sulcus and area 20. (4) EVA is connected reciprocally to a thalamic zone identifiable in cholinesterase-stained material as comprising both the AchE-dark medial tectorecipient part of the nucleus lateralis posterior (LPm) and the adjoining AchE-pale region which we term the nucleus lateralis medialis (LM).

Most neurons in EVA respond vigorously to visual stimulation of either eye. The most common preferred stimulus is a small spot moving rapidly in a particular direction. For a majority of cells the preferred direction contains a horizontal component pointing away from the visual-field midline. It is common for preferred direction to rotate gradually as responses are recorded at successive sites along tracks tangential to the cortical surface. The receptive fields of neurons in EVA range in area from fifty to a few hundred deg^2. They are distributed throughout the contralateral visual hemifield and may extend up to 20 deg into the ipsilateral hemifield. Although we know that receptive-field position tends to shift systematically with position in the cortex, we have not yet fully analyzed the complex pattern of retinotopy present in EVA.

The functions of the ectosylvian visual area must be far removed from those of areas 17, 18 and 19. EVA appears to be specialized for processing visual motion rather than form. Moreover, areas 17, 18 and 19 directly innervate neither EVA nor those extrastriate areas that project heavily onto it nor the thalamic region from which it receives input.

268.7 SPATIAL PROPERTIES OF NEURONS IN THE CAT'S LATERAL SUPRASYLVIAN VISUAL CORTEX. Martin S. Gizzi, Ephraim Katz and J. Anthony Movshon. Department of Psychology, NYU, New York, NY 10003.

We have studied the selectivity of neurons in the lateral suprasylvian visual cortex (LS) for the orientation, direction of movement and spatial frequency of sine-wave gratings and checkerboards. Our recordings were mostly confined to the representation of the central visual fields in area PMLS.

Most LS cells respond as well to gratings as they do to lines or spots, although the suppressive surrounds present in some cells may require that the grating be confined to the excitatory zone of the receptive field. A comparison of direction selectivity for gratings and checkerboards reveal that LS neurons have a genuine sensitivity to the orientation of gratings, as well as their previously-reported direction selectivity. A substantial minority of LS cells have indefinite receptive fields when mapped with lines and spots; some of these give well-defined responses to gratings.

The range of orientation selectivity seen in LS is similar to that in V1 and V2, though broadly tuned cells are more common in LS. About half of LS neurons are direction selective, in that they give no excitatory response to optimally oriented gratings moving in one of the two possible directions. Another third of LS cells are directionally biased, responding more than twice as well to one direction as to the other. The remaining cells are bidirectional.

The optimum spatial frequencies of LS neurons cover a wide range, from below 0.1 to over 1 c/deg. Their bandwidths are somewhat broader than those seen in V1 and V2, ranging from about 1 octave to over 3 octaves. Thus LS cells respond both to the high spatial frequency range processed by V1 and the lower range processed by V2. Cells preferring high spatial frequencies (in the V1 range) tend to be more selective for orientation and spatial frequency than other cells.

Thus neurons in LS have spatial tuning properties generally similar to those seen in V1 and V2; there is little evidence that neural processing in LS cortex is designed to enhance the spatial selectivity elaborated earlier in the pathway. Rather, the cells' large receptive fields and prominent sensitivity to motion suggest a more general integrative function for LS.

268.8 WILL THE REAL MEYNERT CELL PLEASE STAND UP? M. Tigges, J. Tigges, and C. D. Sporborg*. Yerkes Regional Primate Res. Ctr. and Dept. of Anatomy, Emory Univ., Atlanta, GA 30322.

In 1867, Theodor Meynert described in layers 4 and 6 of his 8-layered human visual cortex "pyramids of extraordinary caliber". Because of their isolation by gaps up to 2 mm wide, he named them "Solitärzellen". With the advent of the Golgi method, Cajal, in 1899, described these solitary cells in his layer 7 with prominent features such as their extremely long ("from 0.3 mm to equal length of the apical dendrite"), thick, thorny, branching basal dendrites with exclusive horizontal orientation parallel and close to the white matter. The stout apical dendrite, after giving off side branches in layer 6, ascended unbranched to layer 1, where it ended in a tuft of horizontal branches. Recent descriptions of Meynert cells from Golgi material of area 17 of Macaca (Chan-Palay et al., J. Neurocytol., 3:631, 1974; Lund, J., J. comp. Neur., 147:455, 1973; Lund and Boothe, J. comp. Neur., 159:305, 1975) conflict with respect to soma size and distribution as well as to dendritic arborization pattern. In our Golgi material of area 17 of Macaca and Saimiri, we found at the junction between layers 5 and 6 a pyramid with a relatively large, triangular soma, usually wider than high, which conforms to Cajal's description in distribution and dendritic arborization pattern; the thick, spineous basal dendrites travelled up to 2 mm parallel to or in the white matter. At least one other type of pyramid with a large soma, but higher than wide and with much shorter basal dendrites of predominant vertical direction towards the white matter, was found regularly in layers 5 and 6 in our material. The Meynert cell is reported to project to area MT (Spatz, Brain Res., 92:450, 1975). After we injected HRP into area MT of Saimiri, numerous neurons, covering a wide range of soma sizes, including the largest ones, were labelled in layers 5 and 6 of area 17. Thus, the Meynert cell is only one type of cell projecting from area 17 to area MT. In our experiments, large HRP-filled cells were also found, among smaller labelled neurons, in the line of Gennari, probably in Meynert's layer 4. These large cells displayed no apical dendrite and, under the EM, revealed a larger number of axosomatic contacts than is the rule for pyramids, thus indicating their stellate nature. Polyak (The Vertebrate Visual System, Univ. of Chicago Press, Chicago, 1957) described a neuron of similar shape and location also as a solitary cell of Meynert. We propose to restrict this term to those relatively large and isolated cells at the junction between layers 5 and 6 of area 17 which correspond strictly to Cajal's classic description.

(Supported by NIH Grant RR-00165 to the Yerkes Regional Primate Res. Ctr. of Emory University, and NIH Grant EY-00638.)

268.9 RESPONSE PROPERTIES OF SINGLE NEURONS IN THE MIDDLE TEMPORAL VISUAL AREA (MT) OF ALERT MACAQUE MONKEYS. W. T. Newsome and R. H. Wurtz. Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, MD 20205.

The response properties of neurons in the middle temporal visual area (MT) were studied in rhesus monkeys while they fixated a small spot of light. Of 151 cells examined, 67% were selective for the direction of motion of visual stimuli within the receptive field, 17% were biased for direction of motion, and 15% were not directional. For 72 cells for which quantitative data were obtained, indices of directionality were similar to those observed in anesthetized monkeys. Responses of MT cells were not dependent on the form of the stimulus; robust responses were generally elicited using small spots of light as well as larger slits and bars. Neuronal responses were frequently biased for a range of velocities. In 13 cells for which quantitative data were obtained, the preferred velocities ranged between 10°/sec and 150°/sec with the majority lying between 10°/sec and 40°/sec. In all these aspects, passive visual properties of MT neurons in the alert monkey are consistent with the results of previous studies in anesthetized animals.

Single cell responses were examined as monkeys made saccadic eye movements to stationary (n = 26) and moving (n = 12) spots of light within a neuron's receptive field. We have not observed any visual enhancement or discharge related to the eye movement itself when the visual stimulus was the target for a saccadic eye movement.

Neuronal responses were compared under two conditions of retinal stimulation: 1) when the stimulus was moved across the receptive field as the monkey fixated; and 2) when the monkey tracked a moving target and thereby moved the receptive field across a stationary stimulus. The large majority of MT cells responded similarly to equivalent retinal stimulation whether that stimulation was caused by moving stimuli during fixation or by stationary stimuli during smooth pursuit eye movements. However, preliminary evidence suggests that many direction sensitive neurons medial and anterior to MT respond during smooth pursuit eye movements in ways which cannot be fully explained by their passive visual properties observed during fixation.

268.10 ORGANIZATION OF DIRECTIONALLY SELECTIVE CELLS IN AREA MT OF MACAQUES. T.D. Albright*, R. Desimone* and C.G. Gross. Dept. Psychology, Princeton Univ., Princeton, NJ 08544 and Lab. Neuropsychology, NIMH, Bethesda, MD 20205

Area MT, also known as the "motion area of the STS", is located in the posterior portion of the superior temporal sulcus of macaques. MT is visuotopically organized and receives direct projections from striate cortex. Relative to other visual areas, MT has a high proportion of cells that are selective for the direction of stimulus movement but are relatively nonselective for stimulus form or color (Zeki, J. Physiol., 236:549, 1974). In this study we report on the spatial organization of directionally selective cells in MT. Single neurons were isolated every 50u along tangential, oblique or nearly normal penetrations. Projected spots or slits were moved on a tangent screen and the optimal direction and axis of stimulus movement determined for each cell. (Axis of movement is the orientation of the linear path defined by a moving stimulus and varies from 0° to 180°.)

Among 458 MT units recorded on 14 penetrations in three animals, 81% responded optimally to one direction of movement, 9% to two directions 180° apart (bidirectional) and 10% were not directionally selective. For all cells the optimal direction of stimulus movement was independent of whether the stimulus was a spot or a slit, although the maximal response was dependent upon the form of the stimulus for 40% of the cells. In long tangential or oblique penetrations through MT the prefered axis of movement of cells changed smoothly and systematically. Often the axis of movement would progress in a clockwise or counterclockwise direction for up to a few hundred microns and then reverse. By contrast, there were few long systematic progressions of optimal direction of movement, both because there were frequent 180° reversals in the optimal direction of movement and because of the presence of bidirectional cells.

The rate of change of optimal axis of movement was, on the average, greater along penetrations approximately parallel to the cortical surface than along penetrations more normal to the surface. This result suggests a vertical ("columnar") organization of axis of movement. An estimate of the column size is provided by the maximum rate of change of axis of movement, viz, approximately 180°/.5 mm of cortex.

The representation of axis of movement in MT is similar to that of orientation in striate cortex. For both, a full 180° cycle is represented in about 0.5mm of cortex. Furthermore, just as the ocular dominance system is superimposed on that for orientation in striate cortex, it is conceiveable that in MT there is some type of direction of movement system that is superimposed on that for axis of stimulus movement.

268.11 ABSENCE OF NARROWING OF THE SPECTRAL BANDWIDTH OF COLOR-SELECTIVE NEURONS FROM THE RETINA TO THE AREA V4. F.M. de Monasterio* and S.J. Schein (SPON: H. Wagner), Clinical Branch, National Eye Institute, NIH, Bethesda Md. 20205.

Because of the antagonistic signals that color-opponent cells receive from different cone mechanisms, these cells have spectral sensitivities narrower than the cone absorbance spectra. In addition, the peak sensitivities of these cells are spectrally displaced from those of the underlying cone mechanisms mediating their responses. Little is known regarding the degree of variation of spectral bandwidth at the different levels of the geniculo-striate pathway of the monkey visual system. If the spectral information were to be influenced at each successive level by color-opponent interactions, one could expect that the average spectral bandwidth of cortical cells would be narrower and their peak sensitivity spectrally more displaced than that of ganglion cells. Recent cortical work (Zeki, Nature 284:412-418, 1980) has suggested that this may be the case.

We describe the spectral response bandwidths of several types of color-opponent ganglion cells of the macaque retina, and we compare these results with published data from neurons of subsequent levels of the macaque visual pathway, including the extrastriate area termed V4. Our findings indicate that most color-opponent cells have specific "signatures" in plots of response bandwidth vs. wavelength of peak sensitivity. Such a specificity allows for an acceptable estimate of the type of cone input(s) mediating the wavelength-dependent responses of the neurons. Furthermore, the results show that there are no significant differences between the averaged spectral response bandwidth of color-opponent cells located as peripherally as retinal ganglion cells, and as centrally as V4 cells.

In association with recent results indicating that the relative concentration of color-selective cells in area V4 is not significantly different from that of antecedent cortical areas (Schein, Marrocco and de Monasterio, Neurosci. Abstr., 1980), our results indicate that current claims of a color specialization of this extrastriate area may have to be revised.

268.12 LIMITS OF VISUALLY RELATED CORTEX IN THE MONKEY'S PARIETAL AND TEMPORAL LOBES AS DELINEATED BY THE 2-DG TECHNIQUE. K. Macko, C. Kennedy, L. Sokoloff, and M. Mishkin. NIMH, Bethesda, MD 20205.

The parietal and temporal lobes of the monkey contain areas that are critical for higher cortical visual functions, but the full extent of these areas is still unknown. To delineate their borders we analyzed the brains of four rhesus monkeys, each with a combined unilateral optic tract section and forebrain commissurotomy, in which the 2-DG technique had been applied while they actively viewed visual patterns. The borders of the visually related areas were established by quantitative comparison of the metabolically inactive tissue in the "blind" hemisphere with the active tissue of the "seeing" hemisphere.

Nonvisual tissue first appears on the anterior lip of the intraparietal sulcus (ip) just rostral to the junction of the lunate sulcus and ip. As one proceeds rostrally, the visual-nonvisual (VN) border moves 1) ventromedially to the medial parieto-occipital sulcus (pom) and 2) ventrolaterally to about halfway down the anterior bank of ip. Near the posterior tip of the lateral fissure (la) the visually related tissue below these borders becomes separated into two parts, parietal and temporal, by nonvisual tissue appearing in the superior temporal gyrus.

Within the parietal lobe, the ventral VN border first appears in the fundus of la, and then moves out of la along the cortical surface to the posterior lip of ip. The dorsal VN border, which remains on the anterior bank of ip, gradually descends to the fundus. The two borders merge within ip approximately 5mm behind its anterior tip to form the rostral limit of visually related parietal cortex.

Within the temporal lobe, the dorsal VN border first appears at the fundus of la and moves quickly to the anterior lip and then halfway down the anterior bank of the superior temporal sulcus (ts). It remains at this depth through the posterior half of ts and then descends gradually to the fundus of ts. The ventral VN border, near pom posteriorly, moves gradually to the calcarine and then to the hippocampal fissure (h). It continues along the posterior half of h, moves laterally to the medial lip of the occipitotemporal sulcus, and then medially to the fundus of the rhinal sulcus. The dorsal and ventral borders merge on the ventral surface just in front of the anterior tip of ts to form the rostral limit of visually related temporal cortex.

Within visually related cortex metabolically different subareas could be delineated, as in the posterior bank of ip and the anterior bank of ts. Both VN and subareal borders were frequently sharp and consistent among animals. Preliminary analyses suggest that these borders separate architecturally different areas, lending new functional validity to architectonics.

269.1 CONNECTIONS OF THE "UNRESPONSIVE ZONE" IN THE GREY SQUIRREL (Sciurus carolinensis). H. J. Gould, III. Dept. of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70119.

The sources of afferent connections to the special agranular, "unresponsive zone" (UZ) within the S I koniocortex of the grey squirrel were studied using the technique of retrograde transport of horseradish peroxidase (HRP). The borders of the UZ were determined electrophysiologically in four squirrels using the summary maps of Sur et al. ('78, J. Comp. Neurol., 179:425) as a guide. At the end of the recording session, HRP was injected through glass micropipets into the center of the UZ either by pressure or by application of an iontophoretic current. After a two day survival, the animals were perfused and the tissue was sectioned in the coronal plane.

As expected peroxidase labelled neurons were found within the contralateral anterior parietal cortex in a homotopically located agranular area. The cells were primarily medium-sized pyramidal cells and occupied layers III and V. Only a very few labelled cells were observed in the contralateral koniocortex. Ipsilaterally, peroxidase labelled neurons were found in the frontal, lateral parietal and anterior parietal areas of cortex and in a posterior portion of the ventral nuclear group of the thalamus. Cortical neurons in the frontal and lateral parietal areas were pyramidal-shaped and usually occupied layers III and V. In contrast, the interpretation of laminar distribution of labelled neurons in the anterior parietal cortex is equivocal because it was not possible to distinguish transported peroxidase from perikaryal filling within the limits of the spread of the injection. The cells, however, were found in all layers and did not extend beyond the borders of granular parietal cortex. In the thalamus, large multipolar neurons were densely filled in an area that lies just dorsal to the ventral posterior nucleus and corresponds in position to the central intralaminar nucleus (CIN) as defined in the oppossum and the hedgehog (Killackey and Ebner, '72, Brain, Behav. Evol., 6:141). The spread of the injection into adjacent granular cortex usually revealed in an additional small population of lightly labelled neurons in the medial to central portions of the ventral posterior nucleus. These results support the observations previously reported for the rat (Lin et al., '80, Soc. Neurosci. Abst. 6:62).

Although preliminary, the results suggest that a distinct group of thalamic neurons may directly affect interhemispheric connections between special agranular areas in the rodent cortex. These areas have been proposed as interhemispheric relays for adjacent acallosal regions of somesthetic cortex that contain representations of non-midline or highly lateralized portions of the body surface (Gould and Kaas, '81, J. Comp. Neurol., 196:489)

269.2 A SINGLE AND DOUBLE RETROGRADE STUDY ON THALAMIC PROJECTIONS TO SI AND SII IN CATS. R. Spreafico*, N.L. Hayes, and A. Rustioni (SPON: H. Krebs) Depts. of Anatomy and Physiology and the Neurobiology Program, The University of North Carolina at Chapel Hill, Chapel Hill, NC 27514, USA, and the Neurological Institute "C. Besta", Milan, Italy.

Single and double retrograde experiments were performed in cats to label thalamic neurons projecting to somatosensory cortical areas. In a first series of animals, HRP was injected in either SI or SII, and the distribution of labelled neurons was reconstructed in serial coronal and horizontal sections. After injections in SI limb representations, densely and lightly labelled neurons are consistently found throughout VPL and show some preferential pattern of organization. Outside VPL, moderate retrograde labelling is present in POm, even in cases in which the injection did not encroach upon area 5. After HRP injection in the anterior ectosylvian gyrus, it appears that as the injection is shifted from posterior to anterior, labelling of neurons in the thalamus shifts from the lateral portion of the posterior group (POl) and the caudal region of the medial portion of this group (POm) to involve progressively more rostral portions of this nucleus and also VP. SII-projecting neurons are confined primarily within the lateral portion (VPLl) and in posterior cap of VP, while in VPLm they are confined mainly in the periphery of this nuclear subdivision and are sparse within its core region.

In cats with injections of HRP in SI and ^{3}H-apo-HRP in SII of the same hemisphere, neurons projecting to SI, SII or to both areas are not distributed homogenously within the VP. Rather, their differential distribution define three divisions of the thalamic somatosensory relay. The region in which neurons projecting to SI are distributed among neurons projecting to SII and neurons projecting to both areas constitutes a shell of neurons within VPL. This inner shell is situated between a central core region of VPLm, which contains predominantly neurons projecting to SI, and a previously defined outer shell -- outside VPL -- which is characterized, as a whole, by widely divergent cortical connections. These three regions, distinguished from one another by their pattern of cortical projections may correspond to similar differential sites of afferent projections, such that each zone -- core, inner and outer shells -- would be dominated by a different ascending pathway.

Supported by USPHS grants NS12440 and MH14277 and by a Fogarty International Fellowship (TW02718).

269.3 THALAMOCORTICAL SYNAPSES WITH CORTICOTHALAMIC NEURONS IN MOUSE SmI (POSTEROMEDIAL BARREL SUBFIELD) CORTEX. Edward L. White and Steven M. Hersch. Dept. of Anatomy, Boston U. Sch. Medicine, Boston, MA. 02118.

The application of combined anterograde-retrograde tracing techniques to the study of thalamocortical relations has shown that discrete regions of the cortex are reciprocally connected with corresponding regions of the thalamus (see White, E.L. Br. Res. Rev. 1: 275, 1979). Other evidence suggests thalamocortical relay cells are postsynaptic to corticothalamic afferents (e.g.Jones E.G. and Powell, T.P.S. Proc. Roy. Soc. B 172: 173,74) however, until now, the question of whether corticothalamic projection neurons are postsynaptic to the axon terminals of thalamocortical relay cells has been unresolved. An examination of this question has disclosed synapses between the spines of corticothalamic cells labeled by the retrograde transport of horseradish peroxidase (HRP) and the axon terminals of thalamocortical afferents identified by lesion induced degeneration. To do this, injections containing 40 % HRP were placed in the ventrobasal thalamus of young adult, male CD/1 mice. One day later, electrolytic lesions were made at the injection site, and about four days after this the animals were perfused with aldehydes. SmI cortex ipsilateral to the injection and lesion sites was tissue chopped and the sections then reacted for HRP using a modification (White et al., Neurosci. Let. 19: 149, 1980) of the diaminobenzidene-$CoCl_2$ method of Adams (1977). This procedure yields large numbers of corticothalamic projection neurons so well labeled with HRP reaction product that they resemble Golgi impregnated cells. The somata of these neurons average about 10 μm in diameter and occur in the upper half of layer VI and in the lower half of layer V; each has an apical dendrite which usually terminates within or just below layer IV, but which in some instances, extends nearly to the pial surface. Examination of long series of coronal thin sections cut through the layer III-V portions of the apical dendrites of several corticothalamic cells shows each to possess several spines which are postsynaptic to degenerating thalamocortical axon terminals. These findings provide unequivocal evidence of a direct thalamocortical projection to corticothalamic neurons and suggest a mechanism whereby the thalamus can monitor the effects of its input to the cortex with the shortest possible latency. Further, this pathway might serve as part of an excitatory feedback loop whose function is to exaggerate the differences in excitation levels between different thalamocortical circuits by lowering the threshold of excitation for select thalamocortical relay cells.

Supported by N.I.H. grant NS.14838.

269.4 SYNAPTIC RELATIONS OF GABAERGIC INTRINSIC NEURONS IN MONKEY SOMATIC SENSORY CORTEX. S.H.C. Hendry, C.R. Houser, E.G. Jones, and J.E. Vaughn Dept. Anatomy & Neurobiology, Washington University, School of Medicine, St. Louis, Mo. 63110 and Div. of Neurosciences, City of Hope Res. Inst., Duarte, California 91010.

Gamma-aminobutyric (GABA) is widely accepted as an inhibitory transmitter in the mammalian neocortex. GABAergic neurons of the monkey first somatic sensory cortex (SI) were identified immuno-cytochemically using antiserum to glutamic acid decarboxylase (GAD). Five cynomolgus monkeys were injected intracerebrally with colchicine 24-48 hours before perfusion with paraformaldehyde or mixed aldehydes; tissue from the pre- and postcentral gyri were processed for light or electron microscopy. GAD was localized by the indirect, PAP, method.

Labeled puncta which mostly represent GAD-positive axon terminals are concentrated in dense bands in layer IV and in the superficial part of layer I of all fields of SI. Labelled somata fall into two size ranges: small (7-12 μm) and large (15-25 μm). The smaller somata are present throughout the depth of the cortex but are concentrated in layer IV. Larger labeled somata and their dendrites are present exclusively in the deeper layers (layers III B-VI). No pyramidal cells are GAD-positive, indicating that the GABAergic cells of SI cortex are interneurons with local connections.

Somata and dendrites of GAD-positive cells receive many synaptic contacts, both with symmetric and asymmetric thickenings. The morphology of the somata and the processes of some GAD-positive neurons permits a correlation with certain forms of Golgi impregnated interneurons (Jones J. Comp. Neurol. 160: 205, 1975). Horizontally oriented, GAD-positive, myelinated axons present in the deeper cortical layers probably arise from the large GAD-positive somata which can be correlated with the basket cells. Beaded, unmyelinated GAD-positive axons which give rise to en passant terminals belong probably to one or more types of smaller GABAergic neurons.

GAD-positive synaptic terminals make only symmetric contacts. They are found in large numbers on the large GAD-positive somata and dendrites and to a lesser extent on the somata and dendrites of the small GAD-positive neurons. In addition, they synapse on the somata, dendrites and axon hillocks of pyramidal cells and on other unlabeled processes, possibly belonging to other forms of non-GABAergic neurons.

We are currently examining material from animals with thalamic lesions to determine whether the GABAergic interneurons receive degenerating thalamocortical axon terminals.

Supported by NIH Grants NS12116 and NS10526.

269.5 THALAMIC CELLS OF DIFFERENT SIZES PROJECT TO DIFFERENT LAYERS OF THE SOMATIC CORTEX. G.R. Penny, K. Itoh and I.T. Diamond. Dept. of Psychology and Neurobiology Program, Duke University, Durham, NC 27706.

Parallel pathways of different cell sizes and fiber sizes have played a large part in the study of the somatic system since the pioneer work of Ranson, Erlanger, Gasser and Bishop. The dorsal column system projecting to the ventral posterior nucleus was viewed as an exclusively large fiber system, in contrast to the small fiber lateral column system. More recent evidence by Willis shows that the dorsal columns in fact contain fibers ranging in size from small unmyelinated to very large myelinated fibers. Certainly it has been clear that the ventral posterior nucleus contains a mixture of both very large and very small cells. This difference between the large and small cells could be dismissed according to the orthodox interpretation that most if not all of the small cells serve as interneurons. However, there is evidence in several species that very small cells in the lateral geniculate project to the striate cortex and to several other cortical areas and further that layer I seems to be the special target of such projections.

The present study was undertaken to determine whether the small cells in the ventral group of thalamic nuclei could be selectively labeled by HRP applications restricted to the superficial layers of the cortex. Small iontophoretic injections of HRP were placed in cortical areas 4, 3a and 3b of the cat. Labeled cells in the thalamus were drawn under a 63x or 100x objective and their cell areas were determined using an Apple computer and graphics tablet. In each of these cortical areas, injections of HRP into multiple layers labeled a wide range of cell sizes. Injections chiefly restricted to layer I labeled only small cells. Injections chiefly restricted to layers III and IV labeled medium and large neurons but few small cells. For example, after a layer I application in area 3b, labeled cells in the lateral division of the ventral posterior nucleus had a mean soma area of 119 μm^2. After an injection chiefly restricted to layer IV the mean soma area of the labeled cells was 322 μm^2. An injection involving most of the layers of the cortex in area 3b labeled a distribution of cells whose mean was 364 μm^2 and range was 100 to 1280 μm^2.

These results lead to the idea that there may be a simple principle underlying the organization of all thalamocortical projections. As a first approximation this principle concerns the difference between small cell (and presumably small fiber) systems terminating in layer I and large cell-large fiber systems that terminate in layers III and IV.

269.6 A THALAMIC BASIS FOR THE PLACE AND MODALITY SPECIFIC COLUMNS OF MONKEY SOMATIC SENSORY CORTEX. E.G. Jones and D.P. Friedman Dept. of Anatomy and Neurobiology and McDonnell Center for the Study of Higher Brain Functions, Washington University, School of Medicine, St. Louis, Missouri 63110.

Previous anatomical studies (Jones et al. 1979 J. Comp. Neur. 183: 833.) have indicated that thalamic input to a small focus in monkey first somatic sensory area (SI) emanates from a narrow elongated "rod" of cells extending through the anteroposterior dimension of thalamic nuclei VPLc or VPM. A thalamic rod could be the basis for afferent inputs to the place and modality specific columns of the SI cortex. We have confirmed and extended this by a correlative anatomical and single unit study in cynomolgus monkeys (M. fascicularis).

Punctate injections of horseradish peroxidase ca. 1mm in diameter, made through micropipettes at points in area 3b from which neurons activated by localized natural peripheral stimuli were recorded, led to retrograde labeling of a single thalamic "rod" in the "cutaneous core" (Friedman and Jones, J. Neurophysiol. 1981 45: 59) of VPLc or VPM.

Focal injections of tritiated amino acids made through micropipettes at defined sites in the dorsal column nuclei led to anterograde labelling of lemniscal fibers in a sequence of clusters that are also aligned to form one or two narrow rods extending anteroposteriorly through VPLc.

Microelectrodes penetrating the cutaneous core of VPLc or VPM horizontaly from behind encounter long sequences of units whose modality properties and receptive field positions do not change for up to 800 µm anteroposteriorly. Microelectrodes traversing the nuclei vertically from dorsal to ventral or horizontally from anterolateral to posteromedial, encounter systematic but sudden jumps in modality properties and receptive field positions over distances of 50-100 µm.

Punctate injections of [^{3}H] amino acids made at defined sites in the cutaneous core of VPLc or VPM lead to anterograde labeling of thalamocortical terminations in one or two short strips in area 3b. Similar focal concentrations of labeled terminations can be detected in computer assisted grain counts of the uninterrupted lamina of thalamocortical labelling that ensues from large thalamic injections.

The results suggest that a place and modality specific column of the somatic sensory cortex receives its input from a narrow elongated rod of thalamic cells whose place and modality characteristics are imposed upon then by a bundled aggregation of incoming lemniscal fibers. Each thalamic rod forms a smaller division of the well known lamella organization of VPLc & VPM.

269.7 SUBMODALITY AND ITS RELATIONSHIP TO SOMATOTOPY WITHIN AREA 3b OF THE CAT. R. W. Dykes and D. Sretavan*. (SPON: I. Bruce) Surgery, Neurology and Neurosurgery, and Physiology, McGill University, Montreal, Quebec, H3A 1A1.

The forearm portion of area 3b in cat somatosensory cortex was investigated. Experiments were performed in nembutal-anesthetized cats using tungsten electrodes to obtain multiunit recordings. Vertical penetrations were used to construct detailed maps of somatotopic and submodality organization. Tangential penetrations were then used in the same animal to examine the sequences of receptive fields encountered at 50 µm intervals across the cortical surface. Data from each experiment were analysed separately, providing the following results: (i) Regions of SA and RA submodalities were each arranged as bands varying between 0.5 and 1.5 mm wide. These bands branch and interdigitate with each other throughout this part of area 3b. (ii) In all animals, the ulnar forearm was most heavily represented. The radial aspect of the forearm, if encountered, was consistently under-represented and appeared to lie at the anterior and posterior borders of area 3b. (iii) There was a complete duplication of the forearm map within area 3b. For a given animal, if a point on the forearm was represented in one band it was also represented in the other; we were unable to detect any parts of the forearm represented in one submodality which were not also found in the other. As a result, the forearm representation in the RA and SA submodality bands is very similar. (iv) During horizontal penetrations, both in the anterior-posterior direction across area 3b and in the lateral-medial direction along area 3b, the progression of receptive fields appeared continuous when sampled at 50 µm intervals. Even when boundaries between the two submodality regions were traversed, abrupt shifts in receptive field location were not observed. We infer that there are similar maps of the forearm in both the SA and RA bands. Each of these interdigitating maps displays a smoothly changing gradient of receptive fields within itself and across the submodality boundaries. The nature of the submodality interdigitations may be determined by a requirement to maintain a continuous somatotopic gradient within area 3b.

269.8 AN ELECTROPHYSIOLOGICAL AND ANATOMICAL INVESTIGATION OF THE ORGANIZATION OF THE SECOND SOMATOSENSORY AREA, S-II, IN OWL MONKEYS. C.G. Cusick*, J.T. Wall, D.J. Felleman, and J.H. Kaas. Psy. and Anat. Depts., Vanderbilt Univ., Nashville, TN 37240.

The goal of the present study was to describe the somatotopic organization of the second somatosensory area, S-II, using electrophysiological mapping methods and injections of anatomical tracers. Multi-unit recordings were made in 32-101 vertical penetrations in 8 owl monkeys anesthetized with ketamine HCl or urethane. In monkeys, the S-II representation lies buried in the lateral sulcus. Because the owl monkey has a smooth-surfaced brain, multiple recordings in single vertical penetrations can be used to relate the mapping data to 3 cortical levels: a superficial recording level, and 2 deep levels representing the upper and lower banks of the lateral sulcus. Receptive field locations determined at these 3 recording depths lead to the following general conclusions regarding the organization of S-II. (1) Most of S-II in owl monkeys lies under Areas 3a and 4 at the superficial recording level. Portions of the face representations in S-II lie under the Area 3b hand and lower face representation. (2) Recording sites located on the upper bank of the lateral sulcus reveal a convergence of the cutaneous representations of the head in Areas 3b, 1, and S-II. Areas 3b and 1 have a common border along the midline of the upper face. S-II appears to adjoin part of the lower face representation of Area 3b. In the region of the head top representation, S-II may have a common border with both Areas 3b and 1. (3) Both the trunk and forelimb representations usually lie near the fundus of the lateral sulcus, and the extent of their distribution on the upper and lower banks varies. (4) The forelimb and hand representation is located anterior to the trunk representation. (5) The hindlimb and foot representation is usually found posterior to the hand region on the lower bank of the lateral sulcus.

Additional observations derived from the recordings are that receptive fields in S-II are mainly contralateral and that receptive field sizes in S-II are generally larger than in Areas 3b and 1. Additional regions outside of S-II on the lower bank of the lateral sulcus respond to cutaneous or to pacinian input, and deep receptor input has been found on the upper bank. In some of the mapped cases in this study, injections of HRP were made into the hand digit, chin, and foot representations of Area 3b. The distribution of labelled neurons stained with the TMB method confirms the physiological mapping data regarding the overall somatotopic organization of S-II. The results indicate that the lateral sulcus contains representations of the contralateral body surface corresponding to Areas 3b, 1, and S-II as well as additional somatic representations. Supported by NIH Grant NS 16446.

269.9 PATTERNS OF 14C-2DEOXYGLUCOSE LABELING WITHIN THE LATERAL FISSURE OF THE MONKEY. S. Juliano, P. Hand, B. Whitsel. Dept. of Animal Biology, Sch. of Vet. Med., and Inst. of Neurol. Sci., U. of PA, Phila., PA 19104; and Dept. of Physiol., UNC, Chapel Hill, NC 27514.

The metabolic labeling pattern in the lateral fissure (LF) of fasicularis monkeys was investigated using the ^{14}C-2-deoxyglucose (2DG) technique coupled with precise somatic stimulation. Previous studies by this laboratory have shown that in monkey somatosensory cortex (SI) 2DG labeling occurs as elongated medio-laterally oriented strips. In this study, similar characteristics were observed in the LF, with some distinct differences.

Five unanestheized, paralyzed monkeys received a pulse injection of 2DG followed by a controlled somatic stimulation consisting of brush strokes at 27 cm/sec, flutter vibration at 15 hz,or joint movement of the elbow at 22°/sec. One animal received the joint movement stimulation of one arm and the flutter vibration stimulation on the index finger of the opposite hand. Otherwise, the animals were unilaterally stimulated on various parts of the forelimb ranging from the distal tip of the index finger to the proximal forearm.

Both banks of the contralateral LF and the insula were examined for 2DG labeling. In individual sections the labeling occurred as column-like patches, most often extending from lamina II-V and most densely labeled in laminae IV and IIIB, as in SI. The LF patches ranged in mean tangential width from 475 to 690 um, which is significantly wider than the patches measured in area 3b for similar stimulation. The LF patches were also more irregular in shape than those in SI.

Two-dimensional surface reconstructions demonstrated that the patches combined to form strips of label which occasionally branched and merged and were oriented along the antero-posterior axis of the fissure. When the labeling was compared to somatotopic maps of the second somatosensory area (SII) (Friedman, et al.,J.Comp.Neurol.192, 1980, and Whitsel, B., unpublished observations), an excellent correlation was found between the body region stimulated and the cortical area of representation predicted by SII somatotopic maps. Preliminary results from reconstructions of the ipsilateral LF and the bilaterally stimulated animal indicate that ipsilateral 2DG labeling patterns have features in common with the companion contralateral cortex, but of lesser extent and density. The observations of this study, combined with those of SI, indicate that the parcelling of the cortex into elongated strips may represent a basic functional unit of neocortical organization.

269.10 KETAMINE ALTERS RESPONSE PROPERTIES OF S-I NEURONS IN MONKEY. G.H. Duncan*, D.A. Dreyer, T.M. McKenna and B.L. Whitsel. Dental Research Center and Departments of Neurobiology and Physiology, University of North Carolina, Chapel Hill, NC 27514.

The primary objective of the present study was to investigate the influence of the general anesthetic Ketamine on neural properties that are relevant to the study of S-I somatotopy. The effects of intramuscularly adminstered Ketamine on the spontaneous activity and evoked discharge of S-I neurons were studied in 10 monkeys (Macacca fasicularis). The majority of the data was obtained from 4 behaving monkeys trained to accept somatic stimuli delivered to the upper extremities. Additional studies were performed in 6 unanesthetized monkeys maintained under neuromuscular blockade. In both behaving and paralyzed animals, the response properties of cortical neurons were characterized, first while the monkey was in the unanesthetized state, then after injection of various doses of Ketamine, and finally after recovery from the effects of the anesthetic. No specific or general differences in the data derived from the two approaches could be demonstrated.

Spontaneously firing units frequently demonstrated dramatic Ketamine-induced changes in their pattern of discharge that appeared to be epileptogenic or "bursting" in character. In addition, both spontaneous and stimulus-evoked activity increased following low doses of Ketamine (less than 3 mg/kg), but typically decreased at higher doses. This drug-induced decrease in responsiveness was manifest as an elevation of the threshold of S-I neurons to mechanical stimulation of the skin, a reduction in the receptive field size, and a depression of the mean rate of discharge evoked by either punctate or surface-parallel moving stimuli. All effects on spontaneous and stimulus-evoked activity exhibited a dose and time dependency. These effects of Ketamine were observed for S-I neurons located in different cytoarchitectural areas, with different receptive field locations, and with stimuli applied to different locations within the receptive field.

The results of this study indicate that S-I is not spared the disruptive influence of even low doses of Ketamine. This general anesthetic has been found to alter significantly the size and configuration of the peripheral territories providing input to individual S-I neurons. Dosage and time course of recovery from Ketamine anesthesia are variables which influence the data from which maps of S-I topographical organization are prepared.

269.11 UNUSUAL RECEPTIVE FIELD AND RESPONSE PROPERTIES OF NEURONS IN THE UPPER LAYERS OF THE S-I CORTEX OF THE CAT. T.M. McKenna, A.R. Light, B.L. Whitsel. Dept. of Physiology and Dental Research Center, Univ. of North Carolina, Chapel Hill, NC, 27514

Extra- and intracellular recordings were obtained from S-I of unanesthetized cats with HRP or K citrate filled micropipettes. Within either lamina II or upper III a population of neurons was identified for which the preferred stimulus was a gentle brushing stimulus moved at low velocity (<1 cm/sec) over the skin. Stimuli moving faster than 10 cm/sec were inhibitory. In addition to preferring gentle, slowly moving stimuli, these neurons also exhibited decreased responsiveness to mechanical skin stimulation for protracted periods following repetitive adequate stimulation. Rapidly repeated high-velocity brushing stimuli frequently were observed to lead to complete and prolonged periods of total insensitivity to mechanical stimulation of the RF. Other unusual properties of these neurons were prominent stimulus-evoked after-discharge, and low rates of spontaneous activity which tended to increase in the absence of stimulation and to be suppressed subsequent to repetitive adequate stimulation. The RFs of some of these neurons consisted of discrete points of high sensitivity separated by insensitive zones which could not be mapped precisely. In penetrations in which such unusual neurons ("slow brush" or SB neurons) were encountered (usually 1 to 3 per radial penetration), further advance of the electrode into lower lamina III and IV (below 400 u) always sampled cutaneous neurons exhibiting RF and response properties similar to those reported in earlier studies of S-I. The latter preferred moving stimuli applied at velocities between 5-50 cm/sec, and had well-defined RF borders. To date, the three SB type S-I neurons which have been labelled intracellularly by iontophoretic injection of HRP were small pyramidal cells in either lamina II or upper III. Distinct from both the SB type neurons of the upper layers and the "typical" neurons of the middle cortical layers in S-I, was another class of upper layer neurons which possessed very large, bilateral RFs ("wide-RF" or WF neurons) that could be mapped using either gentle punctate or brushing stimuli moved across the skin at any of a wide range of velocities. To date, the one WF cell labelled intracellularly with HRP was a small pyramidal neuron in upper layer III. The data suggest that the upper and lower lamina of S-I cortical cell columns may contribute differentially to somesthesis.

269.12 REACTION-TIMES PROVIDE A TOOL FOR MEASURING THE PERCEIVED INTENSITY OF CUTANEOUS STIMULI IN MONKEYS. Esther P. Gardner and Janet M. Tast*, Dept. of Physiology & Biophysics, NYU School of Medicine, New York, N.Y. 10016.

To study the magnitude of tactile sensations produced by airpuffs of several intensities and spatial patterns, we trained two rhesus monkeys and five human subjects in a reaction-time (RT) task. The monkey or human subject initiated each trial by depressing a telegraph key. A 10 msec airpuff stimulus was delivered to the forearm skin at a random time 0.5-4 sec later, and the subject was required to release the key as soon as the stimulus was felt. The RT was defined as the time interval between airpuff and key release, and was measured in 121 sessions with monkeys and in 72 with humans. The number, spacing and peak force of the airpuffs were varied in different sessions.

Mean RTs ranged from 228 to 287 msec in monkeys, and from 247 to 315 msec in humans, depending upon the intensity and number of airpuffs delivered to the skin. RTs were narrowly distributed around the mean, with standard deviations as small as 30 msec. Stronger airpuffs produced shorter mean RTs and increased stimulus detectability (d') over the range tested (400-1600 dyn peak force). Mean RTs could be significantly shortened ($p < 0.02$) and stimulus detectability improved by increasing the number of points stimulated from one to three. Three closely-spaced airpuffs (15 mm apart) evoked slightly shorter mean RTs and slightly larger values of d' than three widely spaced (30 mm) airpuffs in monkeys, but the differences were not statistically significant ($p > 0.05$). These changes in behavioral performance were due to increased d' rather than to alterations in the subjective criterion used to perform the task. Our findings extend previous magnitude estimation studies in humans, and demonstrate that the RT task provides a powerful tool for measuring relative magnitudes of sensory experiences in experimental animals.

Three simultaneously presented airpuffs have been shown to elicit higher numbers of impulses and to activate more neurons in somatosensory cortex of monkeys than single airpuffs of the same intensity. The present psychophysical observations suggest that this larger active cortical population is related to a parallel increase in sensation magnitude. Thus perception of a more intense and more easily detected sensation may result from increased number and degree of activity of cortical neurons.

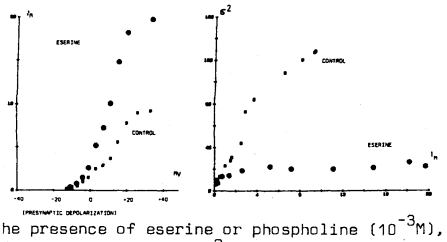
270.1 IS THERE A NON QUANTAL RELEASE COMPONENT AT A CHOLINERGIC NEURO-NEURONAL SYNAPSE ? M. Simonneau* & L. Tauc* (SPON : J. Bruner), Lab. Neurobiologie Cellulaire, C.N.R.S. 91190 Gif sur Yvette, France.

A leakage of acetylcholine (ACh) was revealed, at the neuromuscular junction, by ionophoretic application of curare, in the presence of an anticholinesterasic agent (antiAChE) (Katz & Miledi, 1977, Proc. Roy. Soc., Lond, 196:59-72). Determination of Ach quantal release parameters -amplitude and decay time (τ)- of miniature postsynaptic currents (MPSCs) was recently made possible in a cholinergic neuro-neuronal synapse in Aplysia (Simonneau & al., 1980, Proc. Natl. Acad. Sci., 77:1661-1665). Postsynaptic current fluctuations obtained by depolarization of the presynaptic neuron in the presence of tetrodotoxin were analyzed as the summation of individual MPSCs. The relationship between the variance (σ^2) and the mean (I_m) of the current was not linearly related for larger values of I_m. One possible explanation is that a voltage-dependent non quantal component contributed to I_m.



In the presence of eserine or phospholine (10^{-3}M), this non-linearity was enhanced ; σ^2 was lower than control and I_m was increased. This depression could be due to (i) a curare-like effect of antiAChE and/or (ii) a decrease in the response quantal content. This was tested by comparing the spike-induced response with ACh ionophoretically induced response. Iontophoretic injection of Carbachol (up to 40 nA) in the neuropile mimicked the effects of antiAChE on σ^2 and I_m. The quantal content was decreased but the size and τ of MPSCs did not change. These results show the presence of a non quantal component in the clamped postsynaptic current and its kinetics, especially in the presence of antiAChE suggest a voltage-dependance. The present results do not exclude the possibility that this component may be built up from ACh of the released quanta.

270.2 DIRECT EVIDENCE THAT Ca^{++} ACCUMULATION MEDIATES POST-TETANIC POTENTIATION IN APLYSIA. Robert Kretz*, Eli Shapiro, Eric R. Kandel (SPON: J. Koester). Center for Neurobiol. & Behavior, P & S, Columbia University, New York, N.Y. 10032.

We have examined the presynaptic ionic mechanisms underlying post-tetanic potentiation (PTP) in Aplysia by carrying out voltage-clamp experiments on the presynaptic neuron L10, while assaying transmitter release by recording the synaptic potential in its follower cells in the abdominal ganglion. 50 msec depolarizing command steps in high divalent cation seawater solution containing 30 µm TTX elicit stable PSPs in follower cells when presented at 0.2 Hz. Tetanic stimulation of L10 (100 command pulses at 4 Hz) elicits PTP of 200-800% that lasts up to 5 min. PTP is correlated with a slow outward current that we identified as a Ca^{++}-dependent K^+ current (Kretz, Shapiro and Kandel, 1980). This current provided an assay of changes in the free Ca^{++} level of the neuron (Gorman and Hermann, 1979) and its correlation with PTP provided indirect evidence for a residual Ca^{++} hypothesis of PTP (Rahamimoff, 1968).

To obtain direct evidence that intracellular Ca^{++} accumulation produced by tetanic stimulation is causally related to PTP we injected EGTA, a Ca^{++}-buffering agent, into L10 and examined its effect on the size and time course of both the PTP and the Ca^{++}-dependent K^+ current. Prior to the injection of EGTA, two control runs of PTP separated by 10 min were performed. Approximately 2.0 nL of 0.5 M EGTA in KOH at pH 7.5 was then pressure injected into cell L10 and PTP runs were followed over the next several hrs. As previously reported EGTA injections decreased the transient and steady-state outward currents, and increased the inward Ca^{++} current (Connor, 1979; Brehm, Eckert and Tillotson, 1980). In addition, EGTA affected the amplitude of the PSP and the time constant of PTP. Beginning 5 minutes after injection of EGTA control PSPs were progressively reduced so that 1-2 hrs after the injection pretetanic stimulation elicit only small or no PSPs. During and following the tetanus build-up of PSPs and PTP still occurred but the time constants of PTP were now changed. Normally, both PTP and the slow outward current have two matching time constants -- a fast one (τ=5-10 s) and a slow one (τ=50-150 s). Within 10 min after EGTA injections neither the outward current nor PTP show a fast time constant. Both the PSP and the outward current can now be fitted with single slow exponential functions. With further time after the injection this slow time constant decreases progressively.

These results indicate that increasing presynaptic capability for buffering Ca^{++} can alter the time course of PTP and directly support the idea that PTP involves the residual Ca^{++} that accumulates following a tetanus. This Ca^{++} accumulation results from saturation of the normal Ca^{++}-buffering capacity by the Ca^{++} influx accompanying the tetanus.

270.3 SENSITIZATION IN APLYSIA: SEROTONIN ELICITS A DECREASE IN SENSORY NEURON K^+ CURRENT NOT RELATED TO I_K EARLY OR $I_K Ca^{++}$. J.S. Camardo*, M. Klein*, and E. R. Kandel (SPON: L. Cote). Center for Neurobiology and Behavior, Depts. of Physiology and Psychiatry, Columbia University, P & S, New York, N.Y. 10032.

Sensitization of the gill-withdrawal reflex in Aplysia californica is mediated by presynaptic facilitation of transmitter release from sensory neurons which innervate the mantle. Increased transmitter release is correlated with an increase in the duration of the action potential, which results in increased Ca^{++} influx. Both the broadening of the spike and the enhancement of release can be elicited by connective stimulation, by application of serotonin (5HT), and with intracellular injection of cyclic AMP or cAMP-dependent protein kinase. Voltage clamp analysis has shown that the increase in duration of the action potential produced by 5HT is due to a decrease in outward K^+ current elicited by depolarizing voltage steps.

Three K^+ currents have been described in molluscan and other neurons, and we have found each of these currents in Aplysia sensory neurons: 1) Ca^{++}-dependent I_K; 2) Early I_K; 3) Delayed I_K. To determine which, if any, of these currents is decreased in sensitization, we studied the effect of 5HT on these currents in voltage-clamped sensory cells, and have found that 5HT exerts its action on a K^+ current which is neither the early I_K nor the Ca^{++}-dependent I_K.

The effect of 5HT on early I_K was studied in cells voltage-clamped at a hyperpolarized potential. Depolarizing voltage steps elicit the early I_K and slower outward currents. 5HT reduced the slower outward currents, but did not affect the early I_K, which subsequently was blocked by 4-aminopyridine.

The Ca^{++}-dependent K^+ current was studied in voltage clamped cells bathed in solutions in which the Ca^{++} current was blocked. The effect of 5HT persists in the presence of extracellular cobalt and nickel, and in low Ca^{++} solutions with EGTA. In addition, the 5HT response is not blocked by substitution of barium for calcium to reduce $I_K Ca^{++}$. Finally, intracellular injection of Ca^{++} elicits an outward current that is unaffected by 5HT.

Since reduction of the early I_K and the $I_K Ca^{++}$ does not account for the 5HT response, the biophysical phenomena which accompany sensitization and presynaptic facilitation in Aplysia seem to involve an action on delayed rectification or on a novel, serotonin-sensitive, K^+ current.

270.4 PROTEIN INHIBITOR OF THE CYCLIC AMP-DEPENDENT PROTEIN KINASE CAN BLOCK THE ONSET OF, AS WELL AS REVERSE THE ELECTROPHYSIOLOGICAL CORRELATES OF SENSITIZATION OF THE GILL-WITHDRAWAL IN APLYSIA. V. F. Castellucci, J. H. Schwartz, E. R. Kandel, A. Nairn*, and P. Greengard. Center for Neurobiology and Behavior, Columbia University, P & S, and Dept. Pharmacology, Yale University.

Sensitization of the gill-withdrawal reflex is due to presynaptic facilitation at the excitatory synapses made by sensory neurons on gill motor neurons. The facilitation is accompanied by an increase in the duration of the action potential in sensory cells; this increase is greatly enhanced in the presence of tetraethylammonium (TEA), resulting in an increase of Ca^{++} influx and a greater release of transmitter from sensory neurons (Klein and Kandel, 1978, 1980). There is evidence that serotonin is the facilitating transmitter and that the depression of the K^+ current produced by serotonin is mediated by cyclic AMP dependent protein phosphorylation (Brunelli et al.,1976; Paris et al., 1980). Pressure injection of the catalytic subunit of the cyclic AMP-dependent protein kinase into cell bodies of individual sensory neurons causes spike-broadening and increases in the release of transmitter and thereby mimics facilitation (Castellucci et al., 1980).

To test further the role of the cAMP-dependent protein kinase and of protein phosphorylation in sensitization we have attempted to prevent or reverse the development of electrophysiological correlates that accompany sensitization. In the presence of TEA we have pressure injected individual sensory cell bodies with the Walsh inhibitor, a specific and a stable protein inhibitor of the cAMP-dependent protein kinase while serotonin (10^{-6}M) was applied in the bathing solution to produce spike broadening. Pairs of cells were run in parallel (a non-injected cell and a cell to be injected with the protein inhibitor). The dramatic increase in spike broadening that accompanies facilitation was prevented or diminished by injection of the inhibitor. Moreover, injection of the inhibitor could reverse fully the developed spike broadening produced by a prior application of serotonin. No effect was obtained by injecting the vehicle alone. These findings strengthen the evidence for the involvement of protein phosphorylation in presynaptic facilitation, and suggest that the rate of decline of the memory does not reside in the persistence of a phosphorylated state in the absence of kinase activity but in a decline of the kinase itself. This decline is perhaps determined by the slow decay in the elevated level of cAMP produced by brief activation with serotonin (Cedar and Schwartz, 1972).

270.5 POSSIBLE INVOLVEMENT OF ACTIN IN THE RELEASE OF TRANSMITTER BY AN IDENTIFIED MOLLUSCAN SYNAPSE. E. Shapiro, D. A. Harris, and J. H. Schwartz. Ctr. for Neurobiol. and Behav., College of Physicians and Surgeons, Columbia U., New York, N.Y. 10032

Cell L10 is a cholinergic interneuron presynaptic to several follower cells in the Aplysia abdominal ganglion. This interneuron has been utilized as a model system for studying synaptic physiology and presynaptic ionic mechanisms of synaptic plasticity. To test the role of actin in transmitter release we have injected DNAse I, a protein that binds actin specifically and stoichiometrically and which causes depolymerization of actin filaments, into L10. DNAse has previously been shown to inhibit fast axonal transport of serotonergic vesicles when injected intracellularly in another Aplysia neuron (Goldberg, D. J., Harris, D. A., Lubit, B. W. and Schwartz, J. H., Proc. Natl. Acad. Sci. USA 77:7448-7452, 1980). Our standard experimental protocol involved recording from L10 and one of its follower cells in the isolated abdominal ganglion. L10 was stimulated at a constant frequency (1-5 Hz in different preparations) either continuously or as 2 min trains with 5-10 min intervals of rest. After recording stable baseline PSP's for up to 1 hr a concentrated solution of DNAse (40 ng/nl in 5 mM Na acetate, pH 5.0, with an activity of 0.08-0.11 Kunitz units/nl) was pressure-injected into the soma of cell L10. In successful injections, 1.5 - 2.5 nl of DNAse was injected, and the injection did not cause significant changes in input resistance, membrane potential or spike amplitude. In seven such experiments, the PSP's were reduced up to 50% following the injection. Inhibition occurred within 10 min and persisted for as long as the cell was monitored (up to 40 min after the injection). Preliminary examination of how the DNAse effect varies with stimulus frequency indicates that blockage of transmitter release is greater at lower stimulation frequencies, or with 5-10 min intervals of rest between trains of stimuli. Control injections with acetate buffer or with bovine serum albumin did not inhibit the PSP's. Preparations of the pancreatic nuclease may be contaminated with proteolytic enzymes. Proteolysis is unlikely to cause the inhibition in synaptic transmission observed, however, because injection of DNAse treated with the protease inhibitor phenylmethylsulfonyl fluoride, was equally effective. We are also testing other actin-binding proteins to strengthen the evidence for the involvement of actin in transmitter release, including brevin, a protein purified from rabbit serum which shortens actin filaments.

270.6 PROPERTIES OF TRANSMITTER RELEASE IN THE SQUID GIANT SYNAPSE VIA VOLTAGE CLAMP RECONSTRUCTED PRESYNAPTIC ACTION POTENTIALS. R. Llinás, M. Sugimori* and S. M. Simon*. Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., New York 10016.

Previous studies of the transmission properties in squid giant synapse via presynaptic voltage clamping techniques allowed us to propose a model for transmission at that junction (Llinás et al.: Biophys. J. 33, 289-322, 1981). The model was derived from Ca^{++} currents obtained by presynaptic square voltage clamp steps after blockage of g_{Na} and g_K. From this model the time course and amplitude of presynaptic Ca^{++} current and the postsynaptic potentials generated by action potential-like depolarizations of different amplitudes and duration were numerically obtained. In order to test the validity of the model directly, potentials resembling presynaptic spikes were generated across the presynaptic terminal by feeding the command amplifier of the voltage clamp system with the presynaptic action potential recorded from the same synapse prior to the pharmacological blockage of Na^+ and K^+ conductances with TTX and TEA + 3-AmP respectively. Reconstruction of the presynaptic action potential via the voltage clamp was demonstrated to generate a potential profile almost indistinguishable from the original action potential at a recording site in the middle of the presynaptic terminal This artificial spike produced synaptic potentials of similar amplitude and latency as those obtained prior to spike blockage. The results indicated that the blockage of Na^+ and K^+ conductances did not affect in any measurable way the properties of synaptic transmission at this junction. Following a set of results obtained at different amplitudes and duration for the presynaptic spike-like voltage step, a similar set of depolarizations was repeated following the addition to the bathing fluid of 500 microMole CdCl, known to block presynaptic Ca^{++} current and synaptic transmission. Subtraction of the currents obtained before and after Cd^{++} administration gave us a direct measurement of the time course and amplitude for the Ca^{++} currents during these action potentials and their relationships to the amplitude of the postsynaptic responses. These results matched quite closely those obtained by the numerical solution of our equations confirming the validity of the model. Supported by USPHS grant NS13742 from NINCDS.

270.7 BURSTING, CA SPIKES, AND SPIKE BROADENING RECORDED INTRACELLULARLY FROM CRAB NEUROSECRETORY TERMINALS. I. Cooke and M. Nagano*. Békésy Lab. of Neurobiol., Univ. of Hawaii, Honolulu, HI 96822.

Peptide neurosecretory cells of mammals and molluscs characteristically fire impulse bursts. Bursting, both spontaneous and in response to brief electrical stimuli, is sometimes observed during intracellular recording from somata, axons, or terminals of the isolated X-organ-sinus gland neurosecretory system of crab (Cardisoma carnifex, Podopthalmus vigil) eyestalks. Most frequently observed are bursts lasting 10-20 sec with intraburst firing frequencies of 2-5/sec, recurring more or less regularly at 1-6/min. The impulses are superimposed on a depolarized plateau having an amplitude of up to 30 mV from resting potential (- 80 - - 60 mV). Occasionally, the plateau occurs without superimposed impulses. Such bursting was once recorded continuously from a terminal for 8 hr. Extracellular recording from the axon tract indicates that impulses originate near the soma. A brief (1 msec) shock applied to the axon tract illicits a burst in some units not exhibiting spontaneous bursting. If the impulses of a burst recorded in a terminal are viewed superimposed, their overshoot remains constant, but their duration progressively increases from 10 msec (at 1/2 amp.) to as much as 30 msec. By contrast, impulses recorded in an axon are of short duration (2-5 msec) and do not show spike broadening. Some, but not all, terminals of units not exhibiting bursting show spike broadening when tested by repetitive axonal stimulation. Axon impulses are reversibly blocked by perfusion of Na-free or TTX saline. Terminal impulses, however, can be elicited in these salines by depolarizing current passed through the recording electrode. The response in Na-free or TTX saline is reversibly blocked by addition of 0.1 mM Cd. Thus terminal, but not axonal, action potentials include a major component of Ca current. In the absence of evidence, morphological or physiological, for synaptic interaction between neurons in this isolated system, we infer that bursting is an endogenous property of some of the neuronal population. Bursting is a labile property, easily impaired by electrode-induced injury which leaves other responses unaffected. Thus, we cannot estimate how much of the population is capable of bursting. Light and EM studies show terminals of 6 morphological types, and at least 4 peptide hormones have been characterized. Hence, heterogeneity of electrical properties may be expected. In view of the demonstrated importance of Ca to peptide secretion in this and other systems, bursting, augmented voltage-dependent Ca channels in terminal membrane, and spike broadening may represent specializations for secretion.

270.8 THE EFFECTS OF HYPERTONICITY AND ANION BLOCKERS ON QUANTAL TRANSMITTER RELEASE. W.D. Niles, Department of Physiology, University of Wisconsin, Madison, WI 53706

The effects of hypertonicity and the anion flux blockers Probenecid, DIDS, and pyridoxal phosphate were examined on quantal transmitter release at single excitatory synaptic sites on the crayfish leg opener muscle. Focal extracellular recording methods were used to measure the quantal content (m) and synaptic latencies of responses to nerve stimulation of 2Hz at 1.0-4.0°C.

Hypertonic solutions ranging from 537-1298 mosM/l made by adding either melezitose or NaCl to the normal Van Harreveld's solution of 430 mosM/l increased resting quantal release rates from .013 to .098/sec to .031 to .98/sec. Mean quantal contents were reduced from 0.1-2.5/impulse to 0.02 to 1.2/impulse, depending on the osmolarity. The mean synaptic latency increased with hypertonicity with no significant change in axon conduction velocity. After an impulse, the probability of any quantal release decreases from its peak value with time. The time constant of this decline (t) showed osmolarity-dependent increases; at one site t increased from 3.5 to 5.6 upon a change from 430 to 860 mosM even with a simultaneous increase in bath temperature from 1.0 to 4.0°C.

Probenecid and DIDS at > 200 μM blocked action potential initiation. These drugs in the range of 10-1000 μM and Pyridoxal phosphate in the 0.1-1.0 mM range reduced m with half-maximal inhibiting doses of 20 μM (DIDS), 100 μM (Probenecid) and 0.5 mM (Pyridoxal phosphate). No effects of these agents on the resting release rate or on the synaptic delays were detected

The facilitatory agent 5-HT at 10 μM increased the resting release rate by about 100-fold and increased m by a factor of 2-6 with a decrease in synaptic latencies. Hypertonic solutions reduced m and increased t at sites previously treated with 5-HT. However, 5-HT in 860 mosM/l saline elevated m without affecting t at sites previously equilibrated with 860 mosM/l saline.

It is concluded that hypertonic solutions affect the time course of quantal release by action potentials. The ability of 5-HT to potentiate release at previously depressed synapses indicates that reduction in nerve terminal volume does not underlie this effect. Similarly, the inability of anion channel blockers to alter t suggests that impulse transmission failure alone does not account for these results. This dissimilarity of hypertonicity and drug effects suggests that they do not act on a common mechanism to reduce quantal release.

270.9 ACh RECEPTOR CHANNEL POPULATIONS IN CULTURED XENOPUS MYOCYTE MEMBRANES ARE NON-HOMOGENOUS. R.B. Clark and P.R. Adams, Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

The "infinite seal" patch clamp technique of Neher and Sakmann was used to measure single ACh receptor channel currents from embryonic Xenopus myocytes after 2 to 7 days in culture. Recordings from all cells always showed two different amplitudes of single channel events (e.g. Fig A), but the relative number of "small" and "large" currents varied considerably from one cell to another. Histograms of channel amplitudes showed two clearly separated peaks (Fig B). The ratio of mean "large" current amplitude to mean "small" current was relatively constant from one cell to another (1.39 ± 0.02, mean ± S.E., 7 cells) and was not significantly dependent on membrane potential. The current-voltage relation was approximately linear over the range +50 to -60 mV with respect to resting potential and the conductance of the channels from the slope of I-V plots was 42 ± 4 pS for the "large" and 33 ± 5 pS for the "small" channels (n = 5).

Channel open time had an approximately single exponential distribution at sites where one type of channel event predominated. At 5 sites where more than 90% of events were "small" channels, the mean open time was 3-8 ms (-50 to -100 mV from rest, 1μM ACh). At sites where the numbers of both types of channel events were comparable, the mean open time of "small" channels was 2-3 times greater than the mean open time of "large" channels recorded from the same patch at the same membrane potential. The differences in conductance and open time between these two channel populations appear analogous to the differences between junctional and extrajunctional ACh receptor channels of adult amphibian muscle membrane.

270.10 CHOLINE SENSITIVITY OF POSTSYNAPTIC RECEPTORS IN APLYSIA BUCCAL GANGLIA. R.L. Ruff*, R.L. White* and D. Gardner. Depts. of Physiology and Neurology, Cornell U. Med. Coll., NYC, NY 10021.

Choline has been identified as a partial cholinergic agonist in both classical (Dale, 1914) and recent (Krnjevic & Reinhardt, 1979) literature. Acetylcholine (ACh) is a neurotransmitter in several molluscan ganglia, responsible for many synaptic actions. We have investigated the effects and role of choline on identified neurons of the buccal ganglia of the mollusc Aplysia californica. We now report that several cholinoceptive neurons of the buccal ganglia respond to choline, raising the possibility that choline itself may normally mediate some synaptic conductance changes.

Choline and ACh were iontophoresed or pressure injected onto voltage-clamped neurons, and the resulting currents analyzed. Different groups of identified neurons produced consistent responses to each of the two agonists: 1) All conventional inhibitory follower cells (BL or BR3,6,8-11) responded to both ACh and choline (n=37), although some cellular regions responded only to ACh. The peak amplitude of the choline response was 10 to 100% of the peak of the ACh response (167 trials, 25 cells). Reversal potentials were similar: E_{ACh} = -78 ± 2 mV; $E_{Choline}$ = -77 ± 2 mV (SEM, n=12). The choline responses were reversibly blocked by 10^{-4} g/ml curare (n=4). Eserine potentiated the ACh response without affecting the choline response (n=11). 2) Excitatory follower cells (BL or BR13) or self-inhibitory interneurons (BL or BR4,5) responded to ACh but not to choline (156 trials, 23 cells). 3) In follower cells BL or BR7, cholinergic PSPs are diphasic, with excitatory and inhibitory components. With these cells clamped at -20 mV, postsynaptic currents (PSC) also were diphasic, with early inward and late outward components. The late component reversed at -67 ± 4 mV (n=7). Eserine (10^{-4} g/ml) selectively abolished the late component. With agonist iontophoresis, ACh always produced either diphasic responses or the early response alone, while choline produced only the late response (39 trials, 7 cells); $E_{Choline}$ = -68 ± 4 mV (n=7).

We suggest: 1) Buccal ganglia neurons are choline sensitive. 2) The existence of choline-insensitive ACh receptors implies that choline sensitivity is a non-trivial property. 3) Choline produced by hydrolysis of released ACh may be partially responsible for some postsynaptic conductance changes.

270.11 DEGRADATION OF ACETYLCHOLINE RECEPTORS IN INNERVATED MYOTOMES OF XENOPUS LAEVIS MAINTAINED IN ORGAN CULTURE. P.M. Frair* and M.W. Cohen (SPON: R. Capek). Department of Physiology, McGill University, Montreal, Quebec.

Myotomal muscles of Xenopus embryos and tadpoles were isolated together with the spinal cord (SC) and were maintained in culture under sterile conditions for periods of about 1 day. The culture system permitted continued development of embryonic SC-myotome preparations. For example, at the end of the 1 day period in culture, preparations isolated from 1-day-old embryos exhibited increased localization of acetylcholine receptors (AChRs) at presumptive sites of innervation and the total number of AChRs in the preparations had increased to 80% of the value in intact animals. Synaptic activity was also recorded from the muscle cells at the end of the culture period.

Degradation of AChRs in these SC-myotome preparations was assessed by measuring the radioactivity remaining in the tissue at different times after pulse labelling with ^{125}I-α-bungarotoxin and extensive washing. In SC-myotome preparations obtained from stage 40-44 tadpoles (3-4 days old) the radioactivity remaining in the tissue declined slowly with time and was still 80-85% of the original value 24 hr after pulse labelling. This corresponds to an apparent half-life of about 3-4 days for the AChRs. Similar measurements were made on SC-myotome preparations obtained from stage 26-27 embryos (29-31 hr old), less than 12 hr after the onset of innervation. In these young preparations 72-77% of the radioactivity was still present in the tissue 24 hr after exposure to the iodinated toxin, corresponding to an apparent half-life of about 2-3 days for the AChRs. These findings suggest that the half-life of AChRs in innervated Xenopus myotomes increases with maturation. Radioautographs of the preparations are being processed in order to determine whether junctional and extrajunctional AChRs are degraded at different rates. (Supported by the Medical Research Council of Canada).

270.12 GATING AND BLOCKING OF ENDPLATE CHANNELS BY TRIMETHYLAMMONIUM DERIVATIVES. A. Auerbach*, M. Titmus* and J. del Castillo. Lab. Neurobiol., UPR Sch. Med., San Juan, P.R. 00901

The binding of ACh and other nicotinic agonists to endplate receptors causes the transient opening of ion channels across the muscle membrane. Channels opened by different agonists close at different rates. We have determined channel closing rates for two groups of trimethylammonium (TMA) derivatives. Synaptic regions of frog sartorius muscle fibers were voltage clamped. The agonists were applied electrophoretically or added to the bath. Channel closing rates were determined either from the decay times of membrane current relaxations in reponse to voltage jumps, or from spectral analyses of current noise. The first group of agonists include methyl (Me), ethyl (Et), pentyl (Pe), benzyl (Bz) and allyl (Al) TMA. MeTMA and EtTMA open channels which close at 3-4 times the rate of ACh channels. These compounds do not appear to act as channel blockers; conductance and voltage dependence of their channels are similar to those of ACh, and current relaxations were single exponentials with decay rates independent of the mean increase in current. PeTMA, BzTMA and AlTMA appear to both open and block channels; current relaxations show a rapid outward component followed by a slow inward one, while noise analyses yield conductance and voltage dependence estimates significantly lower than for ACh. The second group of agonists include carbachol (CCh), acetylthiocholine (AtCh), 4-ketopentylTMA (4kPeTMA), and cholinethiol (Chth). In agreement with previous results we find that CCh and AtCh, as MeTMA and EtTMA, open channels which close 3-4 times faster than those of ACh without acting as channel blockers. 4kPeTMA opens channels which close at similar rates as those of ACh but also can act as a channel blocker. The apparent channel closing rate for Chth is similar to that of MeTMA but in voltage jump experiments there is an additional slow outward component which reverses slowly if at all. These results suggest that both the ester group of ACh and the ketone group of4kPeTMA slow the channel closing rate (relative to MeTMA). In addition, the ester group prevents ACh from blocking endplate channels. Thus, the ester moeity plays an important role in determining the action of the natural transmitter. (USPHS NS-07464,NS-14938, & MDA)

270.13 MODULATION OF TRANSMITTER RELEASE BY ISOLATED RETZIUS CELLS IN CULTURE. J.G. Nicholls, P.A. Fuchs and L.P. Henderson. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Chemical transmission develops between individual Retzius cells and P sensory neurons dissected from the CNS of the leech and maintained in culture. These connexions have been observed as early as 3 days, although the majority of the recordings were obtained from cell pairs which were 10 to 21 days old. Impulses in the Retzius cell evoke hyperpolarizing potentials in the P cell that can be reversed by hyperpolarization or intracellular injection of Cl. The synaptic potentials are blocked by raised levels of Mg and enhanced by high Ca in the culture medium. Both facilitation and depression occur depending on the frequency of firing. In addition, steady depolarization without impulse production in the Retzius cell can evoke synaptic potentials in the P cell. As at other synapses studied in the leech, Aplysia, squid and elsewhere, the synaptic potentials are markedly influenced by a) alterations in the amplitude of the presynaptic impulse and b) the steady value of the membrane potential from which the action potential arises: thus, hyperpolarization of the Retzius cell from -50 to -70 mV, produces a three-fold reduction in the size of the synaptic potential evoked by an action potential.

Preparations consisting of two identified cells in culture, with their somas in close contact, offer certain advantages for analyzing in detail membrane properties and release characteristics of presynaptic terminals.

271.1 LOCAL AND DISTANT DENERVATION AND REINNERVATION INDUCED CHANGES IN ACHE ACTIVITY OF FAST AND SLOW MUSCLES. K. E. Misulis* and W-D. Dettbarn. Dept. of Pharmacology and Jerry Lewis Neuromuscular Ctr., Vanderbilt Univ., Nashville, TN 37212.

With denervation and subsequent reinnervation of skeletal muscle there are changes in the activities of enzymes associated with neuromuscular transmission. The best studied changes are the loss of AChE activity in muscles of rat after denervation. While in reinnervated extensor digitorum longus (EDL) recovery of AChE exhibited a slow rise to control levels over 5 weeks, AChE recovery in the slow soleus (SOL) was characterized by a rapidly developing overshoot to over 200% of control levels during the initial 3 weeks of reinnervation, with a decay to normal in over 5 weeks. Since these changes were observed following crush of the sciatic nerve at the mid-thigh level, reinnervation of the slow SOL by "fast" nerve fibers may have been responsible for the recovery discrepancy. Fast muscles such as the EDL, as well as its nerve, have higher AChE activity than the slow SOL and the nerve fibers innervating it.

To examine this possibility we have denervated the SOL and EDL muscles of the rat 2 mm before the entrance of the innervating nerves into the muscles. This allowed for no reinnervation by nerve fibers destined for other muscles. The results of these experiments showed the same patterns of AChE loss and recovery observed for the EDL and SOL with high sciatic crush. That is, in the soleus there was the same overshoot of AChE activity to over 200% of control.

Since the rat SOL has a small population of fast fibers (32%) the overshoot could have been due to the effects of initial reinnervation by fast motor axons and sprouting. Therefore experiments were repeated using guinea pigs, which have exclusively slow fibers in SOL. In these experiments, as well, there was a similar overshoot of AChE activity in SOL but not in EDL.

The results of these experiments suggest that during the early phase of reinnervation the SOL reverts to a fast muscle type, and only with full functional activity develops the biochemical characteristics of a mature SOL. This is supported histologically by a reversible increase in the number of type II fibers high in ATPase activity during denervation and beginning reinnervation in the SOL.

CHANGE IN ACHE WITH DENERVATION AND REINNERVATION

AChE as % of control	1	2	3	4	5 weeks
Soleus	41	46	264	173	112
EDL	45	47	48	68	88

271.2 CONTRACTILE PROPERTIES OF OVERLOADED RAT FAST MUSCLE. R.R. Roy*, I.D. Meadows*, K.M. Baldwin*, and V.R. Edgerton (SPON: R. Zernicke). Dept. of Kinesiology, UCLA, L.A. CA 90024.

Chronic overload of a fast skeletal muscle by removing its synergists produces hypertrophy and marked changes in its metabolic and biochemical properties. The purpose of this study was to determine if these morphologic and biochemical alterations were associated with changes in its contractile properties. After bilateral removal of the soleus and gastrocnemius, adult female rats were maintained post-surgically for 12-14 weeks. In situ isometric and isotonic contractile properties of overloaded plantaris (OP), normal plantaris (NP), and normal soleus (NS) muscles were tested at 33 ± 1°C. OP muscles were 97% heavier than the NP muscles and produced 43% and 46% higher twitch (P_t) and tetanic (P_o) tensions, respectively. However, NP muscles produced more tension per cross sectional area than the OP muscles (26.2 ± 1.37 vs 1.27 ± N/cm², P 0.001). Isometric twitch time-to-peak tension (TPT) and half-relaxation time (½RT) were significantly longer in the OP muscles (36.4 ± .79 vs 32.5 ± .60 ms and 23.9 ± .83 vs 18.4 ± .84 msec respectively). Mean V_{max} (mm sec^{-1}/1000 sarcomeres) was 34.1 for the NP and 18.1 for the OP (P< 0.001, see Fig. 1). The degree of conversion toward a normal slow soleus of the maximum velocity of shortening (V_{max}) was 74% compared to only 19 and 14% for TPT and ½RT. In addition, OP muscles produced a higher proportion of Po at a given stimulation frequency than the NP muscles and showed less fatigue than NP after 1, 2, 3 and 4 min of repetitive stimulation. These data demonstrate that although the maximum tension of OP muscle can be markedly enchanced it may not be in proportion to the increase in muscle mass.

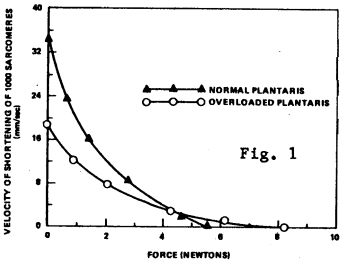

Fig. 1

271.3 DIRECT STIMULATION ACCELERATES SYNAPSE ELIMINATION IN NEONATAL RAT SOLEUS MUSCLE. W.J. Thompson, Department of Zoology, University of Texas, Austin, TX 78712.

Neonatal skeletal muscle fibers of the rat undergo a transient period of polyneuronal innervation before the adult state of single innervation is established at ca. 2 weeks of age. A number of reports have implicated use or disuse of the muscle and its nerve as an important determinant of the rate at which synapses are lost during this postnatal period (eg. O'Brien, et al., J. Physiol. 282:571). I have investigated the effects of chronic stimulation of the soleus muscle of neonatal rats.

Seven day old pups were taken from their mothers, placed in an incubator, and reared using an artifical diet delivered continuously through an intraoral cannula (Hall, Science 190:1313). Teflon insulated stainless steel wires were drawn underneath the skin and the uninsulated tips implanted into the muscles anterior and posterior to the right soleus. To avoid causing pain during stimulation, the spinal cords were transected at T11. Neither spinal transection nor artifical rearing produced alterations in the normal rate of synapse loss.

Stimuli were 1 msec, 4-6 mA pulses sufficient to produce ankle extension. When stimuli were presented in trains (1 sec duration, 100 Hz, 1 train/100 sec), within 2-3 days the stimulated muscle showed a reduction in ACh sensitivity, a markedly decreased twitch/tetanus ratio, an increased tetanic fusion frequency, and a decreased contraction time, all consistent with effective stimulation of the muscle. In addition, 50% of the muscle fibers were found to be singly innervated, a level of polyneuronal innervation found in animals 2-3 more days advanced in age. None of these changes were observed in the contralateral, unstimulated muscles. Almost all of the fibers in these control muscles were polyneuronally innervated. However, when stimuli were presented continuously at 1/sec (same # of stimuli as above), these changes were not observed in the stimulated muscles. Therefore, stimulation of the soleus muscle and its nerve accelerates synapse elimination and this acceleration shows a dependence on stimulation pattern similar to that for reduction of ACh sensitivity in denervated adult muscle (Lømo & Westgaard, J. Physiol. 252: 603).

271.4 QUANTITATIVE HISTOCHEMICAL CHANGES IN MOUSE CORTICAL BARRELS AFTER WHISKER CLIPPING AND WHISKER REGROWTH. W.D. Dietrich, D. Durham, O.H. Lowry, and T.A. Woolsey. Depts. Pharm., and Anat. and Neurobiol., Washington U. Sch. Med., St. Louis, MO 63110.

The large whiskers on the face of mice project to contralateral barrels in a one-to-one fashion. Last year at these meetings we demonstrated that enzyme activities could be determined quantitatively in individual barrels with the use of microchemical techniques. We also showed that, by selectively damaging whisker follicles, the levels of enzymes in corresponding barrels could be significantly altered and could be followed as a function of time after whisker damage (Dietrich et al., '81, J. Neuroscience). For instance, 115 days after whisker damage, citrate synthase and malate dehydrogenase activity decreased to 65% and 70% of controls respectively, while glycogen phosphorylase increased to 132% of control. We interpret these changes as a metabolic plasticity in response to reduced activity in this central pathway after damage to peripheral afferents.

The present study was undertaken to see if similar enzymatic changes could be observed after removal of whisker hairs without damage to the neural sensory periphery. Further, we were interested in whether enzymatic changes, if any, could be reversed by reversing the deprivation, i.e. letting the whisker hairs grow back. Results are taken from a number of adult and newborn mice; and in each case, the whiskers of one side of the face were clipped every other day for 60 days with the use of a dissecting microscope. At this point, some animals were sacrificed, and in others the whiskers were allowed to grow back. Individual barrels were analyzed in hemispheres opposite clipped whiskers, with samples in opposite hemispheres serving as controls. In adult animals, sensory deprivation resulted in changes in enzyme levels of citrate synthase, malate dehydrogenase and glycogen phosphorylase, which when expressed as % of controls, were 67%, 75% and 133%, respectively. These changes were similar to those observed following peripheral sensory damage, indicating that sensory deprivation is sufficient to produce a metabolic plasticity. Animals in which whiskers were allowed to grow back had identical values for the enzyme citrate synthase in control and experimental barrels. The time course of the restoration of enzymatic levels is apparently faster than the changes observed during the deprivation.

271.5 EFFECTS OF CHRONIC PARTIAL SENSORY DEPRIVATION: A (^{14}C)-DEOXY-GLUCOSE STUDY OF THE VIBRISSA-BARREL SYSTEM IN THE ADULT RAT. P.J. Hand and C.L. Hand* Department of Animal Biology, School of Veterinary Medicine and Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, PA 19104.

Stimulation of mystacial vibrissa #3 of row C (C3) coupled with a (^{14}C)-deoxyglucose (2DG) injection produced candle-pin shaped metabolic labeling (vibrissal column C3) in layers I-VI of the contralateral first somatosensory barrel field (SI) of the adult rat (Hand et al., Neurosci. Abst.,'78). In subsequent adult studies, effects of vibrissae denervation (C3 whisker spared) on the "spared" C3 column was examined (Kossut et al., Neurosci. Abst.,'79). Though the labeled "spared" C3 column was similar in appearance to that of the control side, it was enlarged by 20% and local cerebral metabolic rates of glucose (LCMRG) reduced by 7% as measured in lamina IV. Lower layer V, however, exhibited an elevated LCMRG (18%). In addition, the activated region surrounding the C3 column was more extensive, particularly within layers I-IV.

In the present investigation the contribution of sensory disuse to the previously observed metabolic changes in the C3 vibrissal column following contralateral vibrissa follicle denervation was examined. All vibrissae excepting C3 were regularly clipped unilaterally for 3 months in 6 adult rats. The experiment consisted of an intravenous pulse injection of 50 uCi of 2DG followed by 45 minutes of precisely controlled rostro-caudal brush stroking (3-4 hz) of C3 vibrissa bilaterally (C3 stimulation on the unclipped side served as a control). LCMRG in layers I-VI were determined quantitatively. The spared C3 column was 27-51% larger (average 34%) than the control C3 column. The enlargement primarily involved neighboring barrels of row C and produced a less sharply delineated columnar image than that of the control side. Thionin stained sections revealed no enlargement of the C3 barrel itself. LCMRG in all six laminae were 11% less than those of the control C3 column. 2DG labeling in barrel rows B and D, immediately surrounding the spared C3 column, was 12% less than on the normal side. In conclusion, chronic, partial somatosensory disuse has produced alterations of 2DG labeling in a spared C3 vibrissal-barrel column in contralateral SI of the adult rat. The compensatory metabolic alterations produced by partial sensory disuse, though differing in detail, resemble functional changes resulting from partial vibrissa denervations in adult rats. Thus neocortical effects of denervations in this adult sensory system are primarily due to sensory disuse and not disruption of a trophic effect of receptor integrity as with neonatal vibrissa follicle ablations (Kossut et al., '79). (Supported by USPHS grant NS-14935)

271.6 SENSORY DEPRIVATION AFFECTS MITRAL CELL SYNAPSES BUT NOT SIZE OR NUMBER. T.E. Benson and J.W. Hinds. Department of Anatomy, Boston University School of Medicine, Boston, MA 02118.

Unilateral neonatal naris cauterization results in a functional deprivation of the ipsilateral olfactory bulb (OB) and a smaller volume of its laminae (excepting the olfactory nerve layer and ventricular/subependymal zone) as compared with the non-deprived (ND) OB (Benson & Hinds '80 Neurosci. Abstr., 6:637). Meisami ('78 Prog. Brain Res. 48:225) has reported a 26% reduction in the number of mitral cells (MC) due to unilateral deprivation in 25 day old rats. For 30 day old CD-1 mice we have determined the number of MC's, their nuclear and soma size, the number of nucleoli per nucleus, and lateral olfactory tract cross sectional areas from deprived (D) and ND OB's in coronal 1 μm plastic sections. For soma areas electron micrographs were used as well.

We have found no differences between the D and ND sides in the number of MC's (37,606 D, 38,355 ND; n=4 mice; P=0.5824), MC nuclear radius (5.28 μm D, 5.26 μm ND; n=4; P=0.8311) MC soma cross sectional area (193 μm^2 D, 198 μm^2 ND; n=6; P=0.6160), the number of nucleoli per nucleus (1.05 D, 0.98 ND; n=4; P=0.1953), or lateral olfactory tract cross sectional area (0.152 mm^2 D, 0.163 mm^2 ND; n=6; P=0.2652). Our MC totals derive from raw counts of all MC nuclei which were then corrected by the Floderus equation. We have used plastic sections because in our experience the identification of small MC's in thick paraffin sections was unreliable. We identified MC's by cytological criteria such as a pale nucleus and patterns of Nissl substance and not by "the special miter shape" which Meisami required for counting. These different procedures may explain the different results.

In contrast to these results, our electron microscopic, stereological, blind analysis of MC associated soma synapses has shown a markedly lower number per surface area (N_S) for both MC to granule cell (GC) and GC to MC synapses on the D side. For MC-GC synapses N_S=0.0812 μm^{-2} D, 0.1255 μm^{-2} ND (n=4; P=0.0005). For GC-MC synapses N_S=0.049 μm^{-2} D, 0.104 μm^{-2} ND (P=0.0034). Since soma area was the same for the D and ND side, there must be fewer synapses per MC soma on the D side.

A chi-square analysis of the MC-GC/GC-MC ratios showed that the D side was higher, as would be expected at an earlier developmental stage (Hinds & Hinds '76 J.C.N. 169:15).

Thus the functional deprivation seems to affect MC and GC synapses but not MC soma size or the number of these prenatally generated cells. One could hypothesize, in light of no difference in the lateral olfactory tract size, that soma size chiefly reflects axon development, which may not be affected by the deprivation. (Supported by USPHS Research grant AG-00001.)

271.7 **EFFECTS OF DEAFFERENTATION ON SPINOCERVICAL TRACT NEURONS IN THE CAT.** **A.G. Brown*, P.B. Brown, R.E.W. Fyffe* and Lillian M. Pubols. Dept. of Vet. Physiol. Univ. of Edinburgh, Edinburgh EH9 1QH, U.K.**

In 9 cats the L_6 and L_7 dorsal roots of one side were sectioned extradurally central to the dorsal root ganglia, under pentobarbitone anesthesia with strict aseptic precautions. Between 27 and 75 days later, under chloralose anesthesia and paralysis with gallamine triethiodide, spinocervical tract (SCT) neurons were recorded, extracellularly and intracellularly. Neurons were injected with horseradish peroxidase (HRP) for subsequent histological examination.

The results were unequivocal and similar for each cat irrespective of the survival time following deafferentation. A variety of responses to cutaneous stimulation were observed in deafferented segments. 1. In 17 cells recorded intracellularly, 5 had no receptive fields, 4 responded with either e.p.s.p's or impulses to brusque tapping, 4 responded with e.p.s.p's to hair movement or sustained pressure to part or all of their receptive field and 4 responded with apparently normal impulse discharges to hair movement. 2. In 20 cells recorded extracellularly, 6 had no receptive fields, 4 responded only to tapping and 10 had apparently normal responses.

There were no alterations in the normal somatotopy of the dorsal horn. Of 15 SCT neurons injected with HRP, 11 had appropriately located fields; the remaining 4 cells had no responses. There were no obvious morphological differences between the 15 stained SCT cells and those in normal cats.

It is concluded that after deafferentation SCT neurons lose part or all of their afferent input and that within 75 days of dorsal root section do not show any signs of new or inappropriate connexions.

271.8 EFFECTS OF NEONATAL MONOCULAR ENUCLEATION ON PROJECTIONS FROM THE SUPERIOR COLLICULUS TO THE LATERAL POSTERIOR NUCLEUS IN THE RAT. Richard T. Robertson and Scott M. Thompson*. Department of Anatomy, College of Medicine, University of California, Irvine, CA 92717.

The effects of neonatal monocular enucleation on secondary visual projections were studied using the retrograde transport of horseradish peroxidase (HRP). Hooded rat pups were monocularly enucleated 1-2 days after birth. After reaching adult size, the enucleated animals and normal controls received unilateral or symmetrical bilateral injections of HRP in the lateral posterior nucleus (LP) of the thalamus. Following 2 day survival times, frozen sections were processed for HRP histochemistry, using benzidene dihydrochloride as the chromagen. Only injections that were confined to LP were considered.

All injections resulted in retrograde labelling of cells in the pretectum, superficial layers of the superior colliculus, and striate and peristriate cortices. The numbers of labelled cells were compared between each of three experimental groups: Injections ipsilateral to the enucleation, contralateral to the enucleation, and in normal control rats. Although the total number of labelled neurons resulting from a given injection varied with the size of the injection, the relative proportions of labelled cells within each of the afferent regions (pretectum/tectum/cortex) remained generally constant for different cases within each experimental group.

The major finding was that the number of labelled cells in the superior colliculus (measured as the ratio of tectal cells to cortical cells) resulting from injectionsin LP contralateral to the enucleated eye (i.e., the partially denervated tectum) was significantly smaller (Mann-Whitney U = 6; $p < 0.01$) than the number of labelled tectal cells following injections in LP ipsilateral to the enucleated eye and was significantly smaller than the number of labelled tectal cells in normal controls (U = 4; $p < 0.01$). In contrast, the number of retrogradely labelled neurons in the pretectum (measured as the ratio of pretectal cells to cortical cells) showed no significant differences between the three experimental groups.

These results suggest a dramatic reduction in the development or maintenance of tectothalamic neurons following early eye removal. In addition, partial denervation appears to exert a differential effect on pretectal and tectal projection neurons.

271.9 LATE SEGREGATION OF GENICULATE AFFERENTS TO THE CAT'S VISUAL CORTEX AFTER RECOVERY FROM BINOCULAR IMPULSE BLOCKADE. M.P. Stryker. Physiology, UCSF, San Francisco, CA 94143.

In the developing visual cortex of monkey (Hubel et al, Rakic, PRSB 278, 1977) and cat (LeVay et al, JCN 179, 1978), ocular dominance columns appear to form by a progressive segregation within layer IV of geniculate afferents serving the left and right eyes. In kittens younger than 2 weeks of age, physiological and several types of anatomical evidence suggest that afferents serving the two eyes make intermingled connections (LeVay &Stryker, Soc Neurosci Symp 4, 1979). By 6-8 weeks of age the segregation process appears from similar evidence to be complete or nearly so.

Last year at this meeting, I reported that blockade of all impulse discharge in the two optic nerves (by repeated intravitreal injections of tetrodotoxin) between 2 and 8 weeks of age prevents the segregation process. In such animals autoradiographic studies disclosed no periodic variation in labelling density within layer IV. Following brief recovery from the blockade, microelectrode recordings revealed nearly all cells within layer IV to be driven well by both eyes, suggesting that intermingled left and right eye afferents had maintained intermingled functional connections. In contrast to these effects of binocular impulse blockade, dark-rearing, binocular lid-suture, systemic infusion of TTX, or repeated intravitreal injections of vehicle solution all allowed the segregation process to occur.

The present study asked two questions. (1) At what time during normal development is the arrangement of the geniculocortical afferents no longer plastic? (2) If binocular impulse blockade is maintained up to this time, will the geniculocortical afferents then be able to segregate to form ocular dominance columns?

The first question was addressed by studying the effects of several months of monocular deprivation begun at progressively later ages. Deprivation beginning at or after 8 weeks of age produced no obvious effects on the cortical labelling pattern following injection of one eye, suggesting that the geniculocortical afferents were no longer plastic. To answer the second question, 5 cats were raised with binocular impulse blockade between 2 and approximately 8 weeks of age and were then allowed binocular visual experience for an additional 8-12 weeks. After this recovery period, microelectrode recordings revealed that many cortical neurons were monocularly driven, and autoradiography in every case showed apparently normal ocular dominance columns.

271.10 REORGANIZATION OF HAND REPRESENTATION WITHIN AREA 3b FOLLOWING DIGIT AMPUTATION IN OWL MONKEY. A. Schoppmann, R.J. Nelson, M.P. Stryker, M. Cynader, J. Zook, M.M. Merzenich. Coleman Lab and Physiology Dept, UCSF, San Francisco, CA 94143.

Earlier studies have revealed that after a zone of the Area 3b hand representation is deprived of its normal input by section of the median nerve, this zone is progressively and topographically reoccupied by other inputs. Immediately after nerve section, scattered responses from the dorsum of digits 1 and 2 are detectable in territory formerly responding only to the glabrous, now-denervated skin. After several weeks, this territory displays a complete and strictly topographic map of the digits' dorsum.

This study asked two questions: (1) Does reorganization of the cortical map occur when the rapidly-unmasked input from the dorsum is eliminated? (2) Does movement of a representation into a deprived zone of cortex require overlap of terminals?

Both questions were addressed by studying the reorganization resulting from amputation of digits. Amputation eliminates the easily unmasked input from the dorsum, and the cortical representations of the digits are, for the most part, discrete (that is, receptive fields of cortical neurons usually do not extend over the glabrous surfaces of adjacent digits except at the base). Digits 2 or 3 or both were amputated and the four digital nerve stumps ligated. Closely-spaced microelectrode maps (200-400 penetrations) of the Area 3b hand representation were made 2-5 months after, and in some cases before, amputation.

Adjacent glabrous digital and palmar surfaces completely occupied the former cortical representation of a single amputated digit. With amputation of two digits, occupation of the deprived zone of cortex was similar but usually incomplete. After reorganization, the deprived zone represented primarily the tips of adjacent, intact digits, and receptive fields were were commonly smaller than normal. Area 3b then contained a single orderly map of the remaining hand, suggesting that the representations of portions of the intact digits moved out of their normal territory into the deprived zone. Over much of the deprived zone, however, neurons were neither so strongly nor so unanimously driven as in normal cortex.

271.11 EFFECTS OF MONAURAL OCCLUSION ON CELL SIZES OF BRAINSTEM AUDITORY NEURONS: AN EVALUATION OF CRITICAL PERIOD OF DEVELOPMENT. Albert S. Feng and Barbara A. Rogowski, Dept. of Physiol. & Biophys., Univ. of IL, Urbana, IL 61801.

We have earlier examined the normal developmental pattern (Rogowski and Feng, 1981) and effects of aural occlusion on morphological development (Feng and Rogowski, 1980) of bipolar medial superior olivary (MSO) neurons in the rat. Those results indicate that left-right dendritic dominance of this bipolar neuron population was altered following early monaural occlusion, but not binaural occlusion in favor of dendrites receiving normal inputs. The effect was thought to be a result of selective increase of dendritic resorption since dendrites and soma size reached the peaks of development early in life (PND 8-14) when the occlusion was implemented. In the current study, the effects of aural occlusion on soma sizes of bipolar MSO neurons and, large spherical cells in the anterior ventral cochlear nucleus (AVCN) consisting of the primary source of ascending afferents to MSO neurons, at various stages of development were investigated.

The experimental animals, comprising several groups of rats with more than 10 animals per group, were monaurally (M) occluded at PND's 12, 30 and 60 with silicone rubber cement and sacrificed 48 days later. Additionally, another group of PND 12 animals were raised with binaural (B) occlusion. Cell area and diameter of brainstem auditory neurons were drawn from Nissl stained frozen sections and processed by a computer. It was found that in almost all PND 12 M animals tested, the large spherical cells in the AVCN of the occluded side had significantly smaller cell areas than their counterparts on the opposite side as shown also by others (Webster and Webster, 1979; Coleman and O'Connor, 1979). On the other hand there was no significant difference in the average cell areas or diameters of these cells on the two sides of PND 12 B animals. In other monaurally occluded groups, significant difference was found in all but one PND 30 animals, whereas for PND 60 animals all but two showed no significant difference between the means of cell areas of these AVCN cells on the two sides. Data from MSO were less clear cut and will be discussed subsequently. This research is supported by a N.I.H. grant NS-14488 and a Biomedical Research Support grant awarded to the University of Illinois.

271.12 PROGRESSIVE INCREASES IN ENVIRONMENTAL COMPLEXITY PRODUCE MONOTONIC CHANGES IN BRAIN AND BEHAVIOR. Michael J. Renner, Mark R. Rosenzweig, Edward L. Bennett and Marie Alberti*. Dept. Psych. and Melvin Calvin Lab., UC-Berkeley, Berkeley, CA 94720.

Considerable previous research has shown that rearing in different environmental conditions alters cerebral and behavioral measures. Little has been done, however, to examine directly the extent to which a set of environments of ordered complexity will produce similarly ordered brain and behavioral measures.

Male Berkeley S_1 rats (n=40) were placed at weaning into one of four conditions: "Superenriched" (SEC), three large cages (ea. 75 X 75 cm.) connected by tunnels, containing toys and a maze, changed daily, through which the rats had to run for access to food and water; Enriched, one large cage with a variable complement of toys; Grouped rats, housed together in a large empty cage; and Impoverished, wherein rats were housed individually in small cages. After maintainance in these conditions for 69 days, rats were pretrained and tested over 20 days on the Hebb-Williams problems and then sacrificed. The SEC rats were tested to insure equal treatment of groups, but their behavioral data were excluded from the analyses due to their prior maze experience.

Total cortical weight correlated positively with ordinal rearing complexity ($r=+0.55$; $p<0.05$ for all reported correlations), as did the weight of the ventral cortex, including hippocampus and amygdala ($r=+0.45$), and the dorsal cortex ($r=+0.44$). Neither somesthetic cortex nor the combined cerebellum and medulla were significantly different in weight between the rearing conditions. The numbers of repeated errors on the Hebb-Williams problems were negatively related to complexity of the rearing environment ($r=-0.46$), as were running times ($r=-0.42$).

Relationships between brain and behavioral measures were larger than had previously been reported. The weights of occipital cortex samples, while not significantly different between the rearing conditions, correlated significantly with repeated errors ($r=-0.43$). Dorsal cortex sample weight was also correlated with repeated errors ($r=-0.37$). Somesthetic cortex weights, which generally show the least response to environmental differences, were not significantly correlated with any behavioral measure.

A multiple linear regression equation, calculated using non-invasive measures (body weight, ordinal complexity of the rearing environment, and repeated errors), accounted for 37.2% of the variability in total weight of the cortex in these rats, giving moderate predictive power. These results indicate that even simple linear modeling of the influence of the environment on brain measures can have heuristic value. Replication and expansion of this study are in progress.

272.1 THE AUDITORY BRAINSTEM RESPONSE (ABR) IN SEVERAL VERTEBRATE CLASSES: A PHYSIOLOGICAL FACET OF BRAIN EVOLUTION.
Jeffrey T. Corwin, Theodore H. Bullock, and Jeff Schweitzer*. Dept. Neurosci., Sch. of Med., and Neurobiol. Unit, Scripps Inst. Oceanogr., U.C.S.D., La Jolla, CA 92093.

ABR's are short latency microvolt potentials evoked by acoustic stimuli and recordable with remote electrodes and averaging. ABR's have been recorded in several mammalian species and are in wide clinical use. Yet virtually nothing has been known concerning far-field acoustic potentials in nonmammals.

Here we report on far-field ABR's recorded in eight species representing five of the six extant classes of nonmammalian vertebrates. ABR's were averaged from wire electrodes contacting cerebrospinal fluid near the medulla and telencephalon in rays, gars, surfperches, leopard frogs, clawed toads, painted turtles, ring doves, and adelie penguins. Like mammalian ABR's these appear at short latency as a series of sharp peaks followed by slow waves. This suggests that a substantial fraction of acoustic neurons remain well synchronized at brainstem levels in a range of species from fish to man. ABR's are similar for individuals within a species, but appear to differ between some classes. The bird's response most closely resembles the mammalian ABR, with at least five peaks in 10 ms. The elasmobranch's least resembles the mammal's, with only two peaks in 20 ms.

ABR's from a given species appear to have certain all or none features independent of the stimulus over ranges of intensity, frequency, rise time, and repetition rate. However, latency changes with these parameters, and both form and latency change when the brain is heated or cooled.

In correspondence with mammalian studies our manipulations of recording geometry, comparisons with microelectrode recordings, and transections of the brain indicate that the early peaks originate in the periphery, the middle peaks in the hindbrain, and the latest initial peaks in the midbrain or higher. Therefore, the different number of peaks in ABR's suggest physiological differences in ascending pathway complexity. These differences, together with the uniformity of ABR's reported for diverse mammals (Ridgway et al. P.N.A.S. in press), suggest that ABR's may reflect the broad characteristics of taxa higher than orders and not the specializations of individual species.

ABR's have been used here to evaluate auditory thresholds, dynamic ranges, frequency tuning, and phase sensitivity. In some cases we have recorded with surface electrodes; in several using chronic electrodes in awake animals. The technique is relatively simple and appears particularly promising for other neuroethological studies.

272.2 THE MAUTHNER CELL IS NOT THE ONLY NEURON THAT CAN INITIATE C-TYPE FAST-STARTS IN ADULT GOLDFISH.
R. C. Eaton, W. A. Lavender* & C. M. Wieland*. Dept. Biol., E.P.O., Univ. Colorado, Boulder, 80309

Goldfish Mauthner (M-) cells are a pair of large, identified reticulospinal neurons found at the level of the ear in the hindbrain. M-cells receive a major afferent input from the auditory system. Each M-axon crosses the midline and synapses on motoneurons innervating the contralateral trunk musculature.

Recent evidence shows a strict, one-to-one, correlation between firing of the M-cell and the onset of C-type fast-start, or "startle", responses following a sudden and unexpected stimulus.

Is the M-cell the only neuron that can initiate this behavior? To study this question, we electrolytically lesioned M-cells in adult goldfish by passing 7 μA for 20 s from a metal microelectrode penetrating the M-axon initial segment. For two animals, the lesioning electrode was chronically implanted at the site of the lesion and was used for recording to show that the M-cell did not recover. C-type fast-starts were elicited by dropping a 74-gm ball into an aquarium holding the fish. Responses were filmed at 500 frames/s.

The damaged M-cell did not fire during any behavioral responses. Responses initiated on the side contralateral to the lesioned M-cell (non-M responses) were not different in mechanical performance from those initiated contralateral to the intact cell. But, there was a significant increase in behavioral response latency associated with the non-M responses. The difference in means was 7 ms.

In two other animals, the M-cell was allowed to degenerate for one month after the lesion. A chronic electrode was then placed next to the intact M-cell, and M-initiated and non-M responses were compared. Again, no difference in performance was detected, and response latency for the non-M responses was significantly longer than for the M-initiated responses.

Responses in a fifth animal with both M-cells lesioned were also no different in mechanical performance from putative M-initiated responses seen in a control fish with a single M-cell lesion.

We conclude that the M-spike is causally related to the onset of C-type fast-starts but that the M-cell is not necessary for this behavior in goldfish. Because non-M C-starts were seen within a few hours after the M-cell lesion, we conclude that the non-M responses were not triggered by new neural circuits arising from loss of the M-cell. Such responses might be triggered by other reticulospinal neurons.

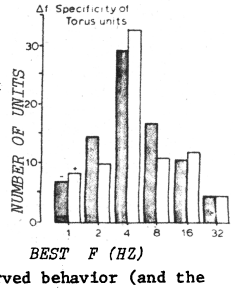
272.3 MAUTHNER FIBER REFLEX: DESENDING ACTIVITY MEDIATES "HABITUATION" OF THE RESPONSE TO MAUTHNER FIBER STIMULATION.
M.V.L. Bennett and J.W. Day, (Spon.: A.L. Harris), Div. of Cellular Neurobiology, Dept. of Neuroscience, Albert Einstein Col. of Med., Bx, N.Y.

As earlier reported, the tail flip response to intracellular stimulation of the Mauthner fibers (Mf) is depressed by repetition at 1/2 sec(Aljure et al., Brain Res. 188: 261, 1980). This depression is side specific for axial musculature, but bilateral for the pectoral fins. Since the two Mf's activate pectoral motoneurons via common interneurons transmitting electrotonically and responses of the interneurons are not depressed at these frequencies of stimulation, postsynaptic inhibition is implicated as responsible for the depression. Furthermore, paired stimulation which produces no response of axial musculature because of crossed inhibition in the spinal cord still leads to depresstion of the responses to either Mf. In deteriorated animals the depression can become greatly reduced, again implying an active process rather than fatigue or reduced effectiveness of transmission at an excitatory synapse.

It is possible to externally record Mf impulses from the caudal peduncle where they have an amplitude of about 0.1mV. The Mf, which are apparently the lowest threshold elements in the spinal cord, can then be specifically stimulated with external electrodes adjacent to the anterior spinal cord. Depression of responses to Mf stimulation has been studied in this manner and is the same as that observed with intracellular stimulation. Following high spinal section responses to Mf stimulation are absent for about ½ hour and then recover. At this point they are no longer depressed by stimulation at the lower frequencies that previously blocked them completely. The effect of spinal section confirms that desending activity, presumably inhibitory, is responsible for the depression of responses to repeated Mf stimulation. The underlying circuitry may operate in behavioral habituation or allow the animal to control the amplitude of the tail flip response in spite of the all-or-none nature of the desending command signal.

272.4 NEURONAL BASIS OF A SENSORY FILTER IN THE JAMMING AVOIDANCE RESPONSE:NO GRANDMOTHER CELLS IN SIGHT.
B.L. Partridge, W.F. Heiligenberg, J.A. Matsubara. Scripps Institution of Oceanography, La Jolla, CA. 92093.

The Jamming Avoidance Response (JAR), during which weakly electric fish modulate their electric organ discharge rate in response to an electric signal of nearly the same frequency is strongest for frequency differences (Δfs) between 3-8 Hz. We have searched for neural correlates of this behavioral specificity. Single unit recordings in the anterior lateral line ganglion (ALLG), the posterior lateral line lobe (PLLL) and the torus semicircularis (TS) of Eigenmannia virescens were made during electrical stimulation simulating jamming by a nearby conspecific.



Contrary to previously published reports (Scheich, 1974, 1977) we conclude that Δf specificity does not lie in a single class of receptors or higher-order units in the PLLL tuned to the most effective Δfs. No tuning is seen at the receptor level of the PLLL. Specificity seems to be a population effect first visible at the level of the torus semicircularis, with individual units responding most strongly to different Δfs, but with most units tuned to approximately + and -4Hz. By having cells tuned to a variety of Δfs but occuring in proportions corresponding to the observed behavior (and the degree to which Δfs impair electrolocation), animals would be better equipped to carry out other tasks such as detection of relative motion of objects in space and would also be better able to "read" complex stimuli corresponding to the more usual case of simultaneous jamming from several Conspecifics.

Two classes of TS units (the first described previously by Bastian and Heiligenberg, 1980) were observed which showed differential patterns of firing for positive and negative Δfs. These TS units, unlike their counterparts in the PLLL show different patterns of firing as a function of stimulus field geometry (eg. transverse or oblique to the body axis of the fish). Predictions these findings make about the wiring of TS units with respect to units in the PLLL are supported by preliminary efforts to localize the complex receptive fields of these units.

272.5 LABELLING OF FUNCTIONALLY IDENTIFIED NEURONS IN ELECTRIC FISH BY INTRACELLULAR INJECTION OF HRP. W.Heiligenberg and J.Dye * Neurobiology Unit, Scripps Institution of Oceanography and Department of Neurosciences, University of California at San Diego, La Jolla, Cal. 92093

Electric fish show a number of relatively simple natural behavioral responses which remain intact in neurophysiological preparations of the central nervous system. This greatly facilitates identifying the role of certain types of neurons in the control of these behaviors. In the particular case of the Jamming Avoidance Response (JAR) of the genus Eigenmannia, it has been demonstrated that this behavior is driven by specific modulations in amplitude and phase of electroreceptive afferences from different parts of the body surface. These two stimulus variables, amplitude and phase, are encoded by so called P- and T-type electroreceptors respectively. Primary afferents from these receptors project, in a somatotopic manner, to a laminated structure in the posterior lateral line lobe (PLLL) of the hind brain. Amplitude information and phase information are relayed to different classes of neurons which are located in separate layers of the PLLL.

By means of iontophoretic injection of HRP, we have labelled single primary afferents from electroreceptors. These units could be identified as being of the P- or T-type respectively, and the location of their receptor pore on the body surface was determined by applying localized electric stimuli via a small dipole. After survival of 2 to 4 hours, animals were perfused, their brains sectioned, and the sections processed by the Hanker-Yates reaction (as modified by Thomas Finger). In most instances, processes of primary afferents could be traced to their termination in the PLLL. The units were found generally to project to 3 different sites , with the most anterior termination in the lateral region of the PLLL, and with posterior terminations of the same unit in 2 distinct areas of the central region of the PLLL. Present data indicate the possible existence of 3 separate somatotopic maps in the PLLL. Their behavioral significance will be discussed.

272.6 SPAWNING IN GOLDFISH: PERIPHERAL AND SPINAL MECHANISMS OF SPERM RELEASE. L.S. Demski, J.G. Dulka* and P.J. Hornby*. School of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506.

Experiments have been performed on goldfish (anesthetized in 2% urethane and then immobilized by 1.5 mg/kg of d-tubocurarine) in order to identify the motor system mediating sperm release (SR) evoked by electrical stimulation of the CNS (see Demski, Soc. Neurosci. Abstract 285, 1978). Several possible mechanisms have been ruled out as being of primary importance for SR. Control by a striated muscle urogenital sphincter (innervated by spinal nerves) is unlikely since SR can be elicited following paralyzing doses of d-tubocurarine and removal of all but the rostral 4 to 6 segments of the spinal cord. Mediation of SR by increased intra-abdominal pressure is also unlikely since the response persisted following the removal of large areas of the abdominal cavity wall and deflation of the gas bladder. In addition, intra-abdominal pressure increases could not be measured during evoked SR. A pressure gauge system sensitive to 1 cm or less of water was used. Pituitary and urophyseal hormones were also eliminated from consideration because SR was readily elicited after removal of these glands. In contrast, electrical stimulation in the vicinity of the sperm ducts (SD) does result in evoked SR and anatomical observations indicate that the SD has considerable smooth muscle interspersed between numerous ductules. Thus, contraction of the SD appears to be the primary motor mechanism controlling SR. SR was also evoked by IP injection of 10^{-2} M acetylcholine in the vicinity of the SD and this response was blocked by similar injection of 10^{-4} M atropine. SR evoked from the brain was also blocked by atropine injections (10^{-4} and 10^{-5} M). The results strongly suggest that SR is controlled by a muscarinic-cholinergic system. Spinal cord transection experiments revealed a critical area for SR in the rostral cord (segments 4-6 in a 16.5 cm fish-SL). SR could be evoked from the brain only when this area remained connected with the medulla and stimulation of isolated pieces of cord in only this area resulted in SR. SR in response to electrical stimulation of the subvertebral area following its isolation from surrounding structures and removal of the spinal cord indicates that the motor pathway descends from the rostral cord in a subvertebral position (near the midline) to the level of the caudal extent of the body cavity where it turns ventrally to reach the area of the SD. This subvertebral position is coincident with the location of the sympathetic trunks and it can be suggested that the SR is mediated by this automonic system. Supported in part by the Biomedical Research Support Grant RR 07114-09.

272.7 NEURAL CONTROL OF CHROMATOPHORES USED AS A SOCIAL SIGNAL. L. E. Muske*and R. D. Fernald (SPON R. F. Lane). Inst. of Neurosci., Univ. of Ore., Eugene, Ore. 97403.

Haplochromis burtoni, a colonial cichlid fish, relies on visual signals during social interactions. Important cues are provided by the dermal chromatophores, which produce color patterns characteristic of an individual's sex and social status. Territorial males have a distinctive dark vertical bar extending from the eye to the corner of the mouth, which can appear and disappear quickly, independently of the other markings. In some adult males the vertical eyebar is completely absent, although other territorial colors and behaviors are identical to barred animals. There are no intermediate morphs. The eyebar influences aggressive behavior in other males (C. Y. Leong, Z. Vergl. Physiol. 65: 29, 1969). Thus, the existence of barless morphs raises interesting questions about the function of this signal and about the mechanism by which it is controlled. This study was undertaken to investigate whether peripheral structures or mechanisms could be found to account for barred/barless polymorphism.

Histological examinations of eyebar pigment cells show distinct differences between the two morphs. Barless males have a lower density of melanophores. Only barred males have a dense network of irridescent pigment cells underneath the melanophores, which account for the intense, velvet-like blackness distinguishing the eyebar from other black stripes.

A small nerve containing post-ganglionic sympathetic fibers branches off from the maxillary (Vth cranial) nerve to innervate eyebar pigment cells. The effects of unilateral lesions of this nerve were assessed by comparing lesioned and intact eyebars in normally behaving animals. In barred males, the two sides are identical. In barless males, there is an "eyebar" on the lesioned side only, which is much less intense than a normal bar. Neither morph is able to turn "off" the eyebar thus produced.

Monopolar or biphasic stimulation of nerves controlling facial chromatophores produced rapid melanophore pigment aggregation (paling) in locations consistent with the lesion studies. Threshold curves reveal no differences in response, either between barred and barless males or between eyebar and other head melanophores, indicating that differential control of the eyebar is mediated at a site central to the chromatic-motor nerve.

This evidence that the eyebar contains unique pigment cells and is neurally controlled by the CNS supports behavioral observations that the eyebar is an important element in the repertoire of social signals. Supported by NIH 5T32 GM07257.

272.8 VISUAL FIELD AND RETINAL PROJECTIONS IN THE AFRICAN CICHLID FISH, HAPLOCHROMIS BURTONI. Russell D. Fernald*. Institute of Neuroscience, University of Oregon, Eugene, Oregon 97403.

The African cichlid fish, Haplochromis burtoni, has a highly evolved social system in which behavioral interactions are mediated by bright chromatic and spatial patterns on the fishes' bodies. The temporal margin of the retinal contains cell densities 2-4 times greater than other retinal regions for all retinal cell types except rods. To understand how this retinal specialization might affect visual performance, the size of the visual field has been analyzed.

To determine the extent of the visual field, a surveyor's transit was modified allowing rotation of a fish about the center of the lens. By rotating around two orthogonal axes, the limits of the visual space could be measured along equidistant meridians around the margin of the eye.

The visual field is eccentric in shape towards the nasal pole. The long axis of eccentricity coincides with the nasotemporal axis of the eye. This nasal extension of the visual field results in considerable binocular visual space in front of the animal. The visual field extent remains approximately constant as the animal grows larger, even though the eye increases greatly in size. The relationship of the visual field to the retinal field has been examined and correspondence demonstrated. The implications of the eccentric visual field for central neural connections will be discussed.

(Supported by USPH grant EY-02284.)

272.9 VISUAL AND ELECTROSENSORY RESPONSES IN THE OPTIC TECTUM OF A WEAKLY ELECTRIC FISH. J. Bastian. Dept. of Zool., Univ. of Okla., Norman, OK 73019.

Single unit responses were recorded from the optic tectum of the electric fish Apteronotus albifrons. Many of the cells encountered could be driven by visual as well as electrosensory stimulation. Simple visual stimuli, such as strobe flashes, were usually effective however simple electrical stimuli, such as amplitude modulation (AM) of the animal's electric organ discharge (EOD), which affect the entire fish simultaneously were usually ineffective. The majority of the cells were sensitive to more natural electrical stimuli such as small conducting or non-conducting objects moving within a few cm of the fish. Such objects evoke responses when the animal is in total darkness eliminating the possibility of visual stimulation. The responses changed form or even disappeared when identically shaped non-conducting objects were substituted for conductors. This eliminates the possibility that mechanoreceptive inputs are solely responsible for the responses since the mechanical effects are independent of object conductivity. These cells frequently had no spontaneous activity, responses occurred only when the stimulus moved through the cell's receptive field. Changing object conductivity usually shifted the position of this response relative to the fish. Responses were also influenced by movement direction. In the extreme cases movement opposite the most effective direction produced no response.

The stimulus objects contained a small light source and could provide a visual as well as electrosensory stimulus. The size of the visual stimulus was large, about 23^{o} of visual angle, and was usually moved 1 cm lateral to the fish. Simultaneous visual and electrosensory stimulation usually changed the intensity or the area over which a response occurred compared to electrical stimulation alone. Diffuse illumination of the animal's eyes, in a way that did not allow the fish to see the moving object, also altered the responses but in a different fashion.

The electrosensory response of most of the tectal cells seen was sensitive to jamming. A 4 Hz continuous AM of the animal's EOD, 2 mV/cm in amplitude, was applied to the fish while objects were moved as before. This jamming stimulus reduced the response to moving objects without visual input by as much as 50% of the normal value. These cells gave no response to the jamming stimulus alone. Addition of the moving visual stimulus frequently restored the jammed response to near normal values. The opposite effect was also seen, in some cases the addition of the visual stimulus further reduced the electrosensory response in the presence of jamming.

272.10 SIGNIFICANT DIFFERENCES IN VOLUME OF SONG CONTROL NUCLEI IS ASSOCIATED WITH VARIANCE IN SONG REPERTOIRE IN A FREE RANGING SONG BIRD. R. Canady*, D. Kroodsma*, and F. Nottebohm (Spon: D.R. Griffin). Rockefeller U., N.Y., NY 10021,and Dept. of Zool., U. of Mass., Amherst, MA 01003.

In the adult canary a positive correlation exists between the number of songs an individual produces (repertoire) and the volume of two telencephalic nuclei known to be involved in song production; hyperstriatum ventrale, pars caudale (HVc) and nucleus robustus archistriatalis (RA)(Nottebohm et al, Br. Res. in press). In an effort to determine how general this phenomenon may be and to look at a possible extreme example of it, a free ranging species of song bird with marked repertoire variance was studied.

The Long Billed Marsh Wren (Cistothorus palustris) is a species in which song repertoire size occurs as a seemingly continuous cline, increasing east to west, across North America. Populations on the west coast have repertoires that average 2-3 times that of those on the east coast with little or no overlap in distribution. An eastern population located on the Hudson river near Tivoli, New York and a western population located in the Grisely Island national park near San Fransisco, California, both with males in full song and at very similar stages in breeding cycle, were analyzed with respect to repertoire size and the volume of 4 well defined, discrete brain nuclei; HVc, RA, nucleus rotundus, (Rot), and spiriformis medialis (SpM). SpM and Rot are not involved in song production and were used as controls.

For confirmation of the west-east repertoire difference up to 600 songs were recorded from each of 7 western males and 15 eastern males. Recorded and unrecorded males were captured, perfused with 10% formalin in 0.9% saline, the brains removed and processed for nuclei volume estimations (Nottebohm, op. cit.). 28 brains and 14 repertoire estimates are included in this report.

The samples differed in several respects. Western birds were slightly lighter (av. 5% $p<.01$) with brains showing a trend in the same direction (av. 4% $p<.1$). The control nuclei showed the same trend, in volume (Rot av. 12% $p<.01$, SpM NS). The difference in volume seen in Rot and the difference in weight seen in whole animal and brain were in the opposite direction of the repertoire size difference (west > east) and the difference in volume of HVc and RA. HVc and RA were 33% ($p<.01$) and 37% ($p<.01$) larger, respectively, in the western population than in the eastern population. Correcting for brain wt. differences by dividing each HVc by its control nuclei gives a west-east difference of 50% (west > east, $p<.001$).

To our knowledge this is the first demonstration of a difference in brain nucleus volume associated with a behavioral variable within a species of free ranging song bird.

272.11 A NEURAL MECHANISM FOR ECHO-DETECTION AND ECHO-RANGING IN FM BATS. S.A. Kick* (SPON: J. Simmons). Institute of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

The threshold for the detection of echoes by the sonar receiver of Eptesicus fuscus corresponds to the distance at which a sonar target returns an echo sound-pressure in the region of 0 dB SPL. Echo-detection at this low an amplitude is consistent with a neural mechanism for recognition of echoes that is organized around the temporal synchronization of neural discharges in auditory-nerve fibers. It is probable that weak echoes are initially represented in VIIIth nerve fibers by a cluster of spike activity associated with the echo's time-of-occurrence, as plotted in a pulse-echo inter-stimulus- interval (ISI) histogram. As echo amplitude increases above the detection threshold, the small peak of spike activity associated with the echo's time-of-occurrence in the ISI histogram would also increase, providing progressively better estimates of target range. On a neural level, the processes underlying echo-detection and the perception of target-range information must be closely intertwined. The representation of information about sonar echoes by the cross-correlation function between pairs of emissions and echoes, which has been shown to govern target-range perception by bats, is similar to the representation of nerve-spike timing by ISI histograms, suggesting that a single neural mechanism may be responsible for several aspects of the performance of echolocating bats.

272.12 PHYSIOLOGICAL AND BEHAVIORAL CHARACTERISTICS OF DENTATE GRANULE CELLS. G. Rose*, D. Diamond* and G. Lynch (SPON: J. Masserano). Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

The efferents of the granule cells of the dentate gyrus are generally considered to serve as the major pathway for information transfer into the hippocampal formation. Thus, knowledge of the conditions under which the granule cells are active should provide important clues as to the behavioral function(s) of the hippocampus itself. Sixty-three single neurons were recorded from the granule cell layer of 10 Sprague-Dawley albino rats which had been prepared for recording by cementing the base for a microdrive system to the skull overlying the dorsal hippocampus. A bipolar stimulating electrode was placed in either the entorhinal cortex or angular bundle to allow activation of the perforant path input to the hippocampus.

The neurons were divided into three classes using the duration of the extracellularly recorded action potential as the criterion. Durations of unfiltered action potentials were: Class I - 0.20-0.25 ms; Class II - 0.30-0.40 ms; Class III - 0.60-1.0 ms. Neurons of Classes I and II were always observed to fire single action potentials, while Class III cells fired both single and complex spikes. Fifty-two of the 63 cells (83%) recorded from the granule cell layer were identified as Class I neurons. Forty-six of these cells were orthodromically activated by perforant path stimulation at a mean latency of 3.4 ms (range 1.7-5.0 ms). Four Class II neurons were observed, 3 of which were activated by electrical stimulation of the perforant path. Seven Class III neurons were recorded, none of which could be discharged by perforant stimulation, even at high stimulus intensities.

Behavioral correlates for all neurons were observed during unstructured activity and while the animals acquired and performed a simple appetitive discrimination task. The most obvious behavioral correlate of Class I and Class II neurons was movement, although Class II neurons also showed increased firing under conditions of high arousal. Most Class III cells exhibited no obvious behavioral correlate, but three neurons had the characteristics of "place cells" as described by others. No new behavioral correlates for the neurons of any class were seen as a function of conditioning.

The principal conclusion from this work is that the majority of dentate granule cells are Class I neurons. These cells share the physiological and behavioral characteristics of the "theta" cells of Ranck (Exp. Neurol., 41: 462-531).

273.1 DEVELOPMENTAL INCREASE IN ADRENAL MESSENGER RNA CODING FOR PHENYLETHANOLAMINE-N-METHYLTRANSFERASE (PNMT) E.Sabban,* M. Goldstein, M.C. Bohn and I.B. Black, Neurochemistry Laboratories, Dept. of Psychiatry, N.Y.U. Med.Center New York, N.Y. 10016 and Dept. of Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

We have been studying expression and development of the adrenergic phenotype by following the ontogeny of PNMT, the epinephrine-forming enzyme. To determine whether the increase in PNMT catalytic activity during development of the rat adrenal is paralleled by comparable changes in mRNA coding for the enzyme, total poly(A) RNA was isolated from newborn and adult rat adrenals. Their translation was monitored in a cell-free system. Translation was assessed by measuring the incorporation of ^{35}S-methionine into total protein.

Pilot experiments measuring translation of bovine adrenal medullary poly(A) RNA demonstrated that translation was linear for 60 min. at 25°C. Optimal concentrations for Mg^{++} and K^{+} were 1.6 mM and 132 mM respectively, and RNA concentrations were defined for each experiment. The newly synthesized polypeptides were separated by gradient SDS gel electrophoresis and the dried gels were processed for fluorography and exposed to x-ray film. The amount of PNMT translated was estimated by indirect immunoprecipitation with rabbit anti-rat PNMT antiserum followed by SDS gel electrophoresis. Although total translational activity and the ^{35}S-polypeptide profiles were similar in neonate and adult, several polypeptides appeared greatly enriched in the translation of adult mRNA. Immunoprecipitation of equal amounts of ^{35}S-methionine - labelled translation products showed that the density of the PNMT band (MW = 38,000) was strikingly greater in adult than in neonate. Densitometer scans and scintillation counting of eluted bands revealed that there was at least a 10-fold increase in incorporation into PNMT translational product using mRNA from adult adrenal. Catalytic activity of PNMT per adrenal was approximately 40-fold higher in adult. These results suggest that the developmental increase in PNMT activity may be largely attributable to increases in specific mRNA. This work was supported by NIH grants NS 06400, NIMH 02717, NS 10259, HD 12108 and NS 06801.

273.2 BIOCHEMICAL DEVELOPMENT OF THE NUCLEUS LOCUS COERULEUS (l.c.) IN VIVO AND IN CULTURE. C.F. Dreyfus and I.B. Black. Div.of Developmental Neurology, Cornell University Medical College, New York, New York 10021.

Although extensive work is beginning to elucidate phenotypic expression and ontogeny in the peripheral nervous system, the molecular mechanisms underlying brain development are largely unknown. To approach this problem, we have initiated parallel in vivo and in vitro studies of the mouse l.c. The activity of tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine biosynthesis, was used to monitor development of this brain nucleus.

TH activity was initially detectable at 13 days of gestation (E13) and increased approximately 20 - fold by E-18, immediately prior to birth. From birth to adulthood TH activity increased an additional 10 - fold.

To determine whether comparable development can occur in vitro, explants of embryonic brainstem were placed in organotypic culture as previously described (Dreyfus et al., Brain Res. 161 '78, Dreyfus et al., Brain Res. 194 '80). Explantation of E-12 brainstems, initially devoid of TH activity,as measured by a sensitive catalytic assay,resulted in the de novo appearance of enzyme activity after approximately 1 week in culture. Activity subsequently increased approximately 5 - fold, reaching plateau values by 14 days in vitro, and persisting to at least 21 days. Explantation at E-18, after TH has already appeared, also resulted in an increase in activity, but 3 - week plateau values were significantly higher than those in E-12 explants. Our studies suggest that the development of discrete brain nuclei may be quantitatively monitored in vivo and in vitro. Moreover, it may be possible to define the factors governing initial phenotypic expression and development of specific transmitter phenotypic characters in central structures. (Supported by NIH grant NS 14990 and NSF grant BNS 80 - 24081).

273.4 IMMUNOCHEMICAL STUDIES OF PERIPHERAL NEUROGENESIS USING MONOCLONAL ANTIBODIES. G. Ciment*, G. Spady* and J. Weston*. (SPON: C. Kimmel). Dept. Biology, Univ. Oregon, Eugene, OR 97403.

The embryonic neural crest appears to segregate several distinct cell lineages during normal development. These lineages ultimately produce all peripheral nervous system neuronal and glial cells, as well as endocrine, paracrine, skeletal and pigment elements. In order to deduce the order of segregation of various lineages, and the intermediate cell types in each lineage, we have developed a battery of monoclonal antibodies which bind to antigens found on subpopulations of neurons within embryonic sensory ganglia. One such antibody (E/C8) is of a class that binds to the cell bodies and fibres of some neurons. Using direct and indirect immunoperoxidase staining methods with this antibody, we have examined cultures, tissue "squashes" and tissue sections containing various crest-derived cells. This antibody mediates staining of a subpopulation of cultured, apparently undifferentiated neural crest cells. In vivo, a subpopulation of cells in nascent (4 day) sensory ganglia and in 7 day sympathetic ganglia stains. The subcellular localization of staining indicates that the antigen is present on the initial segment of the neurite as well as a patch of the adjacent cell body. As development of the sensory ganglia proceeds (days 8 through 13), the amount of neuronal staining increases and becomes more extensive. In contrast, staining of sympathetic neurons becomes more restricted and eventually disappears from the soma altogether. Ultrastructural analyses of the staining patterns on the various crest-derived intermediate cell types should elucidate the role of such antigens in the normal development of peripheral neurons.

273.5 BIOCHEMICAL MATURATION OF EMBRYONIC DOPAMINE NEURONS IN AGGREGATING COCULTURES OF MURINE MESENCEPHALIC TEGMENTUM AND NEOSTRIATUM. Connie Kotake*, Philip Hoffmann*, and Alfred Heller. Dept. Pharmacol. & Physiol., Univ. of Chicago, Chicago, IL 60637.

Dopamine (DA) neurons from the rostral mesencephalic tegmentum (RMT) of embryonic mouse brain were dissociated and allowed to aggregate in vitro with dissociated cells from the neostriatum (NS). Dopamine cells of RMT form a dense axonal plexus only in the presence of target cells of NS (Hemmendinger et al., PNAS 78: 1264, 1981). This plexus is morphologically similar to that seen in vivo. In order to further characterize the differentiation of DA neurons in this system, we examined the development of a number of indices of dopaminergic function, including DA histofluorescence, tyrosine hydroxylase (TH) activity, endogenous DA content, DA accumulation and its sensitivity to either reserpine or 6-hydroxydopamine (6-HDA) in RMT-NS coaggregates cultured for 3-21 days. Fluorescent cell bodies and patches of punctate pericellular fluorescence due to endogenous DA were visualized by the Falck-Hillarp method in 14 day cultures. This pattern of fluorescence was more prominent in 21 day cultures and resembled that seen in intact mouse striatum. Fluorescence was not observed in 3 and 7 day cultures unless they were exposed to exogenous DA (1 μM; 10 min). The estimated Vmax of TH increased by 2-fold between 3 and 14 days in culture to 5.0 pmoles DOPA formed/min/mg protein and remained elevated in 21 day cultures (4.6 pmoles/min/mg protein). Endogenous DA in RMT-NS aggregates increased progressively from 0.56 ng/mg protein at 3 days to 22.6 ng/mg protein at 21 days. The accumulation and retention of exogenous DA (1 μM; 10 min) followed a developmental course similar to that observed for endogenous DA content. At 21 days in culture, the aggregates accumulated 80 ng DA/mg protein; 8-10 times greater than that found in 3 day cultures. Aggregates of various ages were exposed to reserpine (100 nM;24 hr). Such aggregates at 14 and 21 days accumulate 96% less exogenous DA than vehicle-treated aggregates. In younger cultures, reserpine was less effective, producing a 16% decline in DA accumulation in 3 day cultures, and a 48% decline in 7 day cultures. Aggregates cultured for 3,7,14, or 21 days and exposed to 6-HDA (10^{-4}M; 1 hr) exhibited reductions in DA accumulation of 21%, 52%, 92%, and 95%, respectively, 24 hr after 6-HDA exposure. These cultures, therefore, show age-dependent development of mechanisms for accumulation, synthesis and storage of DA. Thus, RMT-NS aggregates display characteristics of anatomical, biochemical and pharmacological development qualitatively similar to those seen in intact brain. This system provides a useful in vitro model for investigation of factors which influence the ontogeny of brain dopaminergic systems. (U.S. PHS MH 28942 and NS 10714)

273.6 GLOBOSIDE AS A POSSIBLE SURFACE MEMBRANE RECEPTOR FOR THE LECTIN SOYBEAN AGGLUTININ IN CULTURED SYMPATHETIC NEURONS. Anne Zurn* and Paul H. Patterson, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The type of transmitter produced by sympathetic neurons taken from neonatal rats and grown in dissociated cell culture can be experimentally controlled. If the neurons are depolarized or made active, they can be maintained in their original noradrenergic state. However, diffusible or surface-bound factors from heart cells can induce the neurons to become cholinergic. In addition to the difference in transmitter, neurons grown under these two conditions also display differences in their surface membranes. One method used to detect such a difference was an electron microscopic analysis of the binding of the lectin soy bean agglutinin (SBA) labeled with colloidal gold. The density of binding is five-fold higher on noradrenergic axons than on cholinergic axons (M. Schwab & S. Landis, Devel. Biol., in press).

Several methods are being employed to identify the molecule(s) acting as a receptor for SBA. When neuronal cultures are dissolved in SDS and run on SDS-PAGE, specific binding of ^{125}I-SBA was found only in an area just ahead of the dye front, which suggested the lectin was binding to lipids and not to proteins. When neuronal glycolipids were extracted, separated into neutral and acidic fractions, and electrophoresed in this system, only the neutral glycolipid fraction labeled specifically. To determine the molecule(s) to which SBA binds in living neurons, cultures were incubated with SBA for 30 min at 20°C and then treated with galactose oxidase and NaB^3H_4. After extraction and fractionation, the labeled lipids were analyzed by TLC. In the presence of SBA, the labeling of the neutral glycolipid, globoside (cer-Glc-Gal-Gal-GalNAc), was decreased by 50%. Maximal inhibition was seen with 100μg/ml SBA, while little inhibition occurred at 10μg/ml. Thus globoside may be a receptor for SBA in extracts and in living neurons.

To see whether there are any differences in the glycolipid composition of noradrenergic and cholinergic neurons, cultures were metabolically labeled with ^{3}H-galactose or surface-labeled with galactose oxidase and NaB^3H_4, extracted, and analyzed by TLC. Quantitative differences are seen in both the ganglioside and neutral glycolipid profiles of these two types of sympathetic neurons. The results of these preliminary lipid composition studies therefore support the suggestion generated by the SBA binding experiments that the glycolipids of cholinergic and noradrenergic neuronal membranes are different. (Supported by the NINCDS, the Rita Allen Foundation, and the Swiss National Fund).

273.7 PREDOMINANTLY CLEAR VESICLES OF CHOLINERGIC SYMPATHETIC NEURONS IN CULTURE BECOME DENSE-CORED FOLLOWING DEPOLARIZATION AND RELOADING WITH NOREPINEPHRINE: PRELIMINARY OBSERVATIONS. M.I. Johnson and D. Higgins*. Dept. Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Adrenergic sympathetic neurons of perinatal rats, under certain culture conditions, acquire cholinergic function, including choline acetyltransferase activity and hexamethonium sensitive synaptic interaction. Whereas early in culture the majority of the synaptic vesicles in the varicosities of these neurons are dense-cored, later, when cholinergic properties can be demonstrated, the vesicles are predominantly clear (Johnson, et al. Nature 262:308-310 1976; S. Landis PNAS 73:4220-4224 1976). The following study asked whether the vesicle population in these cholinergic sympathetic neurons is fixed or whether the vesicle population could be made to become dense-cored by depolarization and incubation in norepinephrine. Single or small numbers (3-7) of superior cervical ganglion neurons were grown in the absence of nonneuronal cells on small (1-2 mm) collagen islands under culture conditions promoting cholinergic function. At 2-3 weeks, electrophysiological methods were used to determine which neurons released acetylcholine; only those islands on which all neurons could be identified as cholinergic were used in the electron microscopic studies. Three treatment groups were used prior to $KMnO_4$ fixation. 1) NE (10 μm) with no choline 2) NE (10 μM) with 30 μM choline 3) K^+ (80 mM) followed by NE (10 μM) with no choline. The vesicles of those neurons treated with NE and either no or 30 μM choline were predominantly clear (94 and 87%). All varicosities had less than 30% dense-cored vesicles. In contrast the vesicles of the neurons depolarized with 80 mM K^+ and incubated in NE (no choline) were predominantly dense-cored (86%). All of the varicosities had >80% dense cores. The vesicle morphology of functionally cholinergic sympathetic neurons therefore can be dramatically altered by depolarization and reloading with exogenous NE. Further studies are directed at the questions: 1) is the population of vesicles involved in cholinergic transmission the same as those with dense cores following depolarization and incubation in NE and 2) can similar reloading occur via an endogenous pool of NE? (Supported by NIH Grants NS 14416 and NS 09809.)

273.8 DEVELOPMENT OF BENZODIAZEPINE AND GABA BINDING IN INBRED MICE: RELATION TO AUDIOGENIC SEIZURES. C. Kellogg and P. Syapin*. Dept. of Psychology, Univ. of Rochester, Rochester, NY 14627; Dept. of Neurology, Univ. of Southern Calif. Sch. of Med., Los Angeles, CA 90033.

Mice of the DBA/2J (DBA) strain have a genetically determined sensitivity to audiogenic seizures (AGS) showing maximal sensitivity around 21 days of age. The seizure response to high intensity sound dissipates with maturation and by 42 days of age the mice are no longer sensitive. Mice of the C57BL/6 (C57) strain are not AGS sensitive at any age. Considering the general inhibitory nature of GABA - containing neurons and the anticonvulsive effect of benzodiazepine compounds, the development of binding sites for these substances was evaluated in the two strains.

Benzodiazepine binding was studied at 21 and 42 days of age using ^{3}H-diazepam (DZ) as the ligand and was carried out using a well washed membrane fraction. Brains were dissected into 5 regions. Scatchard analysis using 6 concentrations of ^{3}H-DZ indicated no difference in the dissociation constant (KD) as a function of strain, age, or brain region (KD=8.11±.26nM). Maximal binding also did not vary as a function of strain or age. However, GABA stimulation of ^{3}H-DZ binding (2-2.4nM) differed between strains. At 21 days, the DBA mice demonstrated significantly greater stimulation than the C57 mice. By 42 days, due to an increase in GABA stimulation with age noted in the C57 mice, a significant strain difference was no longer apparent. Hence GABA stimulation of ^{3}H-DZ binding matures earlier in mice of the seizure sensitive strain and is adult-like during the period of maximal seizure sensitivity.

Analysis of GABA receptors has been initiated using ^{3}H-muscimol as ligand. Total binding has been evaluated in 5 brain regions from mice of both strains at 21, 28, 42, and 60 days of age using a ^{3}H-muscimol concentration of 10nM (with whole brain KD varying from 6.54 to 9.4nM). At 21 days of age, total binding is significantly greater in most brain regions of DBA mice as compared to the C57 strain. However, with maturation, total binding increased markedly in the C57 strain reaching, in some regions, levels considerably higher than in the DBA mice. In the DBA mice, the only region showing an increase in binding with age was the cerebellum. In the AGS mice, therefore, there appears to be an earlier maturation of certain aspects of GABA function, perhaps reflecting some compensatory response to a primary deficit responsible for inducing seizure sensitivity.

273.9 MONOAMINE OXIDASE ACTIVITY IN EARLY QUAIL EMBRYOS AND RAT NEURON CULTURES WITH DIFFERENT TRANSMITTER PHENOTYPES. J.E. Pintar*[1], G.D. Maxwell[2], K.J. Sweadner[3], P.H. Patterson[3], and X.O. Breakefield[1]. [1]Dept. Human Genetics, Yale Med. Sch., New Haven, CT 06510; [2]Dept. Anatomy, U. Conn. Health Center, Farmington, CT 06032; [3]Dept. Neurobiology, Harvard Med. Sch., Boston, MA 02115.

Monoamine oxidase (MAO) is primarily responsible for the degradation of catecholamines and other biogenic amines. Two types of MAO activity (MAO-A and MAO-B) are characterized by different substrate specificites and inhibitor sensitivities, and are mediated by molecules with different covalent structures. We have begun to examine the level, type, and functional significance of MAO activity in embryonic quail and in cultures of rat neurons with different phenotypes. Whole quail embryos (12 hours-4 days incubation; hatching at day 16) were isolated and MAO activity was determined against tryptamine, a common substrate for MAO A and MAO B activity. MAO activity was highest at the earliest stages examined (12-24 hrs incubation); these activity levels (>300 pmol/min/mg protein) are higher than many adult tissues and most cultured cell lines. By 2½ days incubation, MAO specific activity had decreased to 20% of the previous levels. Clorgyline concentrations that selectively inhibit MAO-A but not MAO-B were used to estimate the relative amounts of these two types of activity. At all stages examined, 20-50% MAO activity was retained under conditions that inhibit MAO-A. These results indicate not only that high MAO activity is present at early embryonic stages but also that both MAO A and B molecules are being synthesized. Daily clorgyline injections into eggs (on days 0-3 incubation; 10 μM clorgyline final concentration in ovo) inhibited >90% MAO-A activity, but not MAO-B, as determined by assays on day 4 embryos. This ability to inhibit MAO-A should make it feasible to establish the functional significance of this activity in early embryos.

To investigate the amount and type of MAO activity in specific neuronal cell types, neuron cultures that synthesize primarily either noradrenaline or acetylcholine were derived from newborn rat superior cervical ganglia and subsequently assayed for MAO activity. Levels of MAO-A activity in adrenergic populations were 5-fold higher than in cholinergic populations, while MAO-B activity levels were similar. These data support the ideas that high MAO A activity is associated with adrenergic neurons and that the expression of the adrenergic phenotype involves regulating both synthetic and degradative enzymes used in catecholamine metabolism.

Supported by NS12105 (XOB), NS16115 (GDM), and Basil O'Connor Starter Grant 5-289 from the March of Dimes (GDM).

273.10 ONTOGENY OF MONOAMINE METABOLITES IN BRAIN AND CEREBROSPINAL FLUID IN NORMAL AND 6-HYDROXYDOPAMINE TREATED RAT PUPS. B.A. Shaywitz, G.M. Anderson*, J.G. Young and D.J. Cohen*. Lab. Devel. Psychobiol. & Neurochem., Yale U. Sch. of Med, New Haven, CT 06510

Within the last decade, experiments in a number of laboratories have provided strong evidence to support the notion that the concentrations of monoamine metabolites in cerebrospinal fluid (CSF) may be utilized to assess the functional state of their parent monoamines within brain. However, both technical and ethical limitations in human studies have precluded careful examination of many of the assumptions about the relationship between both the CSF and brain concentrations of the metabolites as well as that between the metabolites and their parent amines in brain.

We utilized recently described assays (Anderson et al, J. Chromatog., 1980) and specially developed techniques for the collection of CSF from the cisterna magna of developing rat pups to examine the concentrations during the first month of postnatal life of homovanillic acid (HVA), 5-hydroxyindoleacetic acid (5-HIAA), tryptophan (TRP), and tyrosine (TYR) in CSF and dopamine (DA), serotonin (5-HT), and norepinephrine (NE) in brain in normal developing rat pups and littermates treated at 5 days of age with desmethylimipramine (DMI) and 6-hydroxydopamine (6-OHDA). Concentrations of all the parent monoamines increased by a factor of two between 12 and 26 days in normal pups. In 6-OHDA pups, DA was reduced immediately and remained at low levels throughout, averaging 21.5% of controls at 26 days. NE and 5HT were not significantly affected by the DMI/6-OHDA regimen. Brain concentrations of HVA were highest at 12 days then declined, while 5-HIAA and TRP remained stable at 12, 19, and 22 days in both normal and treated pups. CSF HVA declined between 19 and 26 days in normal pups while 5-HIAA and TRP remained stable. Pups treated with DMI/6-OHDA as neonates exhibited a significant reduction in CSF HVA to concentrations 30% of controls at 19 and 26 days ($p<.001$), but no change was observed for 5-HIAA or TRP. As expected, significant correlations emerged for CSF HVA-brain DA ($r=.65$, $p<.02$) and for brain HVA-DA ($r=.76$, $p<.001$), as well as for CSF HVA-5-HIAA ($r=.65$, $p<.01$), but surprisingly there were no significant correlations between CSF 5-HIAA and either brain 5HT or 5-HIAA nor did we observe any relationship between CSF TRP and 5-HIAA.

Our findings indicate that it is now possible to reliably determine concentrations of monoamine metabolites in CSF samples obtained from developing rat pups. They further suggest that while CSF HVA is a reasonable estimate of brain DA, correlations between CSF 5-HIAA and its parent amine (5HT) in brain and 5-HIAA in brain are disappointing. Future experiments should provide further insights into the relationship between CSF monoamine metabolites and central monoaminergic mechanisms.

273.11 APUD CELLS OF MOUSE EMBRYONIC PANCREAS ORIGINATE FROM CATECHOLAMINE PRECURSORS. G. Teitelman, T.H. Joh, and D.J. Reis. Lab. of Neurobiology. Cornell Univ. Med. Coll. New York, NY 10021.

A population of cells containing the enzymes tyrosine hydroxylase (TH) and dopa-decarboxylase (DDC) but not dopamine-B-hydroxylase (DBH) nor phenylethanolamine-N-methyltransferase (PNMT) and hence probably dopaminergic (DA),is found in the pancreas of mouse embryos at the 11th day of development (E 11). The presence of TH in embryonal pancreatic cells is transient: such cells containing TH are not observed after E 15 (Teitelman, et al. (Proc. Nat. Acad. Sci. 1981, in press). Thus, the embryonic pancreatic DA cells are part of a wider group of transient catecholaminergic (TC) cells which populate the gut, kidney and spinal cord during development of mice and rats (Teitelman, et al., Dev. Biol., 1981 in press). The fate of the TC cells is unknown. Conceivably, they might die or, alternatively, interconvert into other cells harboring other neuromodulators. In this study we sought to determine whether the pancreatic TC cells transform into peptidergic cells of the endocrine pancreas.

Mouse embryos or pancreases removed from adult mice were processed for immunocytochemical localization of insulin, glucagon, somatostatin, TH and DDC by the PAP method. Embryonal TH cells appear on E 11 and then decline to disappear by E 15. In adults TH reappears in a few cells (Adult DA cells) differing in location and morphology from the embryonal ones. DDC is first observed on E 13. Cells containing DDC increase in number during development. In adults DDC is contained in almost all islet cells. At E 12 glucagon appears in cells of the pancreatic lobe while insulin appear at E 14.5 along newly formed pancreatic tubules. Somatostatin is first observed at E 16 in a few scattered cells. The number of cells containing glucagon, insulin and somatostatin increase during prenatal development and on into maturity. By use of a method for simultaneously detecting two antigens (Teitelman et al, Proc. Natl. Acad. Sci., 1981 in press) both TH and glucagon were visualized in the same cell on E 12 and 13. Double labelled cells comprised 10% of all stained cells. At E 14.5, some of the cells stained for TH also contained insulin. However, at the time somatostatin appears no embryonal cells containing TH remain. The adult DA cells do not contain glucagon nor insulin. We conclude that two cell types of the APUD series, i.e. the glucagon and insulin cells of pancreas, arise from tranformation, in situ, of cells that transiently express a dopaminergic phenotype. These results raise the prospect that other peptidergic cells of the APUD series in periphery and possibly brain may have aminergic precursors.

273.12 EFFECT OF PHENOTHIAZINES ON NEUROENDOCRINE REGULATION OF GROWTH. T. T. Soncrant*, C. L. Sowek* and G. P. Redmond. Depts. of Pharmacol., Med. Technology and Pediatrics, Univ. of Vermont College of Medicine, Burlington, VT 05405.

Growth hormone (GH) secretion is under stimulatory control of noradrenergic and possibly dopaminergic systems in the hypothalamus. Phenothiazines block both of these receptors. Previous work has demonstrated that a single dose of perphenazine (PER), a potent phenothiazine of the piperazine class, blocks spontaneous GH secretion and that chronic administration retards growth. PER treated rats were 29% lighter than controls after 29 daily treatments. Concurrent GH supplementation decreases the growth deficit produced by PER, suggesting that inhibition of GH secretion is at least one of the mechanisms by which PER retards growth. We wished to determine: 1) whether tolerance to the GH-suppressing action of PER developed during chronic treatment, and 2) whether phenothiazines of other classes had similar GH-suppressing activity.

Spontaneous GH secretion was assessed by means of a non-stressful frequent-sampling method previously described (Redmond, Neuroendocrinol. 30:243, 1980). Plasma samples were taken every 15 min for 3 h prior to and 3 h following drug or saline administration; GH levels were measured by RIA. To detect development of tolerance to GH suppression after chronic PER treatment, rats were treated with PER 5 mg/kg, or saline, daily for 29 days. Both chronic PER and chronic saline animals exhibited GH suppression when given PER on day 31 (see table). GH suppressing activity of other classes of phenothiazines was investigated using chlorpromazine (CPZ), an aliphatic phenothiazine, and mesoridazine (MES), a piperidine phenothiazine. Single doses of CPZ, 10 mg/kg, and MES, 2.5 mg/kg, significantly inhibited spontaneous GH secretion:

		MEAN GH LEVEL (ng/ml)		
DRUG	N=	BEFORE DRUG	AFTER DRUG	P<
Saline	14	45 ± 5	61 ± 9	N.S.
CPZ (1 dose)	12	72 ± 12	34 ± 2	0.01
MES (1 dose)	6	35 ± 12	12 ± 1	0.05
PER (chronic)	7	53 ± 9	14 ± 1	0.01

Conclusions: 1) Tolerance to the GH-suppressing activity of PER does not develop with prolonged administration. 2) Since CPZ and MES suppress spontaneous GH secretion as previously demonstrated for PER, this appears to be a property of all three classes of phenothiazines. 3) It is likely that GH suppression by phenothiazines is a mechanism of their growth retarding action. 4) The possibility that other NE and DA blocking drugs may alter growth should be considered.

274.1 GABAERGIC RECURRENT INHIBITION IN NEOSTRIATAL SLICE PREPARATION. J.W. Lighthall and S.T. Kitai. Dept. of Anatomy, Mich. State Univ., E. Lansing, MI 48824.

A short duration recurrent inhibition is demonstrated in a slice preparation from rat neostriatum. Inhibition is observed following both local stimulation of neostriatum and as a result of direct activation of a single neuron recorded intracellularly. Parasagittal slices of rat neostriatum (caudate-putamen), 350-400 μm thick, were obtained and maintained using methods previously described (Lighthall et al., Brain Res., in press, 1981). Intracellular analysis shows the initial response recorded following local bipolar stimulation of neostriatum to be a monosynaptic excitatory postsynaptic potential (EPSP). Although long lasting inhibitory effects of local stimulation could not be observed, monosynaptic inhibitory postsynaptic potentials (IPSPs) 18-43 msec in duration followed EPSPs in 17% of 74 recorded neurons. In paired shock experiments, when a test EPSP is preceded by a conditioning stimulus of equal duration and amplitude, reduction of the test EPSP amplitude occurs over interstimulus intervals (ISIs) of 4-27 msec. Inhibition of test EPSPs occurred in all neurons tested. Test orthodromic action potentials (APs) are also inhibited by a conditioning stimulus. APs triggered by a depolarizing pulse (1-5 msec; 0.2-2.5 nA) were used to condition a test EPSP evoked by local stimulation. Reduction of test EPSP amplitude, indicative of recurrent inhibition (Park, M.R., et al., Brain Res., 194:359-369, 1980) occurred at ISIs less than 25 msec. Test orthodromic APs are also inhibited by a direct depolarizing conditioning stimulus. Twin near-threshold depolarizing pulses of sufficient amplitude to trigger APs were delivered at ISIs of 5-25 msec. No inhibition of the second AP was observed over these ISIs. This suggests that AP currents are not responsible for the shunting of orthodromic test EPSPs and APs. Inhibition observed in double shock experiments was antagonized in a dose-dependent manner following addition of known GABA antagonists bicuculline methiodide (10^{-5}-10^{-4}M), and picrotoxin (10^{-5}-10^{-4}M) to the bathing medium. Inhibition was also blocked by application of penicillin-G (2000 units/ml) to the bathing medium. Potentiation of test EPSPs occurred over ISIs of 4-35 msec. EPSPs conditioned by a depolarizing pulse were potentiated rather than inhibited in bathing medium containing $5x10^{-5}$M bicuculline methiodide. This finding supports previous in vivo studies (Park et al., 1980) which demonstrated neostriatal recurrent inhibition to be mediated by GABA. Inhibition of test EPSPs returned following wash in normal bathing medium. Neurons exhibiting recurrent inhibition were injected with horseradish peroxidase (HRP) and identified as medium spiny neurons. Supported by USPHS Grant NS 14866 (to STK).

274.2 LONG LASTING INHIBITION OF NEOSTRIATAL NEURONS FOLLOWING AFFERENT STIMULATION RESULTS FROM DISFACILITATION VIA CORTICO-STRIATAL AND THALAMOSTRIATAL FIBERS. C.J. Wilson*, H.T. Chang and S.T. Kitai. Dept. of Anatomy, Mich. State Univ.,E.Lansing, MI. 48824.

Stimulation of neostriatal afferents from substantia nigra, thalamus and cerebral cortex produces a complex sequence of excitation and inhibition in neostriatal neurons. The inhibitory portion of this response lasts 100-300 msec and can be seen both as a hyperpolarization of neostriatal neurons or as a reduction of amplitude of EPSPs produced by stimuli conditioned by previous stimulation of neostriatal afferents. Intracellular recordings from neostriatal neurons were compared in intact rats, rats subject to unilateral acute or chronic decortication, or acute decortication combined with unilateral knife cuts through thalamus at the level of the rostral pole of the parafascicular nucleus. Stimuli were applied to ipsilateral cerebral cortex, thalamus, substantia nigra or descending cortical axons at the level of the pons. In acute or chronic decorticate rats, EPSPs evoked by stimulation of intact striatal afferent fibers were not followed by hyperpolarizations. Monosynaptic EPSPs evoked from pons, substantia nigra or thalamus in acute or chronic decorticate rats showed no decrease in amplitude with paired shocks at interstimulus intervals from 30 to 150 msec, a range in which pronounced attenuation of test responses is obtained in intact animals. Polysynaptic EPSP components evoked from pons, substantia nigra or thalamus in acute animals were considerably attenuated in paired stimulus tests over this range of intervals. These polysynaptic responses were abolished by thalamic transection, after which no evidence of long lasting inhibition could be demonstrated. Intracellular recordings from identified brainstem-projecting neurons in the cerebral cortex of intact rats exhibited EPSP-IPSP sequences with the same time course following stimulation at these same sites. These neurons, which have been previously shown to contribute to the corticostriatal projection, exhibited the same responses to paired stimuli as those seen in neostriatal neurons in the intact animal. These findings indicate that prolonged hyperpolarization in neostriatal neurons arises primarily from a temporary cessation of a tonic excitatory corticostriatal input. Attenuation of test responses in paired stimulus experiments likewise affects only polysynaptic components of excitatory responses in neostriatal neurons, and results from inhibition in cortical and thalamic circuits responsible for these responses. Supported by USPHS Grants 17294 (to CJW) and 14866 (to STK).

274.3 LOSS OF NEUROCHEMICAL RESPONSES TO ACUTE AND CHRONIC HALOPERIDOL IN THE INTACT CAUDATE-PUTAMEN OF RATS WITH UNILATERAL LESIONS OF NIGROSTRIATAL DOPAMINE PATHWAYS. K. Gale and H. Bernstein*. Department of Pharmacology, Georgetown University Schools of Medicine & Dentistry, Washington, DC 20007.

The intact caudate-putamen (CP) contralateral to a unilateral 6-hydroxydopamine (6-OHDA) lesion placed in the medial forebrain bundle (resulting in > 95% decrease of tyrosine hydroxylase in the ipsilateral CP), was examined for neurochemical changes in response to haloperidol. Two effects of haloperidol were evaluated: 1) activation of tyrosine hydroxylase (TH), measured as a decrease in the Km for pteridine cofactor, following acute injection of haloperidol (1.0mg/kg i.p. 45 min before killing) and 2) increase in the activity of glutamic acid decarboxylase (GAD) (1.0 mg/kg s.c. daily for 6 weeks). In the acute studies, rats were lesioned with 6-OHDA and then challenged with haloperidol 3, 7 or 21 days postoperatively. Rats which were not lesioned, vehicle-lesioned, or lesioned with 6-OHDA 3 days before, showed a significant decrease (2-3 fold) in the Km of striatal TH for cofactor in response to haloperidol; no change in Vmax of TH was observed. In contrast, in rats which were lesioned with 6-OHDA 7 or 21 days before, haloperidol did not cause a change in the affinity of TH for cofactor, as compared with striatal TH from rats which had not received haloperidol. The TH of the CP contralateral to the 6-OHDA lesions was not significantly different (with respect to Km and Vmax) from that obtained from non-lesioned controls. In the chronic studies, rats were lesioned with 6-OHDA and subsequently (one week later) started on daily haloperidol treatment. Four days following cessation of chronic treatment, rats were killed for measurement of GAD. Chronic haloperidol administration in rats which were not lesioned or vehicle-lesioned caused a significant increase (140%-160% control) in GAD activity in the CP from both hemispheres. In contrast, after chronic haloperidol treatment, rats with unilateral 6-OHDA lesions showed no increase in GAD in the CP of the intact hemisphere when compared with 6-OHDA lesioned and non-lesioned controls (chronic saline injections). In the ipsilateral CP, 6-OHDA lesions caused a significant increase (150% of control) in GAD activity which was not further altered by chronic haloperidol treatment.

These data suggest that unilateral 6-OHDA-induced degeneration of dopamine neurons causes changes to occur in the contralateral hemisphere which render the nigrostriatal circuitry in that hemisphere resistant to acute and chronic actions of dopamine-receptor blockade.

274.4 DOPAMINE ISLANDS AND ACETYLCHOLINESTERASE PATCHES ARE COEXTENSIVE IN THE STRIATUM OF THE FETAL CAT. Ann M. Graybiel and Clifton W. Ragsdale,Jr.* (SPON: W.A. Richards). Department Psychology & Brain Science, MIT, Cambridge, MA 02139.

The first clear indication of compartmental organization in the mammalian striatum was the finding that during development certain incoming dopaminergic (DA) fibers form clumps visible as islands of intense fluorescence in Falck-Hillarp preparations. A high degree of patterning has since been shown also in the mature striatum, where cortical and thalamic afferents, striatal projection cells and some neuropeptides are disposed in mosaics aligned with a network of cholinesterase-poor zones called striosomes. Though several similarly striking inhomogeneities have been described for the immature striatum in addition to the DA islands--including a transient appearance of patches rich in acetylcholinesterase (AchE) activity--information is lacking on the degree of correspondence among these compartmental orderings. To test for one such possible linkage we have compared the distributions of DA and AchE in the striatum of fetal cats by applying the histofluorescence and thiocholine methods to sections from the same brains.

Unfixed 16 μm sections from 3 fetuses (E49-E57) were prepared for catecholamine histofluorescence by de la Torre's modification of the glyoxylic acid method and adjoining sections were processed for AchE activity by the procedure of Geneser-Jensen and Blackstad. Patches of intense fluorescence 200-600 μm wide were scattered through the caudoputamen in each brain, as were discrete AchE-rich patches of comparable size and shape. The two sets of patches appeared to be in close register when serially adjoining sections were compared. The alignment of the DA and AchE patches was directly established by a sequential protocol in which fluorescence sections were photographed, then processed for AchE and rephotographed. The AchE patches in the caudoputamen matched the DA islands precisely, and a correspondence between AchE and DA extended into the ventral striatum-nucleus accumbens district. By contrast, there was no clear alignment of striatal neurons stained for AchE with either the DA or the AchE patches. In both cells and patches the thiocholine reaction product appeared specific for AchE as it was sensitive to BW284c51 and was demonstrable after brief elution of catecholamines with 2 N HCl. These findings are consistent with Butcher and Hodge's speculation (1976) that DA and AchE coexist in the system of dopaminergic island-fibers and suggest that these fibers are not distributed in register with AchE-containing neurons intrinsic to the striatum.

274.5 THE FORMATION OF NEURONAL CLUSTERS IN THE EMBRYONIC PRIMATE NEOSTRIATUM. Scott Brand. Dept. of Anatomy, Uniformed Services Univ. of the Health Sci., Bethesda, MD 20014

An intrinsic cytoarchitectural pattern of cell clustering in the neostriatum has been demonstrated both directly and indirectly in rodents, cats and primates using techniques as varied as opiate receptor localization, acetylcholinesterase histochemistry, autoradiographic analysis of neostriatal afferents and ^{3}H-thymidine analysis of time of neuron origin. At this date there is no information concerning how and when the cell clusters form. To investigate the problem of how such clusters developed, a ^{3}H-thymidine autoradiographic study of four fetal rhesus monkeys was undertaken. Rhesus monkeys were used because of their slow rate of fetal development which allows a pulse of ^{3}H-thymidine to label a small percent of the neostriatum's neuronal population, thus increasing the resolution of the technique. Four pregnant rhesus monkeys were injected on the 40th day after conception (E40) with ^{3}H-thymidine. The total gestation period for rhesus monkeys is 165 days, of which neostriatal neurons are generated between E36 and E80 (Brand and Rakic, Neuroscience, 4:767, 1979). The fetuses were removed via Caesarean delivery and sacrificed at various times after injection, specifically, E44, E48, E65 and E80. The ^{3}H-thymidine labeled cells in the animal sacrificed at E44 were predominately located within the ganglionic eminence (ventricular ridges) in both the ventricular and subventricular layers with only a few cells having migrated into the caudate nucleus. No labeled cells were present in the putamen. On E48, labeled cells were present in both the caudate nucleus and putamen. The labeled cells at first appeared to be ubiquitously distributed throughout the neostriatum. Upon closer inspection there were isolated areas in both the caudate nucleus and putamen of the E48 specimen where labeled cells were not present suggesting the beginning of cluster formation. At this age less than 3% of the labeled cells were found in the ganglionic eminence. In the E65 specimen clusters of labeled cells were seen throughout the neostriatum. The E80 specimen showed similar clusters to the E65 specimen, but the clusters were located farther apart possibly due to the increased growth of neostriatum. Several conclusions can be derived based on the present data: (1) clusters are formed after the neurons have migrated and reached both the caudate nucleus and putamen and (2) clusters begin to form prior to the beginning of synaptogenesis (first neostriatal synapses are formed at E65, Brand and Rakic, Anat. Rec., 193:490, 1979). Supported by N.I.H. grant NS16905.

274.6 ULTRASTRUCTURE OF IMMUNOCYTOCHEMICALLY IDENTIFIED SEROTONINERGIC AXONS IN THE NEOSTRIATUM AND PALLIDUM OF MONKEYS. Pedro Pasik, Tauba Pasik, Jorge Pecci Saavedra and Gay R. Holstein*. Dept. Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

Monkeys (M. fascicularis) were briefly perfused with 4% pure formaldehyde and 0.25% gluteraldehyde in 0.12M phosphate buffer. Some animals received an intracerebral 3 µl injection of 2.5% colchicine solution, 16 hr prior to perfusion. Others were given Pargyline (75 mg/kg) and tryptophane (100 mg/kg) i.p., three and one hour, respectively, before sacrifice. Vibratome 30 µm sections were incubated with rabbit antisera raised against a serotonin-BSA conjugate, and further processed with Sternberger's PAP technique. No immunostain was detected in sections incubated in the same antisera preabsorbed with serotonin-BSA, or coprecipitated with the conjugate plus rabbit anti-BSA.

Light microscopy of the caudate nucleus, putamen and both segments of the globus pallidus reveals the presence of immunoreactive axons, branching profusely into 0.1-0.2 µm diameter fibers with irregularly spaced varicosities up to 0.7 µm in size. Electron microscopy of serial sections shows profiles filled with dense, mostly round particles, of sizes within the range of synaptic vesicles. Occasionally, 26-30 nm electron lucent vesicles are seen in the midst of the denser material; these probably represent cross-sections of vesicles with the label attached to the outer surface. Reaction product is also observed studding outer mitochondrial membranes. The high density of the deposits contrasts with the finely granular reaction product present in perikaryon and dendrites of neurons in the raphe nuclei of the same animals. In the neostriatum, the labeled profiles are near dendrites of Spiny I type neurons, and in some instances are clearly presynaptic to dendritic spines or, less frequently, dendritic trunks. These synapses exhibit a markedly thick postsynaptic membrane. In the pallidum, immunoreactivity is present in profiles of similar morphology to those of the striatum. Sometimes, one such element is seen as a single fiber within a bundle of thin unlabeled axons, probably of striatal origin. Some of the immunostained axons are finely myelinated. Only rarely, a synapse is formed between a labeled profile and a dendritic trunk receiving other unlabeled terminals. The diameter of such dendritic elements suggests that they are distal segments of the dendrites of large pallidal cells.

The results offer a positive identification of serotoninergic terminals, at least in the neostriatum. The marked asymmetry of the synapses supports the physiologically defined excitatory nature of these endings. It is not clear whether the serotoninergic fibers in the pallidum provide similar innervation to this structure or represent passing axons en route to the striatum.

274.7 POSTNATAL DEVELOPMENT OF THE KITTEN SUBSTANTIA NIGRA: A COMPARATIVE GOLGI AND ELECTRON MICROSCOPY STUDY. P.E. PHELPS an A.M. Adinolfi, Dept. of Anatomy, UCLA Medical School, Los Angeles, Calif. 90024.

Rapid Golgi impregnation and electron microscopy were used to describe the morphological maturation of substantia nigra neurons from newborn to 55 days old kittens. Observations were made from 33 animals grouped at 1-3, 7-10, 18-24, and 40-55 days of age. In Golgi preparations, nigral neurons were selected from the pars compacta, reticulata and lateralis. Cell bodies vary in size and range in shape from round or oval to triangular or fusiform. Somatic appendages are found on cells in the younger age groups but are rare in the oldest group. Three to five primary dendrites taper gradually from the cell body and branch infrequently. Neurons located centrally in pars reticulata have dendrites which course rostrocaudally in sagittal sections and ventrolaterally and dorsomedially in coronal sections. Near the ventral border of the nigra, pars reticulata dendrites course parallel to the crus cerebri. Near the dorsal surface, dendrites of pars compacta neurons run parallel to the medial lemniscus but send their longest dendrites ventrally into pars reticulata.

Dendritic shafts at 1-3 days and 7-10 days exhibit prominent varicosities and filiform processes along their shafts and growth cones at their tips. Branching commonly occurs at large varicosities. Ultrastructurally, these dendritic varicosities contain a fine floccular matrix, mitochondria, and a few membranous and tubular elements. The constricted portions of the dendrites are packed with parallel arrays of neurotubules. The filopodia are long and thin and contain an electron dense matrix, glycogen, and a few vesicles. Synaptic contacts occur on the dendrites and filiform processes but much of these surfaces are covered with astroglial processes. The dendrites at 18-24 days are longer thicker, and have more regular contours proximally. Varicosities and filopodia are still present towards the dendritic ends. Most dendrites have many more spine-like appendages in this age group than at younger or older ages. We suggest that these neurons are in a spiny stage of maturation. At 40-55 days, dendrites are longer and most have smooth surfaces which are covered by synaptic contacts. Astroglial processes, apposed to dendritic surfaces in younger kittens, now envelop the axodendritic complexes. Most synapses at all ages form symmetrical contacts and the axon terminals contain an increasing number of mitochondria and pleomorphic vesicles. These have been classified as type I and are neostriatal in origin.

274.8 **ACETYLCHOLINESTERASE-CONTAINING PROJECTION FROM THE BASAL FOREBRAIN TO THE SUBSTANTIA NIGRA IN THE RAT.** Nancy J. Woolf(1) and Larry L. Butcher(1,2) Brain Research Institute(1) and Department of Psychology(2) University of California, Los Angeles, CA 90024.

Evans Blue dye (EB) was injected into the pars compacta of the substantia nigra and retrorubral area. After the brains were sectioned and the tissue examined for retrogradely transported label, slides were counterstained for acetylcholinesterase (AChE). This procedure led to the visualization of EB dye in AChE-containing cells throughout the basal forebrain. Retrogradely labelled neurons were found in the ventral striatum, ventral pallidum, nuclei of the vertical and horizontal limbs of the diagonal band, lateral and medial proptic nuclei, medial septum and nucleus ansa lenticularis. These neurons had light, medium and dark AChE staining charateristics.

Our delineation of the ventral striatum and pallidum is similar to that described by Heimer (in Limbic Mechanisms: The Continuing Evolution of the Limbic System Concept, Eds. Livingston and Hornykiewicz, 1978). Heimer described the ventral striatum in the rat as the subcommissural caudate-putmen that extends by cell bridges to the olfactory tubercle. We, however, define ventral striatum as the ventralmost caudate-putamen extending above and below the posterior limb of the anterior commissure, but not part of the olfactory tubercle. This delineation is based upon the presence of small intensely AChE stained and large lightly AChE stained EB labelled neurons, which are atypical of neurons found in the caudate-putamen.

Since some basal forebrain cells projecting to the midbrain stain intensely for AChE, it is possible that this pathway is cholinergic. This AChE-conaining projection to the midbrain does not originate in the magnocellular basal nucleus, known to give rise to a cholinergic projection to the neocortex (Wenk et al., Brain Res. Rev., 1980, 2, 295-316). Biochemical data suggesting a cholinergic nigral afferent do exist, however. (Butcher, L. L., Ed., Cholinergic-monoaminergic interactions in the Brain). [Support: USPHS NS-10928 to L.L.B.]

274.9 DOPAMINERGIC SYSTEMS CONTROL METABOLISM IN LATERAL HABENULAR NUCLEUS INDIRECTLY VIA THE ENTOPEDUNCULARIS. G. F. Wooten, Dept. Neurology, Washington Univ. Sch. Med. St. Louis, MO 63110

Administration of dopamine (DA) agonists decreased and antagonists increased glucose utilization (GU) in the lateral habenular nucleus (LHN) (Brain Res. 194:117-124, 1980). Six-hydroxydopamine lesions of substantia nigra resulted in an increase in GU in the ipsilateral LHN, an effect reversed by apomorphine but not amphetamine administration (Neurosci. Abstr. 6: 124.2, 1980; J. Neurosci. 1:285-291, 1981). The LHN receives its major source of afferents from the entopeduncularis (EP), but recent studies have also demonstrated the existence of direct projections to LHN from DA neurons in the mesencephalon. To determine whether DA neurotransmission controls GU in LHN by a direct action or alternatively via polysynaptic pathways to LHN via EP, we have made selective lesions in EP with kainic acid and studied the effects of these lesions on GU in the LHN by ^{14}C-2 deoxyglucose autoradiography.

Glucose Utilization in Lateral Habenular Nucleus
(O.D. in LHN/O.D. in mean white matter)

Condition	Left side	Right side
Naive Control	3.7±0.2	3.6±0.2
Apomorphine (1 mg/kg S.C.)	2.9±0.2	2.8±0.3
Fluphenazine (1 mg/kg S.C.)	6.6±0.3	6.9±0.2
Entopeduncularis lesion (on left side)	2.9±0.1	3.8±0.2
Entopeduncularis lesion (Left) + Fluphenazine 1 mg/kg (S.C.)	3.1±0.2	6.1±0.3
Entopeduncularis lesion (Left) + Apomorphine 1 mg/kg S.C.	2.7±0.1	2.8±0.2

Thus entopeduncularis lesions prevent the fluphenazine-induced increase in GU in the LHN. Further, apomorphine administration does not affect GU in the LHN ipsilateral to an EP lesion. These results suggest that dopamine neurotransmission controls GU in LHN indirectly via a polysynaptic pathway requiring integrity of the entopeduncularis.

274.10 SUBSTANTIA NIGRA PROJECTIONS TO THE MESENCEPHALIC LOCOMOTOR REGION. Garcia-Rill, E., Skinner, R. D. and Smith, M.*, Dept. of Anatomy, University of Arkansas, Little Rock, AR 72205.

Recent studies from our laboratories described a small projection from the entopeduncular nucleus (EN) to the Mesencephalic Locomotor Region (MLR) in the cat. Extracellularly recorded EN neurons were activated antidromically from the same posterior mesencephalic site which when stimulated after performing a precollicular-postmamillary transection, elicited locomotion on a treadmill. In parallel anatomical experiments injections of fluorescent dyes into the area of the MLR induced retrograde cell labeling in EN as well as in the substantia nigra (SN).

The present study was undertaken to determine electrophysiologically if there are direct projections from SN to the physiologically-defined MLR. Under short-acting barbiturate anesthesia, the carotid arteries were ligated and the cortex overlying the midbrain removed by suction. A precollicular-postmamillary transection was made, the animal's weight was supported in a hammock and the limbs lowered onto a moving treadmill. A stimulating electrode was stereotactically lowered into the area of the MLR until the lowest threshold for locomotion (and EMG) was obtained (usually 20-50μA, 60Hz, 1 ms duration pulses). The animal was then locally anesthetized and paralyzed for single unit extracellular recording. Cells in the SN were studied for anti- and orthodromic responses to activation of the MLR electrode. Locations of recorded neurons were identified using Fast Green dye injections through the recording electrode.

Our results revealed that less than 10% of SN neurons were antidromically activated from the MLR (mean latency 1.9 ± 0.8 ms). These neurons were located in the posterior part of SN, mostly in the dorsal pars reticulata, both medially and laterally. A few neurons in the retrorubral nucleus also appear to send projections to the MLR. These findings are supported by our previous anatomical experiments. A large number of SN neurons also responded orthodromically in a bimodal distribution according to latency. Close to 16% of SN neurons responded orthodromically at short latency (2.5 ± 0.7 ms), and about 22% of SN cells responded at a longer latency (4.9 ± 1.1 ms).

These findings provide evidence for a small projection from SN to the physiologically-identified MLR. A similar projection from EN also has been described. The convergence of two major outputs of the basal ganglia at the level of the MLR suggests that these projections may trigger and/or modulate sequences of movement involving locomotion. Absence of activity in these pathways may lead to an inability to initiate these sequences of movement (akinesia).

Supported by USPHS grants NS-10304, NS-15359 and NS-16143.

274.11 A REEVALUATION OF THE ROLE OF SUPERIOR COLLICULUS IN TURNING BEHAVIOUR. G. Di Chiara, M. Morelli*, A. Imperato* and M.L. Porceddu*. Institute of Pharmacology, University of Cagliari, Cagliari, Italy.

Much debate does exist over the role of superior colliculus (SC) in turning behaviour. In order to clarify this issue, unilateral kainate lesions were made by infusing 0.25 μg of kainate at two different anterior planes 0.8 mm apart in the lateral or in the medial aspects of the deep collicular layers (DLSC), in the dorsal mesencephalic reticular formation (MRF), or in the lateral periaqueductal grey (PAG), both in normal rats and in rats made unilaterally supersensitive to DA-receptor agonists by unilateral infusion of 6OHDA in the rostral substantia nigra. The effect of kainate lesions on spontaneous as well as on apomorphine-induced motor behaviour was studied. In normal rats, unilateral kainate lesions of lateral DLSC or dorsal MRF resulted in a short-lasting spontaneous ipsiversive turning and in a persistent ipsiversive circling in response to peripheral apomorphine. In 6OHDA rats, kainate lesions of lateral DLSC or of dorsal MRF ipsilateral to 6OHDA denervation reduced or even reversed the contralateral circling normally elicited in these rats by peripheral apomorphine. Lesions of dorsal MRF were always more effective than lesions of lateral DLSC in producing these changes. Kainate lesions restricted to medial DLSC or to the PAG failed to elicit motor asymmetries in normal rats or to significantly modify the intensity of contralateral turning in 6OHDA rats. These results clearly indicate that the lateral DLSC play an important role in turning behaviour. Previous negative conclusions on the role of SC in turning probably derive from inadequate localization and extent of these lesions as well as from the use of bilateral SC lesions. These results also indicate that the dorsal MRF and not the PAG is responsabile for the turning effects obtained by lesions of the subcollicular tegmentum. On the basis of these data we propose that the deep collicular layers and the dorsal MRF form a complex of primary importance as an out-put station for the expression of striatal function.

275.1 PERIPHERAL CAERULEIN, LIKE CCK, ACTS IN THE ABDOMEN AND NOT IN THE BRAIN TO PRODUCE SATIETY IN RATS. C. Jerome*, P. Kulkosky*, K. Simansky and G.P. Smith. Dept. of Psychiatry, Cornell Univ. Med. Coll., The New York Hospital, White Plains, NY 10605.

Peripheral administration of CCK produces satiety in rats by acting at a vagally innervated abdominal site (Smith et al.,1979). Peripheral administration of caerulein, a decapeptide that is structurally similar to CCK, also elicits satiety in rats. We blocked the satiety effect of caerulein by subdiaphragmatic vagotomy (Simansky et al., 1980). This suggests that caerulein, like CCK, acts at a vagally innervated abdominal site.

Stern et al. (1976), however, suggested that caerulein acted directly on the brain because (1) low doses of caerulein administered intraventricularly inhibited food intake; and (2) bilateral ventromedial hypothalamic (VMH) lesions abolished the satiety effect of one dose of caerulein administered peripherally. Given the structural similarities of caerulein and CCK, the possibility that they act at different sites of action is paradoxical. Since the paradox depends on the results of Stern et al., we attempted to replicate them. In the first experiment, caerulein (.01 to 4.0 µg/10 µl CSF) or 10 µl CSF was administered unilaterally to 5 rats through chronic lateral ventricular cannulas. No dose of caerulein inhibited 30-min food intake after 18-h food deprivation:

	Caerulein (µg)				
CSF	.01	0.1	1.0	2.0	4.0
16.0±2.6*	18.4±2.4	19.8±3.5	16.6±2.2	16.0±3.5	18.4±2.6

*Mean ± S.E. (ml/30 min)

In the second experiment, caerulein (.25 to 2.0 µg/kg) was administered peripherally (ip) to 8 rats with bilateral VMH lesions and to 8 surgical control rats. The body weight of the VMH rats was maintained within 20% of preoperative body weight by restricting food intake. All doses of caerulein produced equal inhibitions of 30-min food intake after 17-h food deprivation in VMH and control rats:

	% Inhibition (±S.E.)			
Caerulein (µg/kg, ip)	0.25	0.5	1.0	2.0
VMH	7.3±12.1	35.2±10.0	50.4±13.4	79.1±4.9
Control	16.2±10.0	24.6±8.9	38.6±6.1	64.1±13.8

Since we cannot replicate the results of Stern et al., we conclude that there is no paradox. Caerulein, like CCK, acts at a vagally innervated abdominal site in the rat.

275.2 GASTRIN RELEASING PEPTIDE (GRP) REDUCES FOOD INTAKE IN RATS. Leslie J. Stein*, David B. West*, and Stephen C. Woods. Dept. of Psychology, University of Washington, Seattle, WA. 98195.

Bombesin (BBS),a tetradecapeptide originally isolated from frog skin, has been shown to be physiologically active in mammalian systems. Intracranial administration of nanogram quantities of BBS to rats results in alterations of glucoregulation (Brown et al.,Life Sci., 1977, 21, 1729) and thermoregulation (Brown et al., Science, 1976, 196, 998). Furthermore, peripheral injections of BBS elicit satiety in rats (Gibbs et al., Nature, 1979, 282, 208).

Recently, a 27-amino acid peptide, termed gastrin releasing peptide (GRP), has been isolated from porcine gut (MacDonald et al., Biochem. Biomed. Res. Commun., 1979, 90, 227). GRP and BBS share a common C-terminal decapeptide, and GRP has been reported to reproduce the disruptions of thermoregulation and glucoregulation induced by injections of BBS (Brown et al., Life Sci., 1980, 27, 125). We now report that GRP also mimics the satiety-producing effects of BBS.

Long-Evans rats were deprived of food every day for six hours. After two weeks on this regimen, they were injected intraperitoneally (ip) with either saline or GRP at the end of the deprivation period and then allowed access to a liquid diet (Ensure, Ross Labs) for thirty minutes. Chow was then returned to the rats until the next morning. Injection of 4 µg/kg of GRP resulted in a 16.6 ± 7.1% suppression of liquid food intake compared to saline control days ($p<.02$); 8 µg/kg of GRP reduced food intake by 35.0 ± 5.0% ($p<.001$). Neither dose had any effect on chow intake over the remainder of the day. The percent suppression of food intake induced by ip injections of GRP was comparable to that we have observed with approximately equimolar doses of BBS when given either ip or subcutaneously.

These results lend additional support to the hypotheses that 1) GRP may be a mammalian counterpart of BBS, and 2) BBS/GRP has a role as an endogenous satiety hormone in mammalian systems.

Supported by NIH grant AM-17844. We thank J. Rivier of The Salk Institute for supplying the GRP and BBS.

275.3 LITORIN SUPPRESSES FOOD INTAKE IN RATS. P.J. Kulkosky*, D.J. Fauser*, and J. Gibbs. (SPON: P.R. McHugh). Cornell University Medical College and Edward W. Bourne Behavioral Research Laboratory, The New York Hospital, White Plains, NY 10605.

Litorin (LIT) is a bombesin-like nonapeptide recently isolated from the skin of the frog Litoria aurea (Anastasi, Erspamer, & Endean, 1975). The C-terminal nonapeptide of tetradecapeptide bombesin (BBS) differs from LIT by a single substitution at the penultimate position. BBS has recently been shown to specifically suppress deprivation-induced, tail-pinch-induced, and sham feeding in rats after peripheral injection. We examined the effects of peripheral injections of LIT on ingestion and other behaviors in rats to determine if LIT acts analogously to BBS in feeding suppression.

Six rats were first adapted to an 18-hr food deprivation schedule with 30-min access to 25% liquid diet (EC 116, GIBCO), preceded by an intraperitoneal 0.15M NaCl injection. Intraperitoneal injections of LIT and BBS were then given across a dose range of 0.5-128.0 µg/kg. Significant suppressions of food intake were observed after BBS injections at all doses $\geq$ 1.0 µg/kg, and with LIT at all doses $\geq$ 4.0 µg/kg. Despite threshold differences, feeding inhibition by these peptides did not differ significantly at any dose, with a maximal effect of about 50% at all doses $\geq$ 16.0 µg/kg. However, BBS was more effective than LIT on a molar basis. In addition, both peptides similarly suppressed 3-hr-deprivation-induced liquid diet intake in a second group of rats (n=11).

An observational time-sampling behavioral analysis of demonstrated reliability (Gibbs et al., 1980) revealed that only feeding behaviors were significantly decreased following 8.0 µg/kg LIT, relative to saline control: grooming, standing, resting and other behaviors did not differ significantly from saline. Thus, the characteristic sequence of behaviors which follow normal meal termination appeared intact after LIT injection.

We conclude that litorin, which has previously been shown to share several visceral actions with its analog bombesin after peripheral administration, also suppresses food intake and mimics natural satiety.

275.4 LATERAL HYPOTHALAMIC INJECTIONS OF BOMBESIN SUPPRESS FOOD INTAKE IN RATS. J.A. Stuckey* and J. Gibbs. (SPON: B. Kaplan). Cornell University Medical College and Bourne Laboratory, The New York Hospital, White Plains, NY 10605.

Bombesin (BBS) has been shown to reduce food intake after intraperitoneal or intracerebroventricular administration. We examined the possibility that BBS acts at a CNS tissue site to reduce food intake by injecting BBS into the hypothalamus, an area implicated in the control of food intake and which contains BBS-like immunoreactivity (Villarreal & Brown, 1978) and BBS receptors (Moody et al., 1978).

Eleven male Sprague-Dawley rats weighing approximately 350g were adapted to a 3-h food deprivation schedule; tap water was always available. Following implantation with bilateral stainless steel cannulae directed toward the lateral hypothalamus (from bregma posterior 2.5 mm, lateral 1.75 mm, and 8.2 mm ventral to the skull surface) and recovery, rats received bilateral injections of 0.5, 5.0, or 50.0 ng BBS in 0.5 µl 0.15 M NaCl alternating with equivolumetric 0.15 M NaCl control injections in a crossover design. Liquid food (40% Bioserve EC 116) was presented immediately following injections. Food intakes were measured and behavior was recorded using a reliable time-sampling observational method.

Results of BBS injections on the size of the first meal were as follows:

Dose of BBS (ng)	0.5	5.0	50.0
Percent change ± SEM	+1.5±7.4	-18.3±6.0*	-23.6±8.2*

Both the 50.0 ng and 5.0 ng doses produced statistically significant decreases in the size of the first meal (*p <.02). Analysis of the behavioral data revealed that rats displayed all of the behavioral characteristics of normal satiety in the appropriate sequence following the first meal. The latency to apparent sleep was increased following BBS administration. No abnormal behaviors occurred. Injections of 50 ng BBS had no significant effects on body temperature or water intake. To determine if the structural constraints for this feeding effect are the same as for previously documented biological effects of BBS, rats were injected with [D-Trp^8] BBS (courtesy of J. Rivier, Salk Institute, La Jolla) an analogue which shows only 1% of the biological activity of natural BBS (Rivier & Brown, 1978). Fifty ng of [D-Trp^8] BBS injected bilaterally failed to suppress food intake.

We conclude that BBS injected into the lateral hypothalamus of rats suppresses food intake. It remains to be determined if the satiety effect of peripherally-injected BBS is due to its action at this and/or other brain sites.

This study supported by USPHS grant AM17240.

275.5 BOMBESIN INDUCES GASTROINTESTINAL ABNORMALITIES WHICH REDUCES FOOD INTAKE. J.A. Deutsch* and W.G. Young. (SPON: L. Kromer). Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093.

Bombesin (BBS) (2-16 mcg/kg) reduces food intake in rats (Gibbs et al, Nature. 282, 208-210, 1980). BBS (16 mcg/kg) also produces a conditioned taste aversion to flavored water (Deutsch and Parsons, Behav. Neur. Biol. 31, 110-113, 1981) suggesting that BBS produces malaise. Also, BBS (2-16 mcg/kg) produces gastrointestinal (GI) abnormalities in the form of elevated intragastric pressures and intragastric contraction amplitudes (Young, W.G. Soc. Neurosci. Abstr. 6, 165, 1980). Both the GI abnormalities and the food intake reduction are antagonized by the concurrent administration of diazepam (5 mg/kg) (Young, Deutsch, and Tom, Fed. Proc. 40, 941, 1981). The GI abnormalities suggest that aversion to ingested substances develops through an interaction of the ingested substance and the abnormal GI physiology prevailing after injections of BBS. Therefore, replacing the flavored water in the aversion studies with flavored nutrient would exacerbate the BBS-induced GI abnormalities and produce a quicker aversion with lower dosages. This did in fact occur.

8 Sprague-Dawley rats were trained to feed on undiluted condensed Carnation milk for one week and then divided into two groups. The first group was injected with saline (S) and the second group was injected with 8 mcg/kg of BBS. Both drank banana flavored milk. On the next day, the injections were reversed and the animals were fed on almond flavored milk. On the third day, the animals chose between the two flavored diets. The mean intake of the S-paired flavor was 12.5 ml + 8.7 ml SD and the mean of the BBS-paired flavor was 4.0 ml + 5.6 ml SD. This difference was not yet significant ($t = 1.79$, $p > 0.10$). The pairings were repeated in reverse order on days 4 and 5 and a choice was again presented on the day 6. The mean intake of the S-paired flavor was 16.8 + 7.6 ml and the mean of the BBS-paired flavor was 4.1 + 7.2 ml. This difference was significant ($t = 2.59$, $p < 0.05$).

The aversion to flavored nutrient was swift with this medium dose of 8 mcg/kg. A significant aversive effect was produced with the second pairing. When water was the unconditioned stimulus, three pairings with a higher dose of 16 mcg/kg was necessary. This data suggest that interaction with dietary substances after BBS injections produces aversion greater than with water or when no ingestive substance is used, perhaps through such clinically defined mechanisms as increased gastric emptying, producing a "dumping syndrome".

275.6 FEEDING AND DRINKING ARE AROUSED BY CHEMICAL INJECTION INTO THE INFANT BRAIN. S. Ellis* and A.N. Epstein. Inst. of Neurol. Sci. and Dept. of Biology, Univ. of Penn., Phila., PA 19104.

The responsiveness of the infant brain to neurochemical agents that arouse feeding and drinking in the adult has already been shown by Misantone, Ellis & Epstein (Brain Res., 186: 1980) who elicited water drinking with intracranial injection of angiotensin in new born rats. These experiments extend this line of research to include: 1) norepinephrine (NE), which increases food intake and 2) carbachol (Carb), a well-known intracranial dipsogen in the rat.

In examining their effects on the pups ingestive behavior, we employed the anterior oral cannula developed by Hall that allows the suckling rat to ingest independently of its mother. Weight gain was the measure of intake (fecal and urine losses being prevented by celloidinization of the perineum). Pups of various ages were removed from their mother, placed in a warm (32°C) and moist incubator. They were then satiated with 15s infusions of either milk (Bordon's Half & Half) or water every 2 min for 20 min after which they were reweighed (total infused = 5% body weight). This regime was continued until weight gained tapered off, typically after 1 hour. Animals were then injected intraventricularly with either 100ng AII, 2µgNE or 200ng Carb in a vehicle of 50% India ink and 50% isotonic saline or with 1µl of vehicle alone (cf. Misantone, et al for injection procedure). Pups were replaced in the incubator, the injection regime was continued for 30 min, and they were reweighed at 10 min intervals. After the final weighing they were decapitated and the site of injection was determined by examination of the surface of a coronal section through the head. For AII and Carb-injected pups, the lateral ventricle was designated as the site of a successful injection. For NE-injected animals the IIIrd ventricle was chosen, since the paraventricular nucleus is sensitive for adrenergic stimulation of feeding.

AII-injected rats as young as 2 days old drank significantly more water ($\bar{x}$=.09±.01g) than their vehicle-injected controls ($\bar{x}$=.02±.01g). Similarly, Carb was dipsogenic in 8 day old pups (Carb, $\bar{x}$=.25g; veh, $\bar{x}$=.03). Norepinephrine, when deposited into the IIIrd ventricle of 11-13 day old, milk-sated rats significantly increased milk intake ($\bar{x}$=.52±.08g) over both vehicle controls ($\bar{x}$=.2±.03g) and rats with NE deposited outside the IIIrd ventricle ($\bar{x}$=.2±.03g). Water intake was not affected by injections of NE. Further experiments, i.e, dose-response and blocking studies, are planned.

This work shows that the neurochemical systems for control of ingestive behavior are competent in the infant brain. Their role in suckling and in the development of adult feeding and drinking is under study. Supported by NINCDS 03469 and ITG 07517.

275.7 **BRAIN REGIONAL SEROTONIN IN HYPOTHALAMIC OBESITY: DIFFERENT DEPLETION PROFILES USING LESIONS VS. PARASAGITTAL KNIFE-CUTS.** **D.V. Coscina, J. Chambers*, J. Chang*, A. Chiu* and J.J. Warsh. Sects. Biopsychol. and Biochem. Psychiat., Clarke Inst. Psychiat., Univ. Toronto, Toronto, Canada.**

The possibility that impaired metabolism in brain serotonin (5HT) neurons produces chronic overeating has received considerable experimental attention. At last year's meeting, we presented data (Coscina et. al., Neurosci. Absts., 1980, 6, 783) showing that bilateral radiofrequency lesions of the medial hypothalamus (MH) sufficient to elicit protracted hyperphagia and obesity in female rats was associated with reliable (p<.05) 5HT depletion in hypothalamus (15%), hippocampus (-41%) and midbrain (-30%). Some of this depletion was apparently due to overeating per se as restricting food intake to normal in other MH-lesioned rats produced less depletion in hippocampus (-33%) and no depletion in midbrain. To test further the possibility that deficit brain 5HT levels are necessarily associated with overeating and obesity, independent of method used to induce them, we conducted similar experiments in adult female rats sustaining 3 mm bilateral parasagittal knife-cuts (KCs) between the MH and fornix (n=22 across two replications). As before, half of the KC rats were permitted to overeat ad lib while the remaining half were restricted to normal food intake (n=14 for sham-operated controls across two replications). While KCs were effective in eliciting hyperphagia and obesity similar to MH lesions, brain regional 5HT patterns were quite different. In hypothalamus, KCs were associated with elevations (+23-95%) rather than depletions of 5HT. In hippocampus, KCs produced either no 5HT change or much larger depletions (90%) than lesions. In midbrain, KCs produced no effects on 5HT. Furthermore, for all three brain regions studied, food restriction had no effects. We conclude that while MH lesions and KCs can produce similar effects on ingestive behavior and weight gain, the neuronal systems damaged by each technique appear quite different. This fact questions the ability of either or both technique to provide specific information about the neural substrates of overeating. Moreover, these data show that specific patterns of brain regional 5HT depletion are not necessarily the same in different experimental preparations who overeat and are obese.

275.8 PANCREATIC GLUCAGON INHIBITS REAL FEEDING, BUT NOT SHAM FEEDING IN THE RAT. Nori Geary* and Gerard P. Smith. (SPON: H. Kissileff) Dept. Psychiatry, Cornell Univ. Med. Coll. White Plains, NY 10605

Pancreatic glucagon (PG) may be a hormonal satiety signal. Endogenous PG is released during meals (De Jong et al., 1977; Unger & Orci, 1976) and exogenous PG elicits a specific dose related inhibition of food intake (Martin & Novin, 1977) accompanied by hepatic glycogenolysis and hyperglycemia (Geary et al., 1979). These effects of exogenous PG were demonstrated within the context of all the endogenous satiety mechanisms normally activated by real feeding. To investigate the relative potency of PG to inhibit food intake and elicit satiety when endogenous satiety mechanisms are minimized, we measured the effect of PG on sham feeding. Rats (n=12) were equipped with chronic gastric cannulas and trained to sham feed (SF, cannula open) or really feed (RF, cannula closed) a palatable milk diet after 3hr food deprivation. In the RF condition rats fed for 8-12 min and then displayed the satiety sequence (baseline 30 min FI: 14.5±0.8, $\bar{x}$±SEM, ml). SF rats fed almost continuously and rarely showed satiety (baseline FI: 47.5±2.8 ml). Injection of PG inhibited RF, but not SF:

Change in 30 Min Food Intake (% Control, $\bar{x}$ ± SEM)

PG (µg/kg, i.p.)	0	100	500	2500
REAL FEEDING	-1 ± 9	-8 ± 5	-21 ± 5	-35 ± 8
SHAM FEEDING	6 ± 6	3 ± 5	-1 ± 9	0 ± 8

The possibility that PG did not inhibit SF because it did not elicit hyperglycemia during SF was tested by sacrificing SF rats 8 min after PG injection.

Change in Plasma Glucose (mg/dL, $\bar{x}$ ± SEM)

PG (µg/kg i.p.)	0	500
Portal vein	+3 ± 17	+89 ± 26
Hepatic vein	-16 ± 23	+111 ± 45

These results show that PG fails to inhibit SF despite producing marked hepatic hyperglycemia. The glycogenolytic effect of PG, which has been proposed as the mechanism of PG's satiety effect on RF (Martin & Novin, 1977; VanderWeele et al., 1979), is therefore not sufficient to inhibit SF under these conditions. Some other preabsorptive or postabsorptive mechanism(s) not activated during SF must be necessary for PG's satiety effect.

Supported by NIH Grants MH15455 and MH00149 to GPS.

275.9 EVIDENCE FOR IN VIVO AND IN VITRO MODULATION OF THE OPIATE RECEPTOR BY GLUCOSE. J.E. Morley, A.S.Levine*, S.A. Hess*, D.B. Brown* and B.S. Handwerger*. Neuroendocrine Research Lab, Minneapolis VAMC, Minneapolis, MN 55417.

Food intake in diabetic animals (genetic C57 BL/Ks-db+/db+ and streptozotocin-induced diabetic mice) is suppressed by a 100-fold lower dose of naloxone than in control animals. As the genetic animals are hyperinsulinemic and the streptozotocin animals hypoinsulinemic, this suggested that glucose per se modulates the opiate receptor. Further evidence of glucose involvement in the opiate receptor is suggested by the finding that feeding induced in the insulin hypoglycemic model is highly resistant to the suppressive effect of naloxone (no significant effect of 20 mg/kg compared to a significant effect at 1 mg/kg for starvation induced feeding). We next measured ^{3}H-naloxone binding over a range of 5 nM to 100 nM in whole brain minus cerebellum from obese diabetic animals (db+/db+) and their controls as well as in obese (ob/ob) animals.

	n†	K_D (nM)	B_{max} (cpm/mg protein)
Db/db	5	23.0 ± 2.3	23335 ± 1306
m/m	5	16.1 ± 1.2	21834 ± 2289
Db/db WR*	2	19.5	20972
Ob/ob	3	26.3 ± 3.3	11590 ± 1030
Ob/-	2	26.9	11433

†each number represents results from 3 pooled brains
*WR = weight restricted to control weight.

Db/db animals had a reduced affinity compared to m/m controls with weight restricted animals falling into an intermediate range. Obese animals and their controls had a decreased B_{max} compared to diabetic animals. Next we added glucose at varying concentrations to the opiate receptor assay in vitro. Glucose at 100 mg/dl and 300 mg/dl in the presence of sodium decreased affinity for the antagonist and increased the B_{max}. These data are compatible with glucose shifting the opiate receptor from the antagonist to the agonist form in the presence of sodium.

	n	K_D (nM)	B_{max} (fmol)
Tris + Na	4	16.7 ± 1.0	146 ± 15
Glu(100 mg%) + Na	2	28.2	181
Glu(300 mg%) + Na	3	33.8 ± 3.3	212 ± 23
Tris-Na	4	35.4 ± 8.8	146 ± 24

We conclude that glucose has potent effects on the opiate receptor in both the intact animal and in vitro.

275.10 MORPHINE-INDUCED HYPERPHAGIA: A BEHAVIORAL ETHOGRAM. M. Heft, G. Daniels*, A. Buller*, and A. Riley*. Psychopharmacology Laboratory, The American University, Washington, D.C. 20016.

Because of the efficacy of naloxone hydrochloride in suppressing feeding and drinking under a wide range of conditions (Siviy & Reid, East. Psychol. Ass., 1981), the endorphins have been implicated in regulatory eating and drinking. The fact that narcotic agonists often decrease consumption, however, questions this general role of endorphins in regulatory consummatory behavior (Holtzman, Life Sci., 16:1465-1470, 1975; Stapleton et al., Bull. Psychon. Soc., 13:237-239, 1979). In an account of these effects of agonists on feeding, Riley et al. (Neurosci., 6:783, 1980) suggested that while morphine produces hyperphagia, it also induces catatonia, a response which could mask any morphine-elicited changes in feeding.

To examine if the interaction of catatonia and feeding is responsible for the reported decreases in feeding produced by morphine, groups of animals were injected with either 40 mg/kg morphine sulfate or equivolume distilled water for 28 consecutive days. A range of behaviors including catatonia, feeding, drinking, grooming, sleeping, locomotion, and rearing was monitored for 6 hr post injection.

Following the first morphine injection, rats were catatonic with only minimal activity in the two hr post injection. As catatonia dissipated, the rats ate, peaking at 4 hr following morphine. Over repeated injections, the morphine-induced catatonia was less pronounced and dissipated more quickly. This decrease in catatonia was immediately paralleled by an increase in eating. Grooming and then sleeping always followed eating for the morphine-injected rats throughout the 28-day injection procedure. Throughout the study, control animals slept during the 6-hr observation period.

These data suggest that as the masking effect of catatonia is reduced with time following a single injection and over repeated injections, morphine-induced hyperphagia occurs. As such, these data offer a basis for the aforementioned effects of morphine on feeding and support the view that endorphins may be involved in regulatory consumption.

275.11 PSYCHOPHYSIOLOGICAL SUBSTRATES OF NORMAL AND ABNORMAL FEEDING AND DRINKING. S. Grossberg. Dept. of Math., Boston Univ., Boston, MA 02215.

Psychophysiological mechanisms will be derived which are capable of explaining some difficult motivated behaviors in a unified fashion. These phenomena include hyperphagia, notably the possibility of differential effects on finnickiness and obesity; cholinergic vs. angiotension drinking; schedule-induced polydipsia and related nonhomeostatic effects; self-stimulation to inject insulin at lateral hypothalamic sites; inverted U effects of amphetamine. Basic to our analysis is the notion of a gated dipole, which shows how drive, reinforcer, and arousal inputs are modulated by competitive feedback and transmitter gating effects in the regulation of motivational baseline and reset. Cholinergic-catecholaminergic interactions occur in the theory when conditional reinforcer inputs (cholinergic) are joined to drive and arousal inputs (catecholaminergic) to generate incentive motivational outputs. Hyperphagia emerges as an example of an underaroused depressive syndrome whose properties help to explain symptoms of Parkinson's disease and juvenile hyperactivity in other subsystems.

276.1 EFFECTS OF BOTULINUM NEUROTOXIN DIRECTLY ON THE CNS: HYPOTHERMIA AND DEATH. J. L. Minnich, H. Sugiyama*, R. LoPachin* and T. Rudy. Food Research Institute and School of Pharmacy, Univ. of Wisconsin, Madison, WI 53706.

Botulinum neurotoxin's effects on the central nervous system (CNS) are not well known. We studied the effects of highly purified botulinum neurotoxin, type A (isolated by affinity chromatography) on adult rats. The toxin was injected intracerebroventricularly (i.cvt.), through an indwelling cannula, into the left lateral ventricle. Three experimental groups, of four adult rats each, were employed. In Group (1) the rats received anti-toxin (2.8 IU given i.p. at 1 hr before i.cvt. injection) plus i.cvt. toxin (390 nanograms/10 µl). The complete effectiveness of the anti-toxin dose against the toxin dose was confirmed by injections into mice. The rats in Group (2) received i.p. anti-toxin plus i.cvt. saline. Those in Group (3) received i.p. saline plus i.cvt. saline. All the animals in Group (1) died in hypothermia at 3-5 hrs after toxin injection. In the toxin-injected rats the core (colonic) temperature was 34.72° ± 0.58° at the time of death. This was significantly lower than their initial temperature of 37.75° ± 0.32°. None of the animals in Groups (2) or (3) died or showed temperature changes. The specific toxicity of the toxin used was 100 mouse i.p. LD50's per nanogram. The change in core temperature that we observed after this large dose of botulinum neurotoxin was relatively small, and it seems unlikely that the animals died from hypothermia per se. In at least some of the rats that died, it appeared that the cause of death was respiratory failure. Since both hypothermia and death occurred in animals in which peripheral effects were prevented by systemically injected anti-toxin, it appears that both these effects of botulinum neurotoxin were mediated by a direct action on the CNS.

276.2 SITES OF ACTION FOR THE EFFECTS OF INTRATHECAL NOREPINEPHRINE ON THERMOREGULATION. R. M. LoPachin* and T. A. Rudy. Univ. of Wisconsin School of Pharmacy, Madison, WI 53706.

We have examined the thermoregulatory effects of norepinephrine (NE) (0.01-0.30 µmoles) injected into spinal subarachnoid space of rats via chronic indwelling spinal catheters. Intrathecal (i.t.) NE produced dose-dependent falls in core temperature (T_c) associated with a correlated rise in tail skin temperature (T_{sk}). At the 0.30 µmole dose of i.t. NE, the hypothermia was preceded by a small, transient rise in T_c. Several lines of evidence indicate that the hypothermia and increase in T_{sk} were mediated by an influence of i.t. NE on spinal processes. NE (0.3 µmoles) injected i.t. reduced neural activity recorded from the lumbar sympathetic chain of anesthetized rats. These results suggest a NE-mediated decrease in efferent sympathetic activity. Studies with ^{3}H-NE injected i.t. demonstrated that this amine does not ascend higher than the rostral cervical cord. The changes in T_c and T_{sk} were therefore not mediated by noradrenergic stimulation of supraspinal areas. The studies with ^{3}H-NE have also showed that only after the 0.3 µmole i.t. dose are physiologically significant levels of NE found in the plasma. Thus, it seems reasonable to suggest that the hypothermia and increase in T_{sk} produced by the 0.01-0.1 µmole dose of i.t. NE were mediated by an action at spinal sites. However, the appearance of NE in the plasma is temporally related to the hyperthermia elicited by the 0.3 µmole dose of i.t. NE. This evidence, in conjunction with the finding that mecamylamine (10 mg/kg, i.p.) did not influence the hyperthermia, suggest that the hyperthermic effect of the 0.3 µmole dose was due to an action at peripheral sites. The hypothermia produced at this dose of NE also seems to involve a peripheral component since intraperitoneal injection of 0.3 µmoles NE caused a small fall in T_c, whereas the lower doses tested were ineffective. Thus, i.t. NE produces a dose-dependent change in thermoregulation which, for the 0.01-0.1 µmole doses, is mediated by an effect on spinal processes. In contrast, the effect of the 0.3 µmole dose on T_c and T_{sk} represents an action at both spinal and peripheral sites.

276.3 MORPHINE TOLERANCE ALTERS NOREPINEPHRINE INDUCED HYPOTHERMIA IN SENESCENT RATS. J.N. McDougal, P.R. Marques* and T.F. Burks. Dept of Pharmacology, University of Arizona Health Sciences Center, Tucson, Arizona 85724.

Tolerance and the associated physical dependence are a characteristic feature of opiate use and abuse. These factors are major limitations of the clinical use of opiates. We have previously shown that senescent rats acquire tolerance to the thermoregulatory effects of morphine less readily than postpubertal rats, but rats of all ages will acquire morphine tolerance with pellet implantation. How aging affects the phenomenon of tolerance to drugs is not known.

Several central nervous system transmitters, including serotonin, norepinephrine, dopamine and acetylcholine, have been shown to be involved in either the acute response to morphine or morphine tolerance. Among other receptor changes, β-adrenergic receptor density was shown to be decreased in senescent rats. Norepinephrine levels of the preoptic and hypothalamic regions of rat brain have been shown to decrease with aging. Norepinephrine injected centrally has been shown to cause hypothermia in rats and rabbits. The acute hypothermic responses to morphine are attenuated by intraventricular phentolamine, but morphine tolerance does not alter hypothermic responses to intraventricular norepinephrine is young rats. The purpose of this study was to determine if morphine tolerance alters norepinephrine-induced hypothermia in senescent rats.

Postpubertal (3 month), mature (10 month) and senescent (27 month) Fischer 344 rats from the colony sponsored by the National Institute on Aging were implanted with intraventricular cannulas and allowed to recover for at least 3 days. Norepinephrine hydrochloride (75 ug) was given intraventricularly in a volume of 5 ul. Rats were restrained in a specially designed wire-mesh restrainer which avoids the heat buildup of conventional plastic restrainers. Colonic temperature was monitored at an ambient temperature of 20-21°C. Results were expressed as change from baseline during a 4½ hour period. Norepinephrine caused a maximum hypothermia of 2-3°C in naive rats of all 3 age groups. Repeating the dose three days later showed no single dose tolerance to norepinephrine in any of the age groups. When the rats were made tolerant to morphine by subcutaneous pellet implantation, the hypothermic response to norepinephrine was reduced in the mature and senescent rats but unchanged in the postpubertal group. These results suggest that morphine tolerance alters noradrenergic sensitivity in mature and senescent rats but not in postpubertal rats. (supported by USPHS grants AG01289 & NS15420)

276.4 SET-POINT FOR BODY TEMPERATURE: THE EFFECTS OF SUPERFICIAL AND DEEP BODY RECEPTORS DURING EXERCISE. G.K. Savard*, K.E. Cooper and W.L. Veale. Department of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

To examine the hypothesis that exercise in man does not cause a shift in the body temperature set-point, subjects were brought from a mildly hypothermic (tympanic temperature (T_{ty}) = 35.0 - 35.8°C) to an hyperthermic (T_{ty} = 37.6 - 38.2°C) state relative to the resting (set-point) temperature (close to 37°C). Subjects were seated in a quiet room for 30 min (T = 22 ± 1.0°C). Mean skin temperature (T_{sk}), T_{ty}, rectal temperature (T_{re}), heart rate (HR) and hand heat elimination (accurate measure of average hand blood flow, HBF) measurements were recorded. Subjects were then immersed in water at 17°C until their body temperature had fallen 0.6 - 1.0°C (30-45 min). They were then heated in one of 3 ways: (1) passive rewarming in a whirlpool bath (T_w = 40°C), (2) exercising on a bicycle ergometer at 65% max HR (at normal, resting body and ambient temperature) in a room maintained at 40°C (T_a), or (3) with subjects working in a suit with the water temperature at 40°C in an attempt to clamp T_{sk} between 37 and 40°C (T_a = 40°C) Resting HBF was sharply reduced when subjects entered the cold water, ie. there was almost complete skin vasoconstriction. Initial results show that the point at which HBF starts to increase from its very low level is independent of the T_{sk}, ie. it is similar whether T_{sk} is around 30°C (as in (2))or 40°C (as in (3)). On the other hand, this 'point of onset' of HBF would seem to depend on the core (T_{ty}) temperature. Preliminary results also indicate that this point is similar for both passive and active rewarming, and occurs at a slightly lower T_{ty} than resting T_{ty}.

Hence, peripheral receptor input (ie. removal of cold afferent stimulation and addition of warm receptor stimulation) would seem to have little effect on the return of HBF, whereas the deep body receptors (probably hypothalamic) may play a key role in the initiation of vasodilatation at these low body temperatures. Also because this central drive (T_{ty}) for the return of HBF was similar both during passive and active rewarming, it would seem that the 'controller', ie. the set-point temperature, remained unchanged, and was certainly not raised by exercise.

These results, using HBF as a peripheral indicator, support the hypothesis that there is no shift in the set-point temperature during exercise.

This work was supported by the Medical Research Council of Canada. G.K.S. is a predoctoral student of the MRC.

276.5 COLD EXPOSURE: ITS EFFECT ON CIRCULATING CATECHOLAMINES AND T_4 IN RABBITS RAISED AT 33°C. A.V. Ferguson, W.L. Veale and K.E. Cooper. Dept. of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

We have recently demonstrated that the thermal environment in early life is significant to the development of temperature regulation in both the New Zealand White rabbit and the Sprague Dawley rat. Animals raised from birth at 33.0 ± 0.1°C show changes in their thermoregulatory ability which include a reduced resistance to cold exposure, a reduced and monophasic fever following intravenous injection of endotoxin and a reversal of the normal hypothermia following intrahypothalamic infusion of noradrenaline.

The present work was carried out in order to investigate the changes in circulating catecholamines and thyroxine in warm reared rabbits during cold exposure (4 hrs at 2.0 ± 1.0°C). Animals were implanted with intravenous cannulae a minimum of 1 week prior to experimentation. The cannulae were filled with heparinised saline and exteriorized through the ear. Colonic temperature was monitored continuously by use of Yellow Springs thermistor probes and blood samples were taken at 60 minute intervals throughout cold exposure. Samples were later assayed for adrenaline, noradrenaline and thyroxine.

Colonic temperature of warm reared rabbits fell 4.10 ± 1.20°C during the 4 hr cold exposure, while control animals maintained baseline temperatures throughout this time period (mean 0.07 ± 0.04°C). Baseline plasma levels of both adrenaline and noradrenaline were found to be significantly elevated in warm reared as compared with the levels of control animals. Adrenaline levels were 28 ± 11 pg/ml in control and 377 ± 87 pg/ml in warm reared rabbits, while noradrenaline levels were found to be 362 ± 34 pg/ml and 746 ± 184 pg/ml in control and warm reared animals respectively. Following 4 hrs cold exposure these levels were not significantly changed in control animals, while warm reared animals demonstrated significant increases in both monoamines, to 1980 ± 780 pg/ml for adrenaline and to 1776 ± 477 pg/ml for noradrenaline. T_4 levels in serum were found to be reduced in warm reared (mean 12 ng/ml) as compared to control (mean 26 ng/ml) rabbits, and no significant increases were observed in either group during cold exposure.

Further data on changes in TSH and T_3 during cold exposure are necessary to obtain a clearer picture regarding thyroid function in warm reared animals. However, the increase in plasma catecholamines during cold exposure suggests the sympathetic nervous system to be functional in warm reared rabbits.

276.7 PRECISE ANATOMICAL LOCALIZATION OF THERMAL BIOFEEDBACK SELF-REGULATION AROUND DIFFERENT FEEDBACK LOCI ON THE HAND IN HUMANS. Edward Taub*, Thomas Spalding and John Kunz. Inst. for Behavioral Research, 2429 Linden Lane, Silver Spring, MD 20910.

A biofeedback technique was developed in this laboratory for enabling most humans to establish rapid self-regulatory control of their skin temperature. It involves operant conditioning of small variations in skin temperature by means of changes in a visual information display. Pilot work had indicated that when feedback was given from a single location on the hand the learned temperature change is not diffuse, as might be expected of a response mediated by the autonomic nervous system, but rather develops considerable anatomical specificity around the feedback locus. To verify this observation subjects in this experiment were given feedback from one of several locations, and were trained for at least twenty sessions each. Temperature was recorded from five locations on each hand.

Nine subjects were given feedback electronically averaged from the first three fingers. For the last ten sessions, temperature change at two locations on the metacarpus was significantly less (43%) than on the fingers. Four subjects were given feedback from the web dorsum. For the three subjects who learned the response, the web dorsum exhibited a much greater (384%) effect than the fingers. In addition, temperature change at this location was 299% greater than at the hypothenar eminence, thus producing a clear fractionation within the metacarpus. Two subjects given feedback from the hypothenar eminence learned the response and exhibited a greater temperature response there than on the fingers (154%) or on the web dorsum (260%). Three subjects given feedback from the index finger exhibited the expected significant advantage of the fingers over the metacarpus, and one showed a greater effect on the index finger than on the other fingers. This subject also displayed an exquisite localization of the response to the ulnar surface of the index finger, from which feedback was originally given. When the feedback locus was switched without the subject's knowledge to the radial surface of the finger, the focus of the response gradually switched to that side over a period of days. Supplementary experiments indicate that these effects are not due to movement, isometric muscular contractions or respiratory manuevers.

The results indicate that with the present technique there is a marked specificity within the same hand of temperature self-regulation effect to the anatomical loci from which feedback is given. Thus, neural control over the peripheral vasculature, as reflected in skin temperature changes, can be far more precise than has been generally considered possible.

276.6 MATERNAL INFLUENCES ON DEVELOPMENT OF FEBRILE RESPONSES IN KITTENS J.R. Villablanca and Ch.E. Olmstead. MRRC and Depts. of Psychiat. and Anatomy, UCLA School of Medicine, Los Angeles, CA 90024.

We have described the maturation of thermoregulation in the kitten, both in response to environmental challenge (Physiol. Behav. 23: 489, 1979) and to exogenous pyrogens. In both instances a feature of the developmental profile was the considerable amount of intra- and interlitter variability. Factors to be discussed led us to consider whether the immunological status of the mother, relative to certain feline diseases, might be a significant contributor to this variability. Feline Infectious Peritonitis (FIP) is a major factor in the survival of offspring within catteries and a radioimmunoassay is readily available for evaluating the serology of the mothers (Am. J. Vet. Res. 42: 368, 1981). Eighty three kittens from term litters received i.v. injections of typhoid vaccine diluted 1:100 (dose .5ml/kg at ~10^6 organisms per ml) in numbers and age groups shown in the table. Rectal temperature (T_B) was monitored at an ambient (T_a) of 20-23° for 1 hr prior to and for a minimum of 5 hrs post-injection. Fever was estimated using a thermal index (TI = sum of ΔTB/minutes x 100). Kittens were divided into high (>1:400) and low (<1:100) titer groups on the basis of maternal FIP antibodies. The results are summarized in this table.

		LOW TITER		HIGH TITER
AGE	N	TI(S.E.M.)	N	TI(S.E.M.)
0 - 10	8	3.40 (1.28)	10	2.49 (0.46)
11 - 20	11	1.87 (0.35)	11	1.89 (0.35)
*21 - 30	7	3.90 (0.36)	6	2.17 (0.28)
*31 - 40	9	5.57 (0.65)	7	2.95 (0.52)
*41 - 50	6	7.56 (0.70)	8	4.06 (0.52)

*P < .05, Mann-Whitney U for high versus low titers

In general, kittens from both groups showed higher T_B and fevers in the immediate postnatal period. The T_B of the high titer group was significantly higher than the low during this period. The febrile response developed across the first 5 weeks of life in both groups with the maturational process being significantly slower in kittens from the high titered mothers. No indications of behavioral thermoregulation were seen during the early days in either group. These data indicate that the immunological status of the mother has significant influence on the postnatal development of thermoregulation in the kitten.

277.1 ENTRAINMENT OF CIRCADIAN LOCOMOTOR AND DRINKING RHYTHMS IN OPHTHALMECTOMIZED RODENTS. T.G. Hedberg and A.S. Feng. Dept. Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

The entrainment of various cyclic behavioral functions such as locomotor, feeding and drinking activity to a 24-hour light:dark cycle has been frequently demonstrated in many species of mammals. Ocular photoreception is the primary if not sole mechanism of rhythm entrainment for most species. However, aside from Nelson and Zuckers' (1981) demonstration of the absence of circadian entrainment of wheel-running in blinded ground squirrels we know of no systematic investigations of entrainment mechanisms in diurnal mammals deprived of ocular photoreception.

In this study, the circadian rhythms of feeding, drinking and locomotion were monitored in ten intact Monogolian gerbils (Meriones unguiculatus) kept in a 10:14 LD cycle. Under a light source which approximated natural sunlight in spectral range and intensity, all three activities showed circadian rhythms which became entrained to the photic cycle. Drinking began uniformly within five minutes of photoperiod onset in the three animals monitored. Locomotion and feeding activities in all animals began within a 30 minute span before or after the start of the light phase. After the photoperiod was clock-shifted to begin six hours later, free-run ensued in all three parameters but was followed by entrainment after a delay of six days.

Four months after monitoring began all animals were enucleated bilaterally under sodium pentobarbital anesthesia and returned to the same testing regimen. Activity records compiled for three months after enucleation show persistance of the entrainment of drinking and locomotion but progressive aperiodicity in the feeding rhythm. A three hour clock-shift in photoperiod onset was done 40 days after enucleation. After 13 days of free-run, entrainment of the drinking rhythm in the same three animals became evident again.

We are unable to propose a mechanism for entrainment of these cycles at the present but investigations of the influence of potential zeitgebers such as temperature and sound are currently underway. In addition, the admittedly dim possibility of rhythm mediation by extraretinal photoreception cannot be discounted.

277.2 FEEDING AND LIGHT AS ENTRAINERS OF CIRCADIAN RHYTHMS. Friedrich K. Stephan, James A. Donaldson* and Ann Robbins*. Dept. of Psychology, Florida State Univ., Tallahassee, FL. 32306

Although rats with lesions of the suprachasmatic nuclei(SCN) show only weak or no circadian rhythms in activity in ad lib. feeding conditions, activity can be entrained to restricted feeding schedules with periods between 22 and 31 h (Boulos, Rosenwasser & Terman, Behav. Brain Res., 1:39-65, 1980; Stephan, J. comp. Physiol., in press, 1981). Activity of intact rats can also be entrained to restricted feeding; however, in constant light or darkness a free-running rhythm of activity usually is observed along with feeding entrained activity (Edmonds & Adler, Physiol. & Behav., 18:915-919, 1977; Gibbs, Am. J. Physiol., 236, R249-253, 1979).

The present experiment was designed to study the interaction between light- and feeding-entrainable activity rhythms. 16 rats were then placed on a 24 h feeding schedule with 2 h access to food/day, for 40 days, followed by 25 days on ad lib.

In only 4 cases was the free-running activity rhythm synchronized by the feeding schedule. The period of the free-running rhythm in these rats was very close (15 min) to that of the feeding schedule. In most of the remaining rats, a small change in tau (10-20 min) was systematically correlated with the introduction of the feeding schedule; however, the activity rhythm continued to free-run.

A 2 h light "pulse" delivered near the onset or offset of the free-running activity pattern resulted in the expected phase delays and advances, but had no effect on feeding entrained activity.

A 4 h phase advance of the feeding schedule resulted in advancing transients in feeding entrained activity for 5-7 days and affected the phase of the free-running activity in 2 out of 4 cases. Transients in response to a 4 h phase delay were less systematic and were partially obscured by the free-running activity rhythm.

Return to ad lib. conditions caused considerable instabilities in the free-running activity. These included large phase jumps and increased variability in the onset and in the acrophase of the activity pattern.

These results suggest that feeding entrainable oscillators can be "decoupled" from the free-running rhythm. The latter is light entrainable and presumably driven by the SCN. Entrainment of oscillators by feeding appears to exert some feedback on the light entrainable oscillator(s). The former can entrain the latter if their respective periods are sufficiently close.

277.3 SUPRACHIASMATIC NUCLEI: BILATERALLY DISTRIBUTED CIRCADIAN PACEMAKER SYSTEM? Alan M. Rosenwasser*, Ricardo Eng, and Norman T. Adler (SPON: D. HURVICH). Dep'ts. of Psychology and Anatomy, and Inst. Neurol. Sci., Univ. of Pennsylvania, Philadelphia PA, 19104.

The suprachiasmatic nuclei of the hypothalamus (SCN) have been identified as crucial for the normal expression of circadian rhythmicity in mammals. However, much evidence suggests that the circadian system consists of multiple "coupled" but potentially independent oscillators. Thus, the SCN may function as a master oscillator in a coupled multioscillator system. Furthermore, the SCN may themselves contain multiple oscillators since lesions which spare SCN unilaterally are consistent with considerable sparing of circadian function. In some non-mammalian species, bilaterally distributed pacemaker systems have been identified. Analyses of such systems reveal that the two pacemakers may oscillate independently and that overall circadian organization depends upon the interaction (coupling) between them. Recent reports that the mammalian SCN are connected neurally by fibers crossing the midline in the infundibular tract suggests that the SCN are a pair of neurally coupled bilaterally distributed circadian pacemakers. The present experiments were conducted to investigate this possibility by disrupting the coupling between the two SCN with midline knife cuts.

Female Long-Evans and Sprague-Dawley rats were given parasagittal midline knife cuts using a retracting wire knife. The cuts were aimed to interrupt neural connections between the SCN and to sever the optic chiasm throughout its anterior-posterior extent. These cuts should isolate the SCN from each other and restrict retinal input to that arising from the ipsilateral eye. The subjects were maintained with access to running wheels and exposed to light-dark cycles, light-dark phase shifts, and continuous illumination. While entrainment to the light-dark cycle appeared normal, an altered pattern of reentrainment was observed following phase shifts: the activity rhythm "split" into two components, one of which phase-advanced while the other phase-delayed into the new entrainment phase. These results are consistent with the idea that each nucleus is a potentially independent pacemaker, and that the two SCN are normally coupled by mutual innervation. We are currently further exploring this hypothesis by extending the range of lighting regimens employed and by placing unilateral SCN lesions.

Supported by NIH grants HD04522 and MH15092.

277.4 SPLITTING OF THE CIRCADIAN RHYTHM OF ACTIVITY IN THE GOLDEN HAMSTER IS ABOLISHED BY UNILATERAL LESIONS OF THE SUPRACHIASMATIC NUCLEI (SCN). G.E. Pickard and F.W. Turek. Columbia Univ., College of Physicians & Surgeons, Dept. Anatomy, New York, NY, 10032 & Northwestern Univ., Dept. Biol. Sci., Evanston, Ill., 60201.

The organization of the circadian system in multicellular organisms is based on the interactions of at least two circadian pacemakers. This is evident from the observation that exposure to constant light (LL) can lead, in many species, to a dissociation ("splitting") of the free running rhythm of activity into two distinct components. These two activity rhythms often free-run with different periods and stabilize approximately 180° out of phase. Little is known about the neural interactions underlying the organization of circadian rhythms or how multiple circadian pacemakers might be coupled to each other.

In searching for the neural location of the biological clock in mammals, attention has focused on the SCN since destruction of these nuclei leads to the loss of a number of different circadian rhythms. In view of the fact that the SCN are reciprocally innervated (Silverman and Pickard, Neuroscience Abst. 6:266 1980), we have begun our examination of the neural organization of the circadian system by examining the effect of unilateral SCN lesions on both intact and split circadian activity patterns of golden hamsters housed in LL.

Electrolytic lesions aimed at a single SCN were made in 19 hamsters demonstrating a split rhythm of locomotor activity (splitters) and in 11 animals displaying only a single circadian bout of activity (intacts). The extent of the lesions was determined by both Nissl stain and by the presence of labeled retinal terminals in the SCN following monocular HRP injection. Bilateral destruction of the SCN in splitters and intacts resulted in aperiodicty or ultradian activity patterns (N=6). Complete or partial unilateral lesions of the SCN in intact animals (N=10) did not alter the circadian rhythm of activity. Similarly, incomplete unilateral SCN lesions or lesions made in the neuropil adjacent to the SCN in splitters (N=6) did not alter the split activity rhythm. Importantly however, complete unilateral ablation of the SCN in splitters resulted in the termination of the split phenomenon and re-establishment of a single circadian activity component (N=8).

We have demonstrated that the splitting phenomenon is abolished following unilateral ablation of the SCN. While these findings could be interperted as suggesting that each SCN controls one component of the split activity rhythm, further studies are necessary to determine the complex interaction of both SCN in generating both split and intact circadian activity rhythms. Supported by a postdoctoral fellowship to GEP from the Pharmaceutical Manufacturers Assoc. and by NIH grants HD-09885 and HD-12622 to FWT.

277.5 CONTROL OF THE SUPRACHIASMATIC NUCLEUS TO THE VENTROMEDIAL HYPOTHALAMUS IN RAT BRAIN SLICES. Y. Oomura, S. Shibata, and H. Kita. Dept. Physiol. Facul. Med. Kyushu Univ., Fukuoka, 812, Japan.

It is well known that the suprachiasmatic nucleus (SCN) may act as a main source for many behavioral and hormonal circadian rhythmic changes in rats. Not only bilateral lesions of the SCN but also the ventromedial hypothalamic nucleus (VMH) abolished the circadian rhythms of food intake (Nagai, K., et al. Brain Res., 142: 384, 1978). From circadian rhythmic activity change in the SCN, the lateral hypothalamic area (LHA), and VMH (Koizumi, K. & Nishino, H., J. Physiol., 263: 331, 1976), as well as the anatomical evidence of direct projections from the SCN to the VMH and LHA (Swanson, L. W. & Cowan, W. M., J. Comp. Neurol., 160: 1, 1977), it appears that one of the control mechanisms of rhythmic feeding behavior may be a result of neural modulation of VMH and LHA activity by the SCN. Intracellular responses in the rat LHA neurons to SCN stimuli were demonstrated(Oomura, Y., et al. In: Biological Rhythms and their Central Mechanism. Eds. M. Suda et al., N. Y. Elsevier, p295, 1979).[1] Nevertheless, the effect of SCN stimulation on the VMH is still unclear. In the present study, using brain slice and intracellular recording, permitted clear demonstration of the effects of SCN stimulation of VMH activity.

Hypothalamic slices, included the SCN and VMH, were cut sagittally from rat cerebrum. For SCN stimulation, a bipolar tungsten wire electrode was used. Intracellular recording electodes were filled with 3M K-acetate. Out of 96 intracellurally recorded VMH neurons which had more than 40mV resting membrane potential, 18 elicited orthodromic responses and 6 produced antidromic spike (latency, 2.8±0.3: mean±S.D.). The main orthodromic response(78%) was EPSP's. Of 14 EPSPs, 10 were elicited with fixed latency (3.3±0.7ms), probably monosynaptic, for repetitive stimuli, and responses could follow to double pulse stimulation spaced shorter than 15ms. The reamining 4 exhibited polysynaptic EPSPs(latency, 4.9±0.4ms). Another kind of response which appeared to be an IPSP-like hyperpolarizing response followed by rebound discharges, were observed in 4 neurons(latency, 2.9±0.8ms). This hyperpolarizing response might be a reversed EPSP and not an IPSP since the amplituds of the rebound spike discharges were less than 30mV and the response could reversed by membrane hyperpolarization with a small negative injected current. This idea may be supported by a previous extracellular study, no inhibition of VMH activity by SCN stimuli was observed.[1] In our previous report[1] SCN mainly inhibited LHA neurons multisynaptically. From our present and previous data, it can be concluded that the SCN exerts excitatory influence on VMH activity and inhibitory one on the LHA. This SCN control may partly explain the nocturnal food intake of the rat. Antidromic spike response in some VMH neurons to SCN stimulation may indicate some functional influence on the SCN.

277.6 CIRCADIAN RHYTHMIC CHANGES OF SCN NEURONAL ACTIVITY IN THE RAT HYPOTHALAMIC SLICE. H. Kita,* S. Shibata, Y. Oomura (SPON: J. LaVail). Dept. Physiol., Faculty Med., Kyushu Univ., Fukuoka, 812, JAPAN.

Many studies have demonstrated that bilateral lesions of the suprachiasmatic nucleus (SCN) abolish both behaviolal and hormonal circadian rhythms such as feeding, locomotor activity, sleep-wakefulness, and plasma corticosterone levels in the rat, and suggesting that the SCN may participate in the regulation of these rhythms. Multipule neural unit activity recorded from the rat SCN showed circadian rhythmicity that still remained many days after the deafferentation of the retinal input to the SCN (Inouye,S.T. & Kawamura,H., Proc. Natn. Acad. Sci.,6,5962,1979). However, properties of single unit activity in the SCN were not demonstrated in that study.

The present study, utilizing rat brain slice preparations, demonstrated that SCN single neuronal activity showed changes corresponding with environmental light-dark (L-D) periods, even after the SCN was isolated from other brain areas. Adult wistar rats were adapted for at least one month to either a normal L-D (light, 0800-2000 hr) or a reversed schedule (light, 2000-0800). Food and water were available ad lib. A hypothalamic slice(about 300μm thick) preparation including the SCN was cut coronally from the brain at various clock times. Recordings of single unit activity were begun after a 30 min preincubation.

SCN spontaneous discharges showed very regular intervals with a range of 0.5 to 20 spikes/sec. The unit discharge rate of the SCN prepared from normal L-D rats was significantly different during the L and D-period: the highest (7.0 ± 2.7, mean ± S.D., n=24) from 1400 to 1500 and the lowest (3.8 ± 2.1, n=11) from 0200 to 0300. The unit discharge rate of the SCN prepared from the reversed L-D rats also showed a clear difference between the L and D-periods, however the activity change was shifted approximately 12 hs: the highest (7.9 ± 2.3, n=10) from 0200 to 0300 and the lowest (4.0 ± 2.1, n=13) from 1400 to 1800. Above results indicate that SCN activity itself can be entrained by the environmental L-D cycle with independent of afferent connections from other brain areas and humoral influences.

It has been reported that SCN stimulation produced mainly excitatory responses in the ventromedial hypothalamus and mainly inhibitory responses in the lateral hypothalamus in the rat (Oomura Y., et al., In: Biological Rhythms and their Central mechanism. Eds., M.Suga, H.Nakagawa & O.Hayaishi, N.Y., Elsevier, p 295, 1979). These present and previous evidence may provide a neuronal base for the circadian rhythmic feeding behavior observed in the rat.

278.1 HISTAMINE CHANGES INDUCED BY LOCAL INJECTION OF KAINIC ACID IN THE RAT STRIATUM. G.Sperk, H.Hörtnagl,M.Berger and O.Hornykiewicz. Institute of Biochemical Pharmacology, Univ.of Vienna, 1090 Vienna, Austria.

Intrastriatal injection of kainic acid in the rat results in selective destruction of intrinsic and efferent neurons of the striatum (Schwarcz,R.& Coyle, J.T.,Brain Res.127:235,1977). Recent studies showed that the lesion is followed by an activation of striatal dopamine and serotonin containing input neurons (Andersson,K. et al.,Nature 283:94,1980; Sperk,G. et al., submitted for publication). In the present study we investigated the function of the histamine system, another striatal input system (Schwartz,J.C. et al.,J. Neurochem.35:26,1980), following local injection of kainic acid.

Kainic acid (1 µg/µl) was infused stereotaxically into the left caudate of male Sprague-Dawley rats. The animals were killed after 2,10 and 70 days. Ten days after the injection, striatal glutamate decarboxylase and choline acetyltransferase activity respectively was 20 and 18 per cent of control.

There was a more than 100 per cent increase of striatal histamine levels persisting from two days after the lesion up to ten weeks. This accumulation of histamine seems to be associated with neuronal compartments because: (a) lesions of the median forebrain bundle abolished the histamine increase; and (b) a subcellular distribution study revealed an accumulation of the amine in synaptosomes but not in the P1-fraction. Concomitant with the increase in histamine levels there was a marked (50 per cent) decrease of histidine decarboxylase activity and a decrease in the disappearance rate of histamine after treatment with the histidine decarboxylase inhibitor α-fluoromethylhistidine (20 mg/kg, i.p., 2 hrs).

Our data demonstrate considerable changes in the neuronal histamine system taking place in the kainic acid injected striatum. The increase in histamine levels might be due to a decreased release of the amine, with a subsequent decrease in histamine synthesis rate.

We thank Dr.J.Kollonitsch for α-fluoromethylhistidine. Supported by the Austrian Science Research Fund, project S-25/02.

278.2 LOCALIZATION OF HISTAMINE-LIKE IMMUNOREACTIVITY IN RAT BRAIN. B.J. Wilcox and V.S. Seybold. Department of Anatomy, University of Minnesota Medical School, Minneapolis, MN 55455

In addition to its role in mast cells, biochemical and pharmacological evidence indicates that histamine may act as a neurotransmitter within the central nervous system. The distribution of histamine is reported to be uneven throughout the brain, with the highest concentration found in the hypothalamus, and pharmacological studies indicate that histamine may be involved in control of arousal states.

In order to obtain morphological information concerning histaminergic pathways in the brain, an antiserum against histamine has been generated in guinea pigs. This antiserum has allowed visualization of nerve fibers and cell bodies in rat brain by immunofluorescence.

The primary antiserum was generated in guinea pigs by immunization with histamine-methylated BSA complex. Ten micron frozen sections from normal and colchicine treated rats perfused with buffered 4% paraformaldehyde were processed for immunofluorescence. Adjacent sections were processed as absorption controls. Selected animals were injected with L-histidine (500 mg/kg, ip) thirty to sixty minutes prior to perfusion in order to enhance endogenous histamine levels.

Histamine-like immunoreactivity was observed in varicose fibers in the hypothalamus with the highest density found in the median eminence and in basal hypothalamic areas lateral to the median eminence. Scattered fibers appeared in the amygdala, hippocampus, and throughout the cortex. Histidine loading before sacrifice increased the quantity of visible varicose fibers. Absorption controls showed disappearance of fluorescent fibers when the primary antiserum was preincubated with the histaminemethylated BSA complex, while preincubation with the methylated BSA complex only did not alter labeling. Colchicine pretreatment revealed cell bodies within the lateral hypothalamus. These results are in agreement with existing evidence and support the hypothesis that a portion of the histamine in the brain is contained within a neuronal compartment.

278.3 EFFECT OF RESERPINE ON MOUSE BRAIN HISTAMINE AND ITS SUBCELLULAR DISTRIBUTION. E.L. Orr* (SPON: I.M. Korr). Dept. of Anat., N.T.S.U./T.C.O.M., Ft. Worth, Tx. 76107.

Adult male mice were group-housed in plastic cages in air-conditioned animal quarters with a L:D cycle of 12 hr light:12 hr dark. In experiment 1, mice were injected i.p. with 0.08 ml saline or 5 mg/kg reserpine (Serpasil) and sacrificed 16 hrs. later. Brains were removed and homogenized in 2.5 or 12.5 volumes of ice-cold distilled water. The homogenates were heated, cooled and centrifuged at 40,000 xg for 10 min. Supernatants were assayed radioenzymatically for histamine (Hm) according to Orr & Eichelman (J. Neurochem. 30: 1539,1979). In experiment 2, mice were treated as in experiment 1, but whole brains were homogenized in 10 volumes of 0.32 M sucrose and crude subcellular fractions (P_1, P_2 and S) were prepared. The P_1 and P_2 pellets were weighed and homogenized in 12.5 vol. distilled water. After heating the P_1 and P_2 homogenates and the S fraction, supernatants were prepared and assayed for Hm.

		Saline	Reserpine	P (Sal. vs Res.)
Low Vol.	ng/g	67±2	89±3	<<0.002
High Vol.	ng/g	295±15*	353±19*	<0.05
P_1	ng/fraction	32±4	28±3	NS
P_2	ng/fraction	52±3	53±5	NS
S	ng/fraction	40±3	75±12	<0.02

*P<0.05 high vs. low volume

The above data show that whole mouse brain contains substantial quantities of Hm as previously demonstrated for rat brain (Orr & Eichleman, 1979). Further, reserpine increases the amount of Hm in the mouse brain, apparently by increasing the amount of cytoplasmic Hm. However, in saline-treated mice, the general distribution of Hm in the crude fractions is similar to the distributions reported by others in the mouse and rat brain, although in those reports, only a small fraction of the total brain Hm content was actually measured. In conclusion, mouse brain contains about 300 ng Hm/g wet wt. which is increased by reserpine. The increase is probably due to slow metabolism of intraneuronal Hm released by reserpine from synaptic vesicles into the synaptoplasm.

Supported by a faculty research grant from T.C.O.M.

278.4 HISTAMINE H2-RECEPTORS ON GUINEA PIG ILEUM MYENTERIC PLEXUS NEURONS MEDIATE RELEASE OF CONTRACTILE AGENTS. L.A. Barker and B. Jones Ebersole.* Dept. Pharmacology, Mount Sinai Sch. Med. of the City University of New York, New York, NY 10029.

The actions of the selective histamine H2-receptor agonist, dimaprit, were studied on the isolated ileum and the plexus containing ileal longitudinal muscle preparations of the guinea pig. Dimaprit caused a multiphasic contraction of both preparations. The initial phase was characterized by a twitch response which reached a maximum in 15 - 20 s and was followed by a partial relaxation. The secondary phase consisted of a slowly developing contracture which was sometimes accompanied by oscillatory changes in tension or consisted of a series of twitch responses. Dose-response curves were generated for the inital response; for intact ileal segments the EC50 was 5.1 ± 1.8 µM (mean ± s.d., N=7) and the Hill coefficient was 1.1 ± 0.2 and for longitudinal muscle strips the EC50 was 5.8 ± 1.2 µM and the Hill coefficient was 1.2 ± 0.1 (N=7). Both the initial and secondary components of the contractile responses to dimaprit were non-surmountably antagonized by 0.2 µM tetrodotoxin or 10 µM mefenamic acid and by the production of tachyphalaxis to either substance P or serotonin. Scopolamine, 0.001 - 0.1 µM, non-surmountably antagonized only the initial component of the response. Mepyramine (1.0 µM), hexamethonium (100 µM), and bromolysergic acid (0.25 µM) were without effect on the response to dimaprit. The histamine H2-receptor antagonists, tiotidine and cimetidine, produced parllel dextral shifts in the dose response curve for dimaprit with variable reductions in the maximal response which were reversed upon removal of the antagonist. The apparent pA_2 values for tiotidine and cimetidine antagonism of dimaprit are 7.7 and 6.1 respectively. We conclude that dimaprit acts on H2-receptors located on myenteric plexus neurons to cause the release of contractile substances. The mediators of the contractile response are tentatively identified as acetylcholine, products of the arachadonic acid cascade, and possibly substance P and serotonin.

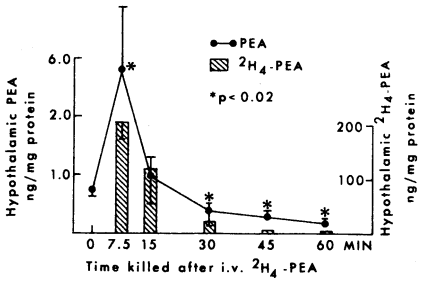
278.5 A SIMILARITY BETWEEN TYRAMINE-INDUCED NEUROTOXICITY AND THE ENCEPHALOPATHY OF REYE'S SYNDROME. B. A. Faraj, F. M. Ali* and E. Malveaux*. Dept. of Radiology (Div. Nucl. Med.), Emory University School of Medicine, Atlanta, GA 30322.

Reye's syndrome is a disease associated with acute encephalopathy with evidence of hepatic dysfunction in children. Clinically, cerebrospinal fluid pressure is frequently elevated, particularly in children who subsequently die from unresolved encephalopathy. Hypertyraminemia is a common metabolic abnormality in Reye's syndrome and correlates with stage and duration of coma (Pediatrics 64:76, 1979; Lancet 2:1097, 1979). Hypertyraminemia was caused primarily from decreased metabolism since lowered activity of monoamine oxidase (MAO) was noted in hepatic biopsy specimens of patients with Reye's syndrome (Pediatrics 65:647, 1980). The objective of the present investigation was to determine whether or not tyramine induces encephalopathy in experimental animals with impaired mitochondrial MAO function, and whether the encephalopathy in these animals was a function of increased CSF pressure. Ten mongrel dogs were treated (orally) daily with the MAO-inhibiting drug, phenelzine (3-9 mg/kg) over a period of one month. At the end of this period, the dogs were anesthetized with sodium pentobarbital (25 mg/kg) and catheters were inserted into the femoral vein and artery for tyramine administration and blood pressure recording. A 20 gauge intracath needle was inserted into the cisternal space for continuous monitoring of CSF pressure. Tyramine was infused (1 mg/kg) over a period of 10 min. The present studies indicated that tyramine infusion caused acute but transient hypertension followed by prolonged elevation in CSF pressure that exceeded 40 mm Hg (initial pressure was 7-10 mm Hg). This was followed by substantial accumulation of tyramine (25 ± 6.1 ng/ml vs 1.5 ± 0.3 ng/ml), dopamine (1533 ± 450 pg/ml vs 10 ± 3.2 pg/ml) and norepinephrine concentrations (6197 ± 1011 pg/ml vs 137 ± 37.5 pg/ml) in CSF of these treated animals at 60 min following dose administration. Intracranial hypertension in these animals correlated significantly with dogs behavior characteristic with the encephalopathy of Reye's syndrome including tremor, rigidity, convulsive seizure and coma. Contrastingly, the administration of tyramine to control dogs caused only the expected transient increase in blood pressure but with no significant effect on CSF pressure (≈7-12 mm Hg). These animals recovered fully from the experiment without any ill effect. The pathogenic role of tyramine in Reye's syndrome may be a consequence of (1) altered transport of tyramine at the blood-brain barrier; (2) increased sensitivity of the brain to tyramine; and/or, (3) increased release of catecholamines from central catecholaminergic neurons.

278.6 BIOCHEMICAL EVIDENCE OF POSITIVE FEEDBACK CONTROL OF PHENYLETHYLAMINE (PEA) RELEASE IN THE RAT BRAIN. F. Karoum, L.W. Chuang and R.J. Wyatt, Adult Psychiatry Branch, National Institute of Mental Health, Washington, D.C. 20032.

The observations that PEA shares many behavioral, electrophysiological and pharmacological properties with amphetamine and that amphetamine increases brain concentration of PEA, have prompted us to evaluate the effect of exogenously administered PEA on the production and release of endogenous brain PEA. For this, we administered a deuterated isomer of PEA ($^2H_4$-PEA), 2.5 mg/kg, i.v. to rats in groups of five and followed their hypothalamic and caudate nucleus concentrations of endogenous PEA and $^2H_4$-PEA over time. The results of our finding on the hypothalamus are summarized in the figure below. Similar results were obtained in the caudate nucleus.



Our results demonstrate that $^2H_4$-PEA very rapidly entered the brain and that it is equally rapidly destroyed. Furthermore, these results suggest a bi-phasic effect of elevated exogenous brain PEA (as demonstrated by $^2H_4$-PEA) on endogenous brain PEA. Increased exogenous brain PEA caused an elevation in endogenous PEA; an effect presumably related to increased PEA release. At a later period when practically all exogenous PEA is destroyed, endogenous brain PEA declined to concentrations significantly below normal. These two effects may respectively be related to a positive and negative feedback regulatory mechanisms of brain PEA release.

279.1 ETHANOL INHIBITS HARMALINE-INDUCED TREMOR AND CEREBELLAR INCREASES OF cGMP CONTENT. M. S. Rappaport*, R. T. Gentry,* D. R. Schneider*† and V. P. Dole* (SPON: N. E. Miller). The Rockefeller Univ., New York, NY 10021 and †Dept. of Pharmacol., Wayne State Univ. Sch. of Med., Detroit, MI 48202.

Neurophysiological and neurochemical evidence suggest that some pharmacological effects of ethanol may result from its facilitation of inhibitory neurotransmission mediated by γ-aminobutyric acid (GABA). We have selected harmaline-induced stimulation of Purkinje cell activity as a means to study the interaction between ethanol and GABA in cerebellum according to the rationale of Costa et al.,(Adv. Biochem. Psychopharm., 14: 113, 1975). Whole body tremor and an increase of cyclic guanosine monophosphate (cGMP) content of cerebellum are established endpoints of harmaline activation of Purkinje cells in mammals.

Tremor was assessed by observers blind to drug treatments; a numerical score of tremor was assigned to individual animals at one minute intervals throughout the study period (35 min). Male C57BL/6J mice (20-25g) were used in all studies. Harmaline HCl (10 mg/kg) was administered 20 min before vehicle (water) or ethanol (0.1, 0.3 and 1.0 g/kg, ip). Prior to measurement of cerebellar cGMP by radioimmunoassay, mice were killed by focused microwave radiation (6 kW, 480 msec) at 7 min following the second injection.

A dose-related suppression of harmaline-induced tremor resulted following ethanol. This effect was maximal within 7 min. Harmaline increased cerebellar cGMP content by 60% ($p<0.01$). This increase was completely attenuated by ethanol (0.3 and 1.0 g/kg).

Oxotremorine induces tremor by a mechanism known not to involve climbing fiber activation of Purkinje cells. Tremor induced by an equivalent tremorogenic dose of oxotremorine (0.25 mg/kg) was relatively unaffected by ethanol. Concentrations of cGMP were not significantly altered by oxotremorine.

These data demonstrate a pharmacological similarity between ethanol and the benzodiazepines which appear to act via GABAergic facilitation and are consistent with the hypothesis that certain pharmacological effects of ethanol are GABAergically mediated. (supported by grants from the John L. and Helen Kellogg Foundation and the Florina Lasker Foundation).

279.2 AN ANIMAL MODEL OF ALCOHOL DEPENDENCE. H. Rigter and J.C. Crabbe. CNS Pharmacology Dept., Organon, Oss, The Netherlands.

Animal models of alcohol dependence should meet a number of requirements. Importantly, the animals need to voluntarily ingest so much alcohol, that the intake exceeds the metabolic capacity of the organism, and that tolerance and physical dependence are induced or maintained. One reason for the relative failure to develop animal models of alcohol dependence may be the aversiveness of the taste of alcohol, or other aversive factors associated with the drinking of alcohol solutions. Accordingly, we wondered whether using another route of administration of alcohol would help the development of an adequate animal model. Forced inhalation of alcohol vapor can produce physical dependence in mice. We have found that mice learn to voluntarily inhale intoxicating amounts of alcohol vapor. The apparatus consisted of two plastic boxes (110 x 60 x 40 cm). Groups of 20 male Swiss mice were used. The mice could move from one box to the other by climbing an interconnecting bridge (slope: 45°). Alcohol (ethanol) vapor (7-10 mg/l air) was led into one box, according to a daily alternating schedule; air was led into the other box. The mice were injected with pyrazole once a day (1 mmole/kg, i.p.), to inhibit metabolism of alcohol. The animals were then placed in the 'air'box. The number of mice selecting the 'alcohol'box was scored hourly. During the first phase of the experiment (days 1-3), the 'alcohol'box was covered with an opaque plate. Mice prefer dark over illuminated spaces; therefore, all of the mice selected the (dark) 'alcohol'box. During the second phase of the experiment (days 4-7) the plate was removed. Pyrazole-treated mice continued selecting the 'alcohol'-box. On day 8, their blood levels ranged from 0.3-1.6 mg/ml blood. When removed from the 'alcohol'box, alcohol-selecting mice exhibited withdrawal convulsions, when picked up at the tail and spun. Withdrawal signs were apparent in some mice for more than 24 h. The mice also were tolerant to the hypothermic effect of alcohol, when tested 6 h after withdrawal. Mice receiving only pyrazole during days 1-3, either avoided alcohol, when alcohol vapor was introduced from day 4 onwards, or had a spatial preference for one of the boxes (resulting in a '50%' alcohol preference). Pyrazole treatment was necessary to produce consistent selection of alcohol within the short time period studied.

279.3 TETRAHYDROISOQUINOLINES ADMINISTERED TO THE NEONATE ALTER ALCOHOL PREFERENCE OF THE ADULT RAT. H.S. Swartzwelder and R.D. Myers. Center for Alcohol Studies and Departments of Psychiatry and Pharmacology, UNC School of Medicine, Chapel Hill, NC 27514.

Certain tetrahydroisoquinolines (TIQs) have been implicated in the abnormal drinking of alcohol. Tetrahydropapaveroline (THP) infused ICV can induce alcohol self-selection in the normally abstinent rat, and salsolinol has been found in the CSF of the alcoholic patient. However, the effect of such compounds upon the developing organism and the characteristics of its subsequent alcohol consumption is not known.

Within 24 hrs after birth, Sprague-Dawley male and female rat pups were given systemic injections of either THP (2.5 µg or 25 µg) or a control CSF solution. Within each of the six litters, the two doses and control vehicle were injected. In another set of five litters, three protoberberine (PBN) compounds and control vehicle were administered according to the same protocol in doses based on their LD-50 toxicity level. All rats were weaned at 21 days and placed in cages individually. Alcohol preference testing was begun at 70 days of age with a two-bottle-three-choice method. An ascending series of alcohol concentrations ranging from 3-30% (v/v) was offered over an 8-day interval with tap water as the alternative choice.

The neonatal treatment with THP in both dosages caused a reduced alcohol preference in the male rat, whereas alcohol drinking in the females was significantly enhanced by this TIQ. PBN compounds differed in their potency in altering alcohol consumption, depending upon their chemical structure; however, the general enhancing and inhibiting effect on alcohol self-selection in females and males, respectively, was similar to those of THP.

Overall, these results suggest that exposure to an amine-aldehyde condensation product during early post-natal life may produce marked and long-lasting functional changes in the brain which influence subsequent addictive behavior. Moreover, this liability may be sex-specific.

279.4 ETHANOL DEPRESSES SYNAPTIC EXCITATION OF LOCUS COERULEUS NEURONS. G. Aston-Jones, S.L. Foote and F.E. Bloom, A.V. Davis Center For Behavioral Neurobiology, Salk Institute, San Diego, CA

The effects of acute ethanol (E) administration on target neurons of the norepinephrine-containing locus coeruleus (NE-LC) system has been previously reported by our lab. We are currently studying the changes induced by E in the impulse activity and sensory responsiveness of the NE-LC neurons themselves.

Single cell recordings were obtained from chloral hydrate-anesthetized rats implanted with bipolar stimulating electrodes in the dorsal noradrenergic bundle and in the frontal neocortex. Baseline data were collected for spontaneous discharge rate, the latency and number of antidromic (AD) spikes stimulated from one of the above placements, and the number of spikes driven orthodromically from sciatic nerve stimuli delivered as foot-shock (FS). E was then injected at a dose of .5g/kg, i.p., and these same measures were again obtained. Data on 6 animals for 2 to 6 sequential, cumulative injections each (1 cell per animal) are presented here. Rectal temperature was maintained between 36 and 37 °C throughout recordings. All data were collected from histologically verified NE-LC neurons.

Our results indicate that E has no significant effect on the electrical excitability of NE-LC neurons, as E administration did not alter the efficacy of invasion of AD spikes into the soma-dendritic membrane. However, E did cause a small (1 to 3 msec) increase in AD spike latencies in a dose-related fashion, indicating that E may effect spike conduction along NE-LC axons to some extent. More pronounced effects were seen on spontaneous discharge rate and on the number of spikes driven from FS stimulation. In a dose-related fashion, E at a dose of 1.0 to 3.0 g/kg decreased spontaneous discharge an average of 27%, and also decreased the number of FS-driven spikes an average of 53%. This indicates that E may substantially alter the ability of excitatory synaptic inputs to affect NE-LC discharge.

Further experiments are in progress to test the effects of anesthesia and sciatic nerve fatigue on these results. We also plan to examine the effects of E on inhibitory synaptic inputs to NE-LC neurons, and on NE-LC axon conductivity during trains of high-frequency AD stimulation. Our results to date indicate, however, that some of the sedative effects of E on behavior may be partially due to a depression of sensory-evoked excitation of NE-LC neurons. Supported by ARC Grant 03504, AA 07273 and NS 16209.

279.5 ANTAGONISM OF DIAZEPAM-INDUCED SEDATION AND ALCOHOL POTENTIATION BY CGS 8216 (2-Phenylpyrazolo[4,3-c] Quinolin-3(5H)-one) IN THE RAT. P. S. Bernard*, D. E. Wilson*, R. Sobiski* and R. D. Robson* (SPON: C. Boast). Res. Dept., Pharma. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

In the rat forebrain, CGS 8216 potently inhibited the in vitro binding of ^{3}H-diazepam to benzodiazepine receptors (Czernik et al., Pharmacologist, Aug., 1981) but did not block metrazol-induced seizures or conflict behavior (Bernard et al., Pharmacologist, Aug., 1981). This latter group characterized the significance of these findings by demonstrating that CGS 8216 antagonized the anticonflict properties of diazepam, meprobamate and sodium phenobarbital; and in addition, blocked the effects of diazepam against metrazol-induced seizures and rotorod performance. Therefore, CGS 8216 appears to be an antagonist of diazepam. In the present experiments we evaluated the ability of CGS 8216 to antagonize diazepam's sedative and alcohol-potentiating effects.

A measure of the sedative properties of diazepam (30 & 100 mg/kg p.o.) was obtained in a variable interval-30 sec operant task (VI-30) where food-deprived rats were trained to press a lever for milk reinforcement. CGS 8216 (20 & 40 mg/kg i.p.) significantly antagonized the diazepam-induced reduction in response rate in this procedure. At the highest dose tested (40 mg/kg i.p.) CGS 8216 alone caused a partial disruption in this behavior which was less evident when it was given in combination with diazepam.

The interaction of ethyl alcohol (1.6 g/kg, 20% soln. p.o.) and diazepam (7.5 mg/kg p.o.) were tested in a rotorod task where the rat had to remain on a rotating bar (16 rpm) for 30 sec, in at least 1 of 3 trials. Diazepam potentiated the alcohol-induced impairment of rotorod performance. CGS 8216 (20 mg/kg i.p.) which completely antagonized diazepam alone, also markedly antagonized the combination of diazepam and alcohol. CGS 8216 failed, however, to antagonize the effects of alcohol alone. By itself, CGS 8216 did not produce any limiting effects.

These unique properties of CGS 8216 indicate that it may be a useful research tool in elucidating the sedative, anxiolytic, anticonvulsant and muscle relaxing properties of diazepam. In addition, they may have implications for the clinical usefulness of diazepam antagonists.

279.6 CHANGES IN CORTICAL SYNAPTOSOMAL PLASMA MEMBRANE FLUIDITY AND COMPOSITION IN ETHANOL-DEPENDENT RATS. E. Majchrowicz*, F.T. Crews and R. Meeks*. Lab. Preclin. Studies, NIAAA, Rockville, MD; Department of Pharmacol., Univ. of Florida Med. Sch., Gainsville, FL and South. Res. Inst., Birmingham, AL

Low concentrations of ethanol (Et) are known to expand and fluidize biological and artificial membranes. The purpose of this study was to determine if there are changes in the fluid properties and composition of synaptosomal plasma membranes (SPM) (prepared according to Jones & Matus) which might correspond to the onset and decay of neurological and behavioral signs and responses characteristic of the phases observed during the Et withdrawal (Wd) period in rats. Physical dependence upon Et was induced (and rated) in male rats (250-350 g) by po administration of Et (20%, w/v) as previously described (Psychopharmacologia, 43:245, 1975). Four groups of animals were used: (1) water treated controls; (2) acutely treated rats (4 hr after po Et, 5g/kg); (3) prodromal detoxication phase group (PrDP) (dependent while still intoxicated), and (4) ethanol withdrawal syndrome group (EtWds) (4-6 hr after the onset of the overt signs and responses of CNS withdrawal hyperexcitability). The apparent microviscosity at various temperatures of SPM from control rats, acutely treated, and rats undergoing EtWdS were similar throughout the entire temperature profile. The decrease in the flow activation energy (ΔE) implied an increase in the organization of SPM from Et dependent rats. The cholesterol/phospholipid (chol/phosphl) molar ratio was highest in SPM from rats in the PrDP, whereas it was intermediate in rats undergoing overt EtWdS as compared with controls or acutely treated animals. The amount of total phosphl per mg of protein was not significantly different in any of the groups tested. Although there was a slight decreasing trend in arachidonic acid (20:4) content during the PrDP there were no significant changes in the fatty acid composition of the SMP phosphl. These results indicate that there is an increase in SPM chol content in rats dependent upon Et. In vitro addition of chol to control membranes altered the apparent microviscosity similar to the changes found in SPM of Et dependent rats. When Et was added to SPM isolated from rats in the PrDP there was an increase in ΔE in the direction of or even beyond the control ΔE value. These findings indicate that the decreased ΔE in SPM of Et dependent rats, which is at least partially due to an increased chol/phosphl molar ratio, could be related to the development of physical dependence upon ethanol and the ethanol withdrawal syndrome.

280.1 TWO MECHANISMS FOR SPECTRAL SLOWING OF TRYPTOPHAN HYDROXYLASE FLUCTUATIONS. S. Knapp and A. J. Mandell. Dept. of Psychiatry, University of California at San Diego, La Jolla, CA 92093

Spectral and exponential analyses of the kinetic fluctuations in rat raphe tryptophan hydroxylase activity over time revealed multiple coherent spectral peaks with wavelengths of from 4 to 40 minutes. Both the frequency and the amplitude (variance) of product concentration fluctuations were sensitive to influence by ions (calcium and lithium) and psychotropic agents such as chlorimipramine. Lithium induced a low amplitude, low frequency fluctuation pattern, whereas the chlorimipramine-induced spectral slowing was associated with higher amplitude of variation.

Continuously versus discontinuously sampled time series of rate processes revealed evidence that the chlorimipramine-induced slowing was related to variable coupling of dissipative nonlinear enzyme protein oscillators, creating multiple configurations of state, through which relaxation (recurrence time) is slow. Lithium-induced slowing, however, appeared to be related to an initial uncoupling of molecules, randomization, followed by the emergence of a single, phase-coherent gaussian population of oscillators whose average frequency is slowed by the large coherent mass as it approaches a limit cycle.

Both lithium and chlorimipramine are known to slow circadian rhythms, and this work suggests statistical mechanical mechanisms for those effects. This research is supported by DA-00265-09.

280.2 IONIC DEPENDENCE AND CHARGE CARRIERS OF THE CURRENTS UNDERLYING BURSTING IN APLYSIA NEURON R15. William B. Adams and Irwin B. Levitan. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

Normal bursting activity in Aplysia neuron R15 is mediated by three currents: (i) a steady-state depolarizing inward current (I_B); (ii) a transient inward current (I_{in}) which maintains the burst once it has begun; and (iii) a transient outward current (I_{out}) which terminates the burst and controls the duration of the interburst. The three currents are voltage-dependent and interact during all phases of the burst cycle. Other workers have shown that I_B is carried by Na^+ and/or Ca^{++} (Barker, J.L. & Smith, T.G.,1978, in Abnormal Neuronal Discharges (Raven) 359-387;Tillotson, D., 1979, PNAS 76, 1497-1500). We have found that I_{in} also appears to be carried by Na^+, but is sensitive to Ca^{++} blockers such as Cd^{++} and Co^{++} and to decreases in external Ca^{++}. The results suggest that I_{in} may be a Ca^{++}-activated Na^+ current. I_{out} is also sensitive to Ca^{++} blockers and to decreases in external Ca^{++}. In these respects its properties resemble those of the Ca^{++}-activated K^+ channel. However, it does not reverse at the K^+ equilibrium potential (nor at any potential between -40 and -120 mV), nor is it affected by changes in external K^+ or by K^+ channel blockers such as Cs^+ or TEA. It is also unaffected by ouabain and by changes in external Na^+. Our results are consistent with the possibility that I_{out} is not a true outward current, but rather is due to a closing of channels which normally carry an inward Ca^{++} current. This decrease in Ca^{++} influx is seen as an outward hyperpolarizing current when measured against the baseline current.

280.3 SPINAL TREMOR INDUCED BY 4-AMINOPYRIDINE. S. Rossignol, R. Dubuc, Y. Lamarre and C. Julien. Centre de recherche en Sciences Neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada H3C 3JT.

4-Aminopyridine (4-AP) in small doses (1 mg/kg) facilitates excitatory and inhibitory reflex pathways in the spinal cord of cats (Lemeignan, Neuropharmacology 11: 551, 1972 and 12: 641, 1973); Jankowska et al, Brain Res. 136: 387, 1977). This could apparently be due to a greater release of neurotransmitters resulting from an increase in calcium permeability. At higher doses, 4-AP produces convulsions and tremor. In 8 decerebrate and paralyzed cats, we have found that a single i.v. injection of 4-AP (20 mg/kg) induced, for several hours, regular rhythmic bursts of activity at frequencies ranging from 3.5 to 7.0 Hz recorded with cuff electrodes in cut muscle nerves of all limbs. This tremor persisted after spinalization at C1. The mean tremor frequency was similar in both forelimbs and in both hindlimbs, but it differed in forelimbs and hindlimbs. Marked beating was observed in the auto-correlograms calculated for several seconds indicating periodic oscillations around the mean tremor frequency of each limb. Beating was also found in cross-correlograms of forelimb-hindlimb activity suggesting that the periodic oscillations in the respective auto-correlograms were due to an interaction between the forelimbs and the hindlimbs oscillators. Indeed, after spinalization at Th13, the rhythmic activity in hindlimbs continued independently of that of forelimbs and the beats in the respective auto-correlograms disappeared. In these low spinal preparations, the activity in the extensor nerves (medial gastrocnemius) and flexor nerves (semitendinosus) on both sides was highly cross-correlated as well as that of extensor and flexor nerves on the same side. The tremor persisted after a bilateral dorsal rhizotomy from L3 to S2. Stimulation of L7 ventral root on one side could reset the tremor rhythm in both hindlimbs. Prolonged unilateral ventral root stimulation could nearly abolish the tremor ipsilaterally while the contralateral tremor continued. It is concluded that 4-aminopyridine can induce a generalized and sustained tremor in the isolated spinal cord of the cat. The spinal mechanisms for generating this tremor as well as the interactions between limb oscillators and supraspinal structures are being investiguated. (This work is supported by a group grant of the Canadian MRC).

280.4 SLOW OSCILLATIONS OF TRANSMEMBRANE POTENTIAL IN MYENTERIC NEURONS. J. D. Wood, C. J. Mayer* and P. Grafe*. Physiology Dept., School of Medicine, University of Nevada, Reno, NV 89557 and Physiologisches Institut der Universität München, Munich, West Germany.

Intracellular recordings of electrical activity of myenteric neurons in guinea-pig small intestine were obtained in vitro. The recording electrodes were glass micropipettes, filled with 3M KCl, through which electrical current was injected into the neuron by use of an electronic bridge circuit. Slow oscillations of transmembrane potential were observed in about 2 percent of the ganglion cells. The oscillations were sinusoidal in appearance, they had amplitudes of 10 to 15 mV measured from trough to crest and occurred at frequencies of 1.8 to 2 per min at 37°C. They spanned membrane potentials between -50 and -65 mV. The oscillations occurred in neurons that fired repetitively during depolarizing current pulses and that showed nicotinic-cholinergic, fast synaptic potentials and also received serotonergic slow synaptic input. Action potentials evoked by intracellular injection of depolarizing current were followed by short-duration hyperpolarizing after-potentials of 2 to 5 sec. The hyperpolarizing after-potentials summated when spikes were evoked at 1 to 2 Hz, and the oscillations began as the hyperpolarization decayed at the end of stimulation. Once started, the oscillatory behavior was continous. Hyperpolarization of the membranes to potentials 10 to 15 mV greater than the trough of the slow waves by injection of current terminated the oscillations. The input resistance of the cells as determined by injection of constant-current hyperpolarizing pulses, progressively increased during the hyperpolarizing phase of the oscillation and decreased during the depolarizing phase. The excitability of the cell, as indicated by action potential discharge at the offset of the hyperpolarizing current pulses, was maximal at the crest of the oscillation. The ionic mechanism for the slow oscillations involves progressive increase in ionic conductance of the membrane during the rising phase (depolarization) and a drop in conductance during the falling phase (hyperpolarization) of the electrical wave.

280.5 OSCILLATORY PROPERTIES OF INFERIOR OLIVE CELLS: A STUDY OF GUINEA PIG BRAIN STEM SLICES IN VITRO. Y. Yarom* and R. Llinás (SPON: J. Rosenbluth). Dept. Physiology & Biophysics, New York Univ. Med. Ctr., New York, NY 10016.

Inferior olive (I.O.) cells are known to fire at a rather low frequency. Furthermore, if stimuli are presented at different time intervals, these cells demonstrate an optimal following frequency of approximately 10 Hz. This oscillatory-like property becomes especially clear in vivo following the administration of alkaloids such as harmaline (Llinas & Volkind: Exp. Brain Res. 18, 69-87, 1973; de Montigny & Lamarre: Brain Res. 82, 369-373, 1974). A central question has been whether this oscillation is generated by the electrophysiological properties of single cells or by the connectivity properties of the I.O. circuit. Intracellular recordings were obtained from I.O. neurons of guinea pig brain stem slices (Llinás & Yarom: J. Physiol. 315, June 1981). I.O. action potentials have several components: (1) a fast somatic Na^+ spike followed by an after-depolarization (ADP) upon which axonic spikes may be seen. (2) This ADP is Ca^{++}-dependent, occurs at dendritic level, and is followed by a larger after-hyperpolarization (AHP) produced by a Ca^{++}-dependent K^+ conductance change which may reach the level of -85 mV and last for 100-200 msec. (3) The AHP is abruptly terminated by a rebound Ca^{++}-dependent somatic spike. This set of ionic conductances was suggested by us as necessary and sufficient to produce the oscillatory behavior of I.O. neurons. In order to test the hypothesis, harmaline at 10 ugm/ml concentration was applied to the Ringer's solution. Following administration of this alkaloid, I.O. cells showed a hyperpolarization (5-10 mV) and clear oscillatory behavior at approximately 5-8/sec when directly stimulated either antidromically or with a short intracellular pulse. This oscillation which could last for several seconds was produced by the enhanced somatic Ca^{++} spike which accompanied the harmaline-dependent hyperpolarization. Because in many cases I.O. neurons could be demonstrated to fire independently from nearby neurons (simultaneous extracellular recordings), it was concluded that the oscillatory behavior of I.O. cells is cellular and not a circuit property produced by the interplay between the rebound somatic Ca^{++} spike and the Ca^{++}-activated AHP which follows the dendritic Ca^{++} action potential. However, because I.O. cells are electrotonically coupled, these neurons may behave as loosely coupled oscillators in the context of the I.O. nucleus as a whole. (Supported by USPHS research grant NS-13742 from NINCDS)

280.6 TETRODOTOXIN REVERSIBLY BLOCKS SODIUM PACEMAKER CURRENT IN R15 OF APLYSIA. K. Futamachi* and T.G. Smith, Jr. Laboratory of Neurophysiology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, Maryland 20205

For several years there has been a controversy over the ionic charge carrier in the persistent, inward pacemaker conductance in molluscan pacemaker cells; namely, is it sodium (Na) (Nature 253:450) or calcium (Ca) (J. Physiol. 254: 129)? We report here that freshly solubilized, high (100 μM) doses of the sodium conductance blocker, tetrodotoxin (TTX), completely and reversibly abolishes the bursting pacemaker potential (BPP) activity, the persistent inward current and, hence, the negative slope region (NSR) of the N-shaped, voltage clamp current-voltage curve in cell R15 of Aplysia californica. This concentration is three times higher than that required to block the Na-spike in this cell. Refrigerated but unfrozen TTX in sea water does not completely block BPP activity or the NSR in R15. The Ca-spike in R15 is not blocked by 100 μM TTX.

Since BPP activity and the persistent inward current amplitudes (1) vary directly with Na_o but inversely with Ca_o, (2) are enhanced, not blocked, by D600, a known Ca-conductance blocker and, (3) as reported here, blocked by Na-specific conductance blocker, TTX, we conclude that the persistance inward current in the depolarizing pacemaker conductance is primarily a Na and not a Ca conductance.

281.1 COMPARATIVE RECEPTOR BINDING EFFECTS IN BRAIN AFTER I.V. LORAZEPAM AND DIAZEPAM ADMINISTRATION. N.M. Spirt*, G. Bautz*, M. Zanko*, W.D. Horst and R.A. O'Brien. Dept. Pharmacology II, Hoffmann-La Roche Inc., Nutley, NJ 07110.

When administered i.v. to man, lorazepam exhibits a more prolonged period of amnesia and sedation than a clinically equivalent dose of diazepam (Brit. J. Clin. Pharm. 4:45, 1977). This occurs even though the elimination half-life of lorazepam is much shorter than that of diazepam. There is also a slower onset of the clinical effects of i.v. lorazepam compared to diazepam. The quicker onset of diazepam is probably due to its having greater lipophilicity than lorazepam, thus allowing for faster penetration of the blood brain barrier. We sought to investigate whether the longer sedative action of lorazepam, at times when blood levels were drastically reduced, could be explained by the persistance of lorazepam binding to central benzodiazepine receptors. In vitro, lorazepam bound to rat brain receptors with a 5-fold higher affinity than did diazepam. IC_{50} values were: lorazepam, 1 nM, and diazepam, 5 nM. Tighter binding to the receptor might explain the longer lasting sedation, since more of an equieffective dose of lorazepam would remain bound to BZ receptors over the period following drug administration. To evaluate this hypothesis, groups of male rats (4) weighing 150 g were administered i.v. lorazepam (0.3 mg/kg) or diazepam (0.75 mg/kg) and killed at varying times after dosing. The brain cortex was used as the receptor source in the ^{3}H-diazepam binding assay of Mohler et al. The percent inhibition of binding was evidence for receptor occupancy by either lorazepam or diazepam. The peak diazepam-induced inhibition occurred at 30 sec, that of lorazepam followed at 10 min after dosing. Subsequently, the inhibition of binding in the diazepam group had returned to baseline after 60 min, the lorazepam-treated rats still displayed 45% inhibition of binding at this time. The data agree with studies in man in which lorazepam slowly passed from plasma to CSF (Acta Pharmaco. tox. 46, 156, 1980) after i.v. dosing. In contrast, diazepam administration to man i.v. was characterized by fast entry into CSF and by CSF levels which paralleled free plasma levels (Psychopharmacol. 70, 89, 1980). We propose that ex vivo binding studies such as those we have described are useful for explaining clinical pharmacokinetic and pharmacological profiles for CNS active drugs in man.

281.2 FACILITATION OF BENZODIAZEPINE RECEPTOR BINDING: A MECHANISM OF ACTION FOR METHAQUALONE? B. Kenneth Koe. Central Research, Pfizer Inc., Groton, CT 06340.

Methaqualone possesses hypnotic, anticonvulsant, muscle relaxant, and anxiolytic properties (Brown and Goenechea, Clin. Pharmacol. Ther. 14: 314, 1973), a pharmacological profile not unlike that of the benzodiazepines. Naik, Naik, and Sheth (Psychopharmacol. 57: 103, 1978) pointed out that the anticonvulsant action of methaqualone may involve GABAergic mechanisms. Recently, benzodiazepine (BD) receptors have been suggested as the site of action, because methaqualone inhibits the binding of ^{3}H-diazepam (IC_{50} 150 µM) and ^{3}H-flunitrazepam (^{3}H-FNP) (IC_{50} 220 µM) to rat brain membranes (Müller, Schläfer, and Wollert, N.-S. Arch. Pharmacol. 305: 23, 1978; Antoniadis, Müller, and Wollert, Neuropharmacol. 19: 121, 1980).

Although methaqualone inhibits ^{3}H-BD binding in vitro, our studies demonstrate that following the administration of methaqualone, BD receptor binding is actually enhanced. In vivo, we found that methaqualone, in a dose-dependent manner, stimulates the binding of ^{3}H-FNP (200 µCi/kg i.v.) to mouse brain in vivo (83% increase at 100 µmol/kg s.c.). Moreover, in ex vivo experiments whole brain membranes from mice treated with methaqualone (100 µmol/kg i.p.) bound more ^{3}H-diazepam than control membranes. Scatchard plots for the ex vivo membranes suggested that the enhanced binding is derived from an increase in the number of binding sites (B_{max}, 33% increase). These in vivo and ex vivo effects of methaqualone were also shown by cartazolate (SQ 65,396), the anxiolytic pyrazolopyridine (Beer, Klepner, Lippa, and Squires, Pharmacol. Biochem. Behav. 9: 849, 1978). Methaqualone competitively inhibited ^{3}H-diazepam binding to rat cortical membranes in vitro (K_D, 187% increase at 320 µM), whereas cartazolate (1 µM) stimulated ^{3}H-diazepam binding in both unwashed and frozen/washed membranes via a B_{max} change (30% and 16% increase, respectively).

Our findings suggest that the benzodiazepine-like actions of methaqualone may be ascribed to a novel mechanism, in which BD receptor binding is facilitated. Possibly, binding of a "natural" BD agonist is enhanced, or in view of the B_{max} increase, a "natural" BD antagonist may be displaced from BD receptors by methaqualone in vivo, freeing more binding sites for a BD agonist. Alternatively, methaqualone may be facilitating BD binding in vivo via GABAergic mechanisms.

281.3 BENZODIAZEPINES INHIBIT THE ACTIVITY OF SUBSTANTIA NIGRA PARS RETICULATA NEURONS. R.J. Ross*, B.L. Waszczak and J.R. Walters (SPON: F.K. Goodwin). NIMH and NINCDS, NIH, Bethesda, Md 20205.

It has been postulated that the central effects of the benzodiazepines are mediated by the ability of these drugs to potentiate the inhibitory effects of GABA on neuronal activity. The substantia nigra pars reticulata has been identified as a region containing neurons which are sensitive to the inhibitory effects of both i.v. muscimol,a potent GABA agonist, and iontophoretically applied GABA and muscimol. This region receives a substantial GABAergic input from the corpus striatum. Here we report the results of electrophysiological studies of the effects of i.v. administration of two benzodiazepines, diazepam and flurazepam, on firing rates of reticulata cells, recorded extracellularly in chloral hydrate anesthetized rats. Both drugs exerted an inhibitory effect on the activity of pars reticulata cells, but there was considerable variability in the sensitivity of individual neurons. When diazepam was administered in exponentially increasing increments to a cumulative dose of up to 8 mg/kg (n=17), 27% of the cells were inhibited by 80% or more; 13% of the cells were inhibited by less than 20%. The average effect produced in the 5-min interval following systemic administration of a single 0.5 mg/kg dose of diazepam was inhibition to 58% of baseline (n=9). The effect could be reversed by the subsequent administration of picrotoxin 4-8 mg/kg (n=5). The diazepam vehicle, administered alone, produced either no change or a modest excitation.

Flurazepam, administered in increasing increments to a cumulative dose of up to 8 mg/kg,also inhibited reticulata cell firing, but had a less potent inhibitory effect (n=16). Sixty-nine percent of cells were inhibited by at least 20%. No cells were inhibited by as much as 80%. The average degree of inhibition following a cumulative dose of 0.5 mg/kg flurazepam was 2% (n=16); following a cumulative dose of 8 mg/kg, it was 39% (n=11). Cells which were insensitive to flurazepam could still be effectively inhibited by i.v. muscimol 3.2-6.4 mg/kg (n=4).

The differences in potency between diazepam and flurazepam may reflect differences in lipid solubility and kinetics of distribution. They are consistent with observed differences in clinical efficacy. For each drug, the variability in the degree of inhibition may be related to differences in tonic GABAergic input among neurons, to different levels of an endogenous ligand for the benzodiazepine receptor, or to differences in numbers or affinities of benzodiazepine receptors. The inhibitory effects of these two benzodiazepines on reticulata cells are of the same order of magnitude as those on locus coeruleus neurons (Grant et al., Life Sci. 27: 2231, 1980). The benzodiazepines may have multiple clinically relevant sites of action.

281.4 BUSPIRONE: AN ANXIOSELECTIVE DRUG WITH SIMILARITIES TO APOMORPHINE. L. A. Riblet, Duncan P. Taylor, J.A. Becker*, D. K. Hyslop* and R .C. Wilderman*. Department of Biologic Research, Mead Johnson Pharmaceutical Division, Evansville, IN 47721.

Buspirone HCl is a novel nonbenzodiazepine antianxiety agent with efficacy comparable to that of diazepam (Am. J. Psychiatry 136: 1184, 1979). In contrast to the benzodiazepines, this anxioselective agent lacks anticonvulsant activity, interacts minimally with CNS depressants and does not cause muscle relaxation. In vitro binding experiments indicate that buspirone is without significant activity at the following binding sites: α_1, α_2, β, cholinergic, glutamate, glycine, H_1, H_2, opiate, 5-H_1, 5-HT_2 and adenosine. Furthermore, it neither stimulates nor inhibits ^{3}H-benzodiazepine binding, does not affect the influence of GABA or halide anion on ^{3}H-benzodiazepine binding and does not interfere with GABA binding or uptake. Buspirone appears to interact only with the dopaminergic system with reasonable potency. In fact, buspirone and apomorphine share many pharmacologic actions. Quantitative cortical EEG profiles from the cat and rat, determined by zero-cross analysis, indicate similarities between buspirone and apomorphine. This was also evident in subcortical recordings from the hippocampus of cat. This similarity between buspirone and apomorphine was also apparent from the drug-induced turning in rats that had received 6-OH-dopamine lesions of the substantia nigra. In addition, in vitro binding experiments in the presence and absence of guanosine triphosphate indicate that buspirone inhibits ^{3}H-spiperone binding in a manner similar to that of other dopamine agonists such as apomorphine, N-propylnorapomorphine and piribedil. The fact that apomorphine is of value clinically in relieving agitation and excitement, may be relevant to the anxioselective action of buspirone.

281.5 ANTIANXIETY EVALUATION OF A NOVEL IMIDAZOBENZODIAZEPINE-3-CARBOXAMIDE COMPOUND (Ro 21-8384) IN THE RAT AND IN THE SQUIRREL MONKEY. F.S. Grodsky*, J.W. Sullivan*, D.N. Mitchell*, and J. Sepinwall (Spons. L. Klevans). Dept. of Pharmacology, Hoffmann-La Roche Inc., Nutley, N.J. 07110

Ro 21-8384† was administered orally to: 1) untrained, water deprived rats in a modified water lick conflict procedure (shock for each 20th lick), 2) to food deprived rats trained to bar press on a single lever during alternating components of a VI 30" (food)/FR 10 (food + shock) multiple schedule, 3) to food deprived squirrel monkeys trained on a two lever concurrent VI 1.5' (food) + VR 24 (shock)/VI 6' (food) schedule of reinforcement.

In the water-lick conflict test, Ro 21-8384 produced marked increases in punished licking rates at doses of 0.08, 0.31, and 1.25 mg/kg.

In rats in the multiple schedule, Ro 21-8384, like diazepam, had an inverted U-shaped anticonflict dose-response curve (M.E.D. = .01 mg/kg). It was 125 times more potent than diazepam and produced selective antipunishment effects over a wider range of dose doublings up to 0.31 mg/kg, while producing no significant change in unpunished behavior. At 0.63 mg/kg and higher doses, significant decreases in unpunished responding were seen, making this compound only 32 times more potent than diazepam with respect to depressant effects. At 6.2 mg/kg punished responding was also significantly decreased.

In the squirrel monkey, Ro 21-8384 also had an inverted U-shaped anticonflict dose response curve; it produced antipunishment effects over a wider range of dose doublings than diazepam, from 0.02 mg/kg (M.E.D.) to 80 mg/kg, the highest dose tested, and was 16 times more potent. Unlike diazepam, Ro 21-8384 did not significantly decrease responding, in either component, within the range of doses tested.

Thus, Ro 21-8384 increased punished responding in procedures used to detect potential anxiolytic properties and would be predicted to be a more potent anxiolytic than diazepam. However, there appeared to be less sensitivity to the rate decreasing properties of Ro 21-8384 shown by the monkey than by the rat, thus, suggesting a difference in sensitivity to the sedative-depressant qualities of Ro 21-8384. Whether this difference is species dependent (e.g., due to differences in biotransformation), schedule dependent, or both, remains to be determined.

† Ro 21-8384: 8-Chloro-6-(2-chlorophenyl)-4H-imidazo[1,4] benzodiazepine-3-carboxamide (Walser et al., J. Heterocyclic Chem. 15:577, 1978)

281.6 CLOZAPINE: AGENTS WITH SIMILAR BEHAVIORAL AND BIOCHEMICAL PROPERTIES. Ronald G. Browne and B. Kenneth Koe. Dept. Pharmacol., Central Research, Pfizer Inc., Groton, CT 06340.

Clozapine, a dibenzodiazepine, with known antipsychotic efficacy, differs from classical neuroleptics in producing few if any extrapyramidal side effects. The use of clozapine has been greatly restricted because of unacceptable incidences of agranulocytosis. Efforts have therefore been made to discover other agents with a clozapine-like mechanism of action. The present investigation examined the ability of various drugs to mimic the behavioral effects of clozapine in a drug discrimination paradigm. In addition, comparisons were made on a spectrum of biochemical alterations produced by clozapine, including changes in dopaminergic, adrenergic, cholinergic, GABAergic and benzodiazepine systems.

Male Sprague-Dawley rats were trained to discriminate 3.2 mg/kg of clozapine from vehicle in a two-lever operant procedure. Discrimination accuracy was established following about 40 training sessions as evidenced by most animals emitting their first FR-10 responses on the appropriate lever in nine out of ten consecutive sessions. Generalization testing indicated that RMI-81,582 (2-chloro-11-3-dimethylaminopropylidene morphanthridine) and cyproheptadine produce discriminative stimuli identical to clozapine, in contrast to neuroleptics such as haloperidol which were discriminated as vehicle.

Biochemical findings demonstrated that clozapine, RMI-81,582, cyproheptadine and thioridazine, in addition to producing similar effects on ^{3}H-spiroperidol and ^{3}H-QNB binding to rat brain membranes in vitro, also facilitated ^{3}H-flunitrazepam binding to mouse brain in vivo. These results support further the hypothesis that atpyical antipsychotic agents such as clozapine may exert their effects in part through GABAergic mechanisms.

The results of these behavioral and biochemical studies indicate that despite structural heterogeneity, RMI-81,582 and cyproheptadine share a pharmacological profile similar to clozapine and that this activity is distinctly different from neuroleptics such as haloperidol.

281.7 NEUROPSYCHOPHARMACOLOGICAL EFFECTS OF A NOVEL POTENTIAL ANTIPSYCHOTIC AGENT: Ro 22-1319 A.B. Davidson*, E. Boff*, D.A. MacNeil, and L. Cook*, Dept. of Pharmacol., Hoffmann-La Roche Inc., Nutley, N.J. 07110

Ro 22-1319, a novel pyrroloisoquinoline compound (Olson, et al., submitted to J. Med. Chem.) with potential antipsychotic activity, was identified in a rat discrete avoidance procedure. This procedure is highly specific for chlorpromazine-like antipsychotic activity and potency of known antipsychotic compounds in this procedure is highly correlated with their clinical potency (r=0.953). The potency of Ro 22-1319 in this procedure (ABD50=0.7 mg/kg, p.o.) approached that of haloperidol (ABD50= 0.4 mg/kg, p.o.) and it exhibited similar high potency in other rat and monkey avoidance procedures, on rat motor activity, and in antagonism of apomorphine induced emesis in dogs. However, although effects in s. nigra lesioned rats indicate activity at dopaminergic sites in the nigro-striatal system, Ro 22-1319 exhibited relatively weaker cataleptogenic and acute antistereotypic activity than haloperidol and minimal effects in a chronic supersensitivity model of stereotypic behavior. These results suggest that Ro 22-1319 would exhibit clinically efficacious antipsychotic activity approaching the potency of haloperidol, but would have fewer or less intense acute extrapyramidal effects and minimal potential for tardive dyskinesia. Ro 22-1319 produced no appreciable cardiovascular or peripheral autonomic effects in dogs. The electrocorticographic activity of this compound was described earlier (Davidson, et al., Neurosci. Abstr.6:366,1980); its biochemical profile, including the interesting separation observed between potent in vivo and weak in vitro dopamine antagonist activity, is discussed elsewhere (Bautz, et al., This Meeting).

	Oral ED50's in mg/kg	
	Ro 22-1319	Haloperidol
Discrete lever avoidance (rat)	0.7	0.4
Pole-climb avoidance (rat)	1.2	0.8
Continuous avoidance (sq. monkey)	0.4	0.3
Motor activity - rearing (rat)	1.0	0.6
Apomorphine emesis antag. (dog)	0.05(sc)	0.02(sc)
Amphet. rotation antag. (SN-X rat)	0.7	0.4
Acute apomorph. stereotypy (rat)	2.4	0.4

Chronic apo. supersensitivity(rat)	+33% @ 4.4	+69% @ 2
	+33% @ 8.8	+95% @ 4

281.8 COMPARISON OF IN VIVO AND IN VITRO ANTIDOPAMINERGIC POTENCIES OF A NEW ANTIPSYCHOTIC-LIKE COMPOUND (RO 22-1319). G. Bautz*, R.A. O'Brien, K. Meyers*, T. Mowles* and W.D. Horst. Depts. of Pharmacology II and Cell Biology, Hoffmann-La Roche Inc., Nutley, NJ 07110.

In several pharmacological tests, Ro 22-1319 (3-ethyl-2,6-dimethyl-4,4a,5,6,7,8,8a,9-octahydro-4a,8a-trans-1H-pyrrolo[2,3-g]isoquinolin-4-one, HCl) exhibits antipsychotic-like activity with potencies comparable to haloperidol (A.B. Davidson et al., these abstracts). However, the in vitro antidopaminergic potency of Ro 22-1319 is considerably weaker than for haloperidol or spiroperidol. The IC_{50}'s for the in vitro inhibition of ^{3}H-spiroperidol binding to rat striatal tissue by Ro 22-1319, haloperidol or spiroperidol are 45, 7.4 and 0.3 nM, respectively. Ro 22-1319 is also less potent than haloperidol in disinhibiting the in vitro release of prolactin from cultured rat pituitary cells (EC_{50}'s = 535 and 25 nM, respectively).

To determine whether or not these discrepancies in the in vivo and in vitro potencies of Ro 22-1319 may indicate a site of action for Ro 22-1319 which is different than for haloperidol or spiroperidol, Ro 22-1319 was tested in vivo for its influences on ^{3}H-spiroperidol binding and prolactin release. Ro 22-1319 or spiroperidol were administered (S.C.) to rats 30 min prior to the i.v. injection of ^{3}H-spiroperidol (1 µg/kg). The rats were sacrificed 2 hr after the ^{3}H-spiroperidol injection. Plasma prolactin levels were determined 1 hr after the administration (i.p.) of Ro 22-1319 or haloperidol. The ED_{50}'s for the in vivo inhibition of ^{3}H-spiroperidol binding to striatal tissue by Ro 22-1319 and spiroperidol are 0.5 and 0.24 mg/kg, respectively. The ED_{50}'s for prolactin release by Ro 22-1319 and haloperidol are 0.30 and 0.29 mg/kg, respectively. Thus, the in vivo antidopaminergic potencies of Ro 22-1319 are similar to haloperidol and spiroperidol.

These observations do not suggest that Ro 22-1319 has a site of action different from haloperidol and spiroperidol. The apparent discrepancy between the in vivo and in vitro potencies of Ro 22-1319 does not appear to result from biotransformation, but may be due to some unidentified factor, inherent in these in vitro procedures, which selectively influences the activity of Ro 22-1319.

281.9 N-Oxides of Phenothiazine Antipsychotics Contribute to Their Pharmacological Actions. M.H. Lewis, E. Widerlöv, C.D. Kilts, & R.B. Mailman. Biological Sciences Research Center, Depts. of Psychiatry and Pharmacology, Univ. of North Carolina School of Medicine, Chapel Hill, NC 27514

The clinical effect of antipsychotic drugs may partly depend on formation of active metabolites, a fact that often has been overlooked. This laboratory recently initiated studies about one major class, the N-oxides. Several N-oxide metabolites of clinically used phenothiazines were screened for anti-dopaminergic activity. In vivo, this was accomplished by using direct lateral ventricular injection of the metabolites or parent compounds. Both fluphenazine N-oxide and trifluoperazine N-oxide (which are piperazinyl-4-N-oxides) had significant anti-dopaminergic activity in vivo, as shown by their antagonism of either amphetamine-induced locomotor behavior or apomorphine-induced stereotyped behavior. In vitro, both of these N-oxides significantly inhibited ^{3}H-spiroperidol binding to brain membranes and also inhibited dopamine-stimulated adenylate cyclase activity in striatal homogenates. In all tests the compounds were equal to or slightly less potent than the parent compounds. Conversely, chlorpromazine N-oxide (side chain oxidation) did not have significant anti-dopaminergic activity in any of these in vivo or in vitro systems. This suggests that oxidation of the nitrogen atom (three carbons removed from the phenothiazine ring) which is believed to mimic the catecholamine nitrogen, results in loss of anti-dopaminergic activity, whereas other N-oxides may possess significant pharmacological effects.

It has been reported by others that CPZ-NO has significant anti-dopaminergic activity when given peripherally. The present data suggest that this may be due to conversion of the N-oxide back to the parent compound or to other active metabolites. This possibility was assessed by measuring the reduction in vivo of N-oxides of chlorpromazine, trifluoperazine and fluphenazine to their respective parents after peripheral or central administration. The compounds were extracted from blood or other tissue, and measured by HPLC on radially compressed silica with 254 nm UV detection. These data also underscore the necessity of understanding both the metabolism and neuropharmacology of antipsychotic agents if valid hypotheses about their actions are desired. (Supported in part by PHS grant HD-10570, and Center Grants HD-03110 and MH-33127.)

281.10 LEVELS OF HALOPERIDOL AND BIOGENIC AMINES IN THE BLOOD, URINE AND CNS OF RATS DURING CHRONIC HALOPERIDOL TREATMENT. P.A. Shea, S.R. Dunlop*, S.E. Wade*, and H.C. Hendrie*. Dept. of Psychiatry and Biochemistry, Institute of Psychiatric Research, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The purpose of this study was to determine the relationship between CNS and peripheral measurements of neurotransmitters and their metabolites after chronic neuroleptic treatment. The distribution of haloperidol was determined in various brain regions, blood, and urine. Six male Wistar rats were injected I.P. for 19 days with 0.25 mg/kg haloperidol along with 6 saline injected animals. On various days, pre-injections and during treatment two 12-hour urine collections were taken. On day 19 all animals were killed, blood collected and brains dissected into 7 regions. In each brain part, levels of norepinephrine, 3-methoxy-4-hydroxy phenylglycol, dopamine, 3,4-dihydroxyphenylacetic acid, 5-hydroxyindoleacetic acid, serotonin, homovanillic acid, and haloperidol were determined by HPLC (biogenic amines) and receptor assay (haloperidol). After 19 days of drug treatment plasma levels of haloperidol were 5.82 $\pm$ 0.98 ng/ml. In brain the highest drug levels were in the hippocampus, 220.86 $\pm$ 70 ng/ml and hypothalamus, 208.9 $\pm$ 80 ng/ml. The midbrain contained the least, 63.9 $\pm$ 27 ng/ml. When compared to saline-treated animals the only statistically significant changes in biogenic amines and metabolite levels were noted in the cortex, caudate nucleus, and septum and this occurred in the dopamine system where HVA and DOPAC were elevated. Urinary levels of haloperidol were highest at day 2, and fell by day 3 to remain constant during the rest of drug injections. There was a definite diurinal variation in drug excretion. The determinations of the neurotransmitter metabolites in blood and urine will be presented along with their relationship to the CNS measurements. (Supported by the Indiana Dept. of Mental Health, Grant 47-869-11).

281.11 REDUCTION OF LOCOMOTOR HYPERACTIVITY BY AMPHETAMINE IN NEONATAL RATS GIVEN 6-HYDROXYDOPAMINE IS MEDIATED BY BRAIN SEROTONERGIC NEURONS. Thomas Heffner and Lewis Seiden. Dept. of Pharmacol. & Physiol. Sciences, University of Chicago, Chicago, IL 60637.

In neonatal rats, destruction of brain dopamine (DA) neurons by intraventricular injections of 6-hydroxydopamine (6-HDA) results in locomotor hyperactivity. Whereas Shaywitz et al.(Nature 261:153,1976) reported that this hyperactivity is reduced by d-amphetamine (d-A),Pappas et al. (Psychopharmacol.70:41,1980)failed to confirm this result. We examined the ability of d-A to reduce hyperactivity caused by 6-HDA as well as the mechanism responsible for this effect. Neonatal rats pretreated with desipramine were given ivt injections of 6-HDA (100 µg) or the vehicle solution at 3 and 6 days of age. This treatment produces large-scale (70-90%) selective depletion of brain DA. Locomotor activity was measured in stabilimeter cages for 1 hr daily from days 12 to 55 of life. Locomotion in 6-HDA-treated rats averaged 866% of the level in control rats during days 15 to 55 of life. At 21 days of age, a d-A dose of 1.0 mg/kg(ip) increased locomotion by 766% in control rats but reduced locomotion by 51% in 6-HDA-treated rats. The d-A-induced reduction of hyperactivity was dose-dependent between 0.25 and 2.0 mg/kg and was consistently seen in rats tested at 10 different ages ranging from 21 to 55 days. This effect was not accompanied by stereotypy or other abnormal behaviors. Methylphenidate (4 mg/kg,ip) also reduced hyperactivity in 6-HDA-treated rats by 57% while increasing locomotion by 477% in control rats. Although the DA antagonist spiroperidol (25-200 µg/kg,ip) provided dose-dependent antagonism of the stimulant effect of d-A in control rats, spiroperidol failed to attenuate the effect of d-A in 6-HDA-treated rats. However, the serotonin antagonist methysergide (0.5-2.0 mg/kg,ip) produced dose-dependent antagonism of the effect of d-A in 6-HDA-treated rats while not altering the stimulant effect of d-A in controls. Fenfluramine (3 mg/kg,ip), a drug that releases serotonin from central neurons,restored locomotion to normal levels in 6-HDA-treated rats while not altering locomotion in controls. The serotonin agonist quipazine (0.5-4 mg/kg,ip) also reduced hyperactivity in 6-HDA-treated rats in a dose-dependent fashion while not altering activity in control rats. Pretreatment with propranolol (5 mg/kg, ip), phentolamine (5 mg/kg, ip), atropine (0.5 mg/kg) or naloxone (10 mg/kg, ip) failed to alter the reduction of hyperactivity caused by d-A in 6-HDA-treated rats. These results indicate that d-A can reduce locomotor hyperactivity caused by DA-depleting 6-HDA injections in neonatal rats and suggest that this apparent therapeutic effect involves augmentation of central serotonergic neurotransmission. (Supported by USPHS NS-12324, RSA MH-10562).

281.12 POTENTIATION OF BARBITURATE-AND HALOTHANE-INDUCED HYPNOSIS AFTER PROBENECID OR SULFINPYRAZONE PRETREATMENT. W.H. Lyness, S. Ramanadham and P.K.T. Pang. Department of Pharmacology and Therapeutics, Texas Tech University Health Sciences Center, Lubbock, Texas 79430.

Recent studies have shown that probenecid, a uricosuric agent, potentiates the duration of i.p., i.v. or intracerebroventricularly administered barbiturate-induced hypnosis. This drug interaction has been attributed to the sedative effects of probenecid, inhibition of hepatic oxidation of the barbiturates, displacement of plasma albumin bound barbiturates (thiopental) and altered renal excretion. All previous studies have used large doses of probenecid (200 mg/kg i.p.). The present study sought to establish whether this is a dose related phenomenon and to eliminate the possible renal, hepatic and pharmacokinetic bases of the potentiation. The latter was accomplished using inhalation halothane. Probenecid pretreatment significantly decreased ($p < 0.05$) the latency to onset of hypnosis after halothane (0.5 to 3.0%) and did so in a dose related manner (10-200 mg/kg i.p., 30 min before halothane). The potentiation of pentobarbital hypnosis was significant only with probenecid doses greater than 50 mg/kg. Sulfinpyrazone, produced results identical to those of probenecid in both the inhalation halothane and pentobarbital studies.

Possible mechanisms of action in the halothane-barbiturate hypnotic potentiation might include a synergism with the sedative effects of both uricosuric agents or increases in cerebral blood flow. Both agents reduce systemic blood pressure in conscious and pentobarbital anesthetized rats when administered i.v. or i.p. Furthermore, both agents will relax isolated helical rat tail arterial strips in a dose related manner (0.1 - 1.0 mg/ml). Probenecid induces a dose related reduction in rectal temperatures of rodents and potentiates pentobarbital-induced hypothermia, suggesting peripheral vasodilatory actions. Sulfinpyrazone does not lower rectal temperatures indicating differences in the vascular beds influenced by these uricosuric agents. (This work was supported by the Tarbox Parkinson's Disease Institute at Texas Tech University Health Sciences Center and the Pharmaceutical Manufacturers Foundation Association).

281.13 INTENSIVE CARE FOR PERIODIC SCHIZOAFFECTIVE ILLNESS-PREVENTION OF "REVOLVING-DOOR" SITUATION.

Eugene Ziskind, George Maison* (University of Southern California, Los Angeles), Irving Chelnek*, Helen Zimnavoda* (Gateways Community Mental Health Center, Los Angeles).

Preventing the "revolving-door" phenomenon in chronic mental illness is the most urgent mental health problem. Towards that end, we have utilized a three stage unique treatment program, all directed by the same full-time p.r.n.-available psychiatrist: I - Intensive hospital milieu therapy with medication, mostly parenteral, devoted to getting the patient out to work as soon as possible; II - Monitoring the patient on and off the job with three weekly psychiatrist sessions of individual, family and peer confrontation group therapies; III - Maintenance medication and therapy sessions to prevent rehospitalization.

The first three patients to have completed the program had been previously ill over an eight to nine year period with repeated hospitalizations. The "revolving-door" situation in these patients has been prevented for five, four and three years. These results are unprecedented in the authors' experience nor have they found similar reports in the literature.

This program is unique in that there is no interruption from one phase to the next, no change of therapist or discontinuance of therapy; and to ensure uninterrupted therapy, a conservatorship is recommended. Initial formidable financing results in long run savings.

Reduplication of these results is now necessary on a much larger scale by some major foundation such as NIMH or the Ford Foundation.

282.1 EFFECT OF COLD-PRESSOR STRESS ON VISUAL SENSITIVITY, d', IN MAN. W.C. Clark, D. Schimmel*, and M. Janal*. N.Y. State Psychiatric Institute and Queens and City Colleges, CUNY.

Stress alters autonomic activity and induces the release of various hormones and neurotransmitters. Certain of these substances, e.g. excess cortisol, have been shown to elevate sensory thresholds in Cushing's disease. However, there have been no investigations of the effect of cold-water stress on the visual sensitivity, d', of healthy subjects.

Measures of visual sensitivity were obtained on 12 volunteers using the 4-alternative spatial forced-choice procedure. The subjects were fitted with artificial 2mm pupils. Visual reports were obtained for an average of 1 min during ice-water immersion of the hand, and for two recovery periods which followed withdrawal, at 0-30 sec and 90-120 sec. For each subject, data were obtained over 10 cycles. For the control session the water was at room temperature.

ANOVA revealed a significantly lower visual sensitivity for the stressed group averaged over the 3 test periods (1.81 vs 1.48), $F(1,10) = 33.1$, $p < .001$. Within each period sensitivity was significantly less under the stressed condition, t-critical (40) $\geq .17$, $p < .01$).

The pain felt during the ice-water immersion period could have interfered with the perceptual task. However, this does not explain the persistence of this lower sensitivity during the subsequent recovery periods when the subject experienced no distress. The duration of the effect suggests the presence of a stress-induced hormone or sympathetic activity which interfered with vision, either by some central action or by shifting accommodation in the lens.

282.2 PITUITARY CYCLIC AMP IN RATS IS INCREASED BY PSYCHOLOGICAL STRESS. B.N. Bunnell, G.J. Kant, R.H. Lenox, L.L. Pennington*, D.R. Collins*, E.H. Mougey* and J.L. Meyerhoff. Dept. Med. Neurosciences, Walter Reed Army Inst. of Research, Wash., D.C. 20012 and Dept. Psychiatry, Univ. of Vermont, Burlington, VT 05405.

Cyclic AMP may be involved in the release or synthesis of pituitary hormones mediating the organism's response to stress. Recently we have shown that a number of different physical stressors, including footshock, produce a significant increase in pituitary cyclic AMP in rats. The present study attempted to extend these findings to psychological stressors by measuring pituitary cyclic AMP and plasma hormone responses in rats exposed to environmental stimuli previously paired with inescapable footshock.

Male rats, adapted to handling for one week, were assigned to three groups: Experimental, Shock Control, or No-shock Control. For four consecutive days, all rats were placed in conditioning chambers for 20 min sessions. Experimental and Shock Control groups were given footshock during the sessions on a variable interval 30 sec schedule. Shock duration was 5 sec. No-shock Controls were placed in the chambers, but no shock was administered. On the fifth day, all rats were placed in the chambers for either 5 or 10 min; Experimental and No-shock Controls did not receive shock, while the Shock Controls were given shock as before. The animals were then sacrificed by microwave irradiation (2.5 KW, 2450 MHz for 5 sec). Pituitary cyclic AMP and plasma prolactin were measured by radioimmunoassay. Behavioral responses to shock were rated throughout the study.

The results are given in pmoles cyclic AMP/mg wet weight ± S.E.M. and ng prolactin/ml ± S.E.M.

	CYCLIC AMP		PROLACTIN	
	5 MIN	10 MIN	5 MIN	10 MIN
EXP	1.47±.20(N=6)	2.97±.90(N=6)	72.4± 7.1	104.3± 6.6
SC	2.07±.50(N=6)	2.11±.35(N=6)	93.7±13.5	140.0±19.8
N-SC	1.06±.08(N=6)	1.06±.09(N=6)	17.0± 6.3	30.6± 8.3

(EXP = Experimental, SC = Shock Control, N-SC= No-shock Control)

Only the Shock Control group received shock on the test day - the other 2 groups did not. The Experimental group's cyclic AMP and plasma prolactin levels were significantly elevated over those of the No-shock Controls, indicating the biochemical responses had been elicited by environmental stimuli previously associated with shock. The 10 min Experimental group actually had higher levels of pituitary cyclic AMP than the 10 min Shock Control group. Behavior ratings indicated that considerable adaptation to shock took place in the Shock Control groups during five consecutive days of shock.

282.3 STRESS ELEVATION OF PERIPHERAL TRYPTAMINE TISSUE CONTENT . S. T. Christian and R. E. Harrison. Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

Recent investigations into the role of tryptamine (TA) in the central nervous system reveal that the compound has an unusually rapid turnover and is found in low nanogram concentrations both centrally and peripherally. In addition, TA is actively transported into the brain, and there are indications that peripherally produced TA is involved in neuromodulation of behavior. Alterations in peripheral TA economy which result in an increase in extracerebral TA concentrations could conceivably have behavioral implications. Since various stress paradigms are known to induce alterations in both behavior and biochemistry of test probands, and in order to elucidate the role of stress in peripheral TA metabolism, we have examined TA tissue concentration in young (60 days old at sacrifice) rats that were either group-housed or stressed by individual housing. TA concentrations in lung, liver, spleen, heart and kidney were determined by a sensitive and specific gas chromatographic/mass fragmentographic isotope dilution assay. Animals were either group-housed (control) or individually housed for 8 or 28 days. Group-housed control animals, and animals that had been individually housed for 8 days had low tissue TA concentrations consistent with earlier reports using radioenzymatic assay, while animals that were individually housed for 28 days showed considerably elevated TA content in all tested organs except the spleen. The greatest TA concentration increases were observed in the lung (62 x control), liver (11 x control) and kidney (6 x control). These results demonstrate that individual housing stress is associated with the production of TA concentrations previously shown to possess pharmacologic activity.

282.4 NUTRITIONAL STATE: EFFECTS ON BASAL AND STRESS-INDUCED INCREASES IN SYMPATHETIC ACTIVITY OF RATS. B. G. Weick, S. Ritter and R. McCarty. Dept. of Veterinary and Comparative Anat. Pharmacol. and Physiol., College of Veterinary Medicine, Washington State Univ., Pullman, WA 99164 and Dept. of Psychol., Univ. of Virginia, Charlottesville, VA 22901.

Food deprivation for 48 hrs decreases norepinephrine (NE) turnover in the heart, pancreas and liver of rats compared to controls fed ad lib. In contrast, ad lib feeding supplemented with an 8% sucrose drinking solution for 48 hrs accelerates NE turnover in several peripheral tissues (Landsberg and Young, New Engl. J. Med. 298: 1295, 1978). In the present experiments, we were interested in examining the effects of fasting and sucrose-supplemented feeding on basal and stress-induced increases in plasma levels of epinephrine (EPI) and NE in rats. Plasma levels of NE and EPI provide an accurate assessment of the functional activity of the sympathetic nervous system and adrenal medulla, respectively.

Sprague-Dawley rats (approx. 300 g) were implanted with tail artery catheters to allow for repeated sampling of blood in undisturbed animals. For 48 hrs following surgery, each rat was assigned at random to 1 of 3 treatments: (i) food deprivation (FD), (ii) food available, ad lib (CF), or (iii) food ad lib with an 8% sucrose drinking solution (SF). Two days after surgery, blood samples (0.5 ml) were collected and direct measures of mean blood pressure (MBP) and heart rate (HR) were taken while rats were undisturbed in their home cages. Rats were then stressed acutely by exposure to 1 min of intermittent footshock (2.0 mA, 0.6 sec duration, every 6 sec). Additional blood samples were collected immediately and 5 min after the termination of footshock. Plasma levels of NE and EPI were measured by a sensitive radioenzymatic assay and plasma glucose was measured by the glucose oxidase method.

There were no significant differences in plasma levels of NE and EPI. Basal blood glucose levels were lower in FD rats (86±6 mg %) compared to CF (116±7 mg %) and SF rats (123±5 mg %). However, stress-induced increments in plasma glucose were similar across groups. Basal HR was significantly lower in FD rats (301±14 bpm) compared to CF (364±12 bpm) and SF rats (384± 15 bpm). Basal MBP's did not differ across groups. These results suggest that acute changes in nutritional state are not attended by significant alterations in basal or stress-induced increases in plasma levels of NE and EPI. The lower basal HR of FD rats suggests that the sympathetic inputs to some but not all peripheral tissues may be altered by acute changes in food availability.

282.5 TIME COURSE OF BETA ADRENERGIC RECEPTOR ADAPTATION TO RESTRAINT STRESS IN RAT BRAIN. E. A. Stone* and J. E. Platt* (SPON: A. J. Friedhoff). Dept. of Psychiat., New York Univ. Med. Ctr., New York, NY 10016.

The present study examined the time course of neurochemical and physiological adaptation to chronic stress. Independent groups of male rats were subjected to 2.5 hours of restraint per day for either 1, 4, 7, 9 or 14 days. Restrained rats and non-stressed controls were killed immediately after the last stress session. The hypothalmus, cerebral cortex and brainstem were assayed for beta adrenergic receptors by the method of Bylund and Snyder (Mol. Pharmac., 12:568-580, 1976) with {^{3}H}dihydroalprenolol ({^{3}H}DHA) as the radioligand, using isoproterenol in place of propranolol to yield a more conservative measure of non-specific binding. In the hypothalmus, restraint produced a highly significant reduction of {^{3}H}DHA binding first evident on day 4 and persisting through day 14. A significant decrease was evident in the cortex on days 7, 9 and 14. In the brainstem, restraint produced a biphasic effect indicated by a significant treatment x day interaction: {^{3}H}DHA binding was increased on days 1 and 4 and decreased on days 7 and 14. Adaptation to restraint stress was measured by the development of resistance to gastric ulcer formation. The incidence of gastric ulcers decreased from 100% on day 1 to 0% on days 9 and 14 with resistance first appearing on day 4 (50%). This decrease in ulcer formation was positively correlated with the loss of beta receptors in the brain (hypothalmus: r = 0.82; cortex: r = 0.70; brain stem: r = 0.76). The above findings suggest that reduced adrenergic receptor function, which is known to occur after antidepressant therapy as well as adaptation to stress, may play an important role in the development of resistance to the adverse effects of emotional stress.

282.6 DISSOCIATION OF PITUITARY-ADRENAL ACTIVATION AND BEHAVIORAL STRESS RESPONSE FOLLOWING TASTE AVERSION CONDITIONING. G.R. Sessions and J.L. Meyerhoff. Div. Neuropsychiatry, Walter Reed Army Inst. of Research, Washington, D.C. 20012.

Stress produces pituitary-adrenal activation in rats resulting in increases in plasma levels of corticosterone and prolactin, and in cyclic AMP in the pituitary. Conditioned corticosterone release has been demonstrated in rats forced under extreme food and water deprivation to ingest a conditioned aversive flavor previously paired with an illness-inducing agent (lithium chloride, LiCl). Non-deprived rats do not show this conditioned pituitary-adrenal response. This dissociation has been interpreted as reflecting greater pituitary-adrenal activation when conflict exists between conditioned taste aversion and deprivation (Smotherman, et al. JCPP, 1980, 94, 25). The present experiment investigated pituitary-adrenal activation in non-deprived rats forcibly exposed to a conditioned flavor.

Two groups of rats received daily 1 ml oral lavage with water followed 5 min later by saline injections i.p. Beginning on the 10th day one group (N=16) received conditioning trials consisting of 1 ml lavage with 0.1% saccharin solution followed 5 min later by injections of 1.2 mEq/Kg LiCl i.p. The remaining animals (N=16) received saccharin solution followed by saline injections. Conditioning trials were given on 4 separate days at 2-4 day intervals. Taste aversion conditioning was assessed in 2-bottle preference tests prior to the 3rd and 4th conditioning trials. After conditioning, the saline and LiCl groups were subdivided into 2 groups each. Half of the animals in each group received 1 ml lavage with saccharin solution, while the other half received water. A 4 point rating scale was used to rate the animals' behavioral responses to the lavage. Fifteen min later the animals were sacrificed by high-powered microwave radiation focused on the head. Trunk blood was collected for hormone assays, and the pituitary gland was dissected from the brains. The plasma was assayed for corticosterone and prolactin, and the pituitary was analyzed for cyclic AMP levels by radioimmunoassay.

Although all LiCl-injected animals demonstrated severe aversions for the saccharin solution in the 2-bottle preference tests and reacted more strongly to the saccharin than controls, no group differences were observed in plasma corticosterone or prolactin, or in pituitary cyclic AMP following exposure to the flavor. Forced exposure to a conditioned aversive flavor thus does not result in a conditioned pituitary-adrenal response in non-deprived subjects. These results are consistent with the view that pituitary-adrenal activation following exposure to a conditioned aversive flavor occurs only in situations involving severe conflict.

282.7 ADRENAL DEMEDULLATION ALTERS THE EFFECT OF AMYGDALA STIMULATION ON RETENTION OF AVOIDANCE TASKS. C.B. Brewton*, K.C. Liang* and J.L. McGaugh (SPON: Beatriz J. Vasquez). Department of Psychobiology, University of California, Irvine, CA 92717.

Performance in an aversive task can be greatly impaired if low-level electrical current is passed through the amygdala shortly after rats are trained. Amygdala stimulation of this kind has been found to affect hormone release from the adrenal medulla, and recent data suggest a role for these hormones in memory modulation. The present study investigates the role of the adrenal medulla in mediating the memory effects of amygdala stimulation.

Male Sprague-Dawley rats were bilaterally adrenal demedullated (ADMX) or sham-operated (SHAM). These rats had previously been implanted bilaterally with bipolar electrodes aimed at the basomedial/basolateral region of the amygdalae. Two weeks after the adrenal surgery, the rats were trained in a one-trial inhibitory avoidance task (1 mA, 2 sec footshock). Two weeks later, they were trained in an 8-trial active avoidance task (640 μA, 30 sec footshock). For each task, approximately half the rats received amygdala stimulation (AS) immediately after training (50 μA/electrode, 30 sec) and the remainder served as implanted controls (IC). Results of the 24 hr retention test are shown in the table.

In both the inhibitory and the active avoidance tasks, amygdala stimulation produced a retention deficit compared with IC for both SHAM groups. In both tasks also, adrenal demedullation impaired retention scores of the IC groups. For inhibitory avoidance, the AS/ADMX group performed significantly better than the AS/SHAM group, and amygdala stimulation of these rats did not produce a deficit compared with the appropriate control group, IC/ADMX. In active avoidance, retention scores of the AS/ADMX rats were comparable to those of the IC/SHAM group, but significantly better than those of either AS/SHAM or IC/ADMX.

The present findings indicate that adrenal demedullation alters the effects of post-training amygdala stimulation on memory. This suggests that the effect of this type of stimulation may be mediated in part by altering the release of hormones from the adrenal medulla.

	INHIBITORY AVOIDANCE Median entrance latencies (sec)		ACTIVE AVOIDANCE Mean no. of avoids (Day 2-1)	
	IC	AS	IC	AS
SHAM	471.4	75.7[a,e]	2.81	1.50[c,g]
ADMX	161.5[b]	347.7	1.65[d,f]	2.79

a. p<.001, b. p<.005, c. p<.01, d. p<.02 different from IC/SHAM
e. p<.05, f. p<.02, g. p<.01 different from AS/ADMX

282.8 EXAGGERATED CONDITIONED VASCULAR RESPONSES IN SPONTANEOUSLY HYPERTENSIVE RATS CAN BE DISSOCIATED FROM EMOTIONAL BEHAVIOR BY A CENTRAL ADRENERGIC AGONIST. J.E. LeDoux, L.W. Tucker* and D.J. Reis. Lab. of Neurobiology. Cornell Univ. Med. Coll. NY, NY 10021

We subjected spontaneously hypertensive rats (SHRs) to classical fear conditioning to determine: (a) whether conditioned changes in arterial pressure (AP) and heart rate (HR) are enhanced in SHRs relative to Wistar Kyoto (WKY) controls; and if so, (b) whether treatment with a centrally acting a-adrenergic agonist, a-methyl DOPA (Aldomet), may selectively affect the expression of such conditioned changes without altering conditioned emotional behavior. Six animals were instrumented for chronic recording of AP and HR while awake and unrestrained. The next day, the animals were subjected to 30 conditioning trials during which a footshock (.5 sec, 1.5 ma) was paired with the termination of the conditional stimulus (CS) (10 sec, 1200 Hz tone). Two hr later, during 3 extinction trials (CS presented without shock) cardiovascular (CV) data were acquired and stored by a microcomputer for analysis. Basal levels of AP (mmHg) were higher in SHRs (181 ± 13) than in WKYs (133 ± 8) ($p < .01$). In the presence of the CS, the average response of AP was greater in SHRs (12 ± 4) than in WKYs (1 ± 1) ($p < .01$) and AP was more variable in SHRs (S.D. of AP in SHRs, 7 ± 1; in WKYs, 2 ± 1; $p < .01$). The magnitude and variability of conditioned HR responses did not differ. An additional group of SHRs was treated with Aldomet (25-38 mg/kg i.v; n=7) or saline (n=4) 1h prior to assessment of conditioned pressor responses and conditioned emotional behavior, which was measured by the duration of freezing in the presence of a 120 sec CS. The conditioned pressor response (mmHg) was attenuated in treated (3 ± 3) vs control (9 ± 4) SHRs ($p < .05$). While the resting AP was lowered in 4 of the treated animals and thus accounted for a lower basal AP in the treated (140 ± 12) vs control (169 ± 8) ($p < .01$) group, there was no relation between the lowering of AP and the attenuation of the conditioned pressor response. Moreover, Aldomet did not reduce the elevations of AP (up to 35 mmHg) occuring during a natural behavior, drinking, nor did it suppress conditioned emotional behavioral responses (secs of freezing) in treated (43 ± 23) vs control (30 ± 23) (n.s.) animals. We conclude: (a) SHRs have larger and more variable conditioned pressor responses than WKY controls; and (b) these responses are selectively reduced by a-methyl DOPA independent of an action of the drug on resting AP. The results suggest that central neurotransmitter systems underlying the expression of conditioned CV responses may be distinct from those underlying the resting and reflex control of AP and also from those mediating the expression of emotional behavior. Supported by HL 18974 and Merck, Sharp, and Dohme.

283.1 A BEHAVIORAL STUDY OF PATTERN & MOVEMENT DETECTION SYSTEMS IN THE CAT. Adrienne L. Graves* (SPON: D.G. Green). Psychology Dept. and Neuroscience Lab., Univ. of Mich., Ann Arbor, MI 48109.

Previous studies have proposed that X- and Y-cells in the visual system may be related to pattern and movement detection respectively (Tolhurst, 1973; Kulikowski & Tolhurst, 1973). This hypothesis is based on the comparison of electrophysiological properties of cat retinal ganglion cells with human psychophysical data. Possible species differences complicate such a comparison. The purpose of the present experiments was to determine if psychophysical data on pattern and movement detection in the cat are consistent with electrophysiological properties of cat X- and Y-cells.

In one set of experiments behavioral contrast sensitivity functions were measured for stationary and drifting (1,2,3,8, & 22 Hz) sinusoidal gratings. While functions for stationary and very slowly drifting (1 Hz) gratings were indistinguishable, contrast sensitivity functions measured at higher drift rates revealed different properties. There was a decreased sensitivity for high spatial frequencies, and for intermediate speeds there was an increased sensitivity for low spatial frequencies. Both the high frequency decrease in sensitivity and the low frequency increase were a factor of 2 or more.

A second set of experiments used adaptation to investigate differences in pattern and movement detection. Viewing a low spatial frequency grating for 2 - 3 minutes caused a decreased sensitivity for that stimulus. A low spatial frequency stationary grating, however, was an ineffective adapting stimulus for low spatial frequency moving gratings.

Both sets of experiments suggest that pattern and movement detection may be separate mechanisms in the cat. Findings are consistent with the following conclusions (Tolhurst, 1973): 1)pattern detection may be related to X-cells, which respond to stationary gratings and to higher spatial frequencies; and 2)movement detection may be related to Y-cells, which respond to lower spatial frequencies and require temporal modulation. (Supported by: NEI 5T32-EY07022 & EY00379)

283.2 WHITE-NOISE MODELING OF MOTION SPEED SENSITIVITY IN THE CAT'S LATERAL GENICULATE NUCLEUS. C. Veraart*, I. Sallets* and V. Pluvinage* (SPON: M. Meulders). Lab. Neurophysiol. Univ. of Louvain. B-1200 Brussels, Belgium.

This work's aim was to develop a mathematical model which would allow to describe information collected in the lateral geniculate body in response to the movement of a specific stimulus in an animal's visual field.

Cats, anaesthetized with a mixture of nitrous oxyde (75%) and oxygen (25%) supplemented by a long acting local anaesthetic (Bupivicaine) were prepared for visual investigations following conventional methods. Sinusoidal gratings were displayed on a Tektronix 606A monitor (P-31 Phosphor) with the help of a HP-1350 graphic translator, driven by a PDP-11/44. Grating parameters could be choosen at will, motion being linear, sinusoidal, or with speed related to a gaussian white noise. Neuronal activity was collected by means of glass microelectrodes filled with a mixture of NaCl (5%) and Pontamine (4%). Neuronal spike trains were sent to the computer. After X-Y determination, neurones were stimulated by presenting grating moving with a constant speed, or with a sinusoidal speed, or with a speed function of a gaussian white noise. After filtering and windowing, the fast FOURIER transforms were computed in order to obtain power spectrum estimate of both input and output of the retinal geniculate system. After smoothing first order and second order WIENER kernels were determined.

Results have shown that non linearities in visual information processing would also be involved in speed coding. Mathematical models were then developed and were used to simulate motion speed sensitivity. Evaluation of fitness of model responses is in progress and will be discussed.

283.3 INVARIANT MODELING AND RECOGNITION OF BINARY PATTERNS FOR VISUAL STIMULI. Faris Badi'i* and Behrouz Peikari* (SPON: Robert T. Matthews). Southern Methodist University, Dallas, TX 75275 and DeVry Institute of Technology, Irving, TX 75062

A brief discussion of the historical background of invariant recognition of binary patterns (digital computer recognition of binary shapes independent of variations in size, location and rotation) is presented. Their limitations and restrictions are discussed. A size, rotation and location invariant recognition model of binary shapes via a geometrical feature extraction approach is introduced. A family of functions relating geometrical properties of shapes are found, and mathematically justified to be invariant under variations in size, location and orientation. A number of test patterns are also presented as experimental support of the model and discriminatory results are given in corresponding tables. The model is mathematically extended to three-dimensional case and a second family of functions is developed for invariant recognition of three-dimensional shapes. A discussion of practical considerations for digitized data is also given.

283.4 SIMULATION OF DECISION-MAKING BY MULTIMODAL NEURONS. R. Martin*, A. Lukton* and S.N. Salthe* (SPON: I. Abramov). Dept. of Chem., Brooklyn College of the City Univ. of N.Y., Brooklyn, N.Y. 11210.

Neuroanatomists have been puzzled by observations that the vertebrate limbic system, striatum, diencephalon, midbrain and hindbrain each receive inputs, either directly or indirectly, from all or most of the neocortex, and that many neurons within these regions receive a large number of heterogeneous inputs from several different sensory modalities. Nauta and Feirtag[1] have written that "an electrical engineer who had this situation described to him would frown; he would say that one could never hope to get anything but noise from it" since information mixed together in this way cannot subsequently be differentiated. The function of multimodal neurons has been examined during computer simulations of simple conceptualization, learning by simile, risk-benefit assessment and game-playing in associative neural networks governed by the following rule: connections are strengthened between neurons which discharge simultaneously or soon after each other, and are weakened when postsynaptic cells do not discharge after presynaptic activity. This learning rule is a modification of Hebb's postulate[2] that neurons become more strongly interconnected when they discharge simultaneously. It means basically that connections which are frequently used are strengthened, while those which are neglected wither, like branches of a tree which receive no sunlight. Networks of this kind are described in detail elsewhere[3-5]. The simulations indicate that multimodal neurons may function as decision-makers which recognize specific combinations of diverse stimuli and then activate appropriate motor and neuroendocrine response pathways. Multimodal neurons within the mid- and hindbrain may spread their dendrites over several millimeters "hoping, it seems, to catch any kind of message"[1] because they need as much information as possible for the complex decisions they make. The simulations also suggest that multimodal neurons may facilitate the use of concepts which include different sensory and response modalities. This model of decision-making suggests that Hebb's hypothesis may be tested with experiments that focus on input pathways to multimodal neurons which trigger motor and neuroendocrine responses.

283.5 MODEL FOR BILATERAL NEURAL PATHWAYS IN THE VESTIBULAR OCULAR REFLEX (VOR). H.L. Galiana*and J.S. Outerbridge* (SPON: W. Feindel), Biomedical Engineering Unit, McGill University, Montreal, Quebec, Canada H3G 1Y6.

A new bilateral model of brainstem pathways in the VOR has been developed, based on known anatomical elements and connections. Leaky ($T \sim .3$ sec.) bilateral brainstem integrators are assumed, each linking burst-tonic (BT) and ipsilateral tonic vestibular (TVP) cells in the vestibular nuceli (VN). In normal operation the output of these integrators faithfully predicts eye position, and the effective integration time constant of the VOR in the slow phase is much longer ($\sim$15 sec.), as observed. The commissural positive feedback loop emerges as an important component of the system, and fast phase generation is achieved through its modulation by reticular burst cells (Hikosaka et al., Exp. Brain Res. 39:301-311, 1980). During nystagmus, the system switches alternately from a compensatory position-tracking mode (slow-phase), to an anticompensatory velocity tracking mode (fast phase). Detailed non-linear analysis of the system shows that modulated commissural inhibition has the effect of keeping BT firing levels above threshold during compensatory phases; as a result, linear analysis is frequently possible and is used here to predict response trajectories during slow phase and fast phase segments.

The model accounts for a number of behavioural and electrophysiological findings, e.g., a) 2^{o} TVP and 3^{o} BT VN cells have sensitivities and decay time constants greater than those of primary fibres; b) tonic type I VN cells reverse their response polarity on section of superficial commissural fibres; c) effective VOR integration deteriorates after cerebellectomy; d) the envelope of eye position at the end of fast phases is a low pass filtered version of head velocity; e) peak fast phase eye velocity is modulated by the current vestibular input as well as the error from target.

283.6 MEASUREMENT OF PASSIVE MEMBRANE PARAMETERS OF HIPPOCAMPAL GRANULE CELLS. D. Durand, P.L. Carlen, A. Ho, P. McMullen & H. Kunov*. Depts. of Biomedical Engineering, Physiology & Anatomy, University of Toronto, Addiction Research Foundation & Playfair Neuroscience Unit, Toronto Western Hospital, Toronto, Ontario.

Combined intracellular recordings and HRP injections have proven to be powerful techniques for analyzing electrotonic properties of nerve cells. Using the in vitro hippocampal slice preparation, HRP injections of adult rat granule cells showed that these cells have dendritic trees with few branching points that closely follow the 3/2 power law and dendrites of approximately identical lengths. These trees are therefore easily collapsable into a single equivalent cable.

Long (LP) and short (SP) hyperpolarizing current pulses (80 and 15 msec respectively) were injected into these cells at varying amplitudes (.1 to 20 nA). The decays of the voltage responses (a sum of exponentials) were analyzed by a computerized peeling technique and by a least-square fitting program (Provencher, Biophys. J., 16:27,1976). Cable equations for both open ended and characteristic impedence terminations then permitted the calculations of the electrotonic length L, and dendritic to somatic conductance ratio ρ.

We have found the short-pulse technique to be usually superior to the long-pulse technique for the following reasons: 1) The resolution of the several time constants is better since the coefficients associated with the faster ones are larger. 2) Provided that the pulse is short enough and the cell input resistance (R_N) linear, the short pulse voltage response is the derivative of the long pulse response eliminating the need for noisy differentiating techniques. 3) Although the hyperpolarizing long pulse sometimes generates a non-linearity (probably a voltage dependent conductance increase), the short pulse can give linear responses and therefore more accurate values of the cell resistance and time constants (see Figure below). (Note the large linear range of the short pulse response).

Preliminary analysis gives values of ρ ranging between 1.5 and 7 with L between .9 and 1.35. The corresponding values of R_m varied between 1500 and 5000 $\Omega.cm^2$ with C_m between 2 and 6 $\mu F/cm^2$.

284.1 ELECTROPHYSIOLOGICAL AND BEHAVIORAL CHARACTERIZATION OF THE NEURAL SUBSTRATE FOR BRAIN-STIMULATION REWARD. I. Kiss*, M. Lapointe* and P. Shizgal. Department of Psychology and Center for Research on Drug Dependence, Concordia University, Montreal, Quebec, Canada.

Electrodes suitable for both chronic stimulation and electrophysiological recording were aimed at various loci along the medial forebrain bundle under stereotaxic and electrophysiological control. Following a post-surgery recovery period of at least four days, the subjects, adult male Wistar rats, were trained to self-stimulate. After behavior had stabilized, estimates of the excitability cycles and conduction velocities of neurons subserving self-stimulation were obtained by psychophysical means.

Field potential recordings were obtained using the same electrodes, currents and pulse durations that were employed during the self-stimulation tests. During the recording sessions, which were interspersed with the behavioral tests, the subjects were anesthesized with sodium pentobarbital.

The field potential records demonstrate the plausibility of the inferences drawn from the behavioral results in that there is a considerable degree of overlap between the two sets of excitability cycle and conduction velocity estimates. In the recording data, recovery from refractoriness begins as early as 0.3 msec and ends as late as 2.0 msec. The behavioral recovery range is 0.4 msec to 2.0 msec. Both methods produce estimated conduction velocities ranging from rougly 2 to 10 m/sec.

Characteristics of directly activated reward-related neurons are inferred from the behavioral data; the electrophysiological findings indicate that neurons with congruent characteristics are, in fact, fired by electrodes and parameters that support self-stimulation. The possible sources of the correlation between data acquired by the aforementioned methods are discussed, as are 1) the sampling biases inherent in the two methodologies and 2) the potential application of this two-pronged approach as a tool for identifying the neural substrate for BSR.

284.2 A GEOMETRIC MODEL TO ACCOUNT FOR NON-LINEAR CURRENT-FREQUENCY TRADE-OFF DATA IN CIRCLING & SELF-STIMULATION. J. S. Yeomans and David Wen* (Dept. of Psychology, University of Toronto, Toronto, Ont., Canada).

Electrical stimulation applied just lateral to the median raphe in rats produces ipsilateral circling at currents as low as 18 uamps (100 Hz, 0.1 msec duration cathodal pulses). Paired pulse studies have suggested that the neurons mediating this behavior have very short (0.32-1.2 msec) absolute refractory periods (Miliaressis, 1981). In this experiment we examined the spatial and temporal summation properties of these neurons by means of current-frequency trade-off functions. Although similar in most respects to data from self-stimulating rats (Gallistel, Shizgal and Yeomans, 1981), the trade-off between current and 1/Frequency is not linear except under special conditions. The non-linearities found are different for different electrode placements, suggesting that the geometrical relationship between the electrode tip and the behaviorally relevant neurons is critical. A simple geometrical model is proposed which accounts for the patterns of non-linearities found. This geometric model also accounts for non-linearities that have been previously found in current-frequency trade-off data from self-stimulating rats (Shizgal, Howlett & Corbett, 1979). This model should be useful in localizing the substrate for behaviors elicited by brain stimulation.

284.3 INTERMEAL INTERVAL, MINIMUM MEAL SIZE AND THEIR INTERACTION: A PARAMETRIC STUDY. T. W. CASTONGUAY*, M. B. P. LEUNG*, AND J. S. STERN* (SPON: V. MENDEL). NUTRITION DEPARTMENT AND FOOD INTAKE LABORATORY, UNIV. CA. DAVIS, DAVIS, CA 95616.

Before analyzing moment-to-moment feeding behavior, two parameters must be defined: intermeal interval (IMI) and minimum meal size (MMS). Typically, investigators choose one definition for determining the end of a meal (the IMI) and one definition for the minimum amount of food required to determine the onset of a meal (the MMS definition) While IMI definitions have been explored by several investigators, MMS and its interaction with IMI's have not been systematically studied. The present experiment details the interaction that is observed in daily meal frequency and average meal size by varying both definitions.

Five IMI definitions were chosen (1,2,5,10, and 15 minutes). Within each of these, four MMS definitions were explored, so that a total of 20 different analyses of the same feeding patterns were conducted. Four genetically obese (fa/fa) and four lean (Fa/-) adult female Zucker rats were used as experimental animals.

Results from the analyses revealed that under most definition combinations, obese rats eat significantly fewer meals than do their lean littermates. For example, when IMI was 5 minutes and MMS was .04 g obese rats ate 17.13 meals and lean rats ate 22.12 meals ($p < .05$). However, long IMI's in combination with small MMS definitions tend to obscure that finding. For a IMI of 15 minutes and a MMS of .01 g there were no significant differences in number of meals eaten by obese and lean rats (17.38 vs. 19.00 $p > .05$, respectively). Further, although the average meal size of the obese rats is significantly greater than that of lean rats, the size of the difference between these genotypes varies widely with the use of different definition combinations.

No one set of combination of definitions was ideally suited to assess the meal patterns of the two genotypes. Although no differences in meal frequency with 5,10 and 15 minutes IMI's were found in obese rats, these same definitions promoted changes in meal frequency when applied to lean rat meal patterns.

It is recommended that meal pattern analysis include more than the customary single set of definitions before drawing conclusions about differences between experimental and control groups.

284.4 AN ON-LINE COMPUTERIZED FEEDING, DRINKING AND ACTIVITY PATTERNS ANALYSIS SYSTEM. P.M.B. LEUNG*, Q.R. ROGERS*, J.S. STERN* and V.E. MENDEL. (SPON: L. CHAPMAN). Depts. of Physiol. Sci., Nutrition, Animal Physiol. and the Food Intake Group, Univ. of California, Davis, CA 95616.

An on-line computerized feeding, drinking and activity monitoring system has been developed to determine detailed changes in each parameter using rats or other small animals under various dietary or choice regimens. The system consists of a plexiglass cage with inter-changeable food tunnels on both sides, Mettler electronic balance(s) fitted with spillage-proof food cup(s) positioned under the food tunnel(s), 3 electronic fluid volume detectors and an activity-wheel with electronic sensors. All devices, interfaced with an on-line computer are housed in a chamber with individual lighting and air circulating system is configured to run the RT-11 operating system (Digital Equip. Corp.). The computer is equipped with floppy and hard disk storage, a full compliment of analogue input and output, serial I/O ports and a custom designed interface to the Cage Communication Bus. Each cage is equipped with digital to analogue converters. The chamber is fitted with circuit boards, a status display panel and several internal Input/Output Registers which may be used as the experiments require. Feeding, drinking and running activities of animals can be monitored in short time lapses from 1/30 of a second to minutes. The detailed data output include: 1) the cage No. being monitored; 2) the type of activity being recorded; 3) the time for the initiation of activities; 4) the durations of such activities in seconds and fraction of a second; 5) the time for the initiation of the dark/light cycle and short-stop time of other events; and 6) the cumulative summations of all the activities during a specific (e.g. 12:12 hr) dark/light cycle. Software developments enable the determinations of meal size and frequency, drinking and running bouts, inter-activities intervals etc. in histogram form or group comparisons with statistics. The system has been used to determine feeding, drinking and running patterns of obese and lean Zucker rats fed diets varied in protein or fat contents, and of animals fed disproportionate amounts of dietary amino acids. These results will be discussed.

284.5 STIMULATION OF SALT APPETITE IN HAMSTERS. D.A. Fitts*, E.S. Corp* & J.B. Simpson. Department of Psychology, University of Washington, Seattle, WA 98195. (Spon. I.L. Bernstein).

The existence of a salt appetite in hamsters has been questioned. Hamsters will normally avoid .15 M NaCl solutions in choice with water, even following DOCA or adrenalectomy. The present study examined free-choice selection of saline or water under two conditions which produce vigorous salt drinking in rats: hyperoncotic colloid dialysis (30% polyethylene glycol (PEG), 1.5 ml/100 g, sc) or a sodium deficient diet.

PEG treatment elevated saline intake, but not water intake, over 48 hr postinjection. This effect on saline intake was small compared to rats, increasing over baseline from 0.8±0.5 to 2.3±2.4 at 24 hr and 2.8±2.7 ml/day at 48 hr (n=10). Not all hamsters, however, responded with saline intake. Increases of sodium and water balances proceded slowly, with only one hamster approximating the proportional accumulations commonly seen in rats. Urinary sodium excretions during the first 24 hr of PEG averaged only 0.121±0.058 mEq, and the volume of urine declined by 50% (5.2±1.3 to 2.6±0.7 ml). Food was always present, with consumption declining from 8.4±0.6 to 4.8±1.8 g after 24-hr PEG. Water and food intakes were highly variable between subjects and were highly correlated ($r(14)=0.96$, $p<.001$) during the first 24-hr PEG.

The sodium deficient diet also increased mean saline intake in 8/10 hamsters over 15 days (from 0.4±0.3 to 0.8±0.6 ml/day). Consumption tended to be episodic rather than continuous, although 4/10 hamsters did develop a regular consumption pattern. The median excretion ratio for Na^+/K^+ during the low sodium diet was 0.02, or only slightly greater than the Na^+/K^+ ratio of the diet (0.01). After a return to the normal diet, saline intake returned to baseline within 6-12 days.

Together these studies indicate that hamsters do have a mechanism for salt appetite, although this species apparently relies heavily on renal mechanisms for compensation of hydromineral balances after PEG or low sodium diet challenges.

284.6 TASK-DEPENDENT PROPERTY OF BRAIN STIMULATION ON DRL REWARD SCHEDULES. N.L. Freedman & J. Law*. Psychology Department, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Enhancement of lever-press responding for brain stimulation reward (BSR) by lengthening current duration to 300 msec. and gradual decline thereafter (Keesey, R.E., J. Comp. Physiol. Psychol., 58: 201, 1964) suggests that longer durations are aversive or produce incompatible responses. The effect is task-dependent (Lyons & Freedman, Unpublished). Identical stimulation delivered to the same rats for wheel-turning produces a monotonically increasing function of BSR duration over a variety of stimulus intensities. Thus, the incentive value of the stimulation depends on task rather than neural substrate underlying stimulation. With differential reinforcement of low response rates (DRL) successful reinforcement depends on withholding responses and is independent of interference by stimulation or response produced inertia in the wheel. The present experiment compares lever-press and wheel-turn over several DRL schedules (2, 4, 8, 16, 32 sec.) for BSR.

Four rats were trained to lever-press and wheel-turn (40 degrees) for 300 msec., 60 Hz, trains of medial forebrain bundle stimulation. Rats were tested one day on the wheel and one day on the lever for 15 min. at each successively longer DRL. Half the rats were trained on the wheel and half on the lever first.

Rats obtained a greater proportion of rewarded responses on the wheel than lever across all DRLs ($F\ 5,15 = 5.06$, $p = .0067$). Such results cannot be attributed to neurochemical substrates since at all DRLs stimulation of the same brains activated identical neurotransmitter systems for both tasks. Results support the previous conclusion that activation of relevant neurotransmitter systems provides task-dependent differential incentive for responding.

284.7 EFFECTS OF ANTERIOR AND POSTERIOR MEDIAL FOREBRAIN BUNDLE LESIONS ON LATERAL HYPOTHALAMIC SELF-STIMULATION REWARD. James R. Stellar and Scott Neeley. Dept. of Psych.& Soc. Rel., Harvard University, Cambridge, MA. 02138

A number of studies have focused upon the effects of electrolytic lesions in the medial forebrain bundle (MFB) on lateral hypothalamic (LH) self-stimulation reward (see Lorens, in Ed. Wauquier & Rolls, Brain and Reward, N.Y.: Elsevier, 1976, pp. 41-50). However, none of these studies have employed the recently developed quantitative techniques for characterizing the reward substrate (see Gallistel, Shizgal, & Yeomans, Psych. Review, in press). This report examines the effects of MFB lesions delivered anterior to, posterior to, and through the LH stimulating electrode on the reward summation function (RSF) described by Edmonds & Gallistel (JCPP, 1977, 91, 362-974).

A single point on the RSF is generated by finding the median speed of running a runway for one burst of LH stimulation. Other points on the RSF are generated by repeating the above step but using a burst with a different number of pulses. This RSF curve has a characteristic inflection point termed the locus of rise which is found by calculating the number of pulses required to sustain half asymptotic running speed. Changes in the locus of rise of the RSF have been shown to reflect changes in the effectiveness of pulses in generating reward; whereas, changes in asymptotic running have been shown to reflect changes in performance variables (e.g. task difficulty).

Large anterior lesions placed at the anterior border of the lateral hypothalamus and occupying about 75% of the crosssectional area of the MFB did not significantly affect the RSF from the LH electrode. Smaller posterior lesions placed just rostral to the MFB produced large shifts in the locus of rise of the RSF, indicative of decreased pulse effectiveness, as well as shifts in its asymptote. Small lesions through the electrode also produced similar shifts of the RSF. These findings suggest that the important reward relevant direction of conduction within the MFB is posterior. This agrees with previous work on LH self-stimulation in the hemiforebrain ablated rat (Stellar, Illes, & Mills, Neuroscience Abstract, 1979) and two electrode hyperpolarization blockade research (Shizgal, EPA symposium, 1981).

284.8 EFFECTS OF MODIFYING THE ENVIRONMENTAL CONDITIONS ON THE SELF-STIMULATION BEHAVIOR AT THE POSTERO-LATERAL AREA OF THE HYPOTHALAMUS. Ph. De Witte* and M. Meulders (SPON: B. Will). Lab. Neurophysiology, Univ. Cathol. Louvain, Faculté de Médecine, Bruxelles, Belgium.

In order to study the relationships existing between the self-stimulation behavior and the positive or negative properties of the environments, six situations were designed: home cage and novel cage into which was added or not a male or a female presenting or not a lordosis behavior. In each 10 min session of self-stimulation, the rewarding value induced by the electrical combinations (.1 msec pulse width delivered at the frequency of 100, 200 and 300 Hz, and .2 msec at 100, 200 and 300 Hz) was estimated by 4 parameters: (1) the total time each animal had effectively self-stimulated (T), (2) the number of bar presses (N), (3) the mean duration of bar pressing ($M=\frac{T}{N}$), and (4) the standard deviation of the duration of bar presses.

Results show that the total time the animal self-stimulates varies with the situation. In increasing order of self-stimulation time, the six situations are: 1° home cage, 2° home cage + female presenting a lordosis behavior, 3° home cage + male, 4° home cage + female not presenting a lordosis behavior, 5° novel cage, and finally 6° the highest total time of self-stimulation was found for novel cage + male.

Moreover, negative coefficient (-.72) of correlation relates the total time spent to self-stimulate to the mean duration of a bar presses as well as between N and S (-.64). Thus, the more the environment seems to be rewarding, the less animals self-stimulate, but the more the mean duration of bar presses increases, and the more often animal self-stimulated, the shorter became the mean duration of the bar presses. Furthermore, novel cage conditions seemed to have a clearly different influence from the other environment.

These experiments show that animals could either compensate the negative effects of the environment (novel cage) by increasing self-stimulation behavior or decrease the latter when environment is positively rewarding.

It is possible, therefore, that there exists a kind of homeostasis regulating the influx from the milieu externe relative to the affective data of the milieu interne, here excited by electrodes in the hypothalamus.

284.9 PREDICTION OF HYPOTHALAMIC "PREPOTENCY" WITH AMPHETAMINE-INDUCED STEREOTYPIES. Susan E. Bachus & Elliot S. Valenstein. Dept. Psychobiology, Univ. Michigan, Ann Arbor, Michigan, 48109.

Individual differences in behaviors elicited by electrical stimulation of lateral hypothalamus (ESLH), which range from locomotor agitation to consummatory behaviors, are not attributable to differential electrode placement; thus they may reflect individual variability in response predisposition or "prepotency" of the animal (Valenstein, Brain Behav. Evol. 2:295, 1969; Bachus & Valenstein, Physiol. Behav. 23:421, 1979). Rather than simulate behaviors exhibited during natural "drive states", responses seen during ESLH parallel in many respects the "stereotypic" behaviors elicited by stimulant drugs such as amphetamine (Valenstein, Nebraska Symposium on Motivation 1974, p. 251; Biology of Reinforcement, ed. A. Routtenberg, p. 39, 1980). However, amphetamine does not facilitate ESLH-induced consumption in rats(Wishart & Walls, J. Comp. Physiol. Psych. 87:741, 1974), presumably because of the anorexigenic effects of the drug.

When durations of discrete stereotyped behaviors (locomote, rear, "nose-hole-poke", groom) were recorded independently, 30 naive male Long Evans hooded rats, observed following 3 separate 1.5 mg/kg ip administrations of d-amphetamine sulphate, displayed consistent individual differences in predominant type of stereotypy elicited. Subsequently, these rats were implanted with bilateral stimulating electrodes in lateral hypothalamus and screened for elicitation of consummatory behaviors (eat, drink, gnaw) by ESLH. Across individuals, duration of stereotypy which entails orientation to external stimuli (nose-hole-poke) recorded during the first amphetamine experience was highly correlated with duration of ESLH-induced consumption ($r=.75$, $p<.01$).

To exclude the possibility that responses to ESLH were influenced by amphetamine history, 12 naive rats were first implanted with electrodes and screened for response to ESLH, and afterward received 3 injections with amphetamine. Again, the duration of ESLH-elicited consummatory behavior was significantly correlated with duration of nose-hole-poke evoked by amphetamine ($r=.62$, $p<.05$). Moreover, statistical analysis of histological determination of electrode placement (Mittleman & Valenstein, Physiol. Behav. 26:371, 1981), for these 42 rats, indicated that exact locus of stimulation did not interact with nose-hole-poke duration in predicting response to ESLH.

These results suggest that stable individual differences in behaviors evoked either by stimulant drugs or by ESLH may reflect more fundamental individual variation in tendency to respond to arousal either with locomotor excitation or with attention directed to stimuli in the external environment.

284.10 BEHAVIORAL SENSITIZATION EFFECTS FOLLOWING REPEATED ELECTRICAL STIMULATION OF THE MEDIAL PREFRONTAL CORTEX. Dale Corbett,* Andre Laferriere*and Peter M. Milner.* (SPON.: Alan Rosenquist) Dept. Psych., McGill Univ., Montreal, Quebec, CANADA H3A 1B1.

Intracranial self-stimulation (ICSS) from the medial prefrontal cortex (PFC) has different properties than ICSS from other brain regions. One such property is that PFC ICSS is acquired slowly, taking 5 or 6 days to establish. During initial training the animals appear little affected by priming stimulations. Over time, the priming stimulation begins to be effective as indicated by the animals beginning to orient towards the lever of the Skinner box.

This behavioral pattern suggested that the electrical stimulation was somehow "sensitizing" the neuronal circuitry involved in brain stimulation reward. Thus we sought to determine if we could hasten the acquisition of PFC ICSS by pretreating the animals with electrical stimulation prior to training. Forty PFC implanted rats were assigned to one of 3 groups: 1) SPACED - stimulation delivered at the rate of 1 train/4 sec for 20" per day for 6 days; 2) MASSED - stimulation delivered at the rate of 1 train/sec for 15" per day for 2 days; 3) CONTROL - treated like SPACED group but received no stimulations. Stimulation consisted of .5 sec trains of 60 Hz sine-wave stimulation at a fixed current intensity of 40 μa (r.m.s.). After the pretreatment phase the rats were placed each day in lever equipped boxes and given a single stimulation. The ICSS acquisition criterion was an overall 30" session response rate of 5/min. (150 total).

Nearly 50% of the SPACED group attained the acquisition criterion on Test Day 1. By the 2nd Test Day this proportion had increased to 80%. In contrast, it was 4 or 5 days before 50% of the other groups reached criterion.

The main finding of this study is that prior stimulation of the PFC results in a more rapid acquisition of ICSS than in animals without a prior stimulation history. Also, it appears that the stimulation is more effective when spaced since the MASSED group did not learn to self-stimulate any more rapidly than did controls. These data suggest that the initial effects of PFC stimulation are not, or are at best, minimally rewarding and that the rewarding effects become strengthened following the modification of as yet unidentified circuitry. However, it is worth noting that synaptic potentiation occurs in the perforant path-granule cell circuit of the hippocampus and that hippocampal ICSS exhibits similar characteristics to PFC ICSS (Campbell & Milgram, 1978).

284.11 MAPPING OF BRAIN-STIMULATION REWARD SYSTEMS WITH THE 2 DEOXY-GLUCOSE TECHNIQUE. E. Yadin and C. R. Gallistel. Department of Psychology, University of Pennsylvania, Philadelphia, Pa 19104.

The 2-deoxyglucose technique (Sokoloff et al., J. Neurochem., 28:897-916, 1977) was utilized to map the neural systems activated by self-stimulation in rats with unilateral electrodes in four different, well-established self-stimulation sites in the brain: the medial forebrain bundle (MFB) at the level of the anterior hypothalamus and at the level of the posterior hypothalamus, the medial prefrontal cortex, and the locus coeruleus.

Rats were trained to self-stimulate in a standard Skinner box. During the 2-DG session rats self-stimulated at a current that produced 3/4 of their maximum responding rate. After a short "warm-up" period the rats were injected intraperitoneally with ^{14}C-2DG and allowed to self-stimulate for 45 min at the end of which they were given an overdose of anesthetic, perfused for 30 sec with a 3.3% buffered formalin solution; the brain was promptly removed and frozen in liquid freon. The sectioning of the brain and the autoradiographic procedure were similar to those originally described by Sokoloff et al. (1977).

The determination of the neural systems exhibiting altered activity as a consequence of self-stimulation was performed using a computer-assisted image analysis. Since the electrodes were unilaterally implanted, comparisons could be made between the stimulated and nonstimulated sides of the same brain. According to such an analysis we found no overlap between the structures activated by the MFB electrodes and the medial prefrontal cortical electrode. The MFB electrodes produced darkening of the length of the MFB, from the anterior ventromedial tegmentum to the diagonal band of Broca and into the lateral nucleus of the septum. The medial frontal cortex electrode seemed to activate the piriform cortex, the anterior olfactory nuclei (both medial and posterior parts), the cortex adjacent to the rhinal sulcus, the enthorhinal cortex, the claustrum, and the dorsomedial nucleus of the thalamus. Indeed, observations of the animals' lever pressing behavior reveal the different nature of these two sites, the former being fast and vigorous, the latter slow and calm.

The neural pattern driven by the locus coeruleus electrode is virtually impossible to trace. In some animals, only the locus coeruleus itself was differentially darker on the stimulated side *and no other structures seemed to be labelled.* In other animals that were behaviorally excellent self-stimulators too, even the locus coeruleus did not appear to take up more labelled 2-DG on the stimulated side versus the nonstimulated side. It is possible that a system with many diffuse projections diverging from a small area cannot be easily detected with this technique.

Supported by NIH grant #NS 14935.

285.1 EEG AND BEHAVIORAL EFFECTS OF GAMMA-HYDROXYBUTYRATE IN THE RABBIT. R. Godbout* and R.T. Pivik. Lab. Neurophysiology, School of Psychology and Department of Psychiatry, Faculty of Health Sciences, University of Ottawa, Ottawa, Ontario K1N 5C8, Canada.

Gamma-Hydroxybutyrate (GHB), a metabolite of gamma-aminobutyric acid (GABA), has been reported to have hypnotic effects at low doses and excitatory effects at high doses. Although these effects have been reported in a variety of species, including man, they have not been examined in the rabbit. Moreover, in man this compound has recently been reported to facilitate sleep onset, reduce the latency to rapid eye movement (REM or PS) sleep, and increase the duration of PS episodes. The present study was conducted to provide data regarding the electrographic and behavioral effects of GHB in the rabbit, with particular reference to sleep-wakefulness variations.

New Zealand White rabbits (n=5) were chronically implanted for recording of EEG, EOG and nuchal EMG activity. Polygraphic recordings, which did not begin for at least two weeks post-operatively, were conducted between 9:00 and 15:00 hrs. Following IV administration of GHB or saline, two consecutive hours of recordings were taken in unrestrained animals housed in sound attenuated, climatically controlled cages. The following nine dosage levels were employed: 25, 50, 100, 150, 200, 300, 500, 750 and 1000 mg/kg, with at least 48 hour intervals between injections. Polygraphic recordings were analyzed in 30 second epochs for sleep-waking state changes. Results were analyzed using repeated measures analyses of variance with post-hoc comparisons based on Dunn's method.

GHB administration did not significantly facilitate sleep onset (drowsy or slow wave sleep: SWS) or latency to PS. At the highest dosages (750 and 1000 mg/kg) PS did not occur within the two hour recording period. This suppression of PS was accompanied by a significant ($p < 0.07$) increase in SWS and a decrease in wakefulness ($p < 0.10$). Other state variations following GHB administration were non-significant.

At dosages of 750 and 1000 mg/kg, high amplitude, slow-waves (250-500 uV; 2-4 Hz) appeared superimposed upon SWS patterns. Evidence of behavioral sedation was present in all animals at these dosages and although increased twitches were present in the nuchal EMG, EEG spike discharge or other epileptoid phenomena were not observed.

Whereas these results do not indicate the presence of hypnotic effects of low-dosages of GHB in the rabbit, the decrease in activated states (W and PS) and increase in SWS at high dosages are consonant with previous suggestions of a depression of the ascending reticular activating system by high doses of this compound.

285.2 THE INFLUENCE OF EXTRA-RETINAL AFFERENTS ON SLEEP STAGE RELATED NEURONAL ACTIVITY IN THE LATERAL GENICULATE NUCLEUS OF THE RAT. G.A.Marks, S.G.Speciale, Jr., J.Farber, H.P.Roffwarg, Department of Psychiatry, University of Texas Health Science Center, Dallas, Texas 75235

Levels of activity of single cells in widespread areas of the brain have been found to be influenced differentially by stage of sleep. This phenomenon appears to be a basic sleep behavior process, and one that might be related to the function of specific sleep stages. The brain mechanism controlling sleep stage-specific cellular activity is unknown, but it is likely to be controlled by just a few neural systems.

Our strategy is to use the dorsal lateral geniculate nucleus (dLGN) as a model for the study of sleep related influences. This area is well suited since dLGN cells exhibit sleep stage related activity (mean discharge rates in excess of 2:1 in REM sleep compared to slow wave sleep (SWS). Stage related activity is maintained after bilateral enucleation indicating that extra-retinal afferents are responsible for the regulation. By local and selective pharmacological manipulation of dLGN inputs it might be possible to identify the neurochemical mechanisms controlling sleep stage-specific cellular activity.

The present study utilized a microwire cannula guide tube assembly implanted bilaterally in the dLGN and standard electrodes used to define the sleep-wake stages. The multiple unit activity derived from the microwires yielded REM:SWS ratios of between 2:1 and 6:1. Specific neurotoxins or receptor blocking agents were pressure injected slowly through a cannula inserted into the guide tube. The contralateral side received a control solution. Mean frequencies of the multiple unit activity were determined within sleep-wake stages between ipsi- and contralateral dLGNs and during pre- and post-drug administration.

Initial data demonstrate that norepinephrine (NE)-depleting doses of 6-hydroxydopamine hydrobromide (4µg/0.5µl, in 0.1% ascorbate-normal saline) significantly increased the REM:SWS ratio by differentially slowing the rate of cellular activity in SWS. These data are consistent with the facilitatory effects of: 1)NE on P-cells; 2)Locus coeruleus (LC) innervation of dLGN and 3) the higher SWS than REM sleep discharge rate of LC cells.

Accordingly, these data not only demonstrate the feasibility of the employed technique, but further fail to support that it is the NE input to dLGN that can account for the differences in neuronal activity observed across sleep stages. Examination of the effects of other humoral systems on dLGN cells will also be presented.

285.3 EFFECTS OF PHENOXYBENZAMINE ON REM SLEEP AND BRAIN MHPG-SO_4 IN NORMAL AND REM SLEEP DEPRIVED RATS. R.C. Walovitch, R. Zak* and M. Radulovacki. Dept. Pharmacology, Univ. Ill. Med. Ctr., Chicago, IL 60612.

The aim of this study was to determine whether α-adenoreceptor blocking ability of phenoxybenzamine (Pbz), as indicated by an increase in MHPG-SO_4, could be correlated with the drug's ability to reduce REM sleep in normal, non-REM sleep deprived (NRD), as well as 48 h REM sleep deprived (RD) rats. To accomplish this, the amount of REM sleep and the amount of MHPG-SO_4, a final brain norepinephrine metabolite, was determined in the following groups of animals: 1. NRD group, 2. NRD rats which received Pbz (Pbz group), 3. rats deprived 48 h of REM sleep (RD group), 4. rats given Pbz prior to 48 h of REM sleep deprivation (Pbz RD group). Two hours before decapitation rats received probenecid, 50 mg/kg. MHPG-SO_4 was determined in the whole brains of rats by the fluorometric method of Meek and Neff (B.J. Pharm. 45: 435, 72). Continuous EEG recordings in the identical 4 groups of animals was done for 60 h. The results show that there was a reduction in REM sleep ($P < 0.002$) in the Pbz group during the first 10 h of EEG recording as compared to NRD groups. The effect of Pbz on REM sleep was over prior to 48-60 h of EEG recording period. This corresponds to the time when MHPG SO_4 level in the Pbz group was indistinguishable from the MHPG SO_4 level in the NRD group (Table 1). The increase in MHPG-SO_4 in the Pbz RD group (as compared to RD group) indicates that Pbz α-blocking activity may still be present 48 h after drug administration. Table 2 shows that REM sleep deprivation tends to potentiate Pbz ability to reduce REM sleep and increase MHPG-SO_4.

TABLE 1 - The Effect of Pbz on MHPG SO_4 in 48 h RD and NRD Rats

NRD(6)473*	Pbz(6)546	RD(7)655^{+}	PbzRD(8)813*$^{+}$

( )=Number of rats. The results are means of pm MHPG SO_4/g of brain tissue wt. $+p < .001$ when comparison is made to NRD, $*p < .002$ when comparison is made to RD using one way ANOVA with Scheffe test for multiple comparisons.

TABLE 2 -

	MHPG-SO_4 (pm/g)	REM Sleep (min)
%Pbz/NRD	+15 (68)	-10 (8 min)
%Pbz RD/RD	+24 (190)	-24 (33 min)

We conclude that, in non-REM sleep deprived rats, Pbz's termination of action on REM sleep corresponds to the termination of the drug's effect on central α-adrenoreceptors.

285.4 SLEEP IN RATS WITH BASAL FOREBRAIN LESIONS. R. Szymusiak* and E. Satinoff. Dept. Psychology, Univ. Illinois, Champaign, IL 61820.

Damage to the medial preoptic area (MPOA) causes disturbances in body temperature (Tb) regulation and sleep/waking behavior. We have previously shown that active sleep (AS) in normal rats is extremely sensitive to ambient temperature (Ta). Therefore, a portion of the AS deficits which follow basal forebrain damage might reflect exaggerated sensitivity to thermal stress.

Male rats were chronically implanted for sleep recordings. Pre- and postlesion recordings were taken for 2 hours at each of 3 Ta's; 20, 25, 30°C. Data were collected at all 3 Ta's on the same day during the light portion of a 12:12 LD cycle.

Prior to lesioning, all rats showed similar sleep patterns. Total sleep time (TST) was longest at 30°C (5440 ± 134 (s.e.) seconds), less at 25°C (4721 ± 167 sec.), and least at 20°C (3954 ± 231 sec.). These differences were largely due to changes in AS: at 30°C, AS=1214 ± 50 sec. and AS/TST=.22 ± .01; at 25°C, AS=677 ± 43 sec. and AS/TST=.14 ± .01; at 20°C, AS=391 ± 57 sec. and AS/TST=.10 ± .01. One day following bilateral electrolytic MPOA lesions, 6 rats were hyperthermic in their home cages with Tb's ranging from 39.5-41°C. None could tolerate 30°C for more than an hour without approaching lethal hyperthermia, nor could they defend Tb when exposed to 5°C. TST was greatly reduced at all Ta's tested (e.g. TST=1296 sec. at 25°C). None of the rats exhibited AS and one was totally insomniac. At 4-5 days postlesion, TST was still depressed, but AS had become sensitive to Ta. For example, the rat that had been insomniac on day 1 was markedly hyposomniac at 20°C on day 5 (TST=690 sec. and AS/TST=0). However, on the same day at 25°C, TST was 2330 sec. and AS/TST was .20. Four of the 6 animals were hyperthermic, and exhibited the most AS at 25°C, whereas prior to lesioning all had shown the most AS at 30°C. The other animals, one of whom was hypothermic and one normothermic, had the most AS at 30°C. So, AS time is maximal at different Ta's in different lesioned rats. Testing animals at a single Ta might give the erroneous impression of an AS deficit.

In summary, we find a relatively Ta-independent reduction in TST immediately after MPOA lesions. However, as early as 4-5 days postlesion AS/TST may be markedly depressed at one Ta, but within control ranges at another. Thus, much of the AS deficit in rats with basal forebrain damage appears to be secondary to thermoregulatory disturbances. Later stages of recovery and results of 24 hour recordings will also be discussed.

285.5 UNIT ACTIVITY OF NE AND non-NE PONTINE TEGMENTUM NEURONS IN THE RAT IN RELATION TO SLEEP-WAKE STATES AND REM SLEEP PHASIC ACTIVITY. P.Gatz*,H.P.Roffwarg and J.Farber (SPON: J.Herman). Dept. of Psychiatry,University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

The role of the nucleus locus coeruleus (LC) and its neurotransmitter norepinephrine (NE) in the mediation and maintenance of REM sleep has not been incontrovertably resolved. Whereas lesion and pharmacological studies indicate significant contribution of the LC nucleus to REM sleep mediation (Jouvet, M., Ergebn.Physiol.64:166,1972),neurophysiological data indicate a paucity of LC unit activity in REM sleep (Hobson & McCarley, Science 201:269,1978;Foote et al,Proc.Natl.Acad.Sci.77:3033,1980). We have recently reported the presence of a PGO-type wave recordable during REM sleep in the pontine dorsal tegmentum,in the area of the LC,(Farber, J., et. al., Science 209: 615,1980). In order to establish whether the pontine PGO waves are events that are related in time to the increases in underlying neuronal activity and identify the characteristics of these neurons, we have studied the relationship of pontine neuronal unit activity to sleep-wake stages and pontine PGO waves.

Male albino rats (Sprague-Dawley, 400-500gms) were implanted with stainless steel recording wells, positioned above the area of the LC.Macroelectrodes were implanted for cortical EEG, neck EMG and pontine PGO activity.For 24 hours prior to the recording session, the rats were sleep deprived to increase the occurrence and to extend theduration of the various sleep stages.Single unit activity was recorded in these unrestrained rats in the LC, sub-LC, nuc. retic. pontis oralis (rpoo), and the dors. and vent. parabrachial nuc. (npd, npv), with glass-coated tungsten electrodes.Significant stage-dependent differences were found in the firing rates of the NE and non-NE cells.As recognized by their long duration action potentials (2msec.) and low firing rates (1. 5 to 3Hz), the NE cells of the LC showed a marked decrease in activity in REM sleep.No relationship was found between the unit activity and the PGO waves.

On the other hand, the activity of cells in the npd, npv and rpoo showed marked differences in firing rates in the four, mutually exclusive, sleep-wake stages: quiet awake(AQ),moving awake (AM), slow wave sleep (SWS) and REM sleep.In REM sleep and in AM, the firing rates of these units substantially increased compared to SWS and AQ.Bursts of activity were temporally associated with the occurrences of PGO waves in the perievent histograms. We conclude that pontine tegmentum PGO waves recorded in REM sleep reflect an increase in the cellular activity of the non-NE neurons in the area.

285.6 UNIT ACTIVITY OF DOPAMINERGIC AND NON-DOPAMINERGIC NEURONS IN THE REGION OF THE SUBSTANTIA NIGRA IN RELATION TO SLEEP-WAKE STATES AND REM SLEEP PHASIC ACTIVITY. J. Farber, J.D. Miller, P. Gatz*, H. Roffwarg and D.C. German. Depts. of Psychiatry and Physiology, U.T. Health Science Center, Dallas, Texas 75235.

It has been proposed that catecholamines may be important for the mediation of REM sleep (Jouvet, M., Ergebn. Physiol. 64:166, 1972). A major thrust in the study of sleep has been directed at the norepinephrine rather than the dopamine (DA) system. However, biochemical studies (e.g. Wojcik, W.J. and Radulovacki, M., Neurosci Abstr., 6:52, 1980) have indicated a role for DA in sleep. We now report on the spontaneous unit activity of DA cells and nearby non-DA cells during wakefulness and sleep.

Male albino rats (Sprague-Dawley, 300-400 gms) were implanted with stainless steel wells stereotaxically positioned above the mid-brain DA cell region. Also, electrodes were implanted for the recording of EEG, EMG and pontine PGO activity (Farber, J., et al, Science, 209:615, 1980). The rats were sleep deprived for 24-48 hrs before the recording session in order to increase the occurrence and extend the duration of the various sleep stages. Single unit activity was recorded in the substantia nigra and ventral tegmental area (VTA) regions, using glass coated tungsten electrodes in the unrestrained rat, while the sleep-wake stages were being polygraphically recorded. The DA cells were recognized by their long duration triphasic action potentials (> 2 msec) and slow firing rates (2-7 Hz). Also, microlesions were made at the DA unit recording sites. The firing rates of the DA cells were not different across four mutually exclusive stages of the sleep-wake cycle: quiet awake (AQ), moving awake (AM), slow wave sleep (SWS), and REM sleep. These cells exhibited a steady firing pattern across all stages. On the other hand, the faster firing (5-30 Hz), short duration (<·2 msec) non-DA cells of the VTA and zona reticulata regions showed marked and significant firing rate differences that were stage dependent: in AM and REM sleep their activity was faster (up to 100%) than in AQ and SWS. Spontaneous activity always increased as the rat entered a REM sleep episode. From perievent time histograms summated over at least 50 PGO wave events, we found a marked increase in the discharge frequency of each of the non-DA cells 20 msec preceding and following the peak of the PGO wave. These data suggest that the non-DA cells of the ventral mesencephalon behave, in relation to sleep-wake stages, in a manner similar to cells of the pons that have been implicated in the mediation of REM sleep. In addition, it seems that DA and nearby non-DA cells do not show reciprocal changes in firing rates across sleep stages. (Supported by NIMH grants MH-31402, MH-27574 and A.P. Sloan Foundation).

285.7 EFFECTS OF BRAIN STEM INFUSION OF PROTEIN SYNTHESIS INHIBITORS ON SLEEP-WAKING BEHAVIOR AND SINGLE-UNIT ACTIVITY IN THE MIDBRAIN AND PONTINE RETICULAR FORMATION OF THE CAT. S.S. Bowersox, R. Drucker-Colin, and D.J. McGinty. Neuropsychology and Neurophysiology Laboratory, VA Medical Center, Sepulveda, CA 91343

Chloramphenicol (CAP), a protein synthesis inhibitor with potent bacteriostatic properties, was shown in previous studies to selectively suppress REM sleep in cats when administered systemically at a dose of 100 mg/kg (Drucker-Colin, et al., 1979, Exp. Neurol., 63:458, Petitjean, 1979, Psycopharm., 66:147). Recent investigations in our laboratory disclosed that, in addition to suppressing REM sleep, chloramphenicol significantly attenuated unit activity in the brain stem reticular formation (RF). Administration of CAP congener, thiamphenicol (TAP), had no impact upon either REM sleep or RF unit discharge, indicating that these findings reflected a specific neuropharmacologic effect. The current study sought to determine whether local application of CAP into the medial reticular formation also depressed unit activity and REM sleep. Toward this end, a combination push-pull cannulae and microwire/microdrive system was developed to record single units within the diffusion field of substances administered through the cannulae.

Eight adult cats of either sex were surgically prepared for EEG, EOG, and EMG recording. The push-pull cannula microdrive system was chronically implanted into the gigantocellular tegmental field of the pontine RF. Experiments were initiated at least 10 days following surgery. All studies were carried out on unrestrained animals while they were exhibiting spontaneous sleep and waking behavior. As predicted, perfusion of RF foci with 10 mg/ml CAP resulted in a substantial attenuation of both midbrain and pontine RF unit activity. This accompanied an increased incidence of abortive REM periods, identified in polygraphic recordings by the presence of PGO spikes without muscle atonia or EEG desynchronization, and a significant reduction in total REM sleep time. In agreement with earlier findings, TAP perfusion had no effect upon either unit discharge or sleep-waking behavior. The increased incidence of transitional SWS→REM periods during CAP infusion indicated that REM deficits were not caused by interference with pre-REM conditions. It is hypothesized that REM was prevented by suppressing the capacity of reticular neurons to sustain critical firing rates necessary for maintenance of this state.

*On sabbatical from UNAM, Mexico, supported by a Guggenheim Fellowship.

285.8 NEURONAL ACTIVITY IN THE PREOPTIC AREA OF THE HYPOTHALAMUS DURING SLEEP AND WAKEFULNESS IN THE CAT. K. Kaitin* (SPON: E. S. Boyd). Dept. of Pharmacology, Univ. of Rochester School of Medicine, Rochester, NY 14642.

The preoptic area of the hypothalamus is considered to be a forebrain-synchronizing area with putative hypnogenic function. The present study was conducted to examine the relationship between the neuronal activity in the preoptic area and the behavioral state of the animal. Spontaneous activity of single neurons was recorded extracellularly from the preoptic area in the basal forebrain of chronically prepared cats. Neuronal firing was studied during alert wakefulness (W), slow-wave-sleep with cortical high voltage slow wave activity (SWS), and REM (paradoxical) sleep.

Of the 86 neurons recorded in three behavioral states, 44% and 40% showed their fastest discharge rate during REM and SWS, respectively, while 16% fired fastest during W. However, there were no significant differences in the mean discharge rates in the different behavioral states: SWS, $\bar{X}$ = 28.5 ± 20.5; REM, $\bar{X}$ = 26.4 ± 21.3; W, $\bar{X}$ = 25.6 ± 21.6.

Individual neurons often exhibited changes in temporal firing patterns associated with a particular behavioral state. In SWS, neurons tended to discharge less regularly than in W or REM. Occasionally, this irregular discharge was accompanied by sporadic bursts alternating with long periods of silence. Similar observations have been made in other brain regions. In the present study changes in the degree of variability of discharge were evaluated quantitatively by comparing the coefficient of variation for each behavioral state. The value obtained during SWS (1.11 ± 0.44) was significantly greater than values obtained during W (0.91 ± 0.24) and REM (0.99 ± 0.24).

Neurons were classed as either fast or slow on the basis of their discharge rate, in relation to the overall mean discharge rate, during SWS. Neurons classed as fast during SWS fired more slowly as the animal's behavioral state changed to either W or REM, whereas neurons classed as slow during SWS fired more rapidly during W or REM. This activity of preoptic area neurons is in contrast to the activity of medial brainstem and motor, primary sensory, and association cortex neurons.

285.9 SLEEP FACTOR FROM HUMAN URINE; LOCALIZATION OF ITS SITE OF ACTION. J.E. García-Arrarás* (SPON: J. Krueger). Dept. of Physiol. Biophys., Harvard Med. Sch., Boston, MA 02115.

Administration of sleep-promoting factor derived from human urine into the cerebral ventricular system is followed by prolonged excess slow-wave-sleep (SWS) in rats, rabbits, and cats (J.M. Krueger et al. Am. J. Physiol. 238: E116-E123, 1980, J.E. García-Arrarás, Fed. Proc. 40: 273, 1981). I now present the results of systematic investigations on the site of action of urinary sleep factor in the brainstem.

Microinjections of urinary sleep factor were made into rabbits with chronically implanted guide tubes. About 15 picomoles of urinary sleep factor dissolved in 1.5 µl artificial cerebrospinal fluid (art CSF) were injected unilateraly in each rabbit. After injection the EEG was recorded for 6 hours. Injections into specific areas of the ventral brainstem extending from the supraoptic area to the rostral mesencephalic reticular formation increased the amount ot time spent in SWS. Injections of art CSF into the same sites were ineffective. The average increase was from 45 ± 2% of 6 hours in SWS after injections of art CSF to 63 ± 3% of 6 hours after injections of urinary sleep factor. Numerous other sites (N=68) were found to be inactive.

The behavioral and electroencephalographic characteristics of the excess SWS following microinjections of sleep factor from human urine were similar to those following intraventricular infusions of Factor S. However, the latency to the effect is shorter after microinjections into the active area.

285.10 EFFECT OF 3 OZS OF 80 PROOF ETHYL ALCOHOL ON THE SLEEP OF PATIENTS WITH OBSTRUCTIVE SLEEP APNEA. L. Scrima & M.A. Cohn*. Sleep Disorders Center, Mount Sinai Medical Center, Miami Beach, FL 33140.

Patients with obstructive sleep apnea (OSA) suffer from repeated upper airway obstruction during sleep, causing apneas that last more than 10sec. The apnea episodes usually end with an arousal. Research in our lab recently demonstrated that only 3ozs of alcohol greatly increased the incidence and severity of apneas in OSA patients (Scrima, L., Broudy, M. & Cohn, M.A., Sleep, 4(3), 1981). The sleep stages from the same study are herein analyzed to assess the impact of 3ozs of alcohol on OSA patients' sleep. Five diagnosed OSA patients, ages 28-67 (4 males, 1 female) were studied. EEG, EOG, chin-EMG, respiration and arterial oxygen saturation were recorded, 30 min after beginning to consume the alcohol. The sleep stages from this research night were compared to those of the previous diagnostic night sleep.

PERCENT STAGE REM	28%	18%	18%	20%	18%	18%	12%	12%	22%	15
PERCENT STAGE 0	2%	1%	0%	0%	0%	35%	0%	0%	7%	10

Overall, after ingestion of alcohol, OSA patients were awake 6.6% less, had more stages REM (4.2%), 1 (4%) & 2 (7%) sleep and 4.4% less stages 3 & 4, than during the no alcohol diagnostic sleep. It is important to note that stages 1, 2 & REM sleep are the very stages during which nearly all OSA episodes occur. Also, reduced stages 3 & 4 can reflect an increase in OSA severity, since more severe OSA during stage 2 causes arousals to stage 1 or 0, thereby preventing stages 3 & 4. These data appear to indicate that 3ozs of alcohol ingested by OSA patients before bed potentiates apneas by increasing the arousal threshold, rather than by depressing the CNS respiratory regulators. OSA patients with alcohol were less able to arouse themselves from apnea episodes, causing more prolonged apneas and less time in bed spent awake.

286.1 NALOXONE DIFFERENTIALLY AFFECTS THE ANALGETIC ACTIONS OF PHYSOSTIGMINE ON THREE BEHAVIORAL MEASURES OF NOCICEPTION. Romano, J., and King, J. US Army Biomedical Lab, APG, MD 21010.

Physostigmine, an anticholinesterase agent, produces an analgesia which is mediated, in part, by an opiate system. This is evidenced by the fact that (1) physostigmine (physo) and morphine interact (Fed. Proc., 1970, 29, 28), (2) cholinergic blocking agents, such as atropine or hemicholinium, attenuate both morphine analgesia (Ann. N.Y. Acad. Sci., 1976, 281, 262) and physo analgesia, and (3) analgesia produced by cold-water swims (CWS), presumably due to liberation of endogenous opiates, was shown to be blocked by benactyzine hcl (ben hcl), an anti-muscarinic drug (Soc. Neurosci. Abstr., 1980, 6, 149.17). These interactions are dependent upon dose and behavioral test since morphine potentiates physo on tail flick (TF) and flinch-jump (FJ), but not hot plate (HP) (Soc. Neurosci. Abstr., 1980, 6, 149.18). Ben hcl (1.8 mg/kg) blocks CWS analgesia on TF and FJ, but not HP.

Physo was tested in conjunction with naloxone (nal), a potent opiate antagonist. Dose response curves of the physo-nal relation were obtained on three behavioral tests of pain. Animals were tested on HP (latency, sec), FJ (threshold, mA), and TF (latency, sec). Analysis of variance showed physo X nal interactions on TF ($p<.03$) and FJ ($p<.03$), but not on HP. Results suggest that opiate and cholinergic systems, in combination, affect those responses since at 3.0 mg/kg nal there is an attenuation of physo analgesia (on HP), while at 3.0 mg/kg and 10.0 mg/kg nal the analgetic effect of physo is enhanced on TF and FJ. Nal alone has no significant effect on any of the tests. All drugs were administered i.p. SE_M's were 3.3 (TF), .06 (FJ), and 2.2 (HP), respectively.

		TAIL FLICK (SEC)				FLINCH JUMP (mA)		
Nal	(Dose)	Sal	3.0	10.0	Sal	.60	.71	.77
Physo	Sal	15.1	15.4	18.4	.32	.72	.67	.74
	.32	25.2	32.2	26.1	.65	.68	.81	.98
	.65	25.1	24.0	40.4				

Both opiate agonists and antagonists potentiate physo analgesia, at least on TF and FJ. These data suggest that (1) physo analgesia may involve both a direct cholinergic mechanism and an indirect (opiate) one, (2) that the relative contributions of the opiate and/or cholinergic components of physo analgesia are different in three behavioral measures of pain, and (3) that the contributions of opiate factors relative to direct cholinergic factors are more significant of HP.

HOT PLATE (SEC)	Nal	(Dose)	Sal	3.0	10.0
	Physo	Sal	12.8	9.4	13.5
		.32	18.5	13.8	17.5

286.2 DOSE-DEPENDENT REVERSAL OF PHYSOSTIGMINE AND COLD-WATER ANALGESIA ON THE HOT PLATE BY BENACTYZINE HYDROCHLORIDE, King, J. and Romano, J. US Army Biomedical Lab, APG, MD 21010.

Previous data from this lab and others have indicated that the analgetic mechanisms underlying the tail flick (TF) and flinch-jump (FJ) tests are cholinosensitive. An interaction between opiate and cholinergic mechanisms has also been shown. Physostigmine (physo), in addition to producing analgesia by itself, potentiates morphine analgesia, and physo, morphine, and cold water stress (CWS) analgesias are antagonized by anticholinergics such as atropine and benactyzine hcl (ben hcl). While results from TF and FJ studies present a relatively clear picture of cholinergic involvement, studies which have used the hot plate (HP) method to assess analgesia have yielded more complex results. Compared to TF and FJ methods, HP results do not indicate the same type or degree of interaction between morphine and physo, nor is HP-measured physo-induced analgesia effectively antagonized by ben hcl at a dose (1.8 mg/kg) effective in TF and FJ tests. Others have postulated that differences seen with HP analgesia may reflect the contribution of supra-spinal, endorphin-related mechanisms in addition to the descending, spinal-mediated mechanisms of TF and FJ analgesia (Brain Res., 1979, 160, 180). One question that arises in regard to potential cholinergic involvement in these analgetic mechanisms is whether physo or CWS analgesia are totally, or relatively, independent of antagonism by anticholinergic compounds such as ben hcl.

Following pretest, ben hcl was administered 4 min prior to analgetic treatment consisting of either (a) .65 mg/kg physo i.p., or (b) forced CWS. Animals were tested 30 min later. Five test doses were employed: saline, .57, 1.8, 5.7, or 18.0 mg/kg ben hcl (i.p.). Also five groups of animals were given ben hcl alone 34 min before HP test (latency, sec); ben hcl alone was without effect on this test. However, ben hcl pretreatment was capable of blocking either physo (5.7 mg/kg) or CWS (18.0 mg/kg) analgesia. The results obtained confirm and extend previous indications that cholinergic interactions with analgetic mechanisms are dependent upon both dose and test system employed. Results also support the postulated dual mechanism theory of HP analgesia in that differences in effective anticholinergic doses needed for antagonizing physo and CWS analgesia may reflect different degrees of cholinergic involvement in the neural mechanisms underlying the two treatments.

286.3 MONOAMINERGIC MECHANISMS OF STRESS ANALGESIA. G. W. Terman*, J. W. Lewis and J. C. Liebeskind (SPON: L. Butcher). Dept. of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

A variety of stressors have been shown capable of producing analgesia. Stress analgesia, however, is not a unitary phenomenon: both opioid and nonopioid pain-inhibitory mechanisms exist that can be differentially activated by stress (Lewis et al., Science, 208:623, 1980). We have shown that exposure to brief continuous footshock reliably produces an analgesia that is neither antagonized by naloxone nor is cross-tolerant with morphine (Lewis et al., J. Neurosci., 1:358, 1981). The neurochemistry of this obviously nonopioid form of stress analgesia has, however, remained elusive. Studies of the neurochemistry of stimulation-produced analgesia suggest an important role for central monoamines in endogenous pain-inhibitory mechanisms (Akil and Liebeskind, Brain Res., 94:279, 1975). In this study, we examined the effects of reserpine, a depletor of all monoamines, on nonopioid stress analgesia.

Male Sprague-Dawley rats were randomly assigned to one of two groups (n=14) and administered either reserpine (2 mg/kg, i.p.) or saline on two consecutive days. One day after the second injection, each animal was tested for baseline pain responsiveness using the tail-flick test. Rats were then given footshock stress according to parameters previously shown to produce nonopioid analgesia (3 min, 2.5 mA, 60 Hz sine waves on continuously). Analgesia testing resumed immediately after stress and continued for 10 min.

Reserpine treated animals were significantly less analgesic to footshock than controls ($p < .01$). Their analgesia was reduced both in magnitude and duration. Baseline tail-flick latencies tended to be lowered by reserpine, although these differences were not statistically reliable.

These results demonstrate an important involvement of monoaminergic mechanisms in nonopioid pain-inhibitory systems activated by stress. The fact that adrenalectomy, which eliminates one major peripheral source of monoamines, has no effects on nonopioid stress analgesia (Lewis et al., Soc. Neurosci. Abstr., this volume), suggests that monoamines of central or sympathetic origin are important to this analgesic response. (Supported by NIH grant #NS07628 and MHTP grant #MH15345.)

286.4 EVIDENCE FOR THE INVOLVEMENT OF CENTRAL CHOLINERGIC MECHANISMS IN OPIOID STRESS ANALGESIA. V. E. Weinberg*, J. W. Lewis, J. T. Cannon and J. C. Liebeskind. Dept. Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Stress may be the natural activating stimulus for endogenous analgesia systems. A single stressor, inescapable footshock, can access neurochemically different analgesia substrates depending only on its temporal parameters (Lewis et al., J. Neurosci. 1:358-363, 1981). Thus, opioid peptides appear to mediate analgesia after prolonged intermittent footshock; nonopioid mechanisms subserve equivalent analgesia caused by brief, continuous footshock. We now report evidence suggesting a role for central, muscarinic cholinergic systems in opioid, but not nonopioid, stress analgesia.

Groups of male albino rats (n=8) were used. Prior to baseline pain testing (tail-flick method), either scopolamine (0.01-10.0 mg/kg, i.p.), methylscopolamine (1.0, 10.0 mg/kg, i.p.), naltrexone (3 mg/kg, s.c.), or saline was administered. Rats were then subjected to either the opioid (2.5mA, 1 sec pulse/5 sec of 60 Hz sine waves for 20 min), or nonopioid (same, except on continuously for 3 min) form of footshock stress, and pain sensitivity was reassessed. Each rat received only one combination of drug and stress treatment.

Both stresses caused potent analgesia lasting several min. The opioid form of stress analgesia was significantly antagonized by scopolamine ($p < .01$ at 0.1, 1.0, 10.0, but not 0.01 mg/kg), or naltrexone ($p < .01$), but was not affected by methylscopolamine (all comparisons made to saline controls). The nonopioid form of stress analgesia was unaffected by all drug treatments. None of the drugs altered baseline latencies or responsiveness of nonstressed control rats.

That scopolamine or naltrexone antagonized the analgesic response to prolonged, intermittent footshock suggests that a muscarinic cholinergic synapse exists in an endogenous opioid analgesia system. Since opioid stress analgesia was unaffected by methylscopolamine, a muscarinic antagonist with only peripheral activity, the cholinergic synapse appears to be central. The cholinergic-opioid interaction suggested by these data is supported by the presence of muscarinic receptors in brain areas known to be highly sensitive to morphine's analgesic action (Wamsley et al., J. Neurosci. 1:176-191, 1981). (Supported by NIH grant #NS07628; JWL was supported by MHTP grant MH15345.)

286.5 KINDLED SEIZURES APPEAR TO CAUSE ANALGESIA PREFERENTIALLY ON THE AFFECTIVE COMPONENT OF PAIN. S. Caldecott-Hazard, Y. Shavit and J. C. Liebeskind. Dept. of Psychology, UCLA, Los Angeles, CA 90024.

Analgesia following an amygdaloid kindled seizure in the rat is seen on hot-plate paw-lick latencies but not on the tail-flick test (D. W. Berman et al., this vol.). Similarly, ECS seizures elicit powerful analgesia on hot-plate escape behaviors but weak analgesia on the tail-flick test (Holaday and Belenky, 1980). Unlike the spinally mediated tail-flick response, the hot-plate test measures pain behaviors thought to be organized predominantly at supraspinal levels. The purpose of the present study was to further characterize the analgesia produced by amygdaloid kindled seizures by using the 3-level pain test of Carroll and Lim (1960). These researchers had shown that a tail withdrawal response to the lowest intensity of tail shock is mediated at a spinal level, a single squeak to intermediate shock intensities is mediated by the brain stem, and multiple squeaks, struggling, and teeth chattering to the highest intensity shock are mediated at diencephalic/limbic system levels.

Rats were implanted with chronic bipolar stimulating and recording electrodes in the amygdala. They were stimulated daily to produce kindled seizures until showing fully generalized (stage 5) seizures on 3 successive days. On test days, all rats were injected with either saline or naloxone (10 mg/kg). Half of each group was then given a kindled seizure and evaluted on the 3-level pain test. The remaining animals were evaluated in the same fashion without a prior seizure. In comparison with non-seizure trials, a kindled seizure significantly raised the threshold for the multiple-squeak behavior, but not for the behaviors elicited by lower shock intensities. This analgesia had a duration varying between 4 and 10 minutes, and it was partially blocked by naloxone. These results suggest that kindled seizures produce an analgesia by influencing principally diencephalic/limbic system structures, which are presumably involved in mediating the affective components of the pain experience. (Supported by NIH Grants #NS07628 and #NS06289.)

286.6 NALOXONE-REVERSIBLE HYPOALGESIA FOLLOWING INTRATHECAL 5,6 DIHYDROXYTRYPTAMINE. Mark S. Brodie* and Herbert K. Proudfit (SPON: L. Isaac). Dept. Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL 60612.

It has been shown that neurotoxic lesioning of serotonin (5-HT) nerve terminals in the spinal cord leads to changes in the nociceptive threshold as measured by the tail-flick (TF) test. Depletion of spinal cord 5-HT by 5,6-dihydroxytryptamine (5,6-DHT) leads to hyperalgesia which subsides to pre-lesion threshold by fourteen days after the injection of neurotoxin. In light of this time-dependent alteration in pain sensitivity, this study was undertaken to observe any further changes in nociception.

Sprague-Dawley derived rats were implanted with intrathecal catheters (PE-10 tubing) extending to the lumbar cord, and were allowed to recover from the surgery for at least one week before receiving an intrathecal injection of vehicle (0.02% ascorbic acid in normal saline) or 5,6-DHT (20 µg in 15 µl vehicle). Animals were tested weekly on the tail-flick apparatus before and after a subcutaneous (sc) injection of morphine (5 mg/kg). There was a decrease of 39% in the mean TF latency compared to vehicle controls one week after 5,6-DHT injection. The magnitude of morphine induced analgesia in the control and 5,6-DHT treated rats was identical, despite the hyperalgesia of the latter group. This observation, reported previously, indicates that the descending 5-HT system is not involved in morphine analgesia. Two weeks after 5,6-DHT injection, both groups of animals had statistically identical TF latencies before and after morphine.

Eight weeks after 5,6-DHT treatment, the baseline TF latencies of the lesioned animals were elevated significantly (220%) above those of the control animals. Ten minutes after injection of naloxone (0.8 mg/kg, sc), mean TF latency was reduced to that of the controls.

While descending 5-HT neurons do not seem to play a role in morphine analgesia, lesioning of the 5-HT nerve terminals with 5,6-DHT causes a marked alteration in heat-induced nociception. Because the tonic hypoalgesia seen several weeks after the neurochemical lesion is reversible by naloxone, it is postulated that morphological changes subsequent to damage caused by 5,6-DHT lead to tonic involvement of enkephalinergic neurons in the pain transmission pathway in the rat.

286.7 THE INDUCTION OF HYPOALGESIA BY CHRONIC RAPHE MAGNUS LESIONS AND ITS REVERSAL BY NALOXONE. Herbert K. Proudfit, Univ. of Illinois at the Medical Center, Chicago, IL 60612.

Bulbospinal neurons located in the nucleus raphe magnus (NRM) have been implicated in the modulation of nociceptive threshold. NRM neurons appear to be tonically active since destruction of these neurons produces decreased nociceptive threshold (hyperalgesia). However, the lesion-induced effects are highly dependent on the time at which measurements are made following the lesioning procedure. Thus, the nociceptive threshold is decreased seven days or less after lesions, but at longer intervals (28 to 35 days) the nociceptive threshold becomes elevated (hypoalgesia). Preliminary studies indicate that the lesion-induced hypoalgesia can be reversed by the systemic administration of the opiate antagonist naloxone. The present studies were done to replicate these preliminary observations.

Twenty female Sprague-Dawley derived rats were randomly divided into two groups: (A) nonlesioned control animals and (B) lesioned animals. Nociceptive thresholds were determined using the tail flick test. The animals in the lesion group received electrolytic lesions placed in the NRM. Seven days after surgery nociceptive thresholds were determined, morphine sulfate (5 mg/kg, sc) was given, and thresholds were again determined 30 min after morphine injection. The animals were similarly tested at 14,21,28, and 35 days after surgery. On days 42 and 49 each of the twenty animals was then given an injection of either saline or naloxone (0.8 mg/kg, sc) using a randomized cross-over design. Nociceptive thresholds were determined 5,15 and 55 min after the injection.

The mean pre-lesion tail flick latency (TFL) for Group A (3.5 $\pm$ 0.2 SEM) was not significantly different from that of Group B (3.4 $\pm$ 0.2). However, at 42 to 49 days after lesioning the mean TFL for Group B (8.1 $\pm$ 0.6) was significantly elevated over that for Group A (4.5 $\pm$ 0.2). The systemic injection of saline had no effect on the mean TFL for either group. Naloxone had no effect on the mean TFL for Group A, but produced a statistically significant reduction in that for Group B.

These results suggest that destruction of raphe-spinal neurons induces changes in either brain stem or spinal cord which augment the activity of enkephalinergic neurons. Similar results following the destruction of serotonergic terminals in the spinal cord (Brodie and Proudfit, Neuroscience Abstr., 1981) suggest that destruction of raphespinal serotonergic neurons is responsible for the hypoalgesia induced by NRM lesions.

286.8 IDENTIFICATION OF NORADRENERGIC NEURONS PROJECTING TO MEDULLARY NUCLEI INVOLVED IN THE MODULATION OF PAIN. Jacqueline Sagen and Herbert K. Proudfit. Dept. of Pharmacology, Univ. of Ill. Medical Center, Chicago, IL 60612.

The nucleus raphe magnus (NRM) and magnocellular reticular formation (MC) in the caudal medulla receive a dense noradrenergic (NA) innervation as revealed by histochemical fluorescence studies. This NA input may enhance sensitivity to noxious stimuli since microinjection of α-adrenergic antagonists in these areas produces an elevation in the nociceptive threshold (Hammond et al, 1980). The present study sought to identify the origin of the NA projection to the NRM and MC using an adaptation of the method of Bjorklund and Skagerberg (1979). A retrograde fluorescent tracer, "True Blue" (TB), was used in conjunction with the glyoxylic acid fluorescence histochemical method. Under ether anesthesia, 0.2 µl of 5% TB was microinjected into the NRM or MC of rats. After 3-5 days survival, rats were rapidly decapitated, their brains removed and frozen on a cryostat chuck. Ten µ sections were cut and processed using the method of de la Torre and Surgeon (1976). Alternate sections were stained with cresyl violet to aid in the identification of the injection site. The sections were examined under a fluorescence microscope for perikarya containing both the retrograde fluorescent tracer and catecholamine (CA) fluorescence. Microspectrofluorometric recordings of individual neurons were performed to confirm the presence of both fluorophores.

Neurons containing both TB and CA were identified in the lateral tegmental groups (A1, A5, A7, and A8 of Dahlstrom and Fuxe, 1964) and in the ventral locus coeruleus (LC), with a preferential distribution depending on the injection site. With NRM injection sites, neurons containing both fluorophores were found primarily in A5 and occasionally in A1, A7, and A8. Few labeled neurons were found in the LC. Injections in the rostral raphe pallidus resulted in double-labeled neurons in the A5 and ventral LC, and occasionally in A1 and A7. When injections were made in the MC region, neurons containing both TB and CA were found primarily in A5 and the ventral LC.

These studies indicate that the CA neurons which project to the ventro-medial region of the caudal medulla are not situated in a single discrete locus, but instead are widely dispersed and are found in several brain areas. Each of these brain areas has been implicated in the modulation of nociceptive threshold. Thus, the present studies provide anatomical evidence to support the suggestion that CA neurons modulate nociceptive threshold by altering the excitability of bulbospinal neurons in the raphe magnus and magnocellular reticular nucleus.

286.9 NALOXONE STIMULATION OF NUCLEUS TRACTUS SOLITARIUS BLOCKS ANALGESIC EFFECTS OF SYSTEMIC MORPHINE IN RATS+. N. Oley, C. Cordova,* M. Kelly* and J.D. Bronzino. Depts. of Psychology & Biomedical Engineering, Trinity College, Hartford, CT 06106.

Recent evidence of opiate receptors (Herkenham & Pert, Proc. Natl. Acad. Sci., 1980, 77, 5532-5536.) in the region of the nucleus tractus solitarius (NTS) suggests that this region of the dorsomedial medulla may participate in an opiate-sensitive pain-suppressive system. To test this hypothesis, an attempt was made to block the analgesic effects of systemically administered morphine with injections into the NTS of the opiate antagonist naloxone.

Sixteen naive male albino rats were each given 30 mg/kg of morphine (ip), morphine (ip) plus 10 µg of naloxone (in 0.25µl of Ringers (ic), morphine (ip) plus Ringers (ic), and morphine (ip) plus 30 µg of naloxone (ic). Injections were given at 1 wk intervals, and the order of naloxone doses was reversed in several animals to control for tolerance to morphine. Tail flick latencies were measured at 10 min intervals before and after morphine injections for up to 4 hrs.

Intracerebral injections of naloxone given 5 mins prior to systemic morphine injections delayed for up to 90 mins the onset of and reduced the magnitude of morphine-produced tail flick analgesia in dose-dependent fashion (in comparison with a Ringer's control injection). Catatonia was also blocked by naloxone. However, self-mutilation, which never occurred with systemic morphine injections alone, sometimes did occur following naloxone injections.

The results of this experiment indicate that the NTS plays a role in opiate analgesia. However, the failure of (ic) naloxone to completely block the analgesia produced by high doses of systemic morphine suggests that systemically-produced analgesia is only partly mediated by pathways leaving the NTS. This interpretation is entirely consistent with reports that systemic morphine can activate other supraspinal structures (such as the PAG) which mediate analgesia, and, in high doses such as were used in this experiment, can also act directly at the spinal level to reduce pain.

286.10 CHANGES IN BRAIN β-ENDORPHIN AND TOLERANCE TO MORPHINE ANALGESIA AFTER A SINGLE DEFEAT IN MICE. Michael L. Thompson*, Klaus A. Miczek and Louis Shuster. Depts. of Biochemistry and Pharmacology and Psychology, Tufts University, Boston and Medford, MA. 02111.

Analgesia following exposure to a variety of stressors has been well documented, but how endogenous opioid peptides are involved in this form of analgesia has been an issue of contention. We have previously reported that a large analgesic response is produced in mice by subjecting them to a social stressor,i.e.,repeated attack by another mouse, and that the analgesia produced by this form of stress does meet various criteria for involvement of endogenous opioid peptides,(i.e. naloxone reversibility, cross tolerance to and from morphine).

Recent experiments implicate brain, rather than peripheral β-endorphin, in this response. Behaviorally inexperienced B6AF$_1$ mice were introduced into the homecage of another mouse; the resident mice reliably attacked the intruder. After sustaining 70-100 attack bites, the intruder mice showed a 5-6 fold increase in tailflick latency. Mice pretreated with naltrexone (1 mg/kg) failed to show significant analgesia following defeat. In contrast, quaternary naltrexone (40 mg/kg), which does not enter the CNS but is active peripherally, was without effect. Dexamethasone pretreatment (400 µg/kg at 24 hrs. and 200 µg/kg at 4 hrs. prior to the test), has been reported to block stress induced release of ACTH and β-endorphin from pituitary but not from brain, and to block some forms of stress-induced analgesia. Such pretreatment did not reduce analgesia in mice subjected to defeat.

In a further experiment, mice were exposed for ca. 10 min. to residents and sustained 100 attack bites. After confirming their tailflick analgesia, their brains were removed, and their forebrain β-endorphin levels were determined by commercially available radioimmunoassay. Forebrain β-endorphin levels were reduced by an average of 40% following defeat.

In additional experiments significant tolerance to morphine was observed in mice tested 7 days after a single defeat experience resulting from 100 attack bites. We had previously reported such an effect after 14 days of daily defeat. Furthermore, these mice showed significantly enhanced naloxone-induced jumping after a small dose of morphine (5 mg/kg) when compared to mice not previously subjected to defeat.

Exposure to a biologically relevant stressor such as defeat appears to readily activate endorphin mechanisms in the brain which mediate a marked analgesis and produce long-lasting tolerance.

286.11 POTENTIATION OF NARCOTIC ANALGESIA BY H_1 and H_2 ANTAGONISTS. Renata Bluhm*, Bruce Diamond, Elemer Zsigmund, and Alon Winnie* Departments of Pharmacology and Anesthesiology, University of Illinois at the Medical Center, and Department of Anesthesiology, Mount Sinai Hospital, Chicago, IL 60612

In the present experiments we tried to identify antihistamines capable of naracotic potentiation and to correlate this with the anticholinergic action of the H_1 antihistamines and the H_1 and H_2 antagonist activity.

Analgesia was measured in mice using latency to jump from a hot plate at 55°C. Drugs were administered IP and animals were tested 45 minutes later.

Suboptimal doses of morphine sulfate (MS) (7.5 mg/kg) were potentiated by diphenhydramine (DH) (12.5 mg/kg), chlorpheniramine (CP) (20 mg/kg), hydroxyzine (HZ) (30 mg/kg) and cimetidine (CT) (200 mg/kg). At the doses used the increase in analgesic response when DH and MS were given together was 168%, with CP and MS it was 154%, for HZ with MS it was 460% and for CT and MS it was 168%. Benztropine did not potentiate morphine analgesia. These drugs had no analgesic effect alone. No measurable motor impairment occurred when measured by a grasp test using a hanging basket.

Apparently, H_1 and H_2 antagonists are effective potentiators of narcotic analgesia while anti-cholinergic activity does not produce this effect.

A possible explanation for the potentiating effect may be that the anti-histamines effect the disposition or metabolism of MS, change the amount of MS entering the brain or it may be due to a relationship of histamine and morphine receptors in the brain.

286.12 ANTINOCICEPTIVE INTERACTIONS AMONG NORADRENERGIC, DOPAMINERGIC, ENDOGENOUS OPIOID AND STRESSFUL MANIPULATIONS: PAIN INHIBITION OR HYPOACTIVITY. R. J. Bodnar, K. P. Merrigan*, N. Nicotera*, A. L. Kirchgessner* and G. Pasternak. Dept. of Psychology, Queens College, CUNY, and Dept. of Neurology, Memorial Sloan-Kettering Cancer Center, New York, NY.

Recent pharmacological and behavioral evidence indicates the existence of heterogeneous pain-inhibitory mechanisms. Acute exposure to stressors increase pain thresholds with some acting through endogenous opioid processes and others acting independently of these systems. Moreover, pharmacological manipulation of noradrenergic, dopaminergic and benzodiazepine systems alter nociceptive thresholds and interact with stress analgesia. In the first series of experiments, clonidine (0, 125, 500 and 1000 ug/kg, ip), a noradrenergic antinociceptive agent (Naunyn-Schmied. Arch. Pharmacol. 292: 119-126, 1976) which develops cross-tolerance with autoanalgesia (Soc. Neurosci. Abstr. 6: 247, 1980) was tested in the flinch-jump paradigm for interactions with morphine (5 and 2.5 mg/kg, sc) and cold-water swims (CWS: 2°C and 15°C baths for 3.5 min). Clonidine itself produced dose-dependent increases in flinch-jump thresholds with 60 min peak effects. The antinociception induced by the 2°C CWS and the 5 mg/kg dose of morphine were potentiated in a dose-dependent manner by clonidine. By contrast, clonidine failed to interact with the lower CWS and morphine analgesic stimuli. Activity levels were dose-dependently decreased by clonidine with the lowest dose exerting the greatest hypoactive effect. While morphine also produced hypoactivity, this was reversed by the higher doses of clonidine. Second, the neuroleptics haloperidol (HAL) and chlorpromazine (CPZ) which decrease restraint and heat analgesia (Life Sci. 27: 185-188, 1980) were tested in conjunction with 2°C CWS, morphine (5 mg/kg, sc), 2-deoxy-D-glucose (2-DG: 450 mg/kg, ip) and chlordiazepoxide (CDP: 15 mg/kg, ip) nociception on the flinch-jump test. HAL (10, 50, 100 ug/kg) and CPZ (1, 3, 5 mg/kg) each increased flinch-jump thresholds dose-dependently and each potentiated the antinociceptive effects induced by CWS, morphine, 2-DG and CDP. This potentiation was additive, not multiplicative. Third, the high-affinity opiate receptor antagonist, naloxazone (Science 208: 514-516, 1980) was evaluated for its central effects upon basal nociception and analgesic responses. Lateral ventricular injections of naloxazone (0, 1, 5, 20, 50 ug/5 ul: 1 ul/15 sec) decreased both basal flinch-jump thresholds and systemic morphine analgesia for up to 24 h after the injection. Preliminary data indicate naloxazone-induced increases in the non-opioid CWS antinociceptive response. (Supported by NIH Grants 14449, 5S05RR07064 and PSC/CUNY Grant 13493.)

286.13 ELIMINATION OF ANTINOCICEPTIVE RESPONSES FOLLOWING ACUTE EXPOSURE TO TAIL PINCH STRESS. D. A. Simone* and R. J. Bodnar (SPON: T.E. Frumkes). Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367.

Acute exposure to a variety of environmental stimuli can alter a number of behavioral processes in the rat. While certain stressors, such as cold water swims (CWS) and cervical probing (CP) increase pain thresholds following stress exposure, other stressors like non-noxious tail pinch (TP) induces eating, licking and gnawing behaviors. The latter syndrome appears to be subserved by dopaminergic and enkephalinergic systems since selective depletion of each system abolishes TP hyperphagia. By contrast, stressors that induce analgesia may or may not be mediated by endogenous opioids, depending on the procedure and parameters employed. Until recently, no link between the hyperphagic effects of TP stress and the antinociceptive effects of other stressors has been investigated. Chiodo (Brain Res. 176 (1979) 385-390) demonstrated that simultaneous exposure to CP and TP stimuli eliminates the eating behavior induced by TP, an effect attributed to reciprocal alterations in dopamine. While CP decreases dopamine unit activity, TP increases it. The present study investigated the complementary relationship, that is, would the activating effects of TP alter basal nociception and change the analgesic responses to morphine and the non-opioid stressor CWS. In the first study, 14 female rats verified for their hyperphagic response to TP, displayed significant decreases in flinch-jump thresholds immediately following TP. This effect occurred whether or not food was available during TP. Second, the time course of TP-induced decreases in flinch-jump thresholds lasted up to 30 min following TP exposure. In a third study, 11 female rats displayed lower latencies following TP across three thermal levels on the hot-plate test. Only the high (55°C) stimulus elicited significant effects which persisted into recovery. Finally, the increases in flinch-jump thresholds following 10 mg/kg and 2.5 mg/kg doses of morphine were reduced and abolished respectively by either pre-injection exposure or pre-test exposure to TP. CWS in a 15°C bath was similarly affected. However, 2°C swim-induced flinch-jump increases were reduced significantly only when TP was administered during the swim-test interval. These data indicate important reciprocal interactions between activating and antinociceptive systems and question whether the observed increases in pain thresholds following antinociceptive procedures are the sole result of activation of pain-inhibitory processes. (Supported by PSC/CUNY Grant 13493 and NIH Grant 5S05RR07064.)

286.14 FUNCTIONAL MAPPING OF PAIN PATHWAYS IN THE CAT SPINAL CORD USING THE [^{14}C] DEOXYGLUCOSE TECHNIQUE. S.E. Abram*, D.R. Kostreva, and J.P. Kampine. Depts. of Anesthesiology and Physiology, Med. Col. of Wis. and VA Med. Ctr., Wood, WI 53193

The spinal cord projections of afferent pain fibers originating from nociceptors in the foot pad of the cat were studied in sodium pentobarbital (35 mg/kg i.v.) anesthetized cats (2-3 kg). Brachial artery pressure and lead II electrocardiogram were recorded using a Grass polygraph. Skin temperature was monitored using a 24 gauge needle thermister placed intradermally into the hindlimb foot pad. A radiant heat lamp was used to produce the noxious heat stimulus. The effectiveness of the noxious stimulus was determined by: recording afferent nerve activity from the cut distal end of a small slip of the medial portion of the tibial nerve; and by monitoring autonomic responses; i.e. heart rate, blood pressure, and breathing frequency, during the noxious stimulus. The threshold temperature at which the averaged afferent nerve activity began to increase was between 44 and 48°C. Elevations of blood pressure, heart rate and respiratory rate began to increase 1 to 5 seconds after the initial increase in afferent nerve activity. On cessation of the radiant heat stimulus, afferent nerve activity, heart rate, blood pressure, and respiratory rate promptly returned to pre-stimulation levels. Once reproduceable changes in heart rate, and blood pressure could be induced, a single bolus of [^{14}C] deoxyglucose (125 uCi/kg) was injected into a femoral vein. The foot pad was then repeatedly stimulated (45 sec on, 30 sec off) for a total of 45 minutes. The entire brain and spinal cord were then removed, frozen in -40°C isopentane, sectioned at 20 um increments and prepared for autoradiography. The sections were covered with Kodak MR-1 film and stored in X-ray cassettes for 12 days. The autoradiographs were then developed and analyzed for the areas having the greatest metabolic activity as indicated by the density of photographic emulsion. Sections from the lumbar and sacral regions of the spinal cord showed markedly increased metabolic activity in the region of the lateral spinothalamic tracts. Caudal sections in the sacral region of the spinal cord showed an increased metabolic activity in the area of the ipsilateral lateral spinothalamic tract. More rostral sections in the sacral and lower lumbar region showed that the activity was distributed in the lateral spinothalamic tracts bilaterally. More rostral sections in the lumbar region indicated that the activity was localized primarily in the contralateral lateral spinothalamic tract. This study demonstrates that the deoxyglucose technique is useful for studying pain pathways in the CNS. (Supported by NIH Young Cardiovascular Investigator Grant HL 21042 and VA Medical Research Service).

286.15 IN VIVO STUDIES ON THE EFFECT OF ZOMEPRIAC SODIUM (ZS = Sodium 5-(4-Cl Benzoyl)-1,4-dimethyl-1H-pyrrole-2-acetate dihydrate) ON CAT CSF LEVELS OF PROSTAGLANDIN E_2 (PGE_2). S. DIVINETZ-ROMERO*, T. L. YAKSH, L. D. MUSCHEK*, and P. J. O'NEILL* (SPON: P. L. SETLER). Depts. of Psych. and Neurosurg., Mayo Grad. Sch. Med., Rochester, MN 55905 and Depts. of Biol. Res. and Drug Metab., McNeil Pharmac., Spring House, PA 19477.

The analgesic ZS has been shown to inhibit prostaglandin (PG) synthesis in bovine seminal vesicles and in platelets. This prompted us to investigate if systemic administration of this drug would depress immunoreactive (IR)-PGE_2 levels in the CSF of unanesthetized cats. PGE_2 has been implicated in pain potentiation and thermoregulation. Adult cats of both sexes were implanted with chronic cannulas in the cisterna magna under Pentobarbital anesthesia. After a 24 hr recovery period, daily CSF samples (1-1.5 cc) were drawn, immediately frozen and extracted with 2 vol. of chloroform:methanol 2:1, evaporated to dryness under N_2, reconstituted with phosphate buffer and radioimmunoassayed within 2 weeks. Highly specific PGE_2 antibody (Pasteur Institute) was used. Values were corrected for extraction losses monitored with both tritiated and cold PGE_2.

Control IR-PGE levels were found to be stable, ranging from 1,042 ± 255 pg/ml CSF one day after surgery to 1,508 ± 369 on the seventh day (mean ± SE). ZS produced a marked effect. Twenty-four hours after a single 3 mg/kg i.v. dose IR-PGE_2 levels decreased from 2,176 ± 332 to less than 86 ± 27 pg/ml CSF ($p < .005$). In animals given a single 0.3 mg/kg i.v. dose, a 60% reduction was noticeable within one hour ($p < .0025$), with a further decrease occurring after 24 hrs (IR-PGE_2 levels falling from 1,850 ± 394 to 72 ± 15 pg/ml CSF, $p < .005$). In these animals IR-PGE_2 levels remained depressed for up to 5 days, returning to control values within one week.

The decrease in IR-PGE_2 levels in CSF was concomitant with detectable levels of ZS in serum and in CSF. Serum levels of the drug were 16 ± 1.5 µg/ml within 1 hr of a 3 mg/kg i.v. injection and 5.3 ± 2.3 µg/ml after 72 hrs. ZS appears rapidly in CSF (detectable at 10 min), reaching approximately 7% of plasma levels within 24 hrs. The prolonged depression of IR-PGE_2 levels in CSF may be related to the long-lasting circulating levels of ZS in this species.

These findings suggest that the analgesic-antipyretic effect of ZS could be mediated by PG synthesis inhibition.

286.16 DIET-INDUCED ALTERATIONS IN SEROTONINERGIC NEUROTRANSMISSION, PAIN SENSITIVITY, AND OPIATE ANALGESIC DRUG POTENCY. TIMOTHY G. BURNS*, PATTI KANNE*, AND LOY D. LYTLE. LABORATORY OF PSYCHOPHARMACOLOGY, DEPARTMENT OF PSYCHOLOGY, UNIVERSITY OF CALIFORNIA, SANTA BARBARA, CALIFORNIA 93106

BRAIN AND SPINAL CORD SEROTONINERGIC NEURONS ARE INVOLVED IN MEDIATING NOCICEPTIVE RESPONSES AS WELL AS SOME OF THE ANALGESIC EFFECTS OF OPIATE NARCOTICS [MESSING, R.B. AND LYTLE, L.D. *Pain 4:* 1 (1977)]. FURTHERMORE, RATS FED A TRYPTOPHAN DEFICIENT, CORN BASED DIET ARE HYPERALGESIC AND HAVE REDUCED BRAIN SEROTONIN LEVELS [LYTLE, L.D. *et al., Science 190:* 692 (1975)], AND SHOW NO ANALGESIA WHEN TREATED WITH MORPHINE [PHEBUS, L. AND LYTLE, L.D. *Proc. West. Pharmacol. Soc. 21:* 361 (1978)]. THE PURPOSE OF THE PRESENT STUDY WAS TO FURTHER EXPLORE THESE PHENOMENA, AND TO DETERMINE IF THE ABOLITION OF MORPHINE ANALGESIA IN CORN-FED RATS WAS DUE TO DIET-INDUCED ALTERATIONS IN CENTRAL NERVOUS SYSTEM SEROTONINERGIC FUNCTION OR TO OTHER FACTORS ASSOCIATED WITH THE MALNUTRITION.

DIFFERENT GROUPS OF MALE ALBINO RATS WERE OFFERED *ad libitum* ACCESS TO AN 18% CASEIN CONTROL DIET, TO A CORN-BASED DIET, OR TO A CORN-BASED DIET SUPPLEMENTED WITH AMOUNTS OF TRYPTOPHAN EQUIVALENT TO THOSE CONTAINED IN THE CASEIN DIET BEGINNING AT 22 DAYS OF AGE. ELECTROSHOCK JUMP RESPONSE THRESHOLDS WERE DETERMINED IN ALL ANIMALS AT WEEKLY INTERVALS FOR UP TO 5 WEEKS. SIX WEEKS AFTER IMPLEMENTATION OF THE DIETS DIFFERENT ANIMALS WERE INJECTED SUBCUTANEOUSLY WITH THE VEHICLE (0.9% SALINE) OR DIFFERENT DOSES OF MORPHINE SULFATE (5 OR 10 MG/KG; SALT WEIGHT) AND THEN WERE TESTED FOR PAIN RESPONSES TO ELECTRIC FOOTSHOCK. ALL ANIMALS WERE KILLED 1 WEEK LATER; PLASMA, MUSCLE, AND LIVERS WERE ASSAYED FOR TRYPTOPHAN AND PROTEIN CONCENTRATIONS, AND TRYPTOPHAN, SEROTONIN, AND 5-HYDROXYINDOLEACETIC ACID WERE ALSO DETERMINED IN BRAINS AND SPINAL CORDS USING FLUORIMETRIC PROCEDURES.

THOSE ANIMALS FED THE CORN DIET OR THE CORN DIET SUPPLEMENTED WITH TRYPTOPHAN WERE HYPERALGESIC TO FOOTSHOCK COMPARED TO THE CASEIN-FED ANIMALS AFTER 1 WEEK FOLLOWING IMPLEMENTATION OF THE DIETS. FURTHERMORE, RATS FED THE CORN DIET, REGARDLESS OF WHETHER OR NOT IT WAS SUPPLEMENTED WITH TRYPTOPHAN, ALSO SHOWED NO ANALGESIC RESPONSES FOLLOWING THE INJECTIONS OF MORPHINE. TISSUE CONCENTRATIONS OF TRYPTOPHAN WERE REDUCED IN ANIMALS WHO CONSUMED THE UNSUPPLEMENTED CORN DIET, AND WERE GENERALLY INTERMEDIATE IN VALUE IN ANIMALS FED THE TRYPTOPHAN-SUPPLEMENTED CORN DIET COMPARED TO CASEIN FED CONTROLS. BRAIN OR SPINAL CORD 5-HYDROXYINDOLE LEVELS WERE REDUCED IN THE UNSUPPLEMENTED CORN-FED ANIMALS BUT THOSE IN THE TRYPTOPHAN-SUPPLEMENTED CORN-FED RATS WERE APPROXIMATELY EQUAL TO THOSE OF THE CASEIN FED CONTROL GROUP. HENCE, MALNUTRITION ITSELF MAY BE A SUFFICIENT CAUSE OF ALTERED NOCICEPTIVE RESPONSES IN CORN FED ANIMALS.

287.1 TOUCH AND SOUND HAVE A COMMON BRAIN PROGRAM FOR THE PRODUCTION AND RECOGNITION OF EMOTION EXPRESSION. M. Clynes, J. Walker* and N. Nettheim*. Music Research Center, New South Wales State Conservatorium of Music, Sydney 2000, Australia.

Dynamic forms of expression for specific emotions appear to be governed by brain functions that are independent of the sensory mode, as evidenced in this report for touch and sound. Touch expressions (measured as pressure transients[1]) were transformed to sound expression so as to express the same quality. The required transform was found to conserve the dynamic form.

Transformation consisted of modulation of a sinusoidal tone in frequency and amplitude by the touch dynamic form, in specific ways.[2] For the frequency envelope instantaneous pressure transforms to instantaneous frequency, with a polarity and modulation index specific for each emotion. Thus the frequency envelope is an isochronous linear transform of the touch pressure dynamic form. The amplitude envelope is also derived from the pressure dynamic form but includes an adaptation time-constant.

Sounds transformed from touch for the emotions anger, hate, love, joy, grief, sex, reverence, were tested on 189 subjects drawn from the United States and Australian college population. Emotions were recognized with a $p < .00001$, except for a degree of confusion shown between love and reverence.

Forty non-english speaking Aborigines of the Walbiri Tribe in Central Australia (Yuendumu) recognized the sounds transformed from white urban touch as well as or better than Australian medical students, and students at MIT and Berkeley. Males and females did equally well.

A transform incorporating the visual sense is likewise being sought.

The results imply that there is a brain program for dynamic emotion expression and its recognition whose algorithm and function is similar regardless of the sensory mode.

287.2 COMPARISON OF FUNCTIONS BETWEEN PARKINSON PATIENTS AND AGED NORMALS. L. Z. Podbros. Dept. of Psychology, SUNY at Stony Brook, Stony Brook, NY 11794.

Parkinson's Disease has been likened to an accelerated aging process. To test this analogy, an individual intensive strategy was used to examine similarities and differences in behavior between 8 idiopathic male parkinson patients (age range 53-69 yrs.) and 2 aged male normals, ages 85 and 90 yrs. A control group of 8 normal males was employed in order to estimate normative performance levels. Subjects were administered a battery of psychomotor and cognitive tasks, yielding 100 dependent measures. Performance measures for the patients and aged were converted to standard z scores. Relationships among skills and abilities were then examined by combining z scores into 18 functional clusters. Clusters were derived on an a priori rational basis but were examined empirically by internal consistency measures. Relationships among the patients' age, parkinsonian medications, disease severity, and performance on tasks were examined by Pearson product moment correlations.

Examination of individual cluster profiles shows that strength for both aged normals was beyond the criterion cutoff level for impairment ($z = -1.96$); in contrast, the strength of all eight patients was within this level. However, the patients showed markedly greater difficulty for speed and for endurance compared to other fundamental skills than did the aged. The relationships among motor and visual-motor skills are similar for the patients and aged: fine motor, bimanual, and visual-motor skills presented the greatest difficulties while visual perception is within normal limits for all subjects. However, marked differences in magnitude of effects can clearly be seen between the patients' and ageds' clusters for motor and visual-motor skills. None of the ageds' clusters approach the levels of impairment observed for the patients. For cognitive skills, however, the opposite is observed: the aged overall show lower functioning compared to the patients, though the magnitude of effects for neither the patients or aged reach those seen for the patients in motor and visual-motor skills.

These differences between the patients and aged in fundamental and cognitive skills and in magnitude of effects for motor and visual-motor skills indicate that idiopathic Parkinson's Disease is functionally distinct from aging per se.

287.3 EVALUATING THE PHOSPHODIESTERASE INHIBITOR, PAPAVERINE, TO FACILITATE PERFORMANCE IN SEVERE CLOSED HEAD INJURY PATIENTS. D. L. Chute. Division of Life Sciences, University of Toronto and Department of Psychiatry McMaster University, Scarborough Ontario, M1C 1A4, Canada.

A number of recent studies in animals have suggested that phosphodiesterase inhibitors like IBMX, Ro-20-1274, and papaverine may facilitate performance, persumably by increasing intracellular cAMP levels with a consequent effect on protein phosphorylation (Chute et al. Soc. for Neurosci. 1980). Papaverine has been investigated with mixed success in human clinical populations, especially the elderly with varying degrees of senile organic brain syndromes. Typically such studies have not directly linked the time of drug administration closely with the evaluation of performance as would seem to be required by the pharmacokinetics of papaverine. In our work using normal college age subjects as their own controls, 180 mg of papaverine or placebo was administered orally immediately after acquisition of a Sternberg type task. In a 24 hour retention test papaverine appeared to facilitate recognition. In a second test of short term memory 20 minutes after drug administration, there was no drug effect compared to placebo in reaction time or errors. Papaverine (200 mg/d) was evaluated in case studies of severe closed head injury patients from the comprehensive rehabilitation programme at Chedoke-McMaster Hospitals. Patients were evaluated on a number of clinical and psychological measures in a double blind, within subjects, placebo controlled repeated measures, clinical trial. Preliminary results suggest a modest performance increment may occur for newly acquired skills temporally contiguous with drug administration. A variety of possible explanations other than elevated cAMP levels may account for such observations.

287.4 THE HUMAN MEDIAL TEMPORAL LOBE CONTRIBUTES TO BOTH THE FORMATION AND RETRIEVAL OF RECENT MEMORIES. E. Halgren, C. L. Wilson, J. Engel, Jr., T. L. Babb and P. H. Crandall*. Calif Compre Epilepsy Ctr, VA Wadsworth Med Ctr, and Depts Psychiat, Neurol and Surg/Neurol, UCLA Med Sch, Los Angeles, CA 90024.

Bilateral damage to the human medial temporal lobe (MTL) is known to produce a profound, permanent, global and specific inability to remember events for more than a few minutes. Standard therapy for uncontrolled complex partial epilepsy is surgical removal of the epileptogenic anterior temporal lobe. Localization of seizure onset often requires bilaterally implanted MTL electrodes. In order to avoid global amnesia (produced if the contralateral MTL is nonfunctional)we evaluate unilateral MTL functional integrity by testing memory during brief biphasic charge-balanced pulses of weak electrical current. Each stimulus pulse induces synchronous neural activity lasting about 400 msec according to concurrent electrophysiological recordings. Multiple sites are stimulated simultaneously with single pulses separated by a minimum of 2 sec in order to avoid afterdischarges while still preoccupying a sufficient neural mass to produce a behavioral effect. 18 color slides of objects and/or people are presented every 2 sec for an exposure of 150 msec (Input). After a delay of about 20 sec with distraction, these 18 slides are presented again in random order with 18 novel slides (Output), while the patient is instructed to indicate whether or not each slide had been seen previously. Synchronization of cognitive processing with the phasic preoccupation is accomplished by presenting the stimulus pulse simultaneous with slide onset. In order to interpret the effects of unilateral stimulation (to be reported elsewhere), it is necessary to determine the effects of bilateral stimulation. Bilateral stimulation during both Input and Output produced a severe ($p < .001$) impairment in recognition. If an identical stimulus pulse was applied but the delay between Input and Output presentations was shortened to 2 sec, then no deficit was observed. There exists considerable controversy regarding whether the inability to remember after MTL lesions reflects insufficient encoding or consolidation, or retrieval. Therefore, we felt it important to determine if stimulation confined to the slides at Input or at Output would be as effective as stimulation at both presentations. It was not: Stimulation confined to either period was partially effective. Thus, the MTL contributes to mnestic processes both at the initial encounter with information, and again when it is presented for recognition.(Supported by NINCDS grant NS02808 and the Ralph Smith Foundation.)

287.5 LECITHIN EFFECT ON NORMAL HUMAN MEMORY. C. M. Harris, M. W. Dysken, P. J. Fovall* and J. M. Davis, Dept. Pharmacol., Univ. Illinois Col. Med., and Illinois State Psychiat. Inst., Chicago, IL 60612.

The level of function in the central cholinergic system has been postulated to be directly related to memory performance. Cholinergic agonists enhance some aspects of memory function, while the antagonist scopolamine has an amnestic effect. Experimental attempts to enhance human memory with the acetylcholine precursors choline and lecithin have produced mixed results, with, at best, small improvements, in young college graduates and medical students (Sitaram et al., Science 201:274, 1978).

We postulated that more striking improvements might be produced in an older, non-student, population. To test this idea, we conducted a double-blind, placebo-controlled, clinical trial of lecithin (Phospholipon-100, American Lecithin Co.) in in nine healthy paid volunteers with a mean age of 39.9 years ± std. dev. = 10.3 years (3 men, 6 women). Cognitive performance was guaged by a battery of psychological tests, including: a categorized serial learning task, a paired associates learning task with both high- and low-imagery forms, a word-recognition task, a test of retrieval, by category, of words from long-term memory, and a digit/symbol substitution test of psychomotor speed. Plasma choline was determined by the radioenzymatic method of Wang and Haubrich (Ann. Biochem. 63:195, 1975). After one practice-session, subjects received drug and placebo, in random order, and were tested on two occasions, separated by at least 48 hours. The drug and placebo were taken orally in single 80 ml doses. Active drug was 20 grams of lecithin in a sugar- and peppermint-flavored aqueous suspension. The taste- and appearance-matched placebo contained flour, water, gelatin, sugar, oil of peppermint and food color. Tests were conducted during the sixth hour after dosing, at the time of an expected peak in plasma choline. Results of t-tests for paired comparisons,performed on cognitive test scores, revealed no change in memory function, although plasma choline levels rose to nearly double the control levels (16.5 ± 2.4 nmol/ml after placebo versus 31.2 ± 7.2 nmol/ml after lecithin). Clinical failure of lecithin for memory enhancement cannot be attributed to slowing of psychomotor speed, or to other adverse drug effects, as no change occured in performance on the digit/symbol task, vital signs were not altered, and all subjects reported feeling well at the time of testing.

(Supported by USPHS training grant DA7067-04 to C. M. H.; study conducted at the Illinois State Psychiatric Institute.)

287.6 PERSISTENT MEMORY DISORDER FOLLOWING CLOSED HEAD INJURY IN CHILDREN: LIMITATIONS ON CEREBRAL PLASTICITY: H.S. Levin, H.M. Eisenberg and M.E. Miner. Division of Neurosurgery, The University of Texas Medical Branch, Galveston, TX 77550.

Twenty children who were 12 yrs. of age or younger when they sustained a closed head injury and had no previous developmental disorder were studied for at least six months postinjury (median = 13.5 mos) to assess recovery of memory. There were 12 children with diffuse injury and 8 cases with a focal intracranial or contusion visualized by computed tomography. According to ratings on the Glasgow Coma Scale (GCS), the initial severity of head injury was severe (GCS ≤ 8) in 12 children and mild or moderate (GCS > 8) in eight cases. Despite the finding of low average intellectual level in both the severe (Verbal IQ = 91, Performance IQ = 88) and mild injury (Verbal IQ = 92, Performance Scale IQ = 91) groups on follow-up examination, impairment of long term memory storage and retrieval ($p<.05$) was relatively more frequent in the severely injured children as was continuous recognition memory ($p<.01$). These findings confirm and extend our previous report of frequent memory deficit in children during the early stages of recovery from closed head injury (Levin, H.S. and Eisenberg, H.M., J. Pediatr. Psychol., 4:389-402, 1979) and suggest that residual memory deficit may persist even in children who evidence normal intellectual ability. In contrast to the impressive evidence for greater recovery of language after cerebral insult in children as compared to adults, a similar sparing of memory may not occur after injury to the young brain.

287.7 MEMORY FOR STABLE VERSUS FLEXIBLE TARGETS IN HUMAN AMNESICS. John A. Walker, Michael I. Posner, Robert D. Rafal*, and Kevin P. O'Brien*. Neuropsychology Laboratory, Neurological Sciences Center, Good Samaritan Hospital & Medical Center, Portland, OR 97210

Recent research with human amnesics has suggested that the class of preserved memory capacities is broader than previously believed (Cohen and Squire, 1980). Current work with animals who have memory deficits suggests close similarities to the human work (Walker and Olton, 1981). Both sets of results suggest that simple, stable, procedural information seems spared in the amnesic, while specific, flexible, episode-related information is lost. However, the different nature of the tasks that have been used with humans and with animals has generally precluded any direct comparison of results. The present study was designed to test human amnesics in a direct analog of a task that has proven to be sensitive to memory deficits in experimental animals.

Chronic amnesics of several etiologies (CVA, temporal/hippocampal surgery, closed head injury, Alzheimer's, Korsakoff's) were tested in a task that required memory for a target word. Each target was chosen from a short list of words. Two types of target lists were developed: in one, the target word was always the same, single word chosen from the list (stable targets), while in the other type, each of the words could appear as a target (flexible targets). Several lists of each type were used repeatedly within a block of trials. On each trial, the target was presented and then, after a variable delay, the word list was presented. The words were presented on a CRT screen, and the subject was required to indicate the spatial position of the target word within the list by pressing the appropriate key on a keyboard. Choice accuracy and reaction time were recorded. At the end of the test session, the subject was required to indicate which words had been presented in the day's session from a list containing stable targets, flexible targets, presented nontargets and nonpresented words.

Analysis of the pattern of choice accuracy and reaction times suggested differences in the subject's abilities to remember target items based in part on whether the targets were stable or flexible. In addition, there were differences in the performance among the patients of different etiologies that suggest differences in the information processing deficit. Although a number of important differences may remain between the human and animal amnesias, there appears to be a common defict when flexible information processing is required.

Supported in part by NIMH Grant 1-R03-MH35802-01 to JAW, and the Neurological Sciences Center Foundation.

287.8 DEMENTIA IN PARKINSON'S DISEASE: A NEUROPSYCHOLOGICAL ANALYSIS. F.J. Pirozzolo, J.A. Mortimer, E.C. Hansch, D.D. Webster* & M.A. Kuskowski*, Geriatric Research, Educ. & Clinical Center, V.A. Med. Ctr., Minneapolis, MN 55417, and Department of Neurology, University of Minnesota Med. Sch., Minneapolis, MN 55455.

An increased association of intellectual deficits and cognitive impairment with Parkinson's disease (PD) has been repeatedly observed in clinical and psychometric investigations. While the use in these studies of global ratings of dementia or standardized tests of mental reasoning have documented the occurrence of cognitive impairment, little agreement has been reached on the issue of a specific vs. more generalized deficit in cognition in the disease. In the present study, an extensive neuropsychological battery was administered to patients with PD in order to elucidate the nature of the cognitive deficit.

Sixty patients with idiopathic PD and an equal number of normal age- and education-matched controls were given a battery of tests measuring such abilities as verbal and nonverbal memory, language, visual-spatial perception, concept set shifting, speeded categorical decision making, and fund of information. Patients performed significantly poorer ($p<.001$) on all measures than controls with the exception of tests for vocabulary and information. The strongest group differences, as revealed by the size of the t-ratios, occurred for tests involving visual-spatial performance and paired associate memory. In order to assess clinical classification efficacy, stepwise discriminant analysis was applied to the data for patients and controls. A derived variable subset of block arrangement, a difficult paired associate memory test, and a letter cancellation test correctly assigned 73% of patients and 87% of controls. This three variable discriminant function when derived from a randomly-selected half of the total sample continued to classify the remaining patients and controls at essentially similar (79% and 77%) levels. To take into account the match between patients and controls, difference scores on the discriminant function were computed for each patient-control pair. These scores indicated that 89% of patients were more impaired than their matched control counterparts.

These results support the contention that cognitive impairment in PD occurs across a wide domain of neuropsychological abilities. On the other hand, the observed strong decrements in several tests of visual-spatial function argue that this aspect of cognition is especially impaired in the disease. Lack of impairment on the vocabulary and information tests suggests a selective sparing of "crystallized" as compared to more "fluid" intellectual abilities. Finally, results of the discriminant analysis suggest that the neuropsychological profile may serve as an independent and relatively accurate predictor of the presence of the disease.

288.1 MORPHOMETRIC CORRELATES OF CORTICAL CELL PATTERNS OF LIMBIC LOBE IN DOLPHIN BRAIN. M.S. Jacobs, P.J. Morgane and W.L. McFarland. Dept. Pathobiol., NYU Coll. Dent., New York, NY 10010; Worcester Found. Exp. Biol., Shrewsbury, MA 01545; NIH, Bethesda, MD 20014.

Studies of the limbic lobe in cresyl violet stained serial sections of perfused brains of the bottlenose dolphin have included quantification of neuronal size, neuronal and neuroglial cell numbers and laminar thicknesses. The quantitative data have been valuable for interpreting organizational patterns of the cetacean limbic cortical formations which incorporate several special features of the dolphin's voluminous neocortex. These latter include (1) relative uniformity of cortical thickness, (2) regional cytoarchitectonic differences that occur gradually and are often less prominent than in terrestrial mammals, and (3) an apparent absence of a small celled internal granular layer IV.

The major cytoarchitectonic patterns of the limbic cortical formations at pregenual (Prgn), supracallosal and retrosplenial (RtSpl) levels reflect increasing laminar differentiation as the cortex is followed radially from its internal, peritectal origin to its external margin; increased cellularity in the posterior supracallosal (PScl) and RtSpl regions as compared to Prgn and anterior supracallosal (AScl) regions; and an unusual phalangeal cell pattern at mid levels of the cortical plate in the RtSpl peritectal zone. In addition, the cortical plate of the subrostral (parolfactory) limbic region exhibits gradual increasing cellularity, widening and laminar differentiation as it is followed radially from its origin. The temporal periarchicortical limbic formations reveal a complexly organized, anteriorized entorhinal region exhibiting numerous subfields, and a posteriorized, rather uniform presubiculum.

Respective listings of quantitative data of neuronal densities (cells/mm^3) and glia/neuron cell ratios for various sectors of limbic cortex proper are: Prgn sector, 5090 and 2.40; AScl sector, 3626 and 4.13; PScl sector, 6762 and 1.96; anterior RtSpl sector, 5638 and 1.89; and posterior RtSpl sector, 5522 and 2.08. The maximum deviation from the mean cortical thickness (1.45 $\pm$ .04 mm) is 0.11 mm, reflecting uniformity of cortical width. Differences in laminar widths are regionally slight, and mean values are: layer I, 0.35 $\pm$ .02 mm; layer II, 0.09 $\pm$ .01 mm; layer III, 0.31 $\pm$ .03 mm; layer V, 0.23 $\pm$ .02 mm; and layer VI, 0.47 $\pm$ .04 mm. In view of the lack of layer IV, it is of special interest that the dolphin counterpart of the granular type of posterior limbic cortex present in land mammals is denso- and parvicellular cortex. Here in the PScl sector, supragranular layers II and III contain cells that are more numerous and have major and minor axial dimensions that are significantly less than corresponding neurons in the AScl sector. (Supported by NSF Grant BNS 79-08660).

288.2 BEHAVIORAL FUNCTION OF SYMPATHETIC SPROUTING AND ITS RELATION TO LIGHTING CONDITIONS AND LIGHTING CYCLES. P. Moes*, D. Graves*, P. Kesslak*, F. H. Gage. Chem. of Behavior Program, Texas Christian Univ., Fort Worth, TX 76129.

Sprouting of superior sympathetic ganglion (SCG) fibers following lesions to the septal nucleus is well documented, and several investigators have studied mechanisms for growth of these fibers into the hippocampus. However, a functional significance of this ingrowth has not been determined. The loss of Ach fibers to the hippocampus appears to be critical for the sprouting of SCG fibers. For this reason, lesions to the medial septal (MS) area (which project Ach fibers to the dentate gyrus) were performed to induce the sprouting, and to produce a behavioral deficit which recovers over time. Since the time course of the ingrowth following the lesion corresponds roughly with the behavioral recovery, it was felt that this new innervation may be mediating the changes seen in the recovery. Because the SCG has also been implicated in the mediation of circadian rythms and response to levels of light, the following conditions were examined: housing in 24 hr. light vs. 12/12 light-dark vivarium, testing in morning vs. evening, and testing in a light room vs. a dark room.

Animals were given MS, or sham, lesions, allowed to recover for 3 weeks, and then received a ganglionectomy or sham ganglionectomy. Daily water consumption was measured and behavioral testing was done each week throughout the study, which included response to footshock and hotplate, and activity in a novel environment (open field). Results show an increase in reactivity following MS lesions that recovers over 1-2 weeks. Following ganglionectomy, there is an accentuation of differences in behavioral responses between light vs. dark testing conditions (compared to animals with sham lesions and ganglionectomies). These results demonstrate a functional significance for septal sprouting and suggest that lighting conditions alter the functioning of this new innervation.

288.4 NON-THALAMIC EFFERENT PROJECTIONS OF THE POSTERIOR CINGULATE GYRUS IN THE RABBIT. J.L. Bassett* and T.W. Berger (SPON: A. Mallinger). Psychobiology Program, Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

Efferent projections of the posterior cingulate gyrus in the rabbit were examined using both horseradish peroxidase and autoradiographic axonal transport techniques. The cytoarchitecture of the posterior cingulate gyrus was defined according to Rose and Woolsey (J. comp. Neurol., 89:279, 1949) for the rabbit. The present analysis deals specifically with its granular cingulate and retrosplenial components.

Large injections of ^{3}H-proline (50 uCi/ul) that involved both retrosplenial and cingulate cortices, and smaller injections that involved only cingulate or retrosplenial subdivisions were made at various locations along their anteroposterior extent. Following a 24-48 hour survival period, the brains were processed in accordance with established procedures (Cowan, W.M. et al., Brain Res., 37:21, 1972). HRP (Sigma, type VI, concentration 30%) in volumes of 0.02-0.05 ul was injected into the various efferents of the cingulate gyrus after which tissue was prepared according to Mesulam (J. Histochem., Cytochem. 24:1273, 1976; ibid., 26:106, 1978).

After tritiated amino acid injections in the posterior cingulate gyrus, silver grain deposits were seen in the dorsal claustrum, medial and lateral pontine nuclei, caudate nucleus, anterior limbic cortex and pretectum.

Injections of HRP into these target regions identified cells in (1) layers V and VI of cingulate cortex as projecting to the claustrum (2) layer V of retrosplenial cortex as projecting to the pons (3) layers V and VI of retrosplenial as projecting to the caudate and (4) layers II and III of cingulate and layers V and VI of retrosplenial as projecting to anterior limbic cortex.

In total, these results identify the cells of origin and site of termination of the major non-thalamic efferent projections of the cingulate gyrus in the rabbit.

Supported by The McKnight Foundation, NSF grant BNS80-21395, and NIMH grant MH00343.

288.5 SUBICULAR PROJECTIONS TO RETROSPLENIAL CORTEX IN THE RABBIT. S.L. Semple-Rowland*, J.L. Bassett* and T.W. Berger (SPON: J. Jennings). Department of Psychology and Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260

Subicular efferents to the posterior cingulate gyrus in the New Zealand white rabbit were examined using anterograde and retrograde axonal transport methods. Injections of tritiated proline were made throughout the septo-temporal extent of the subicular cortex. Autoradiographic analysis revealed a concentration of silver grains in layers I and IV of the retrosplenial subdivision of the posterior cingulate gyrus. The highest density of silver grains was clearly located in the granular, layer IV. Higher than background grain counts were also evident in layers V and VI, though labeling in these layers was light compared to that seen in I and IV, and may have represented axons from the cingulum en route to superficial layers. Subicular-retrosplenial connections are topographically organized such that septal (rostral) subicular regions project to medial portions of rostrally located retrosplenial cortex; more posterior (though dorsal) subiculum projects to medial portions of corresponding posterior retrosplenial cortex; and temporal (ventral) subiculum projects to lateral aspects of the posterior retrosplenial cortex. In addition, results showed that efferents from rostral and (dorsal) posterior regions of subiculum terminate over a much wider region of retrosplenial cortex than efferents from temporal subiculum.

Retrograde analysis of this connectional system using horseradish peroxidase (HRP) revealed the same topographical organization described by autoradiographic methods. In addition, HRP results showed that the cells of origin for retrosplenial afferents were restricted to the subiculum proper, and did not include the presubiculum or other subicular subdivisions.

288.6 NEOCORTICAL INPUT TO ENTORHINAL AND CINGULATE CORTICES IS RELAYED BY THE CLAUSTRUM. T.W. Berger, J.L. Bassett* and S.L. Semple-Rowland*. Psychobiology Program, Department of Psychology and Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

The nature of claustral afferents to the limbic system was studied in the New Zealand white rabbit using anterograde and retrograde tracing methods. Horseradish peroxidase (HRP) injections that involved both medial and lateral entorhinal cortex resulted in dense retrograde labeling of a large number of neurons within the claustrum. Labeled neurons were seen throughout the entire structure, though the majority were located in the dorsolateral and ventral regions. There was also evidence of reciprocal connections between entorhinal cortex and the claustrum, i.e., anterogradely transported HRP was often visible in the claustrum after entorhinal injections. Injections of tritiated proline in the claustrum resulted in silver grain densities that were greatest within the deeper cortical layers (V-VI) of both medial and lateral entorhinal areas.

Injections of HRP in the posterior (granular) cingulate gyrus also resulted in dense labeling of a large number of claustral neurons, though these were restricted in location to dorsomedial regions. Anterogradely transported HRP was also evident in the claustrum after cingulate injections, indicating that both entorhinal and cingulate cortices are reciprocally connected with the claustrum. Autoradiographic results showed that claustral afferents terminate in layers VI, V and possibly I of cingulate (though not retrosplenial) cortex.

These experiments demonstrate the existence of a prominent claustral afferent system to two allocortical brain regions -- the entorhinal and the cingulate cortices. The entorhinal cortex, in particular, is known to be a major afferent to the hippocampal formation (Hjorth-Simonsen and Jeune, J. comp. Neurol., 144:215, 1972), and the posterior cingulate gyrus has been shown to project to the presubiculum (Domesick, Brain Res., 12:296, 1969). Previous studies have demonstrated that the claustrum receives input from virtually all of neocortex (Carmen, Cowan and Powell, J. Neurol. Neurosurg. Psychiat., 27:46, 1964). As a result, the claustrum could function as a major "conduit" for neocortical information to reach the limbic system.

288.7 AUTORADIOGRAPHIC DEMONSTRATION OF THE SPROUTING OF SEPTAL AFFERENTS TO THE DENTATE GYRUS AFTER LESIONS OF THE ENTORHINAL CORTEX IN ADULT RATS. B.B. Stanfield and W.M. Cowan. Salk Institute, La Jolla, CA 92138.

Following lesions of the entorhinal cortex in adult rats there is a striking intensification of the histochemically demonstrated acetylcholinesterase (AChE) activity in the molecular layer of the dentate gyrus. Although it has been shown that the AChE intensification is dependent on the integrity of the septum, the evidence that it is due to collateral sprouting of septo-dentate fibers remains indirect.

To examine this we have employed the autoradiographic method following injections of ^{3}H-proline into the septum of control rats and of animals in which lesions of the entorhinal cortex had been placed one month earlier. By using fairly large injections (20-40 μCi in 0.2-0.4 μl) and relatively long survival times (2 to 5 days) we have been able to demonstrate more clearly the rather sparse septo-dentate projection. In addition, by processing one series of sections for autoradiography and an adjacent series for AChE histochemistry, we have been able to directly compare in each experiment the distribution of transported label in the septo-dentate fibers with the AChE staining pattern.

The septal projection to the dentate gyrus in normal rats is rather diffuse; following a septal injection of ^{3}H-proline the greatest density of transported label is found in the hilus immediately beneath the granule cell layer, but there is also above-background labeling over the molecular layer. Here the density of labeling is more-or-less uniform and we have been unable to identify a correlation between the pattern of labeling in the autoradiograms and the distribution of AChE staining in the adjacent sections.

Septal injections in animals that have had prior lesions of the entorhinal cortex give rise to a quite different pattern. In these cases there is about a ten-fold increase in grain density over the denervated portion of the molecular layer. The region of increased grain density corresponds closely to the zone of gliosis and AChE intensification. The width of these zones varies from case to case depending on the extent of the initial lesion and the distribution of the interrupted entorhinal afferents. Thus, after lesions of the medial entorhinal cortex the zone of AChE intensification and elevated grain density is confined to the middle portion of the molecular layer, whereas after lesions of the lateral entorhinal cortex, the corresponding zone is limited to the outer third of the molecular layer.

These results provide the first direct evidence that there is a proliferation of septo-dentate fibers following entorhinal lesions, and they are consistent with the view that the concomitant AChE intensification is due to this proliferation.

288.8 CYTOARCHITECTONIC MATURATION OF RAT ENTORHINAL CORTEX (AREA 28). Russell E. Ruth and Sara K. Goldsmith*. Il. Inst. Dev. Disabil., Chicago, Il 60608.

Neurons destined to reside within rat cortical area 28 proliferate at the beginning of the third gestational week (Bayer, 1980). It was of interest to ascertain the temporal sequence of morphogenesis in this cortex after proliferation had ended. Brains were removed from anesthetized animals in embryonic or postnatal life, and were processed using routine histologic methods.

In adults area 28 has 3 clearly recognizable cytoarchitectonic divisions: medial (m), intermediate (i) and lateral (l). In fetuses removed by Caesarian section one day prior to parturition only a gross lateral/medial distinction can be made. Lamination is rudimentary, and although layer II of area 28l has split into a superficial and deep lamina cell clustering is not yet observed. Compared to adults (> 90 days old) cell density is high, due to numerous small, densely stained neurons.

By postnatal day 8 cell density has significantly declined, and the individual cells are larger. All three divisions are discernable, with distinct clustering of cells in layer II of area 28l. This division is more adult-like than either area 28m or 28i, paralleling the order of earlier cell proliferation. Finally there is a dramatic increase in the total cortical volume during early postnatal life. It is not clear whether the lowered cell density seen in adults is due to increased volume, to cell death or to both factors. These and other questions are currently being examined in greater temporal detail using reconstructive and quantitative morphometric methods.

288.9 TETANIC POTENTIATION IN THE CINGULATE CORTEX. R. W. Sikes, K.H. Taber, and J. F. DeFrance. Dept. of Neurobiology and Anatomy, Univ. Texas Medical School, Houston, Texas 77025

The projection from the mediodorsal thalamic nuclei(MD) to the cingulate cortex has been well established by anatomical studies. The lateral part of the nucleus sends fibers which terminate primarily in the deep part of layer III of the anterior limbic cortex. Very little, however, is known of the electrophysiology of this pathway. This report will describe the effect of electrical stimulation of MD on the anterior limbic cortex measured by extracellular field and unitary recording techniques.

Stimulation of the lateral part of MD at frequencies below 1 Hz elicit surprisingly little response in the cortex. By increasing the frequency of stimulation to 4-10 Hz, however, large extracellular field responses could be produced. The magnitude of this response increases to a maximum at 7 Hz and then decreases with higher stimulus frequencies. The response is a large negative potential with a 15 msec latency which is followed by a smaller positive potential at 30 msec. The magnitude of the response is greatest in the deep part of layer III and in the superficial part of layer V. This negative-positive response appears reversed at the surface of the cortex.

The magnitude of the response increases gradually during a train of stimuli; often requiring three or four stimuli to reach its maximum. If the frequency is them abruptly lowered to below 1 Hz, the response disappears: i.e., there is no significant posttetanic potentiation.

Single cell recordings show that many cells in the anterior limbic cortex are not affected by MD stimulation. Nevertheless, another group of cells do show frequency dependent excitatory responses. When the MD nucleus is stimulated at low frequencies, these cells discharge with no apparent relation to the stimuli. But when the stimulus frequency is increased to 4-10 Hz, the cells discharge in phase with the stimulus train with a 15-18 msec latency. These discharges occur in relation to the peak of the negative field. The cells do not generally discharge until the field is near maximal amplitude.

These data indicate that while the MD projection is excitatory to the cingulate cortex neurons, the effect is dependent on the frequency of stimulation and possibly to the number of stimuli in the train.

288.10 THE EFFECT OF HIPPOCAMPAL LESIONS ON RAT MATERNAL BEHAVIOR AND SUBSEQUENT ENDOCRINOLOGICAL AND BIOCHEMICAL CONDITIONS PRESENT IN THEIR DEVELOPING OFFSPRING. H. M. Murphy and C. H. Wideman, John Carroll Univ., Cleveland, OH 44118, D. W. Long*, Consolidated Biomedical Laboratories, Columbus, OH 43216, and T. S. Brown*, DePaul University, Chicago, ILL 60614.

Behavioral studies have indicated that maternal behavior is altered in animals with hippocampal lesions. Endocrinological and biochemical studies have also demonstrated a number of changes in such animals. For example, these animals have an altered glucocorticoid response to stress. They have significantly lower levels of serum TSH, total T_4, and free T_4. Animals with hippocampal lesions have significantly higher levels of blood urea nitrogen and significantly lower levels of serum triglycerides and cholesterol. The present study was undertaken in order to gain further insight into the maternal behavior of animals with hippocampal lesions. In addition, the levels of certain chemicals in the serum as well as body weight were ascertained from offspring of female animals with hippocampal lesions.

In the behavioral aspect of the study it was shown that pup survival to weaning (21 days) was significantly lower in animals with hippocampal lesions than in control animals. Mean body weights were significantly lower in pups born of mothers with hippocampal lesions than in controls 5 days after birth. These weight differences disappeared by day 14. Nursing behavior and nest building were significantly poorer in animals with hippocampal lesions. Some differences were also noted in retrieval behavior. Although there were no significant differences in retrieval behavior when pups received no treatment, poorer retrieving was noted in rats with hippocampal lesions when the pups were covered with vaseline or food powder. Poorer retrieving was also noted in these animals when the pups were contaminated with the scent of another rat.

In the endocrinological and biochemical aspect of the study the following chemicals were measured in the serum of the pups: TSH (RIA), total T_4 (RIA), free T_4 (RIA), sodium, potassium, chloride, phosphorus, iron, glucose, uric acid, blood urea nitrogen, creatinine, cholesterol, triglycerides, total protein, albumin, and bilirubin. The tests were conducted 21 days after birth. There were no significant differences between pups born of animals with hippocampal lesions and control animals in any of the above chemical substances. It thus appears that if pups born to mothers with hippocampal damage can survive until weaning, they will not show endocrinological and biochemical abnormalities typically found in the brain damaged mother.

288.11 THE OLFACTORY BULB AND ENTORHINAL AREA HAVE DIRECT PROJECTIONS TO THE DORSAL HIPPOCAMPAL RUDIMENT IN THE MOUSE. M.T. Shipley, G.D. Adamek and Marc S. Sanders*. Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. School, Chicago, IL 60611 and Grad. Prog. in Neurosci., Northwestern Univ., Evanston, IL 60201

The dorsal hippocampal rudiment (DHR) is an enigmatic cortical field classically felt to be a part of the hippocampus (HC). In the mouse, the DHR lies just dorsal to the corpus callosum at the base of the anterior half of cingulate cortex. In coronal sections the field is small but constitutes a fairly long rostro-caudal strip. The connections of the DHR are unknown.

The Timm's staining pattern of the DHR is reminiscent of a mini-dentate gyrus (DG) comprising a layer of granule cells with 2-3 bands of staining in the molecular layer. In the DG these bands correspond to inputs from the lateral and medial entorhinal area (LEA and MEA) and the ipsi-and contralateral association systems. Using anterograde transport of HRP we have found that the LEA and MEA terminate in the molecular layer of the DHR in a manner similar to their projection to the DG. This suggests that the DHR is a displaced portion of the DG.

The olfactory system is known to have a strong indirect influence on the HC via primary and secondary bulbar projections to the LEA. Wheat germ agglutinin-HRP injections confined to the main olfactory bulb (MOB) show a direct projection from the MOB to the DHR.

Both the olfactory bulb itself and retrobulbar structures such as the piriform cortex (PC) convey olfactory information to the LEA; the LEA supplies a major input to the DG. Our results suggest that there is a much more direct pathway whereby olfactory information may influence a cortical region whose histochemistry and direct afferents from the entorhinal cortex suggest that it is part of or closely related to the DG. Thus, the DHR may represent a phylogenetically old olfacto-recipient outpost of the hippocampus.

It has become apparent that there are parallel functional olfactory systems originating in the MOB and accessory olfactory bulb. Taken with the other connections of the mouse MOB (Adamek and Shipley, this volume), the present findings suggest that there may be parallel functional subsystems associated with the MOB itself.

Slotnick and Berman (Br. Res. Bull. 1980) have shown that rats with total transections of the lateral olfactory tract (LOT) can relearn odor discriminations. If the MOB to DHR projection we describe exists in the rat, it may have escaped the LOT lesions and provide a substrate for the animals' ability to relearn.

288.12 EVIDENCE FOR POSTSYNAPTIC ALTERATIONS IN PAIRED PULSE POTENTATION OF CA1 PYRAMIDAL CELLS IN HIPPOCAMPAL SLICES. David Whitehorn, Walter C. Low and Spencer L. BeMent, Dept. of Physiology and Biophysics, Univ. of Vermont, Burlington, Vermont and the Bioelectrical Sciences Laboratory, Univ. of Michigan, Ann Arbor, MI.

The evoked activity of CA1 pyramidal cells in the hippocampal formation has been shown to potentiate in response to paired electrical stimuli of afferent pathways; and evidence suggests that the potentiation of this neuronal population is a result of an enhancement of synaptic transmission. We have previously shown (Brain Res., 1980, 198:472) that an augmentation of the afferent volley is involved in paired pulse potentiation produced by activation of Schaffer collaterals. We now report evidence demonstrating that postsynaptic alterations also contribute to the overall potentiation of CA1 pyramidal cell responses. Our data show that the potentiation of population discharge is greater than would be predicted from the enhancement of synaptic transmission alone.

In rat hippocampal slice preparations, Schaffer collateral fibers were electrically stimulated over a wide range of intensities. Input-output functions (I-O functions) relating the amplitude of the summated discharge of the pyramidal cells (population spike) to the amplitude of the summated dendritic depolarizations (population EPSP) were determined using linear regression equations. I-O functions were determined for both control responses and for potentiated responses obtained with the second of a pair of stimuli delivered with a 30 msec interstimulus interval.

If the paired pulse potentiation of the population spike is a result of potentiation of the population EPSP alone, then the control and potentiated I-O functions should be coincident. On the other hand, if potentiation involves postsynaptic mechanisms, control and potentiated I-O functions should be non-coincident with potentiated functions displaying a greater slope, and/or intercept.

I-O functions were obtained in 28 slices. Sixteen slices exhibited non-coincident control and potentiated functions. In all of these 16 slices slopes and/or intercepts were greater in the potentiated condition. Data from slices exhibiting non-coindent control and potentiated function were further analyzed to determine the relative contributions of postsynaptic and synaptic factors to the overall potentiation. We found that 57 ± 6% of the population spike potentiation could be explained by the enhancement of the population EPSP while 43 ± 6% arose from apparent postsynaptic alterations. These results suggest that alterations in postsynaptic excitability can be a major contributing factor to the enhancement of CA1 cell activity under conditions of paired pulse potentiation. (This work supported by NIGMS grant GM 01289 and USPHS grant NS 08478).

288.13 DOPAMINERGIC STIMULATION OF N. ACCUMBENS CAN REDUCE THE BEHAVIORAL CONSEQUENCES OF HIPPOCAMPAL DAMAGE. J. H. Hannigan, Jr., J. E. Springer* and R. L. Isaacson . Dept. of Psychology and Center for Neurobehavioral Sciences, SUNY-Binghamton, Binghamton, NY 13901.

The intracerebral administration of a specific dopamine agonist, 3,4-dihydroxyphenylamino-2-imidazoline (DPI; see Cools & Van Rossum, 1980) into n. accumbens can reduce several of the usual consequences of bilateral hippocampal damage (Reinstein, Hannigan, & Isaacson, 1980). This suggests that at least some of the behavioral changes following such damage may be due to lesion-induced secondary changes in n. accumbens and possibly other basal ganglia sites.

Secondary changes of behavioral importance may also be occurring in the caudate since alteration in membrane phosphorylation can be found there after hippocampal destruction (Bär, Gispen, & Isaacson, 1981), despite the lack of direct hippocampal formation afferents to the area. Therefore, we undertook to investigate the behavioral effects of intra-accumbens and intra-caudate administration of dopaminergic agents to determine the degree to which the usual behavioral changes found after hippocampal damage would be alleviated.

Rats with sham, cortical, or hippocampal lesions were implanted with a cannula into either the caudate nucleus or the nucleus accumbens. On 4 consecutive days starting 6 days after surgery, rats were injected with increasing doses of DPI into nucleus accumbens or similarly incrementing doses of haloperidol into caudate. The animals' behavior (locomotion, rearing, grooming, and hole poking) was measured in an open field/hole board afterwards. One month later, the injections were reversed (i.e., DPI into caudate, and haloperidol into accumbens) and behavior observed again.

Hippocampally-lesioned animals exhibited characteristic behavioral deficits in locomotion, rearing, and grooming which were selectively attenuated by injection of DPI into accumbens. Haloperidol into either area or DPI into caudate were generally ineffective. Further, control lesion groups were not selectively affected by either drug in either brain area.

These results indicate that the hippocampal lesions induce an enhanced sensitivity to low doses of DPI into n. accumbens and that the presumed activation of the DAi receptors by DPI can result in the normalization of several behaviors influenced by bilateral hippocampal damage. This suggests that the behavioral sequelae of hippocampal lesions may be in part due to alternation in the dopamine system in n. accumbens which develop secondarily to the lesion.

288.14 CELLULAR AND SYNAPTIC CHARACTERISTICS OF FETAL RABBIT HIPPOCAMPUS. P.A. Schwartzkroin and D.D. Kunkel*. Dept. of Neurological Surgery, University of Washington, Seattle, WA 98195.

The development of hippocampus has been well studied by morphologists (Bayer, J Comp Neurol 190:87, 1980; Stensass, J Comp Neurol 129:59, 1967). They have shown that many of the most dramatic changes occur prenatally, during a period when it is technically difficult for physiologists to investigate the development of cellular and synaptic activities. Although hippocampal neurons, initially taken from fetal animals, have been studied using dispersed cell culture (Peacock, Brain Res 169:247, 1979) and tissue culture (Zipser et al., Brain Res 60: 489, 1973) techniques, neither of these situations provides an accurate picture of normally organized hippocampus at known stages of development.

Using the *in vitro* hippocampal slice technique, we have studied the hippocampal pyramidal cell region of fetal rabbits, correlating electrophysiological findings with cell and synaptic profiles shown by electronmicroscopy. Intracellular impalements of cells in the pyramidal cell region of hippocampus were obtained from fetuses 21 through 29 days' gestation (term - 30-31 days). In all experiments, cells were capable of generating action potentials, but spikes were of unusually long duration (sometimes greater than 10 msec). In good penetrations of cells from fetuses 21-25 days' gestation, cell input resistance could be as high as 200 megohms (time constants of 15-50 msec); in cells from older fetuses (25-29 days' gestation), input resistances of 80-90 megohms were not unusual. Intracellular current injection elicited trains of spikes only in the best penetrations. Repetitive discharge was followed by long duration afterhyperpolarizations in some cells.

No synaptic activity could be evoked in fetal hippocampus in the earliest stages we studied. However, by 24 days' gestation, stimulation in the stratum radiatum region could produce depolarizing potentials of extremely long duration. No hyperpolarizing inhibitory synaptic responses were recorded during good penetrations. Electronmicroscopic examination of the pyramidal cell region showed some synaptic profiles, even in our youngest fetuses. Such infrequent profiles occurred on dendritic processes and were all of the asymmetric type.

These experiments indicate that electrophysiological investigation of fetal CNS structures can be carried out in parallel with morphological studies of development.

288.15 STIMULATION-INDUCED CHANGES IN DIMENSIONS OF STALKS OF DENDRITIC SPINES IN THE DENTATE MOLECULAR LAYER. E. Fifková and C. L. Anderson*. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Tetanic stimulation of the entorhinal area has been shown to induce lasting enlargement of the average dendritic spine area and perimeter in the termination zone of the perforant path in the outer two-thirds of the dentate molecular layer. These data were derived from measuring heads of dendritic spines. Since changes in the spine stalk may have a considerable impact on electrical properties of synaptic potentials, we studied the dimensions of the spine stalk and spine head following tetanic stimulation. The lack of identification criteria makes it difficult to sample spine stalks separately. However, a spine stalk can be easily recognized when it connects the spine head with its parent dendrite. Therefore, all measurements were done on spines which satisfied this criterion. Forty mice were divided into four groups. Out of these, two groups were stimulated and sacrificed 4 min and 90 min later. The other two groups were sham controls with survival periods similar to those of the stimulated ones. Tetanic stimulation of the entorhinal area induces in the 4 min poststimulation interval a statistically significant increase in the width of the spine head (21.6%) and spine stalk (42.2%) in the middle third; in the distal third, the enlargements of the head and stalk are 23.2% and 61.7%, respectively. Ninety min after stimulation, both spine head and spine stalk were wider in the distal third by 34.7% and 61.2%, respectively. In the middle third, the stalk width returned to control values; however, the head remained enlarged by 33.6%. The spine stalk was found to be significantly shorter in the distal third of both poststimulation intervals. It, thus, appears that changes in dimensions of the stalk and the head need not persist simultaneously. Given that the spine stalk can be viewed as an avenue communicating electrical and biochemical signals from the synaptic region of the spine head to the parent dendrite and vice versa, such a dissociation may have far-reaching functional implications. In this context, it seems to be noteworthy that the lateral perforant path which terminates in the distal third of the dentate molecular layer shows significantly more long-term potentiation than the medial pathway which terminates in the middle third (McNaughton, et al., Brain Res., 157:277). If the spine stalk enlargement is the substrate of this type of synaptic plasticity, then the earlier return of the stalk width to prestimulation conditions would be in agreement with the observed lower capacity of the medial pathway to generate long-term potentiation. (Supported by NIMH Grant MH 27240-06.)

288.16 SINE WAVE ELECTRICAL STIMULATION AFFECTS SYNAPTIC FUNCTION IN THE HIPPOCAMPAL SLICE. S. M. Bawin, W. R. Adey, M. D. Mahoney* and A. R. Sheppard*. Research Service, VA Hospital, Loma Linda, CA 92357 and Dept. of Physiology, Loma Linda University, Loma Linda, CA 92350.

The effects of sinusoidal currents on field potentials were studied in the CA_1 pyramidal cell layer of rat hippocampal slices.

Transverse, 400 μm slices were continuously perfused (2 ml/min) at 32-35C with a physiological solution saturated with 95% O_2 - 5% CO_2. Warmed gas flowed above the solution in the recording chamber. The extracellular response to test pulses (monophasic square wave, 100-200 μsec, 20-100 μA) in strata radiatum et oriens was monitored using standard microelectrode techniques and recorded on magnetic tape for later analysis.

Focal sinusoidal currents (20-40 μA p-p, 60 Hz, 5-15 sec) through the stimulating electrodes (Pt-Ir, teflon coated, 0.2 mm tip separation, 30-50 Kohm) in either pathway induced short (2-20 sec) and long-term (minimum 5 min) potentiation of the field potential evoked by test pulses in the same pathway. Heterosynaptic depression, lasting for 5-30 sec, was observed concurrently in the non-potentiated synaptic input. Currents of higher intensities (50-100 μA p-p) induced temporary (5-90 sec) mono- and heterosynaptic depression of the evoked response.

Non-focal stimulation of the slices was achieved by sinusoidal currents (200-700 $\mu A/cm^2$) via agar electrodes in contact with the perfusing solution. The electric gradients in the bath were of the order of 10 to 40 mV/cm. Depression of the responses to test pulses in either afferent fiber system was seen occasionally during and shortly after bath current epochs (5-30 sec) in otherwise nonstimulated slices. However, after potentiation of the response either by focal 60 Hz sine waves or trains of pulses (3-10 sec), bath currents induced short lasting depression followed by further enhancement of the population spike amplitude and the number of peaks in the field potential evoked by test pulse stimulation in the potentiated synaptic input. Thus, the sensitivity of the response in the CA_1 pyramidal cell layer to extracellular weak currents appears to be increased by prior repetitive focal stimulation in afferent fibers. (Supported by Dept. of Energy Contract No. DE-AI01-79ET29078 and Southern California Edison Company.)

288.17 LATE DEVELOPMENT OF INHIBITION IN NEONATAL PIRIFORM CORTEX. J.E. Schwob, L.B. Haberly and J.L. Price, Dept. Anatomy, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The piriform cortex of rats is a good system for analyzing the development of neuronal connectivity from either an anatomical or physiological point of view. This study reports in vivo observations on unit activity and field potentials evoked by single and paired shock of the lateral olfactory tract (LOT) in adult rats and in neonatal rats ranging in age from PO (the day of birth) through P17. The rats were anesthetized with sodium pentobarbital (30 mg/kg) and nitrous oxide. The LOT and the cortex were exposed via an orbital approach, and the LOT was stimulated by a bipolar tungsten electrode. Conventional extracellular recording techniques with glass (1-8 M Ω) and tungsten (3-5 M Ω) microelectrodes were employed.

In adult rats units were reliably activated by a single low threshold stimulation of the LOT. In contrast, unit response to a second LOT shock was inhibited for up to 300 msec after the conditioning shock: with intershock intervals (ISI's) less than 100-150 msec single units could not be activated by stimulation up to 8x threshold and multiple unit activity was abolished. These results are similar to previously published observations in opossums (Haberly, J. Neurophysiol., 36: 762) and cats (Biedenbach and Stevens, J. Neurophysiol., 32: 193).

In newborns, units in piriform cortex were activated by stimulation of the LOT, but displayed relatively higher threshold and more variable latency. Inhibition following paired shock was markedly weaker in young pups and was apparent only with long ISI's. For example, from P0-P3 unit activity was actually facilitated with ISI's up to 150-200 msec, as demonstrated by a decrease in single unit threshold, an increase in multiple unit activity and an increase in the size of the population spike component of the field potential. Inhibition of evoked activity was apparent with ISI's of 250-750 msec. At P7 and P10, inhibition was evident shortly after the conditioning shock, but was generally stronger with ISI's exceeding 200 msec. At P15 and P17, a more adult-like pattern was observed. Field potential analysis in neonates demonstrated that paired shock increases the amplitude of the component generated by synaptic excitation of cortical dendrites by the LOT fibers; the timing of this facilitation is coincident with the period of unit facilitation at P0-P3 and weak inhibition at P6-P10. Therefore, the trend in neonates toward stronger inhibition with longer ISI's probably reflects the balance between synaptic facilitation and a weak inhibitory process; inhibition increases in strength as rats mature. (Supported by NIH grants NS09518 and GM 07200).

288.18 PAIRED PULSE FACILITATION IN HUMAN HIPPOCAMPAL FORMATION. Charles L. Wilson, Michael Wang*, Thomas L. Babb and Paul H. Crandall. Brain Res. Inst., Reed Neurological Res. Center, and Dept. of Surg./Neurol., Sch. Med., UCLA, Los Angeles, CA 90024

The excitatory synapses in the hippocampal formation are well known for their sensitivity to potentiation in the several forms in which it has been described (frequency, post-tetanic and long-term). In the present study we obtained preliminary evidence suggesting that synaptic mechanisms similar to those described in animals are present in the human hippocampal formation.

Testing was carried out in epileptic patients who had chronic temporal lobe depth electrodes for localization of seizure foci. Each electrode contained a bundle of platinum 40uM microwires (capable of resolving unit activity), which extended 5 mm beyond the macroelectrode tip. In order to assess the level of excitability of the hippocampus (anterior pes hippocampi, AP, and middle pes hippocampi, MP), entorhinal cortex (middle gyrus hippocampi, MG) and other limbic sites, pairs of conditioning (C) and test (T) pulses were delivered bipolarly to the macroelectrodes and bipolar responses recorded from the microwires (Lomo, Exp. Br. Res., 1973). Pulses were biphasic, symmetrical, 100 usec square waves, and pulse pairs were presented at rates below 0.1 Hz in order to avoid frequency potentiation.

An example of responses to stimulation of the right anterior pes (RAP) at an interstimulus interval of 200 msec is shown below. Recordings are from microwires 5 mm from the stimulating electrode in the same structure (RAP), 12 mm posterior in hippocampus (RMP), and 14 mm posterio-medially in entorhinal cortex (RMG). Three repetitions of the pulse pairs evoked stable C responses followed by prominent facilitation of the field potentials evoked by the T pulse (calibs: 100uV, 200 msec; charge density: 15 uC/cm^2/ph). Declining levels of facilitation (not shown) occurred as C + T intervals were increased to 400 and 800 msec. At 1600 msec intervals there was no evidence of potentiation. Note the facilitation in entorhinal cortex (RMG). Two other patients showed similar paired pulse facilitation of hippocampal field potentials at C + T intervals between 50 msec and 200 msec.

288.19 TRIMETHYLTIN: EARLY POSTNATAL ADMINISTRATION AFFECTS BEHAVIOR IN JUVENILE AND ADULT RATS. Diane B. Miller* and Robert S. Dyer (Spon: L. D. Grant). Neurotoxicology Division, US Environmental Protection Agency, Research Triangle Park, NC 27711.

Trimethyltin (TMT), when administered in a single dose to adult rats, produces hippocampal damage and a unique behavioral syndrome (Dyer et al., Neurobehav Toxicol. 1981). Since some compounds (e.g. triethyltin) produce more severe and lasting neurotoxicity when administered on postnatal day 5 than during adulthood, we characterized the effects of day 5 administration of TMT on learning and locomotor activity in juvenile and adult rats. On the day of parturition litters of Long-Evans hooded rats were cross-fostered and reduced to 4 male and 4 female pups each. On day 5 (birth = 0) one male and one female from each litter received 0, 5, 6 or 7 mg/kg TMT by intubation. Females were tested for their ability to acquire and perform a radial-arm maze learning task as juveniles (beginning at day 23). In this task efficient performance is characterized by a single entrance into each of 8 arms radiating from a center platform to obtain a food pellet. Both males and females were tested for locomotor activity in a figure-eight maze (Reiter et al., Envir. Hlth. Persp., 1975) as adults. TMT-treated rats acquired the radial arm maze task (i.e. entered and ate in all 8 arms) more slowly than controls. Although treated rats eventually acquired the task, there was a dose-related decrease in the efficiency with which they performed. Treated rats required substantially longer session times to obtain the same number of pellets as controls. This poor efficiency was not due to low activity since the treated rats tended to be hyperactive in the radial arm maze task. In the figure-eight maze TMT-treated males were more active than control males, but the TMT-treated females, perhaps because of their prior experience in the radial arm maze, were not more active than control females. These data indicate that postnatally administered TMT produces long-lasting changes in learning and activity. However, a single acute dose of TMT in the adult rat produces a more severe learning deficit (Walsh et al., SON, 1981) and greater hyperactivity (Ruppert et al., SON, 1981) than was found here. Thus the profile of behavioral toxicity for TMT differs as a function of age with adults being more sensitive to this toxicant than neonates.

288.20 A SPATIAL ANALYSIS OF POTENTIAL SPREAD IN HIPPOCAMPAL SLICES USING OPTICAL PROBES. M. Segal* and A. Grinvald (Spon:G.M.Gilad) Center of Neurosciences, The Weizmann Institute of Science, Rehovot, Israel.

A voltage sensitive membrane-bound merocyanine dye (WW 401) was used for optical monitoring of pre-and postsynaptic potential changes, evoked by electrical stimulation of an excitatory afferent pathway in CA1 region of 300 um thick rat hippocampal slices. The dye binds to neural membranes and changes its optical properties in response to changes in membrane potential. The optical signals thus reflect the averaged intracellular potential changes in a population of neural elements. An array of 10 x 10 photodetectors, positioned in the microscope image-plane was used to record electrical activity in a square area of 450 x 450 um. Conventional extra-cellular recording was performed in the stratum pyramidale with a glass micropipette. Stimulation of the stratum radiatum evoked fast signals (2-3 msec) in a strip of 90-180 um. This wave of fast signals travelled at a velocity of 0.2 m/sec along the Schaffer collateral system. These optical signals probably represent action potentials in the Schaffer collaterals, because (a) the signals were evoked in regions containing the Schaffer collaterals; (b) they persisted in low Ca^{2+} medium; (c) they were blocked by TTX; (d) the conduction velocity was similar to values reported previously for central unmyelinated fibers. A second wave of excitation followed the fast spikes with a delay of 2-10 msec. This wave travelled from the activation zone towards the stratum pyramidale and oriens. These slower responses were identified as EPSPs in the apical dendrites of CA1 pyramids. They were abolished by low Ca^{2+} and were enhanced by tetanic stimulation, TEA, picrotoxin, or low chloride. The changes in the optical signals were correlated with the changes in the electrical signals recorded with the microelectrode. Picrotoxin sensitive inhibitory potentials were also detected and had the largest amplitude in the border zone between stratum radiatum and pyramidale. On the other hand, the largest enhancement of excitation, in low chloride medium, was observed in the remote segments of the apical dendrites. Areas with similar morphology frequently showed different patterns of electrical responses. These experiments illustrate the potential usefulness of optical probes in the pharmacological and morphological analysis of local circuits in the mammalian brain. The resolution of optical method can probably be improved to allow recording from single cells. (as in invertebrate ganglia).

288.21 THE BENZODIAZEPINES AND THE HIPPOCAMPUS: MODE OF ACTION. K.H. Taber, R.W. Sikes and J.F. DeFrance. Dept. Neurobiology and Anatomy, U Texas Med. Sch., Houston, TX 77025.

The hippocampus has been widely used in the study of experimental epilepsy and antiepileptic compounds. As with many limbic system areas, it has been implicated in emotional functioning. Recently, benzodiazepine (BZD) receptors have been found within the hippocampus. The hippocampus is therefore an appropriate area in which to investigate the mechanisms of action of the BZDs.

Microstimulation and microrecording techniques were used in conjunction with microiontophoresis of the BZDs diazepam and chlordiazepoxide into specific layers of area CA_1 of dorsal hippocampus of the rabbit. Careful placement of the stimulating electrode allowed selective activation of either the Schaeffer Collateral pathway which terminates on the apical dendrites of the pyramidal cells (stratum radiatum) or the Commissural pathway which terminates on the basilar dendrites of the pyramidal cells (stratum oreins). Stimulation of these hippocampal paths at low frequencies (0.5 Hz) evokes very stable field potentials. Stimulation at higher frequencies (6.0 Hz) evokes a field potential which increases with each succeeding stimulation (tetanic potentiation, TP). Following the tetanus there is a period of increased excitability to 0.5 Hz stimulation (post-tetanic potentiation, PTP).

We have found that iontophoresis of BZDs into the area of Schaeffer Collateral termination in stratum radiatum has no effect on the field potentials evoked by 0.5 Hz stimulation, indicating that the BZDs have no effect on normal synaptic transmission in this pathway. However, both TP and PTP were altered. TP was slightly depressed. PTP was severely reduced both in amplitude and in duration. Iontophoresis of BZDs into the pyramidal cell body layer (stratum pyramidale) caused a decrease in the size of the population spike both at 0.5 and 6.0 Hz, reflecting a decrease in the excitability of the pyramidal cells. Neither TP nor PTP were significantly altered. Preliminary evidence supports the hypothesis that the decrease in the population spike is due to a BZD-mediated enhancement of GABAergic recurrent inhibition of the pyramidal cell body. We are currently investigating the possibility that the decrease in PTP is mediated by a BZD-induced decrease in cGMP in stratum radiatum.

288.22 THE EFFECT OF IONTOPHORETICALLY APPLIED VASOPRESSIN UPON LATERAL SEPTAL NEURONS. J.E. Marchand and N. Hagino, Dept. of Anatomy, Univ. of Texas Health Sci. Ctr., San Antonio, TX 78284.

Recent immunocytochemical studies have localized axonal fibers and terminals of vasopressinergic neurons in the lateral septal nucleus. In the present study electrophysiological techniques were used to examine the effects of iontophoretically applied vasopressin upon lateral septal neurons.

Field and unitary responses were recorded in the lateral septum of twenty-four urethane anesthetized rats after stimulation of the ipsilateral fimbria. In twelve of these rats, part of the cortex was removed, and stimulating and recording electrodes were positioned visually; in the remaining rats, electrodes were positioned stereotaxically. Iontophoresis electrodes, one or two barrels, were filled with 0.15 mM arginine-vasopressin (AVP) (Boehinger-Mannheim) dissolved in 0.15 M NaCl, pH 4.2, or with the NaCl solution alone, and glued to a glass recording pipette, tip separation 25-50 µm. AVP was ejected as a cation, with currents ranging from 15-80 nA.

Fimbria stimulation (100-200 µsec pulse, 100-400 µA) evoked a negative field potential, 5-8 msec latency, in the lateral septum. In twelve of the twenty-three field responses studied, AVP iontophoresis effected a 30% or greater suppression of the negativity. Iontophoresis of the control solution produced no changes greater than 20% of the control response.

For the unitary studies, fimbria stimulation intensities were adjusted to threshold levels, such that action potentials (5-9 msec latency) arising out of the negative field potential were evoked with an average frequency of 70%. Iontophoresis of AVP onto thirty-eight neurons produced a decrease of fimbria evoked action potentials of 30% or greater in twenty-eight of these cells. No increases were seen. Suppression of evoked responses by AVP developed within an average time of two minutes after iontophoretical application. Iontophoresis of the conrol solution on fourteen neurons produced no changes of the fimbria evoked action potentials greater than 30%.

Recent studies have shown that intracerebroventricularly injected vasopressin can increase theta frequencies of the hippocampus. Since theta frequencies are controlled in part by the reciprocal connections between the septum and hippocampus, the present study indicates that the effects of vasopressin on theta frequencies might be mediated by its ability to modulate hippocampal inputs to the lateral septum and, consequently, the lateral septal input to the medial septum. (Supported by NIH Grant NICHD-1007).

288.23 FETAL BRAIN TRANSPLANTS IN HIPPOCAMPAL-LESIONED RATS: PRELIMINARY FINDINGS. D. P. Kimble, R. BreMiller* and C. R. Stickrod*.

Fragments of posterior telencephalic tissue from fetal rats, aged 15 to 19 days (of gestation) were transplanted into the brains of 20 young adult host rats which had just received small bilateral aspiration lesions of the hippocampal formation. All animals used were from the Charles River Sprague-Dawley strain (CD, random bred). The fetal tissue was placed directly into the cavity produced by the lesion. Both donors and hosts were male. Hosts were from 75-90 days of age at time of operation. Six control animals received bilateral hippocampal lesions but no implant (Group HC). Following uneventful recovery from surgery, all animals were trained and retested twice on a battery of three complex spatial mazes in the Hebb-Williams apparatus across a 6 months period. Following sacrifice, sequential cryostat sections from each brain were stained with cresyl violet and luxol fast blue for Nissl material and myelin, with reduced silver for nerve fibers, and with histofluorescent techniques for monoamines. Examination of the host brains revealed that 6/20 (30%) showed little or no surviving graft tissue (Group I). The remaining 14 (70%) all showed some viable tissue with neurons clearly visible in the transplanted material. These were divided into two groups: Group II (N=7) showed viable transplant tissue, but connections between transplant neuropil and host tissue were absent or marginal. Group III (N=7) showed considerable viable transplant tissue and appeared to share a common neuropil with the host tissue. No behavioral differences were seen on maze acquisition scores between any groups. On the two retests, Group III scored from 13 to 28% fewer errors than any other group, but these were not statistically significant differences. A comparison of Groups II and III (some viable transplant tissue) vs. Groups I and HC (no viable transplant tissue) on the two retention tests narrowly missed the .05 level of significance (Mann-Whitney U=55), with the Groups II and III making an average of 141 total errors (6 mazes) as compared with 163 total errors for Groups I and HC. A rank-order correlation of lesion size and error score among Groups I, II and III was not significant (r_s = -0.13).

288.24 ACQUISITION OF HIPPOCAMPAL SELF-STIMULATION IS FACILITATED BY EITHER KINDLING OR BY A SMALL CONTRALATERAL LESION. Kenneth A. Campbell and N. W. Milgram. Dept. of Psychology, University of Toronto, Scarborough College, West Hill, Ontario, Canada.

We have previously reported that while rats are usually very slow to learn to lever-press for hippocampal (HPC) stimulation, acquisition is markedly facilitated by pretreatment with a program of single daily electrical stimuli to the HPC electrode, leading to a gradual development of convulsions (kindling)(Brain Res.,159,458). Facilitation is also obtained if acquisition for self-stimulation (SS) is tested at the homotopic site contralateral to the kindled site, suggesting that the effect is not due to a known local increase in excitability at the kindled site (Neurosci. Abstr.,5,271). However, to rule out such excitability effects at the kindled site, acquisition must be tested at the contralateral locus, following a lesion to the kindled site.

Forty-eight rats were implanted bilaterally with electrodes in CA3 of the dorsal HPC: 32 rats received a 20-day kindling pretreatment; 16 control rats were handled identically but not stimulated. At the end of the kindling phase, half of the rats in each group received a small lesion in one HPC: half of the kindled rats were lesioned at the kindled site and half at the contralateral site. Lesions were $\leq$ 1 mm dia. and were restricted to CA3. After 4 days, the rats were placed in Skinner boxes and allowed to press the lever in daily 30-min sessions. Two days of responding without reinforcement preceded SS training: 16 rats were tested for SS at the kindled site (IPSILATERAL), 16 were tested for SS contralateral to the kindled site (TRANSFER), and 16 UNKINDLED controls were tested in one HPC — with half of the animals in each group having received a lesion contralateral to the SS site. Thus, the kindled site was lesioned only in 8 of the TRANSFER animals.

Results for the intact groups replicated the previous findings: kindling significantly facilitated acquisition whether SS was tested at the kindled site or at the contralateral site. Lesions of the kindled site did not affect the facilitation of acquisition in animals tested at the contralateral site.

An unanticipated result was that the lesion alone significantly facilitated acquisition for SS at the contralateral site. After the first 2 days of SS testing, the magnitude of the facilitatory effect of the lesion was not significantly different from the facilitatory effect of the kindling pretreatment. Since unreinforced operant rates were unaffected, a non-specific effect on activity is unlikely. Hypotheses involving the removal of inhibition of the SS substrate, denervation supersensitivity, and sprouting of CA3 projections are currently under investigation.

289.1 THE EFFECTS OF CHLORPROMAZINE ON THE BRANCHING PATTERNS OF DIFFERENTIATING CEREBELLAR PURKINJE CELLS. R.S. Hannah*, A.W. Spira* and S.H. Roth, Departments of Anatomy and Pharmacology and Therapeutics, University of Calgary, Calgary, Canada.

The purpose of this study was to examine the effect of chronic administration of chlorpromazine (CPZ) on the dendritic growth of developing Purkinje cells in the rat cerebellum. CPZ (15 mg/Kg) was administered subcutaneously to timed-pregnant Long-Evans rats beginning on day 18 post-coitus. Maternal drug administration was continued daily until the litters were killed at various time intervals up to 21 days postnatal (pn). The cerebella were removed and processed using a conventional rapid Golgi technique. Camera lucida drawings were utilized to quantitate the following parameters - order of branching, length of branches and numbers of branches.

The branches were ranked by order according to the reversed Strahler method. By day 9 pn most of the Purkinje cells from the treated animals had established one additional order of branches over that observed in controls. This condition persisted at three weeks pn.

Comparing the lengths of individual orders of branches demonstrated that by two weeks pn the length of the second and subsequent orders of branches in treated animals were significantly greater ($p < .01$) than in control animals.

The mean number of branches per order with the exception of first order dendrites were significantly reduced ($p < .01$) in the treated groups at two weeks pn. By day 21 pn, there was no significant difference in branch number per order, for orders one to four. However, fifth and higher order branches in the treated groups were significantly increased ($p < .01$) over control values.

Over the three week pn period examined, the general reaction of Purkinje cells from CPZ treated animals was increased dendritic growth. The increased growth may reflect an attempt by the Purkinje cells to compensate for the depletion in total Purkinje cell number and reduction of dendritic spine densities reported in previous studies from this laboratory.

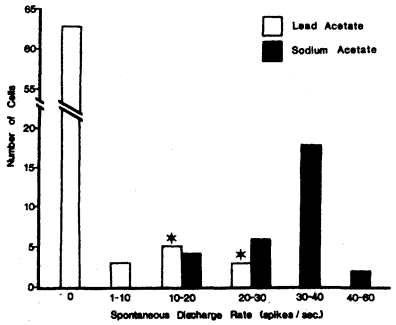
289.2 EFFECTS OF NEONATAL THYROID DEFICIENCY ON RAT BRAIN CATECHOLAMINES, SEROTONIN AND PEPTIDE LEVELS. T. Di Paolo*, A. Dupont*, P. Savard*, Y. Mérand*, N. Barden* and J.H. Dussault* (SPON: G. Pelletier), Dept. d'Endocrinologie Moléculaire and Lab. en Biologie du Développement, Centre Hosp. de l'Univ. Laval, Québec G1V 4G2, Canada.

It is well known that neonatal thyroidectomy results in a marked impairement of brain differentiation and leads to the "cretinoid" condition. Since thyroid disorders can influence biochemical specialization of cells as reflected by changes in the development of neurotransmitter receptors in CNS, we studied the effect of neonatal hypothyroidism on the content of norepinephrine (NE), dopamine (DA), serotonin (SER), substance P (SP) and thyrotropin-releasing hormone (TRH) in various brain nuclei dissected by a micro-punch technique. Rats were made hypothyroid by injection of 125 µCi of carrier-free ^{131}I on the first day after birth. Half of this group of animals were subsequently treated with thyroxine (T_4). A third group of littermates were permitted to mature normally. Rats were sacrificed after 45 days by decapitation and subsequently peptide, catecholamine and serotonin contents were measured by RIA, radioenzymatic and LCEC assays, respectively. Few changes in NE and DA distribution were observed in hypothyroid animals. TRH content was decreased by 75% in median eminence, while little increases were seen in medial preoptic nuclei. In contrast to the very localized effects of hypothyroidism on TRH distribution, the effect on central nervous system SP and SER content were both widespread and stimulatory. Indeed, more than half of the 32 brain nuclei assayed displayed significant increase in SP: among them are substantia nigra, nucleus interpeduncularis, nucleus habenulae lateralis, striatum, tractus diagonalis, nuclei of amygdala and preoptic nuclei. Serotonin was increased in nuclei of the raphe, substantia nigra, area ventralis tegmenti, nucleus interpeduncularis, nucleus mamillaris, amygdaloid nuclei, medial forebrain bundle and several hypothalamus nuclei. While thyroxine replacement therapy corrected all the peptides anomalies, T_4 failed to decrease serotonin to control levels in several of the nuclei studied. Evidently, more information is required to establish the influence of neonatal thyroid deficiency on the development of catecholaminergic, serotonergic and peptidergic systems in the CNS. These significant alterations of SP and SER content lend support for an important participation of the substance Pergic system in brain neurotransmission and its possible interrelationship with serotonergic system.

289.3 ELECTROPHYSIOLOGICAL CHANGES OF CEREBELLAR BRAIN GRAFTS EXPOSED TO CHRONIC LOW LEVEL LEAD DURING DEVELOPMENT. L. Olson*†, H. Björklund*†, Å. Seiger*†, J. Marwaha, M.R. Palmer, D.A. Taylor*, R. Freedman*, and B.J. Hoffer*. (SPON: Dr. S.M. Wuerthele.) Depts. of Pharmacology and Psychiatry, Univ. of Colorado Health Sciences Center, Denver, CO 80262; †Dept. of Histology, Karolinska Institutet, Stockholm, Sweden.

The effects of perinatal lead administration on developing rat brain was studied using cerebellar grafts in oculo. Using 1% lead acetate in the drinking water, little change was seen in the survival, growth or histological organization of the graft. In marked contrast, virtually all Purkinje cell spontaneous discharge was absent in these grafts. This was seen even though 4-5 months had elapsed between recording and the cessation of lead treatment. There was no alteration in electrophysiological properties of transplant Purkinje cells from sodium acetate-treated animals.



Moreover, host in situ cerebellar Purkinje cells in both groups of animals discharged normally. These data indicate that lead administration, eliciting blood levels of 450-550 µg/l, produces a long-lasting selective electrophysiological deficit in developing brain in oculo.

Supported by the Swedish Council for Planning and Coordination of Research (79/1027, Al-5/251), the Swedish Medical Research Council (14X-03185, 14P-5867), and USPHS (ES-02011 and MH-00289).

289.4 BRAIN-DAMAGED NEONATAL RATS: RELATIONSHIP BETWEEN DOPAMINE, NOREPINEPHRINE, AND SEROTONIN AND THE DEVELOPMENT OF OPEN-FIELD LOCOMOTOR ACTIVITY. C. Robert Almli, Mark A. Henault,* Craig A. Velozo,* Patricia A. McGinley,* and Edward B. Truitt, Jr.* Washington University School of Medicine, St. Louis, Missouri 63110 and Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

Brain dopamine depletion in developing rats is suggested as an experimental model of minimal brain dysfunction (Shaywitz et al Science, 1976, 191, 305). The present investigation determined if electrolytic brain damage resulted in developmental activity alteration, and determined the relationship between levels of locomotor activity and brain dopamine (DA), norepinephrine (NE), and serotonin (5-HT).

Forty-eight albino rats were randomly assigned to lateral hypothalamic area (LHA, N=9), ventral tegmental area (VTA, N=11), or control (N=28) groups. At 4 days of age, the LHA and VTA rats sustained bilateral electrolytic destruction.

Body weight and open-field locomotor activity were measured daily from 4 days of age. At 50-60 days of age the straitum and frontal cortex were dissected. Measurement of DA, NE, and 5-HT used Liquid Chromatography with Electrochemical Detection (LC-EC).

LHA rats weighed less than control from the first few days post-surgery. LHA rats displayed higher activity scores than control immediately postsurgery and later during development. Striatal DA (-63%), frontal cortex DA (-82%), and striatal 5-HT (-44%) were depleted. VTA rats did not differ from control for body weight, however, they displayed higher activity scores than control after 16-17 days of age. These rats displayed depletion of striatal DA (-80%) and frontal cortex DA (-87%). A negative correlation (r=-.55) was found for striatal DA and activity level.

Results show that electrolytic lesions of the LHA and VTA of neonatal rats are associated with elevated locomotor activity, and this hyperactivity is associated with DA depletion in striatum and frontal cortex. Hyperactivity was found with (LHA), and without (VTA), body weight reduction. While this supports Shaywitz, it is interesting to note the association of early hyperactivity for LHA rats with striatal 5-HT depletion; and the near-total (>90% depletion) striatal DA depletion for VTA rats with low locomotor activity.

289.5 CHRONIC HALOPERIDOL-INDUCED HYPERACTIVITY IN DEVELOPING RATS: EFFECTS OF LITHIUM AND STIMULANTS. J.T. Concannon and M.D. Schechter. Dept. Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

Chronic administration of neuroleptic drugs has been shown to produce behavioral hyperactivity in neonatal and adult rats and an augmented response to catecholaminergic agonists. Supposedly, these effects result from chronic blockade of central dopamine (DA) receptors which is inevitably followed by DA receptor supersensitivity, as indexed by an increased number of DA receptors. In addition, neuroleptic-induced supersensitivity is generally reduced in adult rats by coadministration of lithium with haloperidol, whether the supersensitivity has a pre- or post-synaptic origin.

In the present experimentation, we investigated if chronic neonatal administration of haloperidol would produce hyperactivity in developing rats in a manner mimicking the human situation. More specifically, we were concerned with whether this model would mirror the temporal onset, duration, and offset of the hyperactivity in humans and whether hyperactivity could be prevented by lithium coadministration or be attenuated by effective doses of psychostimulants. To test these notions, neonatal rats were chronically administered haloperidol subcutaneously at doses of 0, 0.25 or 2.5 mg/kg daily from days 5 to 14 of life. Furthermore, one-half of these pups were raised by mothers exposed to a lithium diet (Pert et al, Science, 201:171, 1978) while the other half were raised by normal-diet mothers. Pup activity was observed using a time-sampling technique at 15, 20, 25 and 30 days of age, 30 minutes after an intraperitoneal injection of either saline, d-amphetamine (0.20 or 0.50 mg/kg), or methylphenidate (0.20 mg/kg) Results showed that high-dose haloperidol produced hyperactivity at 25 and 30 days of age in pups of mothers receiving the normal diet. This hyperactivity was manifest as a failure of the haloperidol group to decrease their activity in early adulthood. Surprisingly, not only did administration of lithium not prevent hyperactivity in haloperidol-treated pups, but rather it too produced overactivity in developing pups. Lastly, neither stimulant was able to reduce activity in haloperidol-or lithium-treated over active rats, although the stimulants did increase activity in control pups receiving neither haloperidol nor lithium. These results cast considerable doubt upon the notion that chronic neuroleptic-induced DA receptor blockade provides a viable animal model of the human hyperkinetic syndrome, since the temporal course is not sufficiently similar to humans and since clinically-useful drug regimens are virtually ineffective in reducing hyperactivity. (Supported by NIMH grant No. 33636-02).

289.6 Neonatal Kepone Exposure Impairs Learning/Retention Abilities in the Rat. K.L. Unger*, C.F. Mactutus, and H.A. Tilson (SPON: C.L. Mitchell). Lab. of Behav. Neurol. Toxicol., NIEHS, Research Triangle Park, NC 27709.

The neurobehavioral consequences of Kepone in animals have been studied following adult, prenatal, and combined pre- and postnatal exposures. The present study examined the consequences of a neonatal exposure to Kepone, during a period of sexual differentiation of the brain, on neurobehavioral development prior to weaning. Learning/retention abilities were evaluated as the use of "cognitive" behaviors are particularly sensitive indices of neurotoxicity (Neurosci. Abst. 6:740, 1980).

Neonatal Fischer 344 rats were given a single s.c. injection (20 µl) of either dimethylsulfoxide (DMSO) or 1 mg/pup of Kepone dissolved in DMSO on postnatal day 4. Body weights were slightly, but significantly, depressed for Kepone exposed males and females by day 14 (11% and 10%, respectively) and remained so through 21 days of age (8%). Other neurotoxic effects included a delay in eye opening for the male pups and precocial vaginal opening for the female pups. Passive avoidance acquisition occurred within 2 trials for all pups, but a significantly greater proportion of Kepone exposed pups required the second trial to attain a 60 sec response withholding criteria (12/48 Kepone vs 3/47 DMSO). This impairment was most pronounced, but not restricted to, the male pups. Independent groups tested 24 or 72 hr post-training indicated a significant loss of memory over time for the Kepone relative to the DMSO males, with no effect in the females. When the male pups originally tested at 24 hr were retested at 72 hr significant extinction had occurred for the DMSO pups, but not for the Kepone pups. This latter "protection of memory" was attributed to increased emotionality expressed by a freezing response as both plasma and adrenal steroid levels were elevated (39% and 45%, respectively) in Kepone relative to DMSO pups sacrificed 5 min after testing.

The highlights of the present data are 1) a significant deficit in learning/retention ability consequent to neonatal Kepone exposure, and 2) the greater resistance of female over male pups to the neurobiological consequences of Kepone exposure on nonsexual behaviors. This latter conclusion stands in marked contrast to the well known alterations induced by the estrogenic qualities of Kepone on female sexual development and behavior.

289.7 GENE EXPRESSION IN BEHAVIORAL SYSTEMS. B. E. Ginsburg, Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT 06268.

Complex behavioral phenotypes have often been shown to have a simple genetic basis. In some instances, this is demonstrably because a structural gene produces a network of effects, all radiating from a single defect produced at a particular time in development (e.g., Grüneberg's "pedigrees of causes"). In others, the genetic differences appear to act as regulators of the expression of gene assemblies, either by shifting thresholds for their expression, or through selective de-repression as, for example, by hormonal mechanisms. Data will be presented from three categories in which the behavioral expression of a complex phenotype is apparently controlled by means of genetic regulation of alternative gene assemblies that are physically present, but depend upon a triggering mechanism for selective activation. These are: brain laterality studies in humans, where a single genetic threshold model has been investigated; heterosomal determination of thresholds to environmental input in the expression of aggression in mice; and the selective expression of species-specific threat behavior in coyote X beagle hybrids. In the latter, the preweaning expression of the behavioral pattern appears to be genetically independent of its post-pubertal expression, which may be hormone dependent. Implications of these data and concepts will be discussed in relation to canid speciation, where the karyotypes, serum proteins, red cell antigens, and tissue antigens are virtually identical, yet the phenotypic differences are profound enough to have resulted in speciation.

This research was supported by USPHS grants MH28021 and MH35908, and by grants from The Harry Frank Guggenheim Foundation and the Connecticut Research Foundation.

289.8 TISSUE-SPECIFIC REGULATION OF SOME GLYCOSIDASES IN CEREBRAL CORTEX AND CEREBELLUM OF WILDTYPE AND MUTANT MICE. W. Wille* and E. Trenkner. Inst. F. Genetik, Univ. of Cologne, Fed. Rep. Germany and Dept. of Pharmacology, NYU Med. Ctr., New York 10016.

Cell surface carbohydrate (CHO) patterns change during development of normal mouse cerebellum (1). These changes are significantly altered in the neurological mutant staggerer (sg/sg) (2). The membrane bound neuraminidase, possibly involved in cell surface CHO-metabolism, is also regulated during development of cerebral cortex and cerebellum; peak activities are observed at postnatal day 3 (P3) and P27 in normal cerebrum and at P3 alone in cerebellum. However, sg/sg cerebellum a comparable peak activity is delayed until P27 and this might be responsible for the aberrant patern of surface CHO also observed (3).

In this study 5 other glycosidase activities were determined during development of cerebellum and cerebrum of +/+ (C57 Bl), sg/sg and weaver (wv/wv) mice. α-glucosidase (pH 3.7) showed no obvious regulation while α glucosidase (pH 6.0) and β-galactosidase decrease continuously with age in both tissues and all strains tested. Significant differences, however, were expressed in N-acetyl-β-hexosaminidase (NAc-β-glucosaminidase and NAc-β-galactosaminidase) in cerebellum compared to cerebrum. While this enzyme in +/+ cerebellum showed a brief peak of activity at P7, cerebral activity increased approx. 2.5 fold between P3 and P16 and maintained this high activity level through adulthood. In sg/sg cerebellum activity of this enzyme was abnormal and corresponded more to +/+ and sg/sg cerebrum than to +/+ cerebellum. Strikingly in wv/wv, no such variation from +/+ was observed even though wv/wv granule cells degenerate to the same extent as in sg/sg.

We conclude that 1. of the enzymes studied only NAc- -hexosaminidase is regulated, 2. that the age-dependent pattern of regulation of this enzyme is different from cerebrum to cerebellum, and 3. that the cerebellum-specific regulation of this enzyme is significantly altered sg/sg but not in wv/wv.

289.9 CORTICAL ORGANIZATION AND CYTOLOGICAL ABNORMALITIES OBSERVED IN SCLEROSIS TUBEROSA. A Golgi Study. R. Armada*, J. Espinosa* and J.P. Machado-Salas. Div. de Neurociencias, Neuromorfología, ENEP Iztacala, UNAM. and Div. de Patología, Depto. Inv. Cient. CMN. IMSS. México D.F

It shall be described the structural changes that were observed in a cortical biopsy from a case of sclerosis tuberosa. The tissue was taken from a 12 year-old female patient, who showed intractable seizures and severe mental retardation. Her father and two other siblings also showed clinical features of epiloia. The biopsy was performed, under written permission, for diagnostic, pronostic and counseling purposes.

Thus far, it has been established a close correlation between the degree of maturation of normal psycho motor functions and the anatomical complexity shown by the neuropile; nevertheless, the opposite has not yet been demonstrated, i.e.: that a given degree of mental retardation has, as a counterpart, a given degree of abnormal neuronal ciruitry. The data here shown aim to stregth this hypothesis.

The tissue was promptly obtained and fixed, and processed with the rapid-Golgi modification. Our observations are: a) Astrocytic proliferation at the superficial and deeper layers of a rather compact cerebral cortex. b) Presence of atypical neurons, with few branches, without spines, and somatodendritic distortion. These cells were spreaded throughout the cortical layers. c) Unusual neuroglial contacts, and d) Bizarre and and abnormal patterns shown by dendritic spines, from long, hairy-ones up to "megaspines".

Our findings have shown: I. The presence of abnormally developed nerve-cells in other places than "tuberes or heterotopies. II. The presence of peculiar neural and glial anatomical abnormalities, and, in some cases, interactions, which may bear some functional significance. And, III. A putative correlation between structure and function, under pathological conditions.

289.10 MORPHOMETRIC ALTERATIONS IN THE HIPPOCAMPAL FORMATION OF DEVELOPING AND ADULT RATS FOLLOWING EARLY POSTNATAL LEAD EXPOSURE. J.B. Campbell*, D.E. Woolley*, V.K. Vijayan and S.R. Overmann* (SPON: G. P. Moberg). Dept. of Animal Physiology, Univ. of California, Davis, CA 95616.

Neurogenesis and differentiation in the hippocampal formation in rodents and man continue during the early postnatal period, and may be influenced by environmental toxicants. Hippocampal malfunction is thought to underlie symptoms of childhood lead excephalopathy such as seizures and behavioral changes. Therefore we examined the structure of the hippocampal formation by light microscopy and analyzed several subfields of the suprapyramidal mossy fiber zone by electron microscopy in lead-exposed and control rats at 15 days and 3 months of age.

In this study 0.2% lead acetate (1090 µg lead/g solution) was substituted for drinking water of dams from the day of parturition until weaning at postnatal day 20 (P20). Litters were culled to 6 females on the day of birth and were maintained at 4-6 pups until weaning. A single pup from 8-10 litters of each treatment group was perfused with aldehydes at P15 and between P90 and P97 for light and electron microscopic analysis of the hippocampal formation.

Lead-exposed rats showed no weight reduction, paraplegia, gross vascular damage, pyknosis or other signs of encephalopathy or overt cytotoxicity. At P15 the areas of some neuropil layers in the dentate gyrus were reduced and the number of neurons/unit area in some areas of the hippocampal formation was increased. In these same regions the number of neurons/unit area in lead-exposed rats at P90-97 was reduced. At P90-97 the area of these neuropil layers in lead-exposed rats was equal to that in controls. At both ages a part of the suprapyramidal mossy fiber zone which is supplied by the infrapyramidal limb of the dentate gyrus showed fewer mossy fiber synaptic profiles per unit area in lead-treated than in control rats.

These data show that neonatal exposure to low levels of lead caused both transitory and long-term alterations in hippocampal neuropil. These effects were limited to late-developing regions, especially those related to the infrapyramidal limb of the dentate gyrus. (Supported by NIH grant #ES 01503.

289.11 NORMALIZATION OF WEIGHTS OF VARIOUS BRAIN REGIONS AFTER TREATMENT OF GRAFT-VERSUS-HOST-DISEASE (GVHD). S. Duncan, J.R. Head, and W.S.T. Griffin (SPON: R.M. Stewart). Dept. of Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

The potential for regrowth and plasticity of the CNS was investigated in 14-day-old rats that received effective immunotherapy for a neonatally induced immunological syndrome, graft-versus-host-disease (GVHD). Previously, we showed that there are a number of alterations in cerebellar development in this disease which is characterized by, among other symptoms, an ataxic gait. For example, cerebellar weight, DNA, RNA and protein contents, DNA and RNA synthesis and the relative abundance of specific messenger RNAs are all significantly altered by GVHD. Further, we have shown that each of these parameters of cerebellar growth are amenable to regeneration. Here, we hypothesized that GVHD would similarly effect the growth of other brain areas. The experimental groups were as follows: One group contained one-third of the pups and received no treatment at birth (C). The other group contained two-thirds of the pups, and each of these pups was grafted by an intravenous injection of 20×10^6 lymph node cells from an allogeneic donor, viz., a DA adult rat (E). This latter group was further subdivided so that one-half of these pups received 3 injections, on postnatal days 11, 12 and 13, of syngeneic serum containing high titers of antibodies to their allogeneic graft, i.e., FI anti-DA serum (I). To test our hypothesis, we weighed hypothalamus, thalamus, pons, midbrain, cortex and hippocampus expecting that the latter two, because of their continued postnatal growth, might be particularly susceptible to a growth retarding disease such as GVHD. Further, we sought to determine whether or not treatment of GVHD with an alloantiserum, which reverses deleterious effects on neuronal cell growth in cerebellum, would be effective in reversing GVHD-induced cerebral growth retardation. We found that similar to cerebellar weight changes, both cortex and hippocampus weights were significantly less in 14 day old diseased animals and that treatment with alloantiserum begun at day 11 permitted a significant weight gain in these areas. It will be interesting to study the concomitant changes in cell acquisition and function which likely accompany the weight changes noted in cortex and hippocampus during and after GVHD.

289.12 NORMALIZATION OF DNA SYNTHESIS AFTER TREATMENT OF GRAFT-VERSUS-HOST-DISEASE (GVHD). C. Pevetoe, J.R. Head and W.S.T. Griffin. Dept. Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

Previously, we showed that as early as postnatal day 11 an immunological disease (GVHD) induced by grafting allogeneic lymph node cells (LNC) into an immunoincompetent neonatal rat, significantly decreases cerebellar histogenesis, i.e., DNA synthesis and the number of newly formed neurons. However, subsequent to immunotherapy, there is a reversal of the deleterious, GVHD-induced alterations. Immunotherapy involves injecting the diseased rats on postnatal days 11, 12 and 13 with alloantiserum specifically directed against the grafted LNC. In order to determine whether or not the time course of the accumulation of DNA was affected in a reversible way by GVHD, we utilized autoradiographic techniques which showed that there were differences not only in the number of cells entering the synthesis phase (S) of the cell cycle, but there was also less synthesis per cell in rats with GVHD. Conversely, alloantiserum treated rats were synthesizing cerebellar DNA more nearly like littermate controls. On postnatal day 14, diseased, serum treated and control littermates were injected with ^3H thymidine and fifteen minutes later, the cerebella were excised and processed. The external granular layer (EGL) at the midsagittal section in the fissure between VIa and VIb was examined in each of the animals. The presence of 6 or more autoradiographic grains above a cell was used to denote active synthesis of DNA. A segment of EGL 0.72 mm in length was searched for labeled cells. GVHD rats had few labeled cells ($\bar{x}=3.8 \pm 2.3$) and the number of grains per cell was low ($\bar{x}=6.6 \pm 0.6$) compared to serum treated rats which had a greater number of labeled cells ($\bar{x}=26 \pm 8.2$) and grains per cell ($\bar{x}=7.4 \pm 0.2$). The control group had the greatest number of labeled cells ($\bar{x}=43 \pm 3.8$) and the greatest number of grains per cell ($\bar{x}=9.5 \pm 0.2$). These results indicate that the decreases in total DNA content and synthesis previously noted in GVHD rats is due to a decreased ability to enter S phase coupled with a slowing of the cell cycle shown by less incorporation of label into the DNA of individual mitotically active EGL cells. Treatment with alloantiserum allowed more cells to enter synthesis, and the cell cycle returned to near the control level. We, therefore, conclude that a systemic immunological process which does not result in cerebellar inflammation can slow the cell cycle. Conversely, alloantiserum treatment reverses the deleterious effect, thus attesting to the plastic nature of neuronal cell acquisition in the developing cerebellum.

289.13 NORMALIZATION OF CEREBELLAR RNA SYNTHESIS AND TRANSLATION AFTER TREATMENT OF GRAFT-VERSUS-HOST DISEASE (GVHD). W.S.T. Griffin, J. Snider and M. Morrison. Depts. of Cell Biology and Neurology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

Analysis of 2d gels (two dimensional gel electrophoresis) of specific abundant proteins synthesized both in vivo and in vitro by rat cerebellar RNAs, shows that the amounts of such messenger RNAs (mRNAs) and their protein products vary with age (2 to 90 days). In addition, the quantities of certain of these mRNAs and proteins, and, indeed the presence of some, are related to the immunological status of the individual. For example, we have shown that neonatal rats with graft-versus-host-disease (GVHD) 1) synthesize significantly less cerebellar RNA, 2) have RNA which is less translationally active and 3) have changes in the proportions of different mRNAs including the induction of one coding for protein "r" which is neither present in control cerebella at any age nor in other brain regions. This systemic disease, induced by intravenous injection of 20 X 10^6 allogeneic (DA) lymph node cells into a newborn Fischer (FI) rat, is characterized by a number of systemic manifestations including an ataxic gait and dramatic alterations in cerebellar cell acquisition and function. Here, we report on the ability of the cerebellum to recover from the previously-reported, GVHD-induced changes in the synthesis of total RNAs and the relative abundance of specific mRNAs. In order to halt the disease, 11-day-old diseased animals were injected with 0.2 ml of hyperimmune serum (FI anti DA) daily for 3 days. By the eleventh postnatal day there are significant decreases in DNA and RNA synthesis and in the number of newly formed neurons. On postnatal day 14, cytoplasmic RNAs were isolated from the cerebella of such serum treated animals, their diseased littermates which were not treated with serum, and littermate controls. After the three days of serum treatment, DNA and RNA synthesis and the acquisition of neurons had returned to near control levels. Comparison, by 2d gel analysis, of in vitro synthesized mRNA translation products showed that "r" was not synthesized by cerebellar RNAs isolated from serum treated animals, indicating that the disease is arrested at the molecular level. This study supports the idea that there are periods in cerebellar development during which deleterious effects can be reversed and suggests that such reversal is accompanied by alterations in the levels of specific mRNAs and their translation products.

289.14 PERSISTENT ALTERATIONS IN BRAIN MONOAMINES FOLLOWING FRONTAL CORTEX LESIONS IN NEONATAL AND ADULT RATS. M. K. Shellenberger and A. S. Kimes, Dept. of Pharmacology & Smith Center for Mental Retardation, Kans. Univ. Med. Ctr., Kansas City, Ks. 66103.

While there exists a fairly large literature concerning the persistent behavioral and morphologic consequences of perinatal brain trauma, there is little information concerning the residual effects on neurotransmitter systems. This study compares the long-term effects of trauma in neonates and adults.

Adult Sprague-Dawley rats were purchased at 12 wks of age and maintained until fully adult (16-20 wks). Infants were bred in our animal facilities. Litters were cross-fostered and reduced to 8 pups within 48 hrs. At 5 days pups were randomly assigned to one of the following treatments: 1) handled but untreated, 2) anesthetized and sham operated, 3) anesthetized and the cortex exposed from the coronal suture to the olfactory bulbs. Frontal cortex was removed bilaterally leaving the poles, olfactory structures and saggital sinus intact. Groups of adult rats were treated in an analogous fashion. Adults were sacrificed 6 to 8 wks later while infants were raised to adulthood and sacrificed at 16 to 20 wks. The brains were sampled and assays performed for dopamine (DA), norepinephrine (NE) and 5-hydroxytryptamine (5-HT).

Neonatal sham surgery caused an increase in cortical DA and decreases in NE in the brainstem regions. These effects were greater in males. The lesion also resulted in a decrease in midbrain NE and in addition significantly decreased striatal DA. In females this was accompanied by increases in both NE and 5-HT. Males were found to have increases in NE and 5-HT in the pons-medulla. In the areas of cortex posterior and lateral to the lesion, 5-HT increased moderately while DA increased several fold.

The sham procedures produced permanent reductions in 5-HT in adult cortex and brainstem. Lesioning produced a decline in striatal DA, as in infants, and decreases in brainstem NE. Lesioning increased 5-HT in males in all areas. Increases in striatum of both sexes were particularly remarkable.

There are marked differences between the manner in which the infant and adult brain monoamine systems respond to trauma and some sexual dimorphism. The effects resemble those seen with carbon monoxide-induced hypoxia. Further exploration of these similarities may shed some light on the common pathways by which various forms of perinatal trauma produce similar behavioral abnormalities. Supported by USPHS Grants MH-27739 and BRSG-S07 RR05373.

289.15 LEAD EFFECTS ON NEONATAL ACTIVITY AND HIPPOCAMPAL AFTERDISCHARGE CHARACTERISTICS. M. McCarren* and C.U. Eccles* (SPON: N. Khazan). Dept. of Pharmacology and Toxicology, Univ. of Md. Sch. of Pharmacy, Baltimore, MD 21201.

Attempts have been made to link neural deficits in children with chronic low level lead (Pb) poisoning. The present study was designed to expose developing rats to low Pb levels and assess spontaneous locomotor activity during that stage of development in which activity levels are characterized by a maturational peak at 15 days of age. An additional approach to studying the neurotoxic effects of Pb is to examine the functional integrity of the hippocampus, a limbic structure that is known to be vulnerable to damage by several neurotoxins, including Pb. We hypothesized that hippocampal abnormalities in rats exposed to Pb during development could be manifested as alterations in the characteristics of the electrically induced hippocampal afterdischarges (ADs).

Sprague-Dawley rats were exposed postnatally to Pb indirectly via the dam's milk. Upon parturition, litters were culled to 6, and water containing 2.5 mg/ml (HL) or 1.0 mg/ml (LL) lead acetate was substituted as drinking water. Controls received a solution of sodium acetate. Such exposure continued until weaning at 22 days. On days 12, 14, 16, 18, 20, and 22, locomotor activity of each pup was recorded for 30 min in a photoactometer. At 3 mos. of age, adult males were implanted with hippocampal and cortical electrodes for chronic electrical stimulation and recording. Following recovery from surgery, AD characteristics produced by stimulation at 25% above threshold were evaluated first in the drug-free state and following treatment with 0, 10, 20, and 40 mg/kg phenytoin.

HL pups exhibited heightened activity on all test days, relative to controls or LL, although a maturational peak was still evident on day 16. In contrast, LL animals demonstrated hypoactivity at 16 days, but by 18 days the level exceeded that of controls. Activity subsequently declined but remained slightly higher than controls. This delay in peak activity indicates that the age of testing is indeed critical to the effect observed. Preliminary results in AD testing indicate that in the absence of phenytoin, Pb effects are seen as subtle changes, most obvious in the cortical response to hippocampal stimulation. The use of phenytoin served to increase the sensitivity of the model. In all groups, phenytoin blocked the AD in a dose-dependent manner. However, in animals in which an AD did occur, Pb exposed rats responded with a dose-related increase in duration of the AD, while in control rats durations remained fairly stable.

289.16 HIPPOCAMPAL AFTERDISCHARGE CHARACTERISTICS IN ADULT RATS PRENATALLY EXPOSED TO METHYLMERCURY. C.U. Eccles*, K. Rauen* and M. McCarren* (SPON: G. Young). Dept. of Pharmacology and Toxicology, Univ. of Maryland Sch. of Pharmacy, Baltimore, MD 21201.

The hippocampal formation is known to be sensitive to the effects of a variety of neurotoxic agents. In the present study, the characteristics of hippocampal afterdischarges (AD) were examined in adult rats exposed to a low dose of methylmercury chloride (CH_3HgCl) during a period of rapid growth and development of the hippocampus, i.e., the third week of gestation.

On day 15 of gestation, 4 pregnant Sprague-Dawley rats were given 5 mg/kg CH_3Hg as CH_3HgCl by means of intragastric intubation. Vehicle alone was given to 4 rats that served as controls. On postnatal day 1 litters were culled to a standard size. At 16 weeks of age, 10 males from each treatment group were prepared for chronic recording of the hippocampal and cortical EEG.

After a two-week recovery period, AD thresholds were determined by the method described by Pinel (Pinel et al, Epilepsia 17:197-206, 1976). A second AD at 3 times threshold intensity was produced 20 minutes after the threshold AD. EEG records were scored according to rules previously described (Dyer et al, Neurobehav. Tox. 1:5-19, 1979). The following parameters were measured: AD threshold, AD durations in cortex and hippocampus, latency to rebound AD in hippocampus, and duration of rebound AD. One month after the initial testing period, a baseline AD was produced at 3 times threshold intensity followed by administration of subsequent stimuli at varying intervals in order to obtain a measure of the duration of the postictal period during which the hippocampus is refractory to additional AD's.

AD thresholds, cortical AD duration, and hippocampal AD duration were not significantly different in control and experimental animals. The duration of the rebound AD was longer in experimental group after the threshold AD but not after the AD produced at 3 times threshold. In both the threshold AD and the second AD the latency to rebound AD was increased in the CH_3Hg-treated rats (116.4 vs. 84.5 sec; 120.8 vs. 81.9 sec). In the second phase of testing, the postictal refractory period was found to be significantly longer in the CH_3Hg rats as compared to control (13.3 vs. 4.9 min).

The origin, significance, and factors that influence the onset of the rebound AD are unknown. Since existing evidence indicates that it is associated, at least in a temporal manner, with recovery from the postictal depression, the increased latency to the rebound AD in the CH_3Hg-exposed rats may reflect a delayed recovery process in this group. The increased length of the postictal refractory period in experimental animals provides additional support for this hypothesis.

289.17 ETHANOL VS. TERTIARY BUTANOL INDUCED MICROCEPHALY IN NEONATAL RATS: DIFFERENTIAL EFFECTS ON BRAIN COMPONENTS. K. GRANT*, H. SAMSON*, J. DIAZ (SPON: G. CLARK). DEPT. OF PSYCHOLOGY, UNIV. OF WASHINGTON, SEATTLE, WA 98105.

A prominent diagnostic feature of the fetal alcohol syndrome (FAS) is microcephaly. However, neither the mechanisms by which ethanol interferes with brain development nor the brain components effected are known. Using an artificial rearing procedure, ethanol administered during the brain growth spurt has been shown to selectively impair brain development in neonatal rats. Tertiary butanol administered under the same conditions also produces microcephaly. Tertiary butanol is another short chain alcohol, not metabolized by the same enzyme systems as ethanol, and is considered to be a metabolic control for the metabolites of ethanol oxidation. The tertiary butanol was given in a dose equivalent to that of ethanol based upon their membrane to buffer partition coefficients. Thus the relative contribution of membrane solubilizing agents on brain development was explored.

To ascertain whether the microcephaly produced by both alcohols represent similar deficits in brain parameters, biochemical assays of several brain indices were performed. Ten days after alcohol exposure the animals were sacrificed, their brains removed, weighed, and sectioned into cerebral and cerebellar portions by a trans-collicular cut. Each brain sample was assayed for total DNA, protein and cholesterol. Total DNA was used as an index of the amount of cells present and DNA per tissue weight represented cellular density. Total protein per total DNA was used as an average protein per cell measure. Finally, total cholesterol to total DNA represented the degree of cellular arborization and myelination.

Compared to controls, neither ethanol nor tertiary butanol appeared to inhibit cellular proliferation in the cerebral samples. However, average protein per cell was decreased in the ethanol group. The DNA levels of the cerebellar samples were decreased in both ethanol and tertiary butanol groups, with no differences in average protein per cell. Compared to either the control or tertiary butanol brain samples, the ethanol group had lower levels of cholesterol per cell in both the cerebrum and the cerebellum. The results indicate that although both alcohols induce microcephaly, they differentially effect brain development. Therefore, FAS microcephaly may be a combination of both the membrane solubilizing and metabolic consequences of ethanol exposure.

289.18 HYPOXIA AND STUNTED PURKINJE CELL DEVELOPMENT: GOLGI AND ELECTRON MICROSCOPIC STUDIES. M.C. Yu*; D. Spero* and F. Hackett* (SPON: H. Edinger). Dept. of Anatomy, New Jersey Medical School, Newark, NJ 07103

We reported previously that hypoxia (10% O_2; 90% N_2) imposed on neonatal rats from postnatal day 5 to day 11 consecutively caused severe stunting in cerebellar development (Yu, M.C. and Yu, W.H.A., Exp. Neurol. 70:652-664, 1980). The reduction in cerebellar size was reflected at day 12 in a smaller number of proliferative and postmitotic cells in the external granular layer (EGL) and a reduction in the width of the molecular layer. At day 22, the cerebellum of the control rat (kept in ambient air) had attained the adult cytoarchitecture but the development of the hypoxic rat cerebellum was still lagging, with the persistence of the EGL cells incorporating tritiated thymidine. The present study was to examine morphologically the effect of hypoxia on the maturation of the Purkinje cells, and the effect of a smaller population of microneurons on the development of Purkinje cell dendritic field. Electron microscopic and Golgi impregnation preparations were made from the control and hypoxic rats at postnatal days 12 and 22, respectively.

At day 12 the Purkinje cells of the hypoxic rats showed a preponderance of free ribosomes and few Nissl bodies. In contrast the Purkinje cell perikarya of the control rats showed well developed Nissl bodies and scattered free ribosomes. Golgi preparations revealed greatly reduced dendritic arborization and spine formation in the Purkinje cells of the hypoxic rats when compared with the control. At day 22, the Purkinje cell perikarya of the hypoxic rats possessed all the cell organelles; however, the number of Nissl bodies was much less than that of the control. Golgi preparations revealed that the field of dendritic branching of the hypoxic rats continued to lag behind the age-matched control. The present studies, in conjunction with that reported previously, indicated that the reduction in size of the cerebellum during the 12- and 22-day periods was the result of hypoxic inhibition on the proliferative activity of the stem cells in the EGL, and on the stunting of development of neuronal processes of the Purkinje cells.

289.19 VISUAL SYSTEM DAMAGE, AND AUDITORY AND ELECTRO-TACTILE STARTLE-REFLEX IMPAIRMENTS IN ADULT RATS FOLLOWING NEONATAL VIRAL INFECTION. A.B. Campo*[1], J.R. Ison[2,3], J.L. Orr*[3], S.J. Mestman*[1], D.A. Grover*[4], A.A. Monjan[5], M. del Cerro[1,4]. 1) Center for Brain Research, Univ. of Rochester Med. Ctr., Rochester, NY 14642. 2) Dept. of Psychology, Univ. of Rochester, Rochester, NY 14627. 3) Dept. of Radiation Biology and Biophysics, Univ. of Rochester Med. Ctr., Rochester, NY 14642. 4) Dept. of Ophthalmology, Univ. of Rochester Med. Ctr., Rochester, NY 14642. 5) Dept. of Epidemiology, School of Hygiene and Public Health, The Johns Hopkins Univ., Baltimore, MD 21205.

Albino and hooded rats infected at birth with lymphocytic choriomeningitis virus (LCMV) develop a cell-mediated immune retinitis, with well documented clinical, electroretinographic, and histological damage to the retina. This begins about 2 weeks after infection and progresses relentlessly throughout the life of the animal (del Cerro et al., in review). To further evaluate the functional status of their nervous system we tested their responsiveness to a graded series of acoustic stimuli (85 to 125 dB, 10 kHz tones, 20 msec in duration) and electro-tactile stimuli (.1 to .9 mAmp, single square wave shocks, 20 msec in duration). Five levels of intensity in intermixed order (a total of 50 trials in each modality) were presented at 20 sec intervals. The force of the animal's reaction was detected with an accelerometer, its output amplified and integrated over a 100 msec period immediately following the stimulus. Normal animals (n=5) showed a monotone increasing response to these stimuli; infected animals (n=5) showed a small and insignificant increase in responding, and their overall level was less than 10% that of the normal subjects. The locus of this reflex impairment (whether, e.g., it is afferent, central integrative, or efferent) is currently under investigation.

It is apparent that perinatal LCMV infection produces deficits involving both visual and nonvisual neural systems. The LCMV infection is a useful and important model for the study of neural-immune system interactions in the developing neonate.

290.1 TOPOGRAPHIC ANATOMY OF TIBIALIS ANTERIOR (TA) MOTONEURONS (MNs) AND THEIR MUSCLE FIBERS IN CAT. A.R. Iliya* and R.P. Dum, Dept. Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Burke et al. (J. Neurophysiol. 40:667, 1977) suggested that a topographic relation may exist between the location of a MN within its motor nucleus and the position of its innervated muscle fibers within the muscle. We tested this hypothesis directly in TA muscle. By selective sectioning of either the anterior (ANT) or posterior (POST) branch of the TA nerve, we determined: 1) the relative nuclear location of the remaining branch's MNs in comparison to the contralateral nucleus by using bilateral intramuscular injection of horseradish peroxidase and 2) the intramuscular position of each branch's innervated muscle fibers by using glycogen depletion.

The labeled MNs occupied bilaterally symmetrical fusiform columns (0.5 mm dia; 6.3 $\pm$ 0.6 mm length) within the L6-L7 ventral horn. Although MNs of the ANT or POST branch intermingled within the same spinal cord region, the MNs of the POST branch in two cats were relatively segregated toward the caudal part of the nucleus in contrast to MNs of the ANT branch which had a rostral bias. This trend was not evident in the third cat whose POST branch contained a much higher proportion of the total MN population (48% vs. 26% & 33%). The distribution of soma diameters of labeled MNs was bimodal, allowing a presumptive division into γ(small) andα(large) MNs. On the average, the POST branch contained 51% of the γ MNs but only 26% of theα MNs.

We determined that the POST branch innervated posteriomedial TA while the ANT innervated anterolateral TA with only a little intermingling of innervation at the border. Hence the muscle fibers innervated by each branch were strictly segregated within each muscle. Using myofibrillar ATPase staining at pH 4.4, we determined the proportions of the three fiber types (I, IIA, IIB) for each branch. The POST branch tended to innervate a high proportion of oxidative muscle fibers (54% types I and IIA) while the ANT branch innervated a high proportion of glycolytic fibers (62% type IIB). Since the POST branch contained 26% of theα MNs and innervated roughly 20% of all TA muscle fibers, the POST branch MNs must, on the average, have lower innervation ratios (hence smaller muscle units) than their ANT branch counterparts.

In conclusion, we observed only a weak topography between the nuclear location of MNs and the intramuscular location of their innervated muscle fibers. Thus, the clear segregation of half the γ MNs and ofα MNs innervating mostly small, oxidative muscle units into the POST nerve which innervated a discrete region of the TA muscle cannot be explained solely on the basis of the anatomical position of these MNs within the TA nucleus.

290.2 LOCALIZATION AND CELL SIZE IN SELECTED MOTONEURON POOLS IN THE OPOSSUM LUMBOSACRAL SPINAL CORD. D.A. Thomas*, J.L. Culberson*. (SPON: G.W. Patrick). Dept. of Anatomy, West Virginia University, Morgantown, West Virginia 26506.

The location of motoneurons that supply specific muscles or muscle groups has been studied previously in several mammals using a variety of methods. By using horseradish peroxidase (HRP) as a retrograde label, it is now possible to identify with confidence those cells that supply individual muscles and to examine morphology and size of these cells. The present study, part of a more extensive study of opossum neuromuscular organization, includes our observations on localization and size of motoneurons that supply the tibialis anterior (TA) and medial gastrocnemius (MG) (antagonists) muscles in the opossum, a generalized mammal. Multiple injections of 2-6% HRP (Sigma - Type VI) were made into the belly of the TA (total volume .25 - .5 ml.). For the MG, the muscle nerve was exposed, cut and soaked for 3 hours in a solution of 20% HRP. Animals were killed after 2-4 days by perfusion with a paraformaldehyde-glutaraldehyde fixative. Spinal cord segments were carefully identified and blocked, then frozen sectioned at 40 μm and the sections reacted using a tetramethyl benzidine (TMB) procedure. Cells were identified by dark field microscopy and traced using a drawing tube. Tracings were measured using a semi-automated image analysis system so that area, diameter and circumference data were available. All motor cells were localized within the L_4-L_6 segments of the spinal cord. Both nuclei were in the centrolateral part of the ventral horn with MG cells slightly more peripheral in position. TA motoneurons were consistantly rostral (in L_4-L_5) to MG cells (L_5-L_6). Cells were typical multipolar cells with size (cross-sectional area) ranging from 100 μm^2 to 2800 μm^2. The mean number of neurons labelled was 54 for TA and 93 for MG. Both the localization and the size range for these motor neurons are comparable to those published from other laboratories for the cells that supply the same muscles in cat and rat, however, the distribution of subpopulations (i.e., alpha and gammas motoneuron pools) does not seem to be so clearly separated in the opossum as in these other species.

Supported in part by NSF Grant #7924172 and grants from the WVU Medical Corporation.

290.3 LOCALIZATION OF THE MOTOR NUCLEI AND SENSORY PROJECTIONS OF THE GLOSSOPHARYNGEAL, VAGUS AND HYPOGLOSSAL NERVES IN THE BRAIN OF THE COCKATOO (CACATUA ROSEICAPILLA). J. Martin Wild. Dept. of Behavioural Biology, Research School of Biological Sciences, Australian National University, Canberra, A.C.T. Australia.

The avian caudal cranial nerves are involved in a variety of species specific behaviours, two of the most important of which are feeding and phonation. In parrots these behaviours are distinctive and probably involve the use of some of the same muscles, including those of the tongue. In order to locate the central motor and sensory components of these nerves, horseradish peroxidase (HRP) was applied to their proximal severed ends, and sectioned brains and ganglia were later processed using Hanker-Yates reagent as the chromagen.

Application of HRP to N IX labelled four rhombencephalic nuclei: (1) a large-celled, retrofacial nucleus supplying M. geniohyoideus, the major tongue extensor; (2) a dorsal nucleus composed of medium-sized cells, projecting to most branches of N IX; (3) a ventrolateral nucleus supplying, amongst other structures, the floor of the pharynx and larynx; (4) a ventral portion of the dorsal motor nucleus of the vagus.

Neurons labelled by application of HRP to the cervical vagus comprise the classically defined dorsal motor nucleus, and a ventrolateral medullary nucleus which is coextensive with that of the glossopharyngeus: Together they probably constitute a nucleus ambiguus.

Application of HRP to hypoglossal branches labelled a large nucleus intermedius (IM) and neurons ventral, ventrolateral and caudal to it. The rostral third supplies most of the tongue muscles, the caudal two thirds the tracheal and syringeal muscles. In addition, neurons of the ventral hypoglossal nucleus (nucleus supraspinalis) were labelled from injections of HRP into upper neck muscles, some of which are innervated by hypoglossal nerve branches.

Many labelled neurons were found in the "jugular" ganglion following HRP treatment of each of the three nerves, especially N IX and N XII, which innervate the tongue. Central projections of these neurons are to nuclei of the descending trigeminus and to largely non-overlapping portions of the principal trigeminal nucleus. It is hypothesized that these afferents provide sensory information necessary for the efficient processing and passage of food in the mouth.

290.4 INNERVATION OF THE FACIAL MUSCLES BY THE BRAINSTEM FACIAL NUCLEUS. EveLynn McGuinness* (SPON: John Allman) Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

We determined the pattern of innervation of the facial muscles from the brainstem nucleus of the facial nerve in rats by injecting the peripheral muscles with 2-5 μl of 20% horseradish peroxidase (HRP) and examining the facial nucleus for labeled neurons. Morphologically using coronal sections we could distinguish four different subnuclei, dorsal, lateral, intermediate, and medial. In some sections the intermediate group could be further subdivided into an intermediate and a ventromedial group but this boundary was not morphologically distinct and did not correspond to a recognizable border between neurons innervating different muscles so we have included both in the intermediate group. The vibrissae are innervated by the lateral subnucleus. There appears to be a degree of topography in the vibrissal representation. Injections into levator labii superoris which in the rat extends from above the eye to the upper lip normally produced labeling only in the dorsal subnucleus. If the injection included any part of the muscle underlying the vibrissae, labeling was also seen in the lateral group. Injections in orbicularis oris produced labeled neurons in the ventral portion of the intermediate subnucleus. We saw no sharp distinction between injections to the upper lip or the lower lip. Injections into zygomaticus resulted in labeling the more dorsal portion of the intermediate subnucleus and injections in the platysma produced rather scattered labeling in the more medial extent of the intermediate subnucleus. In making the later injections the skin and attached layer of platysma were separated from the underlying muscles to prevent spread. Both frontalis and the extrinsic ear muscles were represented in the medial subnucleus. Frontalis was limited to the dorsal portion of the subnucleus, levator auris longus tended to be in the more ventral portion. Injections in the anterior belly of the diagastricus muscle resulted in labeled neurons only in the motor nucleus of the trigeminal nerve as did injections in the massater muscle.

A curious feature emerged in that each innervation site appears to be represented throughout the rostral caudal extent of the facial nucleus. Any given injection will produce labeled neurons in most sections for which the appropriate subnucleus is present. Smaller injections produce fewer labeled neurons per section and/or less densely labeled neurons but the extent of the rostral caudal extent of the distribution of labeled neurons is not changed.

290.5 MASTICATORY REPRESENTATION IN THE MOTOR NUCLEUS OF THE TRIGEMINAL NERVE OF THE CRAB-EATING MACAQUE (Macaca fascicularis). Marguerite Carlton*, R. Dom*, and E. Rawe* (SPON: James Stevenson). Dept. of Anatomy, Medical University of South Carolina, Charleston, S.C. 29425.

The major masticatory divisions and subdivisions of the trigeminal motor nucleus were determined by injecting horseradish peroxidase (HRP) into each of the jaw-opening and jaw-closing muscles and identifying neurons which were HRP positive. The best results were obtained in animals 48-72 hours after injection of HRP. Cross-sections of the trigeminal motor nucleus show the nucleus to be divided into a large figure 8 shaped lateral division and a smaller and less distinct medial division. This lateral division can be further divided into dorsomedial and ventrolateral subdivisions. The lateral division contains the temporalis neurons throughout its dorsomedial subdivision and masseter and medial pterygoid neurons throughout its ventrolateral subdivision. The neuronal pools supplying the masseter and medial pterygoid muscles had considerable, if not complete, overlap. The waist region of the lateral division contains neurons innervating the superior head of the lateral pterygoid muscle. The medial division is divided into a dorsal subdivision which contains neurons innervating the anterior belly of the digastric muscle and a ventral subdivision containing the neurons supplying the mylohyoid muscle and the inferior head of the lateral pterygoid muscle. The caudal portion of this ventral subdivision contains neurons innervating the mylohyoid muscle, whereas the neurons of the rostral part supply the inferior head of the lateral pterygoid muscle. This study indicates that neurons supplying the jaw-closing muscles are situated in its lateral division and the neurons innervating the jaw-opening muscles lie within the medial division. (Supported by NIH grant RR05767)

290.6 SOME CHARACTERISTICS OF THE NEUROMUSCULAR APPARATUS OF THE PELVIC FLOOR IN SPINAL CATS. B. Dubrovsky and P. Pacheco*. Neurophysiology Lab., Allan Memorial Institute, McGill Univ., Montreal, Quebec, H3A 1A1, and U.N.A.M., Mexico.

As S. J. Gould stated, "Bipedalism is no easy accomplishment. It requires a fundamental reconstruction of our anatomy, particularly of the foot and pelvis." Not much data is available, however, on the neural control of pelvic floor musculature The two broad muscle groups of the region, constrictor cloacae: external ani sphincter representative type, and compressor cloacae: levator ani complex muscular group representative type, are assumed to be activated as a mass unit. We studied this proposition. In spinal cats (section of the spinal cord between 1st and 2nd cervical segments under ether anesthesia) we recorded E.M.G. activity from the right and left levator ani and the external ani sphincter muscles. Stimulation of pudendal regions in either side of the body elicited responses of the external ani sphincter; activation of levator ani musculature was lateralized; i.e. cutaneous stimulation (touching or electrical stimulation of the skin of pudendal regions and/or skin of the external surface of the hindlimbs) elicited activation of the ipsilateral levator ani muscle. Section of one pudendal nerve did not alter the level of tonic background activity (1-4/sec) from the recorded muscles. Bilateral section of the pudendal nerve entirely abolished both tonic activity and responsiveness of the external sphincter. Levator ani muscles were not affected by pudendal sections, although bilateralization of responses were observed more frequently after nerve severances. Tactile stimulation of the internal surface of upper hindlimb regions selectively activated the external sphincter of the anus without detectable changes in the activity pattern of the levator ani muscles. Moderate pressure applied on the region of the knee joint or electrical stimulation of the region selectively activated the corresponding (ipsilateral) levator ani muscle, without noticeable change in the activity pattern of the external ani sphincter E.M.G. Pressure on the uterine cervix significantly decreased the level of tonic activity and phasic twitch responses in both levator ani and external ani sphincter muscles. Gentle tapping on perivaginal skin elicited contraction of the external ani sphincter which was frequently, although not always, accompanied by arrest of the tonic activity in the levator ani muscles. These results indicate that muscles of the pelvic floor can be selectively activated and/or inhibited by discrete sets of stimuli. It will be a serious mistake then to record from one muscle and take the results of this functional exploration as representative of the state of all muscles in the region. This research was supported by NICOLO.

290.7 MOTONEURONE SYNCHRONIZATION AND ITS POSSIBLE ORIGINS P.A. Kirkwood*, T.A. Sears* and R.H. Westgaard*(SPON: A. Taylor). Sobell Dept. Neurophysiology, Institute of Neurology, Queen Square, London WC1N 3BG, England.

Intercostal motoneurones demonstrate short-term synchronization, as shown by narrow central peaks (± 3msec) in cross-correlation histograms between the discharges of paired groups of motoneurones, recorded as inspiratory efferent discharges in the cut central ends of external intercostal nerve filaments of anaesthetized cats (1). In that paper and a later paper (2) this synchronization was interpreted as arising from individual pre-synaptic axons which branched to excite both groups of motoneurones. Quantitative predictions from ref. (2) were recently verified (3), thus confirming the interpretation.

We now report that under some circumstances the synchronization can have a different time course. The circumstances include awake animals (motoneurone activity recorded as e.m.g. signals via fine wires previously implanted aseptically under anaesthesia), lightly anaesthetized animals and animals with spinal cord lesions either rostral or caudal to the motoneurones involved. In place of, or in addition to the narrow central peak, longer duration peaks were present (± 10msec to ± 50msec), which could not be explained by the branched presynaptic axon hypothesis. The effect was present for groups of motoneurones for which narrow central peaks were never observed (e.g. between motoneurones on opposite sides of the cord) and was strongest when the respiratory drive was weakest. We believe that the best explanation for the effect is that in these preparations there were groups of as yet unidentified spinal cord interneurones which provided an input to the motoneurones and were themselves synchronized. The broad peaks represent the time course of that synchronization.

290.8 *CHRONIC SPINAL KITTEN: 24 HOUR EMG PROFILE OF SLOW AND FAST ANKLE EXTENSORS.* *M.A. Alaimo*, L.A. Smith* and J.L. Smith. Dept. Kinesiology and Brain Research Institute, UCLA,CA. 90024.*

Previous experiments have suggested that the faster contraction times (CT=30-50ms) observed in the normally slow-contracting soleus (SOL) following cord transection were due to "virtual elimination of motoneuron discharge" (Galego, J. Physiol. 281: 1978). When kittens cordotomized(T_{12}) at 2 wks are exercised daily on a treadmill, the SOL exhibits normal EMG activity (Smith Neurosc. Abst.,1979); nevertheless, the SOL-CTs of the exercised kittens are significantly faster than normal (Edgerton, Neurosc. Abst., 1979).

In an attempt to establish an EMG activity profile of SOL and gastrocnemius (GAST) muscles, EMGs were recorded for 10 min intervals each hr for 24 hrs. During the testing day, the 6-8 mths postcordotomy kittens were housed in walking cages (3 sq m), and every attempt was made to duplicate the normal daily routine. Both raw and rectified-averaged (I-EMG) EMGs were quantified.

In general, the 5 cordotomized kittens exhibited 3 peak activity periods, as measured by total I-EMG, around 5-6pm, 11-1am and 1-2pm interspersed with periods of rest or sleep. All behavior was verified by use of video. Each sampling period was characterized by EMG burst number and duration against the total I-EMG. During peak periods of activity, the SOL exhibited 20-30 short-lasting bursts (200-300 ms). In general, this activity resulted from nonweight-supported movement; however, short periods of weight-support were common during both greeting and feeding behaviors. In general the GAST exhibited fewer bursts with shorter durations.

A 10 min treadmill period in which kittens weight-supported during the stance phase, elicited total I-EMG that were 1.2 and 2.2 times greater than the total I-EMG recorded during the entire 24 hr period for SOL and GAST, respectively. The data suggest that although the spontaneous activity of the hindlimb may be reduced in the chronic spinal kitten, 30 min of treadmill exercise daily increases the activity level appreciably. Preliminary findings suggest that normal sedentary kittens, housed in the same cage are not appreciably more active than the chronic spinal kittens. However, normal kittens exhibit more weight-support spontaneous movements and it is possible that the tension produced by the SOL is greater. We are now testing this.

Our results suggest that the SOL of chronic spinal kittens exhibit spontaneous activity as well as normal activity patterns during treadmill locomotion . The conversion of the SOL from a slow to a fast contracting muscle is not due to the "virtual absence" of motoneuron discharge. Supported by NIH grant, NS 16333 and NS 10423.

290.9 THE ORGANIZATION OF STEM DENDRITES OF DORSAL NECK MUSCLE MOTONEURONS IN THE ADULT CAT. P. K. Rose and D. A. S. TWIDDY*, Dept. of Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Dendritic trees of dorsal neck muscle motoneurons, biventer cervicis (BC) and complexus (CM), are arranged in remarkedly regular patterns. Each motoneuron has three distinct groups of dendrites. One group projects rostrally and caudally from the soma and is located in the ventromedial nucleus. Another group of dendrites is directed dorsomedially toward the central canal and the third group projects dorsolaterally through the spinal accessory nucleus and into lamina VII. A few scattered dendrites are also found directly dorsal to the soma in lamina VIII. In the present study we have examined the distribution of the branches of individual stem dendrites to determine the contribution of each stem dendrite to the overall dendritic tree. The entire dendritic tree of five BC and CM motoneurons was reconstructed from serial histological sections. Stem dendrites and their branches were extracted from these reconstructions and rotated 90^0 to the plane of section to determine their three-dimensional distribution.

Twenty-four of 47 stem dendrites had branches which were confined to one of the three major dendritic groups characteristic of BC and CM motoneurons. One-half of these dendrites were found in lamina IX, seven were located dorsolaterally to the soma and five projected dorsomedially. All of the remaining 23 stem dendrites contributed branches to more than one dendritic zone. Three stem dendrites distributed branches to all regions of the ventral horn occupied by the complete dendritic tree.

Although there are few detailed anatomical studies of the descending and segmental connections to the upper cervical spinal cord, the available evidence suggests that most of the systems which make monosynaptic connections with BC and CM motoneurons terminate in discrete zones. These zones are much smaller than the territory occupied by the complete dendritic tree of BC and CM motoneurons, but are similar in size to the area occupied by stem dendrites whose branches are restricted to a single dendritic group. These stem dendrites may therefore receive a small, but specific set of inputs. Integration with inputs on other dendrites will occur at the soma. In contrast, stem dendrites whose branches are more widely distributed will receive inputs from a wider variety of sources. Integration of these inputs will occur before reaching the cell body. (Supported by the Canadian MRC.)

290.10 Does the ventral spinocerebellar tract contain cervical collaterals? R. L. McBride, P. R. Lennard, and A. W. English, Emory University, Atlanta, GA 30322

A number of lines of evidence have given rise to speculations that the ventral spinocerebellar tract (VSCT) contains collaterals to other parts of the neuraxis. These speculations led Grillner (Physiol. Rev. 55:247,1975) to hypothesize that the cervical collaterals of VSCT neurons may play a significant role in the coordination of step cycles of the forelimbs and hindlimbs during locomotion in cats. This postulate requires that lumbar neurons projecting directly to the cerebellum via the contralateral VSCT also have terminations in the cervical spinal cord. We now report the results of anatomical experiments designed to test this hypothesis. In separate experiments, the retrograde label horseradish peroxidase (HRP) was injected into the cerebellum and the cervical spinal cord. Special care was taken in the case of cervical injections to use very small quantities and to minimize damage to axons of passage. Comparison of results from these single-label experiments indicates that cells in two lumbar cord regions were labelled in both experiments. These were in the base of the dorsal horn (lamina VI) and the medial parts of the ventral and intermediate grey (laminae VII and VIII). This latter region has been implicated as the origin of cells of the VSCT which receive strong group Ib inputs (Hubbard and Oscarsson, J. Comp. Neurol. 18:199,1962). As a direct test of whether the same VSCT cells contain cervical collaterals, a double retrograde labelling protocol was used. HRP and tritiated, inactivated HRP (H^3 apo HRP) were used as labels - one injected into the cerebellum, the other into the cervical cord. Serial sections of lumbar cord were reacted for HRP and then processed for autoradiography. Results of double labelling experiments confirm those using the single label protocol. Cells were labelled from both injection sites in lamina VI and medial VII and VIII. Dorsal and ventral horn cells were not found to be doubly labelled. Some cells in the intermediate grey showed light double labelling, but others were only singly-labelled. Thus it is concluded that propriospinal-VSCT neurons may exist but, if they do, they form a small subset of either the VSCT or the long ascending propriospinal neurons.

290.11 DISTRIBUTION OF SOMATOSTATIN IN THE GUINEA PIG HINDBRAIN. E. Taber-Pierce, S.C. Feldman and E. Lichtenstein* Dept. of Anatomy, Harvard Medical School, Boston, Mass. 02115; Dept. of Anatomy, CMDNJ-New Jersey Medical School, Newark, N.J. 07103; Hospital for Joint Diseases, New York, N.Y. 10035

Immunoreactive-like somatostatin (SRIF) was localized in neuronal elements of the guinea pig hindbrain, using a highly specific antibody to the peptide and the unlabeled antibody enzyme technique of Sternberger. All staining was found to be specific for SRIF as determined by the absence of immunoprecipitate in neuronal perikarya and fibers in tissue in which the antiserum had been previously adsorbed with synthetic peptide.

Labeled neurons, in which the immunodeposit was present in the perinuclear cytoplasm and in processes extending from the cell body, were present in many areas of the brainstem. In the raphe, large and medium-sized neurons were present in the following nuclei: superior centralis, magnus and obscurous. In the auditory system large numbers of SRIF neurons were found in ventral cochlear n., ventral trapezoid n. and ventral n. of the lateral lemniscus; smaller numbers of neurons also were present in the dorsal medial trapezoid n. In the reticular formation large numbers of large and medium-sized neurons were located in n. gigantocellularis; fewer SRIF neurons were also seen in nuclei pontis centralis oralis and caudalis, and n. parvocellularis. SRIF neurons, primarily medium-sized, were also found scattered throughout the remainder of the brainstem: n. intermedius of the spinal trigeminal tract; n. prepositus hypoglossous; n. Roller; area postrema; and n. tractus solitarius.

Many areas in the brainstem contain a neuropil rich in SRIF fibers, particularly: n. tractus solitarius; area postrema; caudal n. of the spinal trigeminal tract; peribrachial nuclei; interpeduncular n.; and the area of the n. locus coeruleus. In addition to these dense plexuses, bands of SRIF-containing fibers were found throughout the reticular formation at all levels, and were also found ascending and descending in the raphe. From this data, it appears that there is a significant SRIF input to most areas of the brainstem. (Supported by a grant from The Foundation of the College of Medicine and Dentistry of New Jersey to S.C.F.).

290.12 THE FUNCTION OF THE LOCUS COERULEUS IN THE ACTION OF CYCLOBENZAPRINE IN THE RAT. J. Daugherty, R. Pierce*, and C. Barnes. Texas Tech University Health Sciences Center, Department of Physiology, Lubbock, TX 79430.

Early experiments on the cat indicate the main site of action of cyclobenzaprine (CBZ) in producing its centrally acting skeletal muscle relaxation is in the brainstem. Of the brainstem sites explored, both the reticular formation and the locus coeruleus (LC) have been implicated as the main locus of action. Subsequent experiments have demonstrated in the cat that the noradrenergic pathway from the LC to the spinal cord is facilatory and therefore that CBZ's inhibition of LC would produce disfacilitation of motor neurons. A recent report, however, states that in rat, CBZ facilitates LC neuronal activity and explains the muscle relaxor action as an increase in descending inhibition. The present studies were undertaken to determine if there is a species difference in the action of CBZ on LC neurons. Experiments were done on adult rats of either sex anesthetized with α-chloralose. Recordings were made from the LC through glass microelectrodes filled with sodium chloride and saturated with fast Green dye. The electrode placement was initially done by stereotaxic coordinates. Once a cell was isolated with a characteristically slow spontaneous discharge rate, tests were made to determine if it would give the characteristic LC cell response to noxious stimulation of the paw; being an initial high frequency burst followed by inhibition. When such a cell had been functionally identified as LC by this procedure, the spontaneous rate and response to noxious stimuli were repeatedly tested after IV administration of CBZ at 1 mg/kg doses to maximum accumulated doses of 7 mg/kg. At the termination of experiments, fast Green was iontophoresed from the electrode tip for histologic verification that the cell was in the LC. In all cases cells identified as LC cells were seen to decrease their discharge rate, usually following 1 mg/kg and always by a 2 mg/kg accumulated dose, to CBZ. These preliminary studies are indicative of there being no species difference in LC response to CBZ between cat and rat. The criteria for functional determination of the identity of a LC neuron may explain differing results among investigators in this area.

290.13 AN ELECTRON MICROSCOPIC STUDY ON THE NORADRENERGIC AXON TERMINALS IN THE SUBSTANTIA GELATINOSA OF RAT SPINAL CORD. K. Satoh, A. Kashiba, H. Kimura and T. Maeda (SPON: S. C. Sung). Departments of Psychiatry and Anatomy, Shiga University of Medical Science, Shiga, Otsu, Japan.

The presence of noradrenergic (NA) fibers in the dorsal horn of the spinal cord, especially in the substantia gelatinosa (SG), has been known since the early histofluorescent studies (Fuxe, 1965). These NA axons are derived from the descending NA system originating from the lower brain stem. Recently, electrophysiological and pharmacological properties of the descending NA fibers have been extensively studied, and all suggest that the NA terminals are able to alter sensory transmission at the dorsal horn level. In the present study, NA terminals in rat SG of the spinal cord was investigated with the histofluorescence technique and electron microscopic cytochemistry using the glyoxylic acid-KMn04 fixation technique (Kimura et al., 1978).

Many green fluorescent nerve fibers were observed in the superficial part of the dorsal horn from cervical to lumbar cords. They were particularly rich in the outer layer of SG. In accordance with the topographical distribution of fluorescent CA fibers, NA terminals containing small granular vesicles were frequently observed under electron microscope in the outer layer of SG and scarcely in the inner layer. These terminals apposed, most frequently, small caliber dendrites, spine apparatus, and seldomly, large caliber dendrites. In some instances, the NA terminals exhibited synaptic contacts with several types of dendrites. Additionally, the NA terminals apposed other non-NA terminals that are characterized by the content of small agranular synaptic vesicles. Although a synaptic membrane specialization was not observed in such axo-axonic contacts, the agranular vesicles aggregated near to the contact membrane in the cytoplasm of non-NA terminals. In the dorsal root rhizotomized rats, there were no NA terminals which contacted directly with the degenerated axon terminals in SG of the lumbar cord. These findings suggest that the NA afferents to SG may exert their influence on the sensory transmission via the dorsal horn cells.

Fuxe, K. (1965): Acta physiol. scand. 64, Suppl. 24, 39-85.

290.14 PROJECTIONS OF THE LATERAL HYPOTHALAMIC AREA TO BRAINSTEM AND FOREBRAIN IN THE RAT. M. L. Berk and J. A. Finkelstein. Dept. Anat., N. E. Ohio Univs. Col. Med., Rootstown, OH 44272.

The lateral hypothalamic area (LHA) regulates food intake and autonomic functions, but the pathways involved are unclear. In this study, the possible anatomical substrates for these activities are explored. Iontophoretic injections of ^{3}H-leucine were stereotaxically placed in LHA at mid-tuberal levels. After 10-14 days survival, the animals were perfused and the brains processed for autoradiography. The mid-tuberal region of LHA was chosen because it contains numerous labeled cells after horseradish peroxidase injections in the spinal cord.

Efferent projections to numerous neuronal regions are evident. Projections to the forebrain include the following: dorsal part of lateral septum, the region adjacent to diagonal band of Broca, bed nucleus of stria terminalis, substantia innominata, partial encapsulation of central nucleus of amygdala, and lateral habenular nucleus (medial and dorsolateral parts). Within the hypothalamus, connections to many medial nuclei are absent, although a few LHA fibers project to dorsomedial and posterior hypothalamus. Significantly, a narrow band of fibers courses to the borders of the paraventricular nucleus. Labeled fibers ascend and descend in the medial forebrain bundle and cross in the supramammillary decussation to the contralateral LHA.

In the midbrain, numerous fibers enter the central gray (bilateral) and central tegmental field (CTF), while fewer fibers are present in the dorsal raphe nucleus, at the lateral margin of the central superior nucleus and the deeper layers of the superior colliculus. Fibers leave CTF to either join other labeled fibers in central gray or course posteriorly to the medial and lateral parabrachial nuclei in the pons. Other pontine nuclei, such as the dorsolateral tegmental nucleus (bilateral) and the nucleus raphe magnus, also receive LHA projections. At medullary levels, LHA fibers in the lateral reticular formation (medial to spinal nucleus of V) sweep dorsomedially to innervate nucleus solitarius; fibers are seen dorsolateral to the lateral reticular nucleus as far caudal as the pyramidal decussation.

Some of the above regions, which are reciprocally connected to LHA, include lateral septal nucleus, central nucleus of amygdala, lateral habenular nucleus, midbrain central gray, dorsal raphe nucleus, lateral parabrachial nucleus, dorsolateral tegmental nucleus and nucleus of the solitary tract. These efferent and reciprocal afferent connections of LHA interrelate various neuronal systems, such as limbic, autonomic, catecholaminergic and serotonergic. These connections of LHA could participate in regulatory mechanisms. (Supported by NIH NS14344 and NS06186).

290.15 PHARMACOKINETICS OF A SINGLE I.V. METHYLPREDNISOLONE DOSE IN CAT SPINAL CORD: CORRELATION WITH EFFECTS ON SPINAL LIPID PEROXIDATION, $(Na^{+}+K^{+})$-ATPase ACTIVITY AND MOTOR NEURON RESTING POTENTIALS. E.D. Hall and J.M. Braughler* Prog. in Pharmacology, Northeastern Ohio Universities Coll. Med., Rootstown, Ohio 44272

Prior studies from this laboratory have shown that acute i.v. administration of methylprednisolone (MP) sodium succinate (15, 30, or 60 mg/kg) produces a resting hyperpolarization of cat lumbar spinal motor neurons (Hall, E.D. The Pharmacologist 22:297, 1980). The greatest effect is observed with a 30 mg/kg dose. It is possible that the increased resting potential might be due to a glucocorticoid activation of an electrogenic sodium pump. Additional studies have been undertaken which have demonstrated a dose-related increase in $(Na^{+}+K^{+})$-ATPase activity in cat spinal cord synaptosomes that is apparent by 5 min, peaks at 1 hr. and returns to control at 24 hr. after steroid injection (Braughler, J.M. and Hall, E.D., Brain Res., in press). Additionally, experiments have been conducted to examine the acute effects of methylprednisolone on lipid peroxidation using the thiobarbituric acid test. These have shown that a 30 mg/kg dose significantly reduces lipid peroxidation by a third while 90 mg/kg increases spontaneous peroxide formation by over 50% when the cord tissue is removed and assayed at 1 hr. after glucocorticoid administration. (Hall, E.D. and Braughler, J.M., Exp. Neurol. 72:in press).

In order to establish a correlation between the tissue levels of the glucocorticoid and it's neurophysiological and neurochemical effects, studies were done to determine the pharmacokinetics of MP in spinal cord vs. plasma after a single large (15, 30, 60 or 90 mg/kg) i.v. dose. MP levels in lumbar cord (L4 and L5) and plasma were measured by HPLC with UV detection (254nM). As would be expected, the spinal levels of MP are linearly related to dose. After i.v. injection, the peak level is observed at the earliest cord removal time of 5 min. At 1 hr. the amount measured in the cord falls slightly, but not significantly and the half-life of the drug in spinal cord tissue which appears to remain fairly constant, is approximately 3 hr. The plasma disappearance of MP is in general much quicker, and conforms to a multicomponent first order process with a gradual increase in the half-life, characteristic of a highly lipid soluble drug.

The relationship between the pharmacokinetics of a single MP dose and the specific requirements for repeated dosing to maintain the previously observed neurophysiological and neurochemical effects will be presented. Furthermore, the implications of these results for the actions of high dose glucocorticoid administration on the normal and the compromised CNS will be discussed. (Supported by the Amyotrophic Lateral Sclerosis Society of America and by NIMH 34111).

290.16 THE UPTAKE OF [^{3}H]-SEROTONIN, -GABA, AND -GLUTAMATE INTO SYNAPTOSOMES AND THEIR BINDING TO SYNAPTIC MEMBRANES OBTAINED FROM SPINAL CORDS OF NORMAL AND PARAPLEGIC DOGS. P.V. Hall*, J.T. Patrick*, E. Chernet*, W.J. McBride and R.L. Campbell*(SPON: S.L. Morzorati), Depts. of Surg., Psych. and Biochem., Ind. Univ. Sch. of Med., Indianapolis, IN 46223.

Spinal cords were obtained from normal mongrel dogs and from dogs made paraplegic by midthoracic crush. Lumbar regions of the spinal cords were removed either one week (before spasticity begins) or 4 weeks (when spasticity is apparent) after surgery. Spinal cords were removed, stripped of meninges and homogenized in ice-cold 0.32M sucrose with a Potter-Elvehjem homogenizer. A crude synaptosomal fraction (P_2), isolated by standard centrifugation techniques, was then subjected to additional centrifugation steps to yield a myelin-free synaptosomal fraction (MFP_2). A portion of MFP_2 was used to study the high affinity uptake of 30 nM [^{3}H]-serotonin (5-HT), 1.0 µM [^{3}H]-GABA and 1.0 µM [^{3}H]-L-glutamate (Glu). A second portion of the MFP_2 was osmotically lysed; a synaptic plasma membrane (SPM) fraction, isolated by centrifugation, was used to study the Na^{+}-independent binding of 5.0 nM [^{3}H]-Glu and 10 nM [^{3}H]-GABA. The uptake of [^{3}H]-5-HT into MFP_2 from the control group was 0.56 ± 0.05 pmole/mg prot/min (N=10). The uptake of [^{3}H]-5-HT was significantly ($P<0.025$) reduced to 67 ± 9% (N=7) and 22 ± 8% (N=3) of the control level in the one-week and 4-week group, respectively. The uptake of [^{3}H]-GABA and [^{3}H]-Glu into the control group was 64 ± 5 (N=10) and 84 ± 10 (N=10) pmole/mg prot/min, respectively. After one week, the uptake of both amino acids was the same in normal and damaged cords. However, in the 4-week experimental group, the uptake of both [^{3}H]-GABA (143 ± 5% of control; N=3 and -Glu (162 ± 8% of control; N=3) was significantly ($P<0.05$) higher than control levels. The Na^{+}-independent binding of [^{3}H]-Glu (0.055 ± 0.013 pmoles/mg prot for control value; N=11) appeared to be higher in the 1-week (138 ± 14% of control value; N=8) and 4-week (164 ± 3% of control level; N=3) experimental groups and may indicate increased numbers of glutamate receptors or greater receptor affinity. On the other hand, the binding of [^{3}H]-GABA (0.035 ± 0.009 pmoles/mg prot for control value; N=8) appeared to be lower in the 1-week (46 ± 9% of control; N=5) and 4-week (61 ± 7% of control; N=3) experimental groups and could indicate a loss of GABA receptors on descending axon terminals. The increased uptake of both [^{3}H]-GABA and [^{3}H]-Glu in the 4-week experimental group could indicate sprouting of GABAergic and glutaminergic (or aspartergic) neurons which might be related to the spastic condition present at this time. (Supported in part by MH00203).

290.17 EXPERIMENTS ON THERAPEUTIC DIALYSIS OF CEREBROSPINAL FLUID (C.S.F.) BY EPIDURAL COOLING IN SPINAL CORD INJURIES.
C. Romero-Sierra, R.R. Hansebout*, S. Sohal* and R.B. Marina*. Department of Anatomy, Queen's University, Kingston, Ontario, Canada, and Department of Surgery, McMaster University, Hamilton, Ontario, Canada.

Secondary traumatic paraplegias (S.T.P.) are due to an autodestructive process, the causal agents of which are the subject of debate.

Local epidural cooling has been carried out successfully in the treatment of S.T.P. It was hypothesized that this treatment method among other beneficial effects (e.g., reduction in: metabolic demands, edema, swelling, vasospasm; and normalization of local blood pressure) in some way trigger C.S.F. dialysis.

By analytical mathematical modeling of this method of hypothermia, it was concluded and reported last year that the cold source in local epidural cooling is an effective mechanism for the generation of C.S.F. flow.

To further explore this hypothesis, an experimental approach was devised. The strategy was to inject a dye into the subarachnoid space of dogs and observe C.S.F. movement in the following conditions: (a) "normal"; (b) local epidural cooling; (c) compression lesion; and (d) compression lesion and cooling.

Eight mongrel dogs, weighing between 45 and 65 lbs., were anesthetized intravenously with pentobarbital. Laminectomy of the upper and lower lumbar vertebrae was performed.

A compression lesion was made by introducing into the epidural space of the middle lumbar vertebrae a thin-walled silastic balloon measuring 10 mm x 12 mm and inflating it to 160 mm of Hg for one hour.

Local cooling of the cord was achieved by using a miniature epidural heat-exchanger constructed of thin-walled silastic material and shaped to fit over the dorsal dural covering of the spinal cord.

0.1 cc of basic dye was injected into the subarachnoid space via spinal roots to avoid leakage.

The results obtained indicate that local cooling speeds the spread of the dye along the longitudinal axis of the cord. Compression lesion delays or blocks the spread of the dye, an effect that is suppressed by cooling the lesioned area. These findings constitute additional support for the hypothesis of C.S.F. dialysis by epidural cooling.

Further experimental work using radioactive tracers will be carried out to validate the results.

290.18 ACUTE FUNCTIONAL AND STRUCTURAL CHANGES FOLLOWING SPINAL CORD COMPRESSION IN UNANESTHETIZED CATS, AND THE EFFECTS OF DEXAMETHASONE (DM) THEREUPON.
A.C. Nacimiento, F. Loew[X] Research Laboratory, Department of Neurosurgery, Saarland University School of Medicine, 6650 Homburg/Saar, FRG

Following exposure, an intact spinal cord L1 segment was suddenly compressed for about 50 ms by an electromagnetically driven metal rod. Quantification was allowed by high reproducibility of pathophysiological events at different degrees of compression. The following functions were monitored for up to 5 hours after injury: a) polysynaptic reflex discharges (PRD); and b) axonal conduction through the injured segment. Experiments were designed so as to allow a comparison with those made previously under Pentobarbital (PB). PRD in control experiments showed less variability than those under PB. A few minutes following intravenously applied DM (3mg/kg) a PRD decrease of about 30-45% set in and settled at that level. No changes were seen in axonal conduction. A 3mm-compression brought about a PRD decrease of about 60-70%, which remained thereafter unchanged. Axonal conduction was blocked immediately following compression. After a few minutes, however, partial recovery was evident reaching a level of about 30-50% (3mg/kg) of control values. Dexamethasone applied intravenously 30 min following compression, did not change neither the reduced PRD nor the partially blocked axonal conduction. These results are at variance with those obtained under PB, where both functional parameters were clearly influenced, bringing about a clear improvement in both reflex activity and axonal conduction. Clear-cut influence of DM could be observed histopathologically. Intensity, extension and spread of edema were reduced to a significant degree. These results allow the following conclusion: a) Course and degree of acute functional posttraumatic changes may be influenced by PB; and b) the apparent inconsistency between functional and structural changes under DM in the unanesthetized preparation suggest an interaction between PB and DM on the injured spinal cord, which is currently undergoing experimental analysis.

290.19 ACTION OF 5-HTP ON MOTOR NEURONS EXCITABILITY IN RATS, MONKEYS AND HUMAN WITH SPINAL CORD TRANSSECTION.
H. Barbeau and P. Bédard. Lab. of Neurobiology, Fac. Med., Laval Univ., Québec, Canada, G1K 7P4.

Rats rendered paraplegic by a spinal cord transsection respond to systemic administration of 5-hydroxytryptophan (5-HTP) by spontaneous discharges in the lower limb muscles. This effect becomes more and more evident in the twenty days following the section. Animals having received an intraventricular injection of 5-7 dihydroxytryptamine (5-7 DHT) twenty days previously, show, the day following the section, a response to 5-HTP of the same magnitude as chronically spinalized animals. Nociceptive reflexes however are not increased by 5-7 DHT pretreatment. The effect of 5-HTP can be blocked completely by cyproheptadine. A similar pattern of response to 5-HTP was observed in one spinal monkey. In the chronic spinal monkey, 5-HTP at 100 mg/kg significantly increases the patellar and the nociceptive flexor reflexes. This action of 5-HTP was mimicked by Quipazine 10 mg/kg and was completely blocked by cyproheptadine 10 mg/kg. Cyproheptadine also reduces the reflexes below the control level.

Preliminary observations suggest that the serotonin, antagonist, cyproheptadine is beneficial in patients suffering from spasticity due either to multiple sclerosis or to spinal cord trauma. Cyproheptadine significantly reduced the numbers of spasms, episodes of clonus and hyperreflexia in six spastic patients. Our results suggest that destruction of descending 5-HT pathways is followed by a denervation supersensitivity of lumbar neurons. This mechanism may play a role in spasticity. The use of serotonin antagonists may be potentially beneficial in spastic patients.

291.1 ACTIVITY DEPENDENT K^+ ACCUMULATION IN RAT OPTIC NERVE: A DEVELOPMENTAL STUDY. B.R. Ransom*, B.W. Connors, & David Kunis*. (SPON: M.W. Siegel). Dept. Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Potassium specific microelectrodes were used to study the extent and kinetics of increases in $[K^+]_o$ resulting from stimulation of rat optic nerves of different postnatal ages (1 day-adulthood). Nerves were dissected free and bathed in physiological saline with $[K^+]_o$ of 5 mM. Supramaximal stimuli (with regard to evoked field potentials) were delivered to the nerves at different frequencies by suction electrodes. The maximum level to which $[K^+]_o$ rose with repetitive stimulation was strongly dependent upon the age of the animal: 1-3 days old, 17.2± 2.4mM (S.D.); 4-12 days old, 12.0± 1.5 mM; 13-21 days old, 10.8± 1.1 and older than 22 days, 9.8± 1mM. Mechanisms which might underlie this striking sequence include developmental changes in 1) K^+ reuptake kinetics, 2) absolute size and activity-dependent variations in extracellular space, 3) the amount of K^+ secreted per nerve impulse, 4) the sensitivity of K^+ secretion to increases in ambient $[K^+]_o$, or 5) the anatomy of this structure. Some of these possibilities were tested experimentally. Evidence of active K^+ reuptake following activity-dependent K^+ accumulation was obtained in optic nerves of all ages. Our data indicate that, if anything, younger nerves dissipate excess K^+ more rapidly than older ones. Stimulation-dependent reductions in the size of the extracellular space, as measured by changes in the concentration of an impermeant ion (choline), were much more prominent in the optic nerves from older animals. This result is contrary to that expected if enhanced K^+ accumulation in young nerves is to be explained on this basis. The amount of K^+ secreted per single nerve impulse declined with age in a manner similar to the age-dependent reduction in maximum K^+ accumulation. This phenomenon may be related to the longer duration of action potentials seen in young nerves and has a developmental time course which is substantially different from that of the development of myelination. Furthermore, stimulation induced K^+ secretion was less inhibited by high levels of ambient $[K^+]_o$ in younger than older nerves. The uniquely massive K^+ accumulation seen in immature nerves could have profound functional consequences, since these levels of $[K^+]_o$ are capable of partially blocking impulse transmission when introduced exogenously. The data so far available suggest that developmental changes in K^+ accumulation may be related to changes in the amount of K^+ secreted per nerve impulse, coupled with an altered sensitivity of K^+ secretion to ambient $[K^+]_o$. Thus, high levels of K^+ accumulation may result when the rate of K^+ release is relatively enhanced compared to that of reuptake.

291.2 IONIC MECHANISM OF POST-TETANIC HYPERPOLARIZATION IN MYENTERIC NEURONS. K. Morita*, T. Tokimasa* and R.A. North (SPON: A.G. Karczmar). Neurophysiology Laboratory, Department of Pharmacology, Loyola University Stritch School of Medicine, Maywood, Illinois 60153.

Intracellular recordings were made from myenteric neurons removed from the ileum of guinea-pigs. Action potentials were evoked by passing depolarizing currents across the soma membrane, or by focal stimulation of a cell process. Repeated action potentials (1-30 Hz, 1-5 s) were followed by a post-tetanic hyperpolarization (PTH). The PTH required extracellular calcium ions, was accompanied by an increased membrane conductance and reversed its polarity at the potassium equilibrium potential. The peak amplitude of the PTH was dependent on the number of action potentials used to evoke it. The peak amplitude, corrected for non-linear summation of voltage, or the peak conductance increase, were both linearly related to the logarithm of the number of action potentials (range 1 to 60). The time course of decay of the PTH, corrected for non-linear summation, or of the underlying conductance change, was double exponential with time constants of approximately 6 and 15 s. Conditioning hyperpolarization increased the amplitude and duration of the conductance change underlying the PTH, without marked change in the time course of decay. This could result from an increased calcium entry and/or a voltage sensitivity of the calcium-dependent potassium conductance. TEA (1 mM) caffeine (1 μM) or doubling the extracellular calcium concentration each prolonged the PTH without significant effect on resting membrane properties. The duration of the PTH may be a useful indicator of the ability of the neuron to reduce its intracellular calcium concentration. The prolongation of the PTH by low concentrations of clonidine and morphine suggests an effect of these drugs on the intracellular calcium concentrations.

291.3 A QUALITATIVE DESCRIPTION OF THE CURRENTS SEEN UNDER VOLTAGE CLAMP OF RAT SYMPATHETIC NEURONS IN CULTURE. Joseph E. Freschi, Physiology Dept., Armed Forces Radiobiol. Res. Inst., Bethesda, MD 20014

Cultured sympathetic neurons in HEPES-buffered Hank's saline were voltage-clamped with 2 microelectrodes (20-50 MΩ). The cells were held at the resting membrane potential (RP), generally -50 to -60 mV. Depolarizing step commands of 10-20 mV from RP evoked a rapid transient inward current that peaked within 1 msec. This current was blocked by tetrodotoxin (TTX). Electrode resistances imposed a technical constraint on quantitative study of the rapid inward current. Depolarizing steps from RP also gave rise to an outward current that comprised 3 components. Small depolarizing steps produced a slowly activating current with a time constant (τ) of 50-100 msec. This current was better studied with hyperpolarizing steps. Such steps caused a small inward relaxation that reversed in direction beyond about -80 mV. This slow current appears analogous to the "M"-current of Brown and Adams (Nature 283: 673, 1980) in frog sympathetic neurons. The other 2 components of the outward current were seen after depolarizing steps 20 mV positive to the RP. Analysis of tail currents showed that one component decayed rapidly (τ about 5 msec) and was blocked by tetraethylammonium (TEA). The other component decayed at least 10 times more slowly and was inhibited by cobalt (Co). The tail currents of the outward currents reversed at about -80 mV. In the presence of TTX, onset of outward current activation occurred within 2 msec. Repolarization from hyperpolarizing steps beyond about -70 mV, and depolarizing steps from a holding potential more negative than -60 mV elicited a transient outward current that peaked within 5-10 msec and decayed over about 50 msec. This current is similar to the "A"-current of Connor and Stevens (J. Physiol. 213: 21, 1971). In the presence of TTX and TEA, a slow inward current was produced by depolarizing steps from RP. The current appeared to peak within 5 msec and inactivated slowly over about 50 msec. Analysis of the activation and inactivation of this slow inward current was complicated by the coactivation of outward currents. The slow inward current was blocked by Co. The overlap of the voltage sensitivities of many of these currents requires pharmacological separation for a more detailed analysis.

In summary, it appears that in these cultured mammalian sympathetic neurons, voltage-sensitive conductances may produce the following currents: A fast inward sodium current, a slow inward calcium current, a fast outward potassium current (delayed rectifier), a slow calcium-dependent outward potassium current, a slow outward potassium "M"-current, and a transient outward potassium "A"-current.

291.4 ANALYSIS OF THE ROLE OF CALCIUM IN RHYTHMIC HYPERPOLARIZATIONS INDUCED BY CITRATE IONS IN BULLFROG SYMPATHETIC NEURONS. Stephen M. McCort* and Forrest F. Weight. (SPON: I. Tasaki). Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

Previous investigations have shown that methylxanthines (theophylline or caffeine) initiate spontaneous rhythmic hyperpolarizations (SRH) in bullfrog sympathetic neurons (McCort, S.M. and Weight, F.F., Neurosci. Abstr., 5:47, 1979; Kuba, K., J. Physiol., 298:251, 1980). Morita et al. (Nature, 283:264, 1980) have reported the occurrence of SRH in these neurons without methylxanthines, using potassium citrate filled microelectrodes. In this study, we have investigated the role of calcium ions in the SRH induced by citrate ions. Type B neurons in the IXth or Xth paravertebral sympathetic ganglia of the bullfrog were studied in vitro. The superfusing Ringer's solution had the following composition (mM): NaCl 112, KCl 2.0, $CaCl_2$ 1.8, $NaHCO_3$ 2.4, and glucose 1 gm/l. Intracellular recordings were obtained using microelectrodes filled with 1 M potassium citrate (electrical resistance 20 to 60 megohms). SRH were observed in 20% of the neurons studied, occurring either spontaneously or resulting from passing a continuous inward (negative) current. The SRH occured approximately every 5 min, had an amplitude of 5-8 mV, and a duration of 1-3 min. By contrast, the methylxanthine induced SRH have an amplitude of 15-20 mV, a duration of 20-30 sec, and they usually occur approximately once a minute. Membrane resistance was decreased during the citrate induced SRH. Passing hyperpolarizing currents of progressively greater magnitude at first increased and then decreased both the frequency and the amplitude of the SRH. The SRH were increased in frequency by Ringer's solutions containing increased calcium (8 mM), A23187 (10 μM) or increased potassium (8 mM). On the other hand, the SRH were decreased in frequency or abolished by a Ca-free Ringer (containing 1.8 mM Mg^{2+}) or by the addition of dantrolene (43 μM) to the Ringer. These data indicate that the mechanism of generation of the citrate induced spontaneous hyperpolarizations appears to be similar to that of the methylxanthine induced events. The results suggest that the spontaneous hyperpolarizations are generated by a calcium-sensitive potassium conductance that involves a periodic intracellular release of calcium.

291.5 THE MACROSCOPIC SPATIAL DISTRIBUTION OF VOLTAGE-DEPENDENT TRANSMEMBRANE CONDUCTANCES ON THE SOMA MEMBRANE OF THE SNAIL NEURON. Carl Scheffey. Dept. of Physiology-Anatomy, Univ. of Calif., Berkeley, CA 94720.

Two extracellular recording techniques were used to examine the distribution of ionic currents on the somata of voltage-clamped Helix aspersa identified giant neurons. The fast vibrating probe technique (*Smith and Scheffey, 1980, Fed. Proc. 39:2129*) was used to measure extracellular current density just outside different areas of the soma surface during voltage clamp programs that activated the various conductances. This vibrating probe measurement represented local membrane current density with a spatial resolution of 30 microns or better. Measurements made at different probe positions were scaled to make equal the jumps in the scaled vibrating probe signals at the beginnings of hyperpolarizing voltage ramps under clamp. The scaled signals were then proportional to current density per unit membrane capacity, and hence (presumably) per unit membrane area. Most conductances examined were uniformly distributed in the soma membrane, with a typical measurement uncertainty of 15%. These included (1) Ca^{++}-independent potassium current activated by depolarization from -40 mV to +20 mV for 200 msec in Co^{++}-for-Ca^{++} ringer, (2) inward calcium current as represented by the peak inward current during a depolarization to +10 mV in a ringer which substituted Ba^{++} for Ca^{++}, Cs^{+} for K^{+}, and tetraethylammonium^{+} for Na^{+}, and (3) Ca^{++}-dependent potassium current activated by a depolarization. Fast inward sodium current was measured as the difference between inward current peaks during depolarizations with and without an inactivating prepulse. In contrast to the other currents, sodium current was not uniformly distributed, but was denser in the axon hillock area than in the area on the soma opposite to the hillock.

Patch recording was done by sealing a 20 micron internal diameter suction pipette to the soma surface. The pipette was connected to a virtual ground-type circuit that held the voltage inside the tip (extracellular to the membrane patch) to that measured by a reference electrode just outside the seal. Patch experiments confirmed that sodium current was denser near the hillock.

291.6 ISOLATION OF THREE NEUROTOXINS FROM CENTRUROIDES SCORPION VENOM AND THEIR ACTION ON SODIUM CHANNELS. G.K. Wang* and G.R. Strichartz, Dept. of Physiology and Biophysics, SUNY, Stony Brook, N.Y. 11794.

Three neurotoxins which modify sodium channel kinetics were isolated from Centruroides sculpturatus venom by cation exchange (Bio-Rex 70, and CM-52) and gel filtration (G-50) methods. The sucrose-gap method on frog sciatic nerve was used to monitor the pharmacological activity during the purification procedure. All toxins had a molecular mass of about 7,500 daltons under SDS-gel electrophoresis. In the presence of 12mM TEA frog Ringer the neurotoxins produced multiple compound action potentials followed by a long plateau of depolarization in response to a single stimulus.

Neurotoxin actions were further characterized on single myelinated fibers isolated from frog or toad sciatic nerve. Each toxin could generate repetitive action potentials following a single 0.3 msec stimulus, and occasionally spontaneous A.P. were observed. Under voltage-clamp these toxins produced an induced inward sodium current upon repolarization from a depolarizing pulse, as previously reported by Cahalan (1975) for Centruroides venom. Each toxin thus selectively modifies the activation function of sodium channels. The concentrations of the three purified toxins required to produce the induced-current were different, ranging from 140ng to 5ug protein per ml.

When the fiber was exposed to a purified toxin from Leiurus quinquestriatus scorpion venom, which slows normal sodium channel inactivation, following its treatment by Centruroides toxin, the induced-current became much larger and its rate of appearance also increased. This result shows that different binding sites are responsible for the modification of activation and inactivation processes of the sodium channel by these toxins and that these processes can be altered simultaneously in an independent manner.

291.7 TETRODOTOXIN SENSITIVITY VARIATION AMONG IDENTIFIED LEECH NEURONS. A.L.Kleinhaus, and J.W.Prichard, Dept. of Neurology Yale Univ. Sch. of Med., 333 Cedar Street, New Haven, Ct. 06510

In leech segmental ganglia, the maximum rate of depolarization of the action potentials of Retzius (R) cells and the cells sensitive to touch (T) cells, pressure (P) cells and noxious stimuli (N) cells all depended to a large extent on $[Na]_o$. In the case of the R cell the relationship was linear and passed through the origin. In the three sensory cells other ions may have contributed to the depolarizing phase of the action potential, but heavy dependence on Na was nevertheless evident. Under voltage clamp in all four cells, apparent inward current declined to near zero as external NaCl was replaced by sucrose, LiCl or choline Cl, but the relationship was not linear. Current carried by other ions, artifacts of incomplete space clamp, or some combination of the two may have caused the departure from linearity.

Tetrodotoxin in doses 20-100 micromolar had a minimal effect on the action potential of R cells. In contrast, the depolarizing phases of the N, P and T action potentials, as measured by electronic differentiation of the voltage signal, slowed in a dose-dependent fashion above 20 micromolar. Under voltage clamp the observed differences in TTX sensitivity between cells were maintained; inward current was not reduced by concentrations up to 100 micromolar in the R cell, but it was quickly, substantially and reversibly depressed in the sensory cells. Measurements of the passive electrical properties of R, N, P and T cells suggested that differences in these could not have been entirely responsible for the observed differences in TTX sensitivity. The differences in sensitivity were also unaffected by duration of exposure.

These data imply the existence of two kinds of Na channels in mature leech neurons. The R cell appears to have Na channels which are distinctly less sensitive to TTX than those of the three sensory cells. Previous studies have shown that there are also calcium conductance variations among these four cells (J.Physiol. 270 : 181, 1977). Careful examination of such variations should lead to better understanding of how particular neurons perform different functions.

291.8 CHARACTERISTICS OF SINGLE SODIUM CHANNEL CURRENTS AND THEIR MODIFICATION BY BATRACHOTOXIN IN NEUROBLASTOMA CELLS. Fred N. Quandt* and Toshio Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Currents through single channels which open in response to membrane depolarization were observed in recordings from N1E-115 neuroblastoma cells. The effects of the sodium channel blocker pancuronium and the sodium channel modulator batrachotoxin (BTX) on these currents were examined. The methods of Sigworth and Neher (Nature 287, 447, 1980) and Horn and Patlak (PNAS 77, 6930, 1980) developed for recording from muscle membrane patches were utilized. Cultured neuroblastoma cells appear to be a good preparation for this application since there is free access to the membrane, the cells can be voltage clamped and perfused internally, and the sodium channel density is low (maximum of 20 per μm^2). Patch pipette openings were $<1\mu^2$ and resistances were 2 to 10 megohms. The pipette-membrane seal resistance was 1 to 10 gigohms. Depolarizations to -40 mV were utilized in these studies since this potential is at the foot of the sodium conductance-voltage curve for these cells. This procedure lowers the probability of opening during a depolarization and permits the measurement of individual openings.

In a typical experiment, inward current jumps having a variable latency from the onset of the pulse were recorded. These currents were then measured for a number of pulses. The population had an amplitude of 1.4±0.5 pA and an open time of 1.7±0.6 msec (mean ± s.d., n = 112, 16°C). These currents appear to be due to the opening of sodium channels for two reasons. First, addition of 135 µM pancuronium to the cytoplasmic side of the excised membrane preparation produces a reversible block of these currents. Second, with well differentiated cells, larger pipette openings, and depolarizations to +10 mV, inward currents having a similar time course to those for sodium currents recorded by conventional voltage clamp methods are observed. The mean sodium channel conductance is estimated to be 15 pS for the typical experiment cited above. The effects of BTX were examined by incubating the cells in a low Na solution having 4 µM BTX. The patch pipette had normal Na (145 mM). Inward currents in response to membrane depolarizations to -40 mV appeared to have a normal amplitude but a prolonged open time. In a typical experiment, a single channel current was 1.3±0.3 pA and an open time was 16.7±9.1 msec (mean ± s.d., n = 133, 22°C). This latter value is consistant with the slower kinetics of the sodium channel in the presence of BTX (Supported by NIH grants ES 02330 and NS 14144).

291.9 DOES MAMMALIAN FAST-TWITCH MUSCLE POSSESS TWO DELAYED-RECTIFIER CHANNELS? P.L. Donaldson & K.G Beam*, Department of Physiology & Biophysics, University of Iowa, Iowa City, IA. 52242.

Based on tail current experiments, Adrian, et al., (J. Physiol. 208: 645-668, 1970) have suggested that voltage activates both fast and slow delayed-rectifier channels in amphibian twitch muscle. We have used the three-microelectrode technique of Adrian et al., (1970) to measure the delayed-rectifier currents in fast-twitch, skeletal muscle of rats at 15° C. The external solution contained (mM): Na+ (151), K+(5), Ca++(10), Mg++(1), HEPES (10) pH=7.4, methylsulfate (146), acetate (27), sucrose (400), and 1 μM TTX. Tail currents were measured at clamp potentials of -120 to -40 mV, which were applied to the muscle following a 25 ms conditioning pulse to either -10 or +10 mV. The reversal potential (E_{rev}) for the tail currents ranged from -90 to -60 mV. The outward tail currents could in most cases be adequately fit with a single exponential, whereas the inward tail currents showed both a fast and a slow phase of decay (τ≈5.0 & 250 ms, respectively, at -90 mV). Increasing the duration of the conditioning pulse caused a depolarizing shift in E_{rev} and a roughly proportional increase in both components of the inward tail currents, suggesting that both are affected by accumulation of potassium within a restricted extracellular space. In experiments where the conditioning pulse elicited relatively small currents, exponential fits of the tail currents revealed that the conductance of either the outward tails or of the inward fast phase agreed reasonably well with the conductance at the end of the conditioning pulse. When the conditioning pulse elicited large currents the agreement was not as close, especially for the rapid inward tails, which tended to meld with the capacity transient. Replacement of external K+ with 5 mM Rb+ abolished inward rectifier currents (over the range -90 to -120 mV). Rb+ also eliminated the slow component of the inward tail currents, after both 25 and 100 ms conditioning pulses. Thus, it appears that the slow phase of the inward tail current is predominantly carried through the inward rectifier.

Rb+ caused the delayed-rectifier channels to rectify: the conductance at the beginning of the outward current tails was approximately equal to the conductance at the end of the conditioning pulse; in contrast, the conductance of inward tail currents was reduced. Compared to tail currents in K+, the decay of inward, but not outward, tail currents in Rb+ was considerably slowed. Activation kinetics were unaffected by Rb+.

Supported by research grants from MDA and NIH (NS 14901) to K.G.B.

291.10 HYPERPOLARIZING REGENERATIVE RESPONSES IN DISSOCIATED FROG ADULT MUSCLE FIBRES AFTER PROLONGED CULTURING. M.I. Glavinovic[1], R. Miledi[2], Y. Nakajima[3], [1] Dept. Anaesth. Res. & Physiol., McGill Univ., Montréal, Canada, [2] Dept. Biophysics, Univ. College, London, UK, [3] Dept. Biological Sci., Purdue Univ., Lafayette, IN, U.S.A.

If a depolarizing current pulse is given to a normal fibre of the frog's lumbricalis muscle or to dissociated muscle fibre kept in tissue culture for several days, an action potential is generated when the membrane potential reaches the threshold. After prolonged culturing of the muscle fibres (4-7 weeks) the action potential can still be elicited although it does not overshoot to as high a membrane potential as in normal muscle fibre and its time course is slower.

Moreover, in some but not all muscle fibres that were dissociated and cultured for a long period of time, a hyperpolarizing regenerative response (hyperpolarizing action potentials (h.a.p.)) could be elicited by hyperpolarizing current pulses when the membrane potential reached a threshold of ≈120 mV. Before this threshold value was attained the hyperpolarization had the form expected for an electrotonic change in membrane potential. After reaching the threshold the membrane potential increased slowly at first, and then more rapidly, reaching a peak, of as low as -240 mV, and then - though the current is still applied - it declined and stabilized close to the threshold, producing a characteristic spike-like appearance, that however lasted hundreds of milliseconds.

The time course as well as amplitude of h.a.p. depended on the intensity of the applied current. With stronger currents the rate of rise and decay were faster and the peak was at a more negative membrane potential. When the polarizing current ceased, the membrane potential quickly returned to the initial preset value (-90 mV). The shape of the h.a.p. was quite labile and depended not only on the current intensity but also on the frequency of application of current pulses, showing refractoriness that lasted tens of seconds.

The above experiments indicate that the regenerative hyperpolarizing responses that occur during continued applications of a constant current, were accompanied and perhaps resulted from an increase in membrane resistance, followed with a subsequent decrease in resistance. Further experiments are necessary in order to determine the ionic mechanism of the hyperpolarizing responses.

291.11 PRODUCTION OF DEPOLARIZING AFTERPOTENTIALS BY HIGH INTERNAL AND EXTERNAL CALCIUM CONCENTRATIONS. Michael Merickel, Richard Gray and R. Blaine Moore*, Department of Neurology, Baylor College of Medicine, Houston, Texas 77030.

We have been interested in studying the involvement of various ionic events underlying the action potential (AP) afterhyperpolarization and repetitive firing behavior of myotubes in primary cultures prepared from adult human biopsy specimens. These studies are motivated by previous work demonstrating that myotubes from patients with Myotonic Muscular Dystrophy often exhibit depolarizing afterpotentials (DAP's) as well as an increased tendency to repetitively fire AP's (Merickel et al, PNAS 78:648-652, 1981).

Initial experiments suggested that the AP hyperpolarization (AHP), typically approx. 10 mV negative to the resting potential (RMP), is not primarily dependent on a Ca^{++}-dependent K^+ current: 1) Substitution of Ba^{++} for Ca^{++} only slightly reduced the AHP amplitude, increased input resistance but did not significantly alter AP duration; 2) Attempts to inject EGTA to chelate $[Ca]_i$ had little or no effect on the AHP amplitude, suggesting the importance of a voltage dependent K^+ current. Unexpectedly, increasing $[Ca]_o$ from 2 to 10 mM caused the AHP to become depolarizing (i.e., producing a DAP). Single electrode voltage clamp experiments demonstrated that the 10 mM $[Ca]_o$ treatment produces a reduction in amplitude and slower time course of activation of net outward current which is probably responsible for the reversal of the AHP. Rapid reversal of the AHP could also be obtained by raising $[Ca]_i$ by inserting an electrode containing 0.5 M $CaCl_2$ and 0.5 M KCl (to permit simultaneous recording) for less than a minute. The reversal of the AHP could be observed after removal of the Ca^{++}-containing electrode by reimpalement with a "normal" KCl electrode. Continued recording with a KCl electrode demonstrated that the afterpotential of the myotube gradually becomes hyperpolarizing, returning to a pre-Ca^{++} shape within 30 to 60 minutes. Neither the reversal of the AHP by increased $[Ca]_o$ or $[Ca]_i$ was associated with a significant change in RMP, indicating that the appearance of the DAP's is not due to a shift in RMP. These experiments suggest that higher than normal levels of internal Ca^{++} are able to reduce the net outward current resulting in DAP's by an unknown mechanism.

The production of DAP's by high internal Ca^{++} is being explored as a possible mechanism accounting for the DAP's and increased repetitive firing activity observed in myotubes from patients with Myotonic Muscular Dystrophy. (Support from the Muscular Dystrophy Association and Kleberg Foundation)

291.12 MODULATION OF THE ACTION POTENTIAL AND IONIC CURRENTS IN PRIMARY CULTURED RAT MUSCLE. R. Gray & M. Merickel. Dept. Neurology and Prog. in Neurosci., Baylor Col. of Med., Houston, TX 77030.

The ionic basis of the action potential (AP) in cultured embryonic rat muscle was studied by comparing changes in ionic currents with changes in the AP in response to ion substitutions and ion channel blocking agents. Ionic currents were measured in isopotential myoballs with a two electrode voltage clamp. Step depolarizations from -60 mV produced a transient inward current which developed into a net outward current, followed by an outward tail current after return to -60 mV. The AP is followed by an afterhyperpolarization which is due to a conductance increase to K and reverses near -78 mV, similar to the reversal potential for the tail current. The AP and all observable rapid inward current were blocked by 1 μM TTX, indicating a Na component of the spike.

Additionally, the AP contains an inward Ca component which activates a slow outward K current based on the following evidence: 1) When $[Ca]_o$ was increased from 2 to more than 10 mM in the presence of TTX an all-or-none AP could be elicited and the AHP was increased in amplitude and duration. 2) 10 mM $[Ca]_o$ caused a small increase in outward currents during clamp commands more depolarized than -30 mV and a larger increase in the outward tail current. 3) Blockage of calcium channels by substitution of Ni for Ca or by addition of verapamil reduced AP and AHP amplitudes as well as outward and tail currents. 4) Substitution of Ba for Ca resulted in membrane depolarization and repetitive firing of APs with long plateau phases. The net outward current was markedly decreased and the tail current became inward after large depolarizing commands.

Reduction of K current by tetraethylammonium ions (TEA) caused a broadening of the spike, a decreased AHP and repetitive AP generation. The net outward current during step commands and the tail current were also reduced. Little change was seen in outward currents during commands in TEA + 10 mM $[Ca]_o$ from that with TEA alone, but the tail current became inward after large depolarizations. These results suggest that the AP in cultured rat muscle contains a Ca component which normally plays a small role compared to Na during the rapid phase of the spike, but a larger role as a modulator of a slow K conductance most easily seen in the AHP and tail current measurements. Support is acknowledged from Muscular Dystrophy Association and the Kleberg Foundation.

291.13 CYCLIC NUCLEOTIDE MODULATION OF NA^+ AND K^+ CURRENTS IN PERIPHERAL NERVE NODE OF RANVIER. T.L. Seelig* and J.J. Kendig. Dept. of Anesthesia, Stanford Univ. Sch. of Med., Stanford, CA 94305.

There is evidence that cyclic nucleotides, and the enzymes necessary to metabolize them, exist within the nodal region of peripheral nerve axons. An important question is whether their localization within the axon is functionally significant in affecting nerve conduction. This possibility was explored electrophysiologically in the sciatic nerves of Xenopus laevis by examining their responses to dibutyryl adenosine 3':5' cyclic monophosphate (d-cAMP).

In 6 preliminary experiments using sucrose gap recording of whole nerve there was a consistent and marked increase in the amplitude of the compound action potential, and a hyperpolarizing drift in the baseline, in response to d-cAMP, or SQ20009, a phosphodiesterase inhibitor.

Specific parameters of this effect were studied using the voltage clamped node of Ranvier. Perfusion of the node with (2mM) d-cAMP resulted, in 4 out of 5 preparations, in (1) a marked increase in the amplitude of the early inward current, (2) an apparent increase in steady state inactivation (h), and (3) a longer time constant for the development of the late outward current.

There is evidence that cAMP may act in some neuronal cell bodies to modify K^+ conductance. To determine whether the action of d-cAMP at the node is dependent upon K^+ conductance changes, K^+ channels were blocked by addition of TEA to the normal frog Ringer's solution. In 3 nodes studied under these conditions d-cAMP had no effect on the amplitude of the Na^+ current, h, or the time constant of inactivation (T_h).

To look specifically at the K^+ conductance changes initiated by d-cAMP, Na^+ currents were blocked by replacing NaCl by choline Cl in the extracellular solution. Preliminary results in 2 nodes indicate that the voltage dependent K^+ current amplitude is increased as a result of d-cAMP treatment. Non-voltage dependent membrane conductance does not change as indicated by an unchanged leakage conductance throughout the experiments.

These findings suggest a role for intra-axonal cAMP in the modulation of action potential parameters. Although the exact mechanism for these effects can not yet be fully explained, it enables one to view the action potential as a much more plastic response than it is traditionally considered. This metabolic modulation of action potential parameters could be physiologically important in increasing the efficacy of specific synaptic connections. 291.14 TEA ENHANCES THE DEPOLARIZING AFTERPOTENTIAL IN SINGLE MYELINATED AXONS: Karen A. Scappaticci* and Ellen F. Barrett. Dept. of Physiology and Biophysics, Univ. of Miami Med. Sch., Miami, FLA. 33101.

Action potentials and afterpotentials were recorded intracellularly from peripheral myelinated axons, either motor axons innervating the dewlap extensor muscle of the lizard (Anolis sagrei) or axons dissected from the isolated sciatic nerve of the frog (Rana pipiens). All the solutions used with the lizard neuromuscular preparation contained 150 μM carbachol to block muscle contraction and all control solutions contained 2 mM calcium. Axons selected for study had resting potentials of -60 to -80 mV, and action potentials with peak amplitudes of 60 to 90 mV. Most axons showed a depolarizing afterpotential with a peak amplitude of 5-20 mV at the resting potential which decayed with a half time of 20-100 msec. Previous work by Barrett and Barrett suggested that this depolarizing afterpotential represents a passive capacitative discharge of the axon membrane through an internodal leakage pathway. In both preparations Tetraethylammonium (TEA, 5 mM) increased the duration of the action potential and markedly increased the amplitude and the time course of the depolarizing afterpotential. Increasing concentrations of TEA (10 and 25 mM) progressively increased the peak amplitude of the depolarizing afterpotential to up to 350% of control and increased its duration to up to 1 sec. These effects of TEA were slowly reversible. The fact that TEA enhances the depolarizing afterpotential in sciatic nerve axons lacking central and peripheral terminals indicates that TEA acts on the myelinated axon itself. These effects are due at least in part to blockade of potassium channels in the resting and depolarized axon, which would increase current flow through the depolarizing afterpotential leakage pathway and increase the passive time constant of the axonal membrane.

In 25 mM TEA motor axons in the lizard neuromuscular preparation showed a prolonged hump superimposed on the depolarizing afterpotential. This hump was blocked by 1 mM manganese, suggesting that the hump reflects a TEA-enhanced calcium action potential reflected electrotonically into the axon from the motor nerve terminal. Concentrations of TEA greater than 25 mM also produced repetitive activity in the lizard motor axons. Supported by the Muscular Dystrophy Association and USPHS grant NS-12404.

291.15 REPETITIVE FIRING CHARACTERISTICS OF MAMMALIAN MYELINATED AXONS: AN INTRA-AXONAL ANALYSIS. J. A. Ruiz*, J. D. Kocsis, and R. J. Preston*. (Spon. M. E. Smith) Dept. of Neurology, Stanford Sch of Med., and V. A. Medical Center, Palo Alto, CA 94304.

Intra-axonal recordings were obtained in vitro with glass microelectrodes from rat ventral root and sciatic nerve fibers. The excised nerves or roots were positioned across bipolar stimulating and recording electrodes in a nerve chamber. Axon impalements with resting potentials of at least -60 mV and action potential amplitudes of 60 mV or greater were selected for analysis. Inflections were occasionally observed on the rising phase of the action potentials. Depolarizing current passage through the recording microelectrode accentuated the inflections and fractionation of the impulse could occur at these points. The amplitude of the action potential was increased by passage of hyperpolarizing current and decreased by depolarizing current. Subthreshold depolarization often induced local responses. Most action potentials were associated with either depolarizing or hyperpolarizing afterpotentials. The amplitude of the hyperpolarizing afterpotential was increased by depolarizing current and decreased by hyperpolarizing current. Current-voltage curves were nearly linear and average input resistance was 18 megohms (N=12).

Current levels necessary for direct spike elicitation varied following either subthreshold depolarizing or hyperpolarizing constant current prepulses. Depolarizing prepulses were followed by a period of increased threshold; and hyperpolarizing prepulses were followed by a period of decreased threshold. The decrease in threshold immediately following hyperpolarizing prepulses was often sufficient to elicit anode break excitation. These threshold changes were both time- and voltage-dependent and may represent changes in sodium inactivation elicited by the prepulse.

Action potentials reliably followed nerve stimulation or intra-axonal pulses (dur.<2 msec) repeated at frequencies of 300 Hz or more. In contrast a long duration depolarization pulse typically produced only one action potential near the onset of the depolarization pulse.

These results suggest that action potentials at mammalian nodal membrane are readily elicited by discrete depolarizing steps. But, sustained depolarization does not elicit repetitive firing as occurs for many excitable membranes. 291.16 CURRENT-VOLTAGE HYSTERESIS AND REPETITIVE FIRING IN MOLLUSCAN NEURONS. L. Donald Partridge. Dept. of Physiology, Univ. of New Mexico, Albuquerque, New Mexico, 87131

Molluscan neurons are capable of maintained repetitive firing at low frequencies, often at less than one spike per second. Such regularly firing neurons, when voltage clamped, exhibit a marked hysteresis in the semi-stationary current-voltage relationship. The study reported here was an investigation of the relationship between the current hysteresis and low frequency repetitive firing.

The currents responsible for this current hysteresis were isolated by stopping the triangle wave clamp command signal at a given voltage during either the depolarizing or the hyperpolarizing phase of the current-voltage curve. Currents measured on the rising phase were subtracted from those measured at the same voltage on the falling phase. This difference current was fitted by the sum of two exponentials, the slower of which had a time constant of 1 - 2 sec. The reversal potential of the slow component of the difference current suggests a potassium mechanism. Both this current and the hysteresis were greatly reduced by procedures known to block calcium currents.

A computer model for repetitive firing was extended to include a calcium activated potassium conductance using published values for calcium diffusion, sequestration, and exchange at the membrane. When the voltage in the model was varied as in a triangle wave voltage clamp, a current-voltage hysteresis was observed. This model exhibited a much more linear frequency vs. stimulus intensity relationship at low current intensities than did a similar model without calcium activated potassium conductance. Neurons with a pronounced hysteresis exhibited a similar linear range of the frequency vs. stimulus intensity relationship.

Other studies have related spike afterhyperpolarization and regulation of repetitive firing to a calcium activated potassium conductance. In the molluscan neurons studied here such a current which has a pronounced influence on the current-voltage relationship is seen to influence very low frequencies of repetitive firing.

291.17 IDENTIFICATION OF THE IMPULSE-RESPONSE FUNCTIONS OF A NEURON AND OF ITS PARTS. C.I. Valenzuela. Neural and Behavioral Biology Program, University of Illinois, Urbana, IL, 61801.

The observable behavior of a linear, time-invariant system is completely characterized by the system impulse-response function. In a previous report (C.I.Valenzuela, Soc. Neurosci. Abstr.,#36.8, 1980) the impulse-response functions (as seen from the soma) of a neuron and of its parts are identified when the neuron consists of a spherical soma concatenated to a finite-length cylindrical dendrite (SS-FCD). The present work develops a method for the more common case where the cylindrical dendrite (or equivalent cable) has a length greater than 3 space-constants. In such case the neuron can be modeled accurately by a spherical soma with an infinite-length cylindrical dendrite (SS-ICD) system.

The identification method was based on the following :

1. Proof that regardless neuron geometry :

$$\int_{t=0}^{t=\infty} H_N(t)\, dt = R_N$$

where : $H_N(t)$ is the neuron impulse-response function, and R_N is the neuron input resistance, both as seen from the soma.

However, for all practical purposes this integral converges to R_N when the upper integration limit equals $5\tau_m$, thereby providing a means to estimate τ_m.

2. Proof that for the SS-ICD system :

$$\int_{t=0}^{t=\infty} +I_{clamp}(t)\, dt = -V_0\tau_m/2R_{dn}$$

where : $I_{clamp}(t)$ is the clamping current (after the soma capacitive discharge) that results from voltage clamping the soma to the resting potential following the steady-state caused by step current, I_{step}, injection at the soma,
V_0 is the soma steady-state voltage prior to voltage clamping ($V_0 = R_N I_{step}$), and
R_{dn} is the dendrite input resistance as seen from the soma.

Thus this integral provides a means to estimate R_{dn}.

3. An algorithm developed to estimate (in the time-domain) the impulse-response function of a linear, time-invariant system given an arbitrary set of system input-output data.

291.18 DELTA MODULATION THEORY CAN BE USED TO OPTIMIZE THRESHOLD HUNTING. L. Richard Carley* and S. A. Raymond (SPON: L. S. Frishkopf). Research Laboratory of Electronics, MIT, Cambridge MA 02139.

It is difficult to measure the firing threshold of nerve and muscle as a single valued function of time. To bound the threshold within a certain range requires that both a successful stimulus and an unsuccessful stimulus be applied to the system. The time interval between the two stimuli must be brief with respect to the rate of change in threshold. Since the first test stimulus will cause an immediate, lasting, and significant change in the threshold, such a measurement scheme fails because successive samples, spaced closely enough to capture all natural fluctuations in the threshold, would perturb the variable.

The french physiologist Pecher and others studied probability density function (PDF) of threshold in resting nerve and observed that outcomes of successive test stimuli were not significantly correlated, in frog sciatic nerve, if stimuli were applied $\simeq$2 s. apart. The most familiar way to use test stimuli to measure the PDF of the threshold is to count the successful fraction of repeated test stimuli of fixed strength. This method does not use information gained from previous trials and therefore takes more samples than necessary and is highly sensitive to drift. Threshold hunting refers to automated methods that use each response and failure of individual fibers to converge on threshold. A threshold hunter tracks changes in stimulus required to hold the firing probability at a fixed percentage (a fixed point on the cumulative distribution function (CDF)) as threshold changes.

Delta Modulation theory applies to threshold hunters that increment (Δ_{up}) or decrement (Δ_{dn}) the test stimulus after each trial. The fixed point on the CDF that the hunter tracks is *i)* $\Delta_{up}/(\Delta_{up}+\Delta_{dn})$. Using the theory we have defined 3 fundamental types of errors: (1) quantization error — occurs because the hunter's output is quantized into steps and is related to the size of the steps by *ii)* $[(\Delta_{up}+\Delta_{dn})^2/16]$, (2) fluctuation error — caused by the imperfect filtering of the natural fluctuations in the running threshold is *iii)* $[\sigma_T(\Delta_{up}+\Delta_{dn})/3.5]$, where σ_T is the standard deviation of the threshold fluctuations, and (3) tracking error — is inversely proportional to step size and is *iv)* $[\delta S/(\Delta_{up}+\Delta_{dn})]$, where δS is the difference between successive stimuli when tracking a fixed point on a moving CDF.

The speed of a threshold hunter can be greatly increased by any approach which reduces the information to be extracted from the nerve. For example, by predicting the derivative of the hunter's output, which can be done throughout an experiment by extrapolating from the accumulated data, the step sized can be adjusted dynamically. Thus the hunter's tracking rate can be matched to the rate of threshold changes, δS. Step sizes are adjusted so that their sum, Δ, is held constant (which keeps the quantization and fluctuation errors fixed). The predicted derivative, $\delta S'$, is used to predict the step sizes as in equations *v)* $\Delta_{up} = P\Delta + \delta S'$ and *vi)* $\Delta_{dn} = (1-P)\Delta - \delta S'$, where P is the firing probability being tracked.

By using several hunters in rotation, each set to converge on a different fixed point on the CDF, the actual shape of the CDF can be tracked.

291.19 NORMAL AND ABNORMAL SIGNAL PATTERNS IN NERVE CELLS. Gail A. Carpenter. Dept. of Mathematics, Northeastern University, Boston, MA 02115.

A fundamental problem of psychophysics is an inverse problem: induce underlying cellular or network mechanisms from signal patterns. The patterns may be observed at various levels: from EEG, extracellular, or intracellular recordings or from psychological experiments. In each case the recorded pattern is an ensemble of events taking place at a finer, and usually unobservable, level. At the center of the present work is the following simple question: which intracellular signal patterns are the result of basic single-cell membrane mechanisms and how are these patterns altered as membrane parameters change? In other words, we consider the inverse problem at the level of the single cell.

A generalized Hodgkin-Huxley (HH) model is defined and mathematical analysis leads to many predictions about the patterns of action potentials. "Prediction" here means a property of solutions of the model in question. If the prediction fails to hold in a particular case, then the observed effect must be due to mechanisms not embodied in the model. For example, the effect could be due to additional ionic currents, slow parameter shifts, or network interactions. Examples are given in which the predictions of the basic model fail, forcing modifications for those cases. With the properties of the core model established, it is relatively easy to see how changes in the model change the solution patterns. (The simplified FitzHugh-Nagumo model is also discussed from the point of view of the present analysis.) The results show that generalized Hodgkin-Huxley models with only the usual Na^+ and K^+ current variables predict complex phenomena previously ascribed to more intricate mechanisms. Many of the predictions focus on burst and regular (evenly-spaced) periodic signal patterns. It is shown, for example, that the HH model predicts the existence of two types of regular periodic patterns or action potentials. One pattern is, in fact, a sequence of "bursts with one spike per burst". The two classes of regular periodic spikes are predicted to behave differently under parametric shifts, and once this fact is observed, examples of the two types are found in the experimental literature.

291.20 EXCITABILITY IN SIMULATED PROTOCELLS FROM PROTEINOID, Aleksander Przybylski* and Sidney W. Fox. Institute for Molecular and Cellular Evolution, University of Miami, Coral Gables, FL 33134.

Vesicles of proteinoid (thermal copolyamino acid) and lecithin display such properties as compartmentation, the abilities to proliferate and to communicate upon conjugation, enzymic activities including the ability to synthesize peptides, and permselective membranes (Fox and Dose, *Molecular Evolution and the Origin of Life*, rev. ed., Dekker, 1977; Nakashima and Fox, *J. Mol. Evol.* 15 161-168, 1980). These results prompted a search for excitability, which has been reported (Ishima and Fox, Abstract Third Annual Meeting, Society for Neuroscience, 17.10, 1973). The studies have been extended (Ishima, Przybylski, and Fox, *BioSystems*, in press).

The ability to form vesicles and to undergo electrical discharge varies with the identity of the proteinoid. Spiking is usually stimulated by shifts in ion concentration in the solution bathing the vesicles. In some cases, spiking is spontaneous; this latter phenomenon is explained by compartments, which are in turn induced by reaction of Ca^{++} with proteinoid. Vesicles are self-healing, and are capable of microencapsulating a number of substances. The microsystems thus permit modelling cellular events, especially those of the neuronal type.

A variety of action patterns has been observed (Fig. 1); some, for example, resemble discharge in *Aplysia* neurons (Chen, von Baumgarten, and Harth, *Pflügers Arch.* 345 179-193, 1973).

Research aided by NASA Grant NGR 10-007-008, the National Foundation for Cancer Research, and Mr. David Rose.

292.1 A DISTINCT ACTIN BINDING PROTEIN IN BRAIN. Robert L. Beach, E. Edward Mena and Carl W. Cotman. Dept Psychobiology, Univ. of California, Irvine, Ca. 92717.

Neuronal cytoskeletal proteins may play important roles in the development and function of the brain. Since actin has been found to be a major component of isolated synapses, and has been implicated in processes such as axon elongation and cellular movements, we have attempted to identify other proteins in brain which may interact with actin. We recently described the presence of a brain myosin, which was distinct from muscle myosins, in synaptic plasma membranes (SPM) and synaptic junctions (SJ).

In the present study we have isolated from brain a high molecular weight protein which binds reversibly to actin filaments. Purification was acheived by ammonium sulfate fractionation, coprecipitation with actin filaments and agarose gel filtration. This protein is a doublet of M.W. about 240,000 and 250,000 daltons on SDS PAGE in the presence of reducing agents, and it comigrates with macrophage actin binding protein. The binding of this protein to actin is reversed in the presence of elevated concentrations of KCL. This actin binding protein is widely distributed in subcellular fractions of brain, and is a signifigant component of SPMs and SJs. However it is solubilized along with the membranes when either of these fractions are treated with n-lauryl sarcosinate to prepare postsynaptic densities. This suggests that this protein may be associated with the membrane component of the former fractions.

We have compared the properties of this protein with other similar high molecular weight proteins. Fibronectin, which has recently been reported to bind actin, nearly comigrates with the actin binding protein doublet, but is distinguishable from this protein by other criteria. Fibronectin is a glycoprotein and it binds ^{125}I-Concanavalin A after gel electrophoresis, however the brain actin binding protein doublet does not. Furthermore two dimensional peptide maps of fibronectin and the brain protein show that the two proteins are distinct. Filamin is a high molecular weight actin binding protein, which was originally found in smooth muscle, but it has been identified in other cells. We have labelled filamin following SDS PAGE using antibody to filamin and ^{125}I-Protein A. The brain actin binding protein doublet does not bind antibodies to filamin. We have also compared this protein with brain myosin heavy chain (M.W.=200,000). The actin binding protein does not bind antibodies to myosin, and the two dimensional peptide maps of these proteins are distinct. Furthermore, unlike myosin, the association of brain actin binding protein is not reversed by ATP. Thus it appears a distinct actin binding protein is present in brain and is associated with subcellular fractions including SPMs and SJs.

292.2 CALCIUM-BINDING PROTEIN IN THE RAT BRAIN. S.C. Feldman and S. Christakos* Depts. of Anatomy and Biochemistry, CMDNJ-New Jersey Medical School, Newark, N.J. 07103.

A vitamin-D dependent calcium-binding protein (CaBP), molecular weight 28,000, has been localized in chick tissues, including CNS. In the rat, a calcium-binding protein with the same molecular weight has been identified in the CNS and shown to cross-react with antisera to the chick CaBP by Ouchterlony double-diffusion analysis (Wasserman, etal., 1977). The present study was undertaken to determine the concentration and distribution of this 28,000 molecular weight CaBP in the rat CNS, using a highly specific antiserum to chick intestinal CaBP (Christakos and Norman, 1980).

The concentration of CaBP in 4 areas of the rat brain was determined by radioimmunoassay (RIA): forebrain, hypothalamus, cerebellum and brainstem. The mean concentration of CaBP was 4.6 $\pm$ 0.8 ng/mg protein and did not vary significantly as a function of area. To determine if CaBP was present in neurons, the protein was localized by immunocytochemistry in Bouin's fixed section of rat forebrain, using the same antiserum as for the RIA. All staining in neuronal elements was judged specific as determined by the absence of staining in sections in which the antiserum had been previously adsorbed with CaBP. CaBP was present in neuronal elements, i.e., neurons and fibers in several areas of the rat forebrain. CaBP-containing neurons were found in: neocortex, primarily in layers II-IV; hippocampal formation, including a small number of cells in the granule layer of the dentate gyrus and pyramidal neurons of CA_1 but not CA_3 or CA_4; basal ganglia, including caudate/putamen and claustrum; hypothalamus, in scattered cells along the midline; thalamus, primarily in the mid-line nuclei; amygdala, in corticomedial and basomedial nuclei; and in substantia nigra, pars compacta. CaBP-containing fibers were present in most major tracts including corpus callosum, optic tract, stria terminalis, mammillothalamic tract and medial lemniscus.

In the chick, a 28,000 molecular weight, vitamin-D dependent protein has been shown to bind calcium. The presence of an immunologically identical molecule in the rat CNS suggests that this protein may have a role in neuronal function in the mammalian CNS. (Supported by a grant to S.C.F. from the Foundation of the College of Medicine and Dentistry of New Jersey).

292.3 CALCIUM-ACTIVATED, PHOSPHOLIPID-DEPENDENT PROTEIN KINASE FROM RAT BRAIN IS INHIBITED BY ACTH. V.J. Aloyo, M.A. Hoogkamer*, H. Zwiers* and W.H. Gispen. Inst. Mol. Biology, Division of Neurobiology, State University of Utrecht, 3508 TB Utrecht, The Netherlands.

Recently a calcium-activated phospholipid-dependent protein kinase (kinase C) from rat brain was described (Inoue et al., J. Biol. Chem., 252:7610, 1977). This enzyme had a molecular weight of 77K and was not activated by cAMP or cGMP. A number of phospholipids, such as phosphatidylserine and phosphatidylinositol, were able to activate this kinase (Takai et al., J. Biol. Chem., 254:3692, 1979).

We have partially purified kinase C according to the method of Inoue et al. After DEAE-cellulose column chromatography and gel filtration on Sephadex G-100, a protein mixture was obtained that was essentially free of substrate phosphoproteins and had a major protein band of 70K as determined by SDS-polyacrylamide gel electrophoresis.

The protein kinase activity present in this preparation was studied using whole histone as the substrate. Phosphorylation of histone was stimulated by the addition of phosphatidylserine and inhibited by chlorpromazine. No effect of cAMP could be detected. These results suggest that this kinase activity closely resembles the one described by Inoue et al. $ACTH_{1-24}$, which is a potent inhibitor of the phosphorylation of certain low molecular weight proteins in synaptosomal plasma membranes from rat brain tissue (Zwiers et al., Neurochem. Res., 1:669, 1976), did not inhibit the phosphorylation of histone by kinase C.

We have tested whether protein kinase C would phosphorylate the ACTH-sensitive phosphorylatable protein B-50 that was purified to homogeneity with isoelectric focussing as the last step in the purification procedure (Zwiers et al., J. Neurochem., 34: 1689, 1980). B-50 appeared to be a good substrate for kinase C, and its phosphorylation was stimulated by phosphatidylserine. No effect of cAMP was detected. But $ACTH_{1-24}$ did inhibit B-50 phosphorylation by kinase C.

Work is in progress to determine the possible identity of protein kinase C and the B-50 protein kinase as isolated by Zwiers et al. (J. Neurochem., 34:1689, 1980).

292.4 ALTERATIONS IN BRAIN mRNA LEVELS FOR SPECIFIC TUBULIN SUBUNITS DURING HUMAN DEVELOPMENT. M. Morrison and W.S.T. Griffin. Depts. Neurology and Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

The ability to isolate undegraded mRNAs from human postmortem brain would facilitate the molecular analysis of various neurological diseases and allow comparisons to be made between prenatal and adult mRNA levels. Our control studies on isolation of cytoplasmic RNAs from rat cerebella showed that 60% of the cytoplasmic mRNA activity was retained after storage of the cerebella for up to 16 hrs at room temperature. Comparison of the abundant mRNA populations by two dimensional gel analysis of their in vitro translation products showed that the mRNAs isolated from stored cerebella were virtually identical to those obtained from fresh tissue. Comparison of mRNAs isolated from two human cerebella, 4 hrs and 16 hrs postmortem, also showed little evidence of selective mRNA degradation postmortem. Similar results were obtained with postmortem human cortex. These experiments show that abundant mRNAs characteristic of the in vivo tissue can be isolated from human postmortem brain. These RNAs can therefore be used to study changes in abundant mRNA populations during human development. The results from human adult cerebellum and cortex show that there is significantly less translatable mRNA for the α_1 and α_2 tubulins and the β_1 tubulin than there is for the major β_2 tubulin subunit. The proportions are therefore similar to those of the different tubulin subunits in adult rat cerebellum (Morrison et al. J. Biol. Chem. 256 (1981) 3550-3556). Analysis of mRNAs from human fetal cortex and cerebellum showed that the levels of translatable mRNAs for the α subunits and the β_1 subunit were dramatically increased relative to those in the adult. These proportions were again similar to the different mRNA levels in the neonatal rat although the levels of the β_1 tubulin subunit mRNA were relatively higher in human fetal cortex than in neonatal rat cortex. Further, the relative amounts of this mRNA were always higher in the cortex than in the corresponding cerebellum. These results suggest that mRNA levels for the minor β subunit are higher in glia-rich brain areas such as cortex than in neuron-rich areas such as cerebellum. The different developmental and regional patterns of tubulin mRNAs may be a reflection of a diversity of roles for the different forms of α and β tubulins during brain development and or within different brain cell populations.

Supported in part by NIH 1 ROl-HD 14886 and grants from the Leland Fikes Foundation, Inc. and the Biological Humanics Foundation.

292.5 ISOLATION OF BRAIN TUBULIN SPECIES FROM IEF GELS. K. von Hungen*, J. Khoury*, R. C. Chin* and C. F. Baxter (SPON: H. Hirsch). Neurochemistry Labs, V.A. Medical Center, Sepulveda, CA 91343.

Brain tubulin is now known to be composed of several closely related species. The relative amounts of these species change during early development for both the alpha and beta subunits (Dahl and Weibel, BBRC, 86:822, 1979), but not during advanced aging (von Hungen et al., J. Neurochem., in press). The species can be separated on isoelectric focusing (IEF) gels (banding between pH 5.2 and 5.4), but the patterns observed are critically dependent upon conditions of the run and on the ampholytes used. It is thus difficult to determine the exact number and relative quantity of species. We have achieved good resolution of species using Bio-Rad pH 4-6 ampholytes. The differences in species which give rise to different isoelectric points are not known, and we have attempted to isolate individual species in order to be able to determine what the differences are. We have found that the tubulin species can be visualized by placing IEF gels in distilled water (or dilute Tris buffer). This permits cutting out of very close bands without staining the gel. Dissected discs from the IEF gels can then be run on SDS slab gels to remove ampholytes. The species are visualized on the SDS gels with KCl solution, cut out, electrophoretically eluted, dialyzed and lyophilized. Using this procedure, we have purified 5 species associated with the alpha subunit and 10 species associated with the beta subunit. When run again on IEF gels, the species run at their original position. Amino acid analyses on these species are in progress. Early data indicate several possible amino acid differences, and notably in one unidentified basic molecule in the protein hydrolysates.

The procedure used for isolation of tubulin species from IEF gels may be of value for isolation of other proteins as well. Tubulin species and several other proteins form white bands in the IEF gel within minutes of being placed in water. These bands are stable indefinitely, although the background increases noticeably after a few days. The gels can be scanned for light scatter (e.g. at 300 nm). Ampholytes, at least those we have tested (Biolytes), do not interfere, while in stained gels interference from ampholytes is frequently a problem. The absorbance appears linear for low concentrations of proteins. Resolution is nearly as good as in stained gels. Sensitivity is good; less than one microgram of many proteins is easily detectable. The sensitivity, however, appears to vary considerably with different proteins. The method works well with tubulin, BSA and alkaline phosphatase, but not with urease. Further characterization of the method with additional proteins will be presented.
(Supported by the Medical Research Service of the V.A.)

292.6 CHANGES OF CYTOSKELETAL PROTEINS IN THE PERIKARYA AND AXONS OF REGENERATING FROG MOTONEURONS. D. V. Sinicropi and D. L. McIlwain. Department of Physiology, University of North Carolina, Chapel Hill, NC 27514

Changes in the amounts of tubulin, actin, and neurofilament proteins were sought in regenerating motoneurons of Rana pipiens. Ventral roots 9 and 10 were unilaterally transected approximately 7 mm from the spinal cord. One to 75 days later, 3 types of samples were taken for biochemical analyses: a) spinal cord segments 9 and 10 divided at the midline into left and right halves, b) left and right ventral roots 9 and 10 from the spinal cord to the site of transection, and c) motoneuronal perikarya isolated from the left and right halves of spinal segments 9 and 10 by a new method employing bulk separation techniques followed by the collection of individual cell bodies with micropipettes. Aliquots of spinal cord and ventral root homogenates were assayed for tubulin by a [^{3}H]colchicine-binding method and for total protein, and another aliquot was analyzed by two-dimensional (2-D) electrophoresis. Proteins extracted from pooled samples of 100-150 isolated motoneuronal perikarya were also analyzed by 2-D electrophoresis. Gels of experimental and control samples were stained with either Coomassie Blue or silver and were compared visually, using ovalbumin as an internal standard. Actin, α and β tubulin, and the lowest molecular weight subunit of neurofilaments (NF1) were tentatively identified on gels by their comigration with purified samples of these proteins.

Data reported below were obtained from animals which were allowed to survive 20-35 days after axotomy, at which time the changes in several proteins became maximal (unpublished) and the tips of regenerating motor axons had exited the vertebral column but had not yet reinnervated muscles. Binding of [^{3}H]colchicine decreased to 50% of control in the transected ventral roots, but no decrease was detected in spinal cord samples. NF1 was markedly decreased, and α and β tubulin also appeared to be decreased in 2-D gels of transected ventral roots. In contrast, the amount of actin was increased in the transected ventral roots. In axotomized perikarya the amount of NF1 was increased compared to controls. Changes in the amounts of actin and tubulin in axotomized perikarya were less obvious and will require quantitative analyses. Quantitative analyses of the 2-D gels by a television-based densitometric method (Aycock et al., 1981, Comput. Biomed. Res., in press) are in progress.

One possible explanation of these data is that the export of neurofilaments and perhaps other cytoskeletal proteins from motoneuronal perikarya is altered after axotomy.

292.7 COMPOSITIONAL MAKEUP OF REGENERATING GOLDFISH AXONS AND IDENTIFICATION OF LOCALLY SYNTHESIZED PROTEINS. E.Koenig and P.Adams* Div. Neurobiology, State Univ. of NY, Buffalo, NY 14214.

We have been utilizing the goldfish retinal explant system, developed by Landreth and Agranoff (Brain Res., 118:299, 1976) to study compositional makeup and the capacity of regenerating axons to synthesize proteins. The explants, when cultured in the presence of 5-deoxyuridine (Johns, et al., Brain Res., 142: 531, 1978), yield axon fasicles free of periaxonal investment and non neural cells (unpublished observations). After outgrowth, axonal fields can be severed from their attachment to explants and incubated with radioactive amino acids. Using direct quantitative microanalytical methods, we have demonstrated that cycloheximide inhibits local incorporation by 80% (Koenig and Adams; submitted). Present studies are concerned with characterizing compositional makeup of major endogenous proteins in regenerating axons and identification of proteins labelled during in vitro incubation with a mixture of ^{3}H-amino acids. For this purpose a gel microslab system, developed in this laboratory, is being used. SDS gel patterns indicate that tubulin and actin are the most abundant proteins present. The molecular forms of neurofilament polypeptides in mature goldfish axons are different from those reported for mammals. Based on relative mass concentration, the putative neurofilament oligomers in goldfish have nominal molecular weights of 145K, 135K and 120K. While a 68K polypeptide is present, it is a relatively minor component. In regenerating axons, the 145K putative neurofilament polypeptide is readily discernible, but it is uncertain whether the 135K and 120K polypeptides are present in significant amounts. These findings are consistent with electron microscopic studies, which indicate occasional single neurofilaments that are randomly distributed in these growing axons. Fluorograms of regenerating axonal extracts separated in the gel microslab system show three principal peaks, corresponding to tubulin, actin and the 64-67K region of the gel. Microcombustion of excised tubulin, actin and the 64-67K portions of the microelectrophoretograms containing control and cycloheximide-treated extracts show that about 25% of the tubulin labelling is cycloheximide-insensitive. Because ^{3}H-tyrosine is present in the amino acid mixture, it seems likely that posttranslational labelling is due to endogenous tubulin tyrosine ligase activity. These preliminary findings indicate that there is an apparent supplementation by local synthesis of two major classes of structural proteins essential for axonal growth.

292.8 POST-MORTEM STABILITY OF PROTEINS WITHIN BOVINE SPINAL MOTONEURONS: A TWO-DIMENSIONAL ELECTROPHORETIC ANALYSIS. Thomas O. Brock, III and D. L. McIlwain. Neurobiol. Prog. and Dept. Physiology, *Sch. Med., Univ. N. Carolina, Chapel Hill, N.C. 27514*

An issue in the use of post-mortem nervous tissue for the study of neurological diseases is the quality of specimens necessarily taken several hours after death. The following experiments were performed to evaluate the effect of harsh post-mortem conditions on the proteins of spinal motoneurons. Perikaryal and axonal proteins extracted from motoneurons of bovine spinal tissue that had been stored at room temperature for one day were compared to proteins from motoneuronal cell bodies isolated promptly from the same animal. Cervical and lumbar enlargements were removed from each of four spinal cords which had been placed on ice within 30 min of slaughter. The enlargements were transected and cell bodies of spinal motoneurons were isolated from combined lumbar and cervical halves of each spinal cord by the procedure of Weil et al. (J. Neurochem. 29: 847-852, 1977). The four purified cell body preparations, along with intradural ventral roots from the same enlargements, were stored at -70°C. The remaining cervical and lumbar halves were wrapped in plastic and left at 24° ± 1°C for one day, after which motoneuron cell bodies were isolated and stored at -70°C with ventral roots from the same day-old tissue.

Total protein was extracted from the isolated perikarya and ventral roots, using O'Farrell's lysis buffer (J. Biol. Chem. 250: 4007-4021, 1975) to which 2% SDS had been added. Proteins were separated by 2-D electrophoresis (O'Farrell, supra vide) and stained with Coomassie blue or silver. Based in part upon light and electron microscopic evidence from sections of bovine ventral roots, we believe that most of the proteins extracted from ventral roots originate from the motor axons, rather than from myelin and other sources. Visual comparisons of 150-200 proteins from gels of motoneuronal perikarya and ventral roots revealed no qualitative differences between control and one-day groups. A few quantitative differences were apparent to the eye and were reproducible from animal to animal. The gels are currently being analyzed by computer-assisted densitometry (Aycock et al., Computers and Biomed. Res., 1981, in press).

These results show that even at room temperature the major proteins in bovine spinal motoneurons are remarkably stable during the first day after death.

Supported by USPHS grant 2R01 NS 12103 and funds from the Amyotrophic Lateral Sclerosis Society of America.

292.9 METABOLISM OF γ-GLUTAMYL-POLYAMINES IN THE APLYSIA NERVOUS SYSTEM: EVIDENCE FOR TRANSGLUTAMINASE AND γ-GLUTAMYLAMINE CYCLOTRANSFERASE ACTIVITIES. Leon Kremzner* and Richard Ambron (sponsor J. Correll), Depts. Rehab. Med., Anatomy, Neurology, P&S, Columbia Univ., N.Y., N.Y., 10032.

Recent studies by a number of investigators have shown that intracellular proteins are post-translationally modified by the covalent incorporation of polyamines; a process catalyzed by one or more Ca^{++}-dependent transglutaminase enzymes. These findings are of significance since transglutaminases are able to directly cross-link proteins. Hence, they may be involved in the modification and stablization of membrane properties (Davies et al., 1980). We have now shown that ^{3}H-putrescine, when injected into the cell body of R2, the giant neuron of Aplysia californica, is metabolized to GABA, spermidine, and spermine. One or more of the polyamines are also incorporated into cellular proteins. Incorporation of ^{3}H-putrescine in an amide linkage at the carboxyl group of protein-bound glutamic acid was demonstrated by exhaustive proteolytic digestion, followed by the identification of the covalently bound putrescine as N-(γ-glutamyl)-^{14}C-putrescine, using an automatic ion exchange column chromatographic procedure. Free ^{14}C-putrescine was liberated from this compound after acid hydrolysis. At least two other polyamine derivatives were also formed.

The existence of transglutaminase activity in Aplysia was also shown by incubation of nervous tissue homogenates with ^{14}C-putrescine, followed by proteolytic digestion and isolation of N-(γ-glutamyl)-^{14}C-putrescine. Recent studies (Fink, Chung, and Folk, 1980) in rabbits, have demonstrated a catabolic pathway for γ-glutamylpolyamines, involving the enzyme γ-glutamylamine cyclotransferase. This enzyme acts on γ-glutamylamines to liberate the free polyamine and 5-oxo-L-proline (5-pyrrolidone-2-carboxylic acid). We have now demonstrated the cyclotransferase activity in Aplysia ganglia. The physiological significance of these findings is being investigated by the isolation and identification of the specifically modified neuronal proteins (Ambron and Kremzner these proceedings). 292.10 PROTEIN SYNTHESIS IN THE RABBIT RETINA FOLLOWING THE INTRAVENOUS INJECTION OF LSD. Bruce D. Clark* and Ian R. Brown, Dept. of Zoology, Scarborough College, University of Toronto, West Hill, Ont. M1C 1A4, Canada.

Polysomes were isolated from the retinas of young adult rabbits and separated into various size classes by centrifugation on 15-45% sucrose gradients. The intravenous injection of LSD at 100 µg/kg induced a disaggregation of polysomes to monosomes in the retina. This effect was transient with maximal disaggregation 1 hr after drug injection and a return to control polysome levels by 4 hr. The disaggregation of retinal polysomes was not the result of RNase degradation of polysomal mRNA since the 80s monosome peak which accumulated following LSD was dissociable in high salt to 40s and 60s ribosomal subunits. Monosomes generated by digestion of polysomes with RNase were not dissociable under these conditions. Our previous results suggest that LSD-induced hyperthermia is involved in the disaggregation of polysomes in total cerebral hemispheres of the rabbit brain and in the induction of a brain protein which is similar in molecular weight (i.e. 74,000) to one of the major 'heat shock' proteins previously reported to be synthesized in tissue culture systems following elevation of ambient temperature. (Freedman et al., Brain Res. 1981, 207, 129-145; Cosgrove et al., J. Neurochem. 1981, 36, 1037-1045; Heikkila et al., J. Neurochem. 1981, 36, 1229-1238). Our present studies indicate that during LSD-induced polysome disaggregation in retina, induction of synthesis of a retinal protein of molecular weight 74,000 is observed in vivo following intra-vitreal injection of [^{35}S]-methionine 20 min after intravenous administration of LSD at 100 µg/kg. Induction of synthesis of the 74,000 molecular weight retinal protein was also observed following translation in a reticulocyte cell-free system of residual polysomes isolated 1 hr following intravenous injection of LSD at 100 µg/kg. [^{35}S]-methionine labeled products from both the cell-free translation system and the in vivo labeling experiments were analyzed by two-dimensional polyacrylamide gel electrophoresis followed by fluorography. (Supported by the Medical Research Council of Canada).

292.11 EFFECTS OF THE SODIUM IONOPHORE MONENSIN ON SYNTHESIS AND PROCESSING OF NEUROSECRETORY PROTEINS IN APYLSIA BAG CELLS. Michael E. Yates and Robert W. Berry, Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. School, Chicago, IL. 60611.

Inhibition of the cell secretory process by the sodium ionophore monensin, through an alteration in formation of Golgi-derived secretory vesicles, has been documented in several non-neural systems (Tartakoff and Vassalli, J Cell Biol 79:694, 1978). More recently, it has been suggested that monensin is able to reduce in amount, at the Golgi appartaus, all ^{3}H-labeled protein destined for fast axonal transport (Hammerschlag, Stone, and Bolen, Trans Am Soc Neurochem 12:144, 1981). These results led us to an investigation of the effects of monensin on a well defined proteolytic processing sequence leading to the formation of neurosecretory products in the bag cells of Aplysia. These cells produce two ca. 4500 Dalton (4.5K) secretory peptides, ELH and AP, from a 29K precursor via a 6-9K intermediate (Berry, Baylen, and Trump, this volume). An additional non-secreted 12K product is produced concomitant with the 6-9K intermediate. We monitored the effect of 10^{-6}M monensin on this processing sequence using pulse-chase labeling protocols in which members of the sequence were identified by mobility on SDS-PAGE.

This concentration of monensin did not inhibit total protein synthesis, but if present for 2hr prior to and during a 6hr labeing period, increased the amount of label in the 29K precursor by 114%. This was accompanied by a 40% reduction in the labeling of both the 12K product and 6-9K plus 4.5K material, indicating a partial blockade of the initial cleavage of the 29K precursor. Furthermore, while the 4.5K products accounted for 20% of the label in control cells at this time point, none was produced in the presence of monensin, suggesting that cleavage of the 6-9K intermediate is also impaired. This was confirmed by labeling cells for 2hr, then chasing for 4hr in the presence of monensin. This produced a mean increase in amount of 6-9K material of 100%, accompanied by a 50% decrease in each of the 4.5K products. These data suggest that monensin blocks two sites in the precursor-product sequence leading to the production of neurosecretory products in the bag cells: 1) the initial cleavage of the 29K precursor, and 2) the subsequent cleavage of the 6-9K intermediate leading to the final products. It seems likely that these processing blockades may reflect impairment of Golgi apparatus function, but this remains to be determined. Supported by NIH grant NS-11519 (RWB).

292.12 IMMUNOCHEMICAL PURIFICATION OF MESSENGER RNA FOR MYELIN BASIC PROTEIN. A.A. Akowitz* and J.H. Carson*. (Spon: S. Pfeiffer). Dept. of Biochemistry, Univ. of Conn. Health Center, Farmington, CT 06032.

An immunochemical procedure for the isolation of myelin basic protein (MBP) specific polysomes from mouse brain has been developed. Brains from 15 day old C57BL mice were homogenized (10% w/v) using a Polytron homogenizer in medium containing .25M sucrose, .025M NaCl, .05M Tris-HCl, .005M MgAc, .007M Mercaptoethanol, 10 units/ml Heparin, 10mM Vanadyl Ribonucleoside. The homogenate was centrifuged at 1,000xg for 30 minutes to remove myelin. Deoxycholate (1%) and Triton X 100 (1%) were added to the supernatant and the polysomes were centrifuged through a 1.5M sucrose cushion at 100,000xg for 3-1/2 hours. The polysomes were resuspended in buffer containing .1M sucrose, .025M Tris, .05M NaCl, .005M MgAc, .007M Mercaptoethanol, 5 unit/ml Heparin and centrifuged through a cushion of 1M sucrose. This step removed adventitiously bound MBP. The recovery of polysomes was 9.0 OD_{260} units/gram brain wet weight.

MBP specific polysomes were isolated from total polysomes by immunoabsorption chromatography. Affinity purified antibody to mouse 14K MBP (7.6 mg IgG with a capacity to bind 8.4 ug MBP/mg) was bound to a Protein A sepharose column. The total polysome fraction (413 OD_{260} units containing less then 8ug MBP) was applied to the column. The column was washed with resuspension buffer to remove unbound polysomes. MBP specific polysomes were eluted with 1% SDS in resuspension buffer. The MBP specific polysomes isolated in this manner constituted 3% of the total polysome fraction and contained 40ng MBP/OD_{260} unit.

Poly A containing mRNA was isolated from the total polysome fraction, the unbound polysomes and the MBP specific polysomes by phenol chloroform extraction and affinity chromatography on poly U sepharose. The MBP coding potential of the isolated mRNA was analyzed by in vitro translation and immunoprecipitation with antibody to MBP. The total polysomes and the MBP specific polysomes were shown to contain mRNA for MBP. The unbound polysomes contained no detectable mRNA for MBP.

292.13 INHIBITION OF DNA SYNTHESIS BY THE NEUROCARCINOGEN ENU ADMINISTERED IN UTERO OR IN WEANLING RATS. M. J. W. Chang and R. W. Hart*. Dept. of Radiology, The Ohio State Univ. Columbus, OH 43210 and Natl. Ctr. Toxicol. Res. Jefferson, AK 72079.

Ethylnitrosourea (ENU) is a perinatal neurocarcinogen and teratogen in rats. The effects of ENU on DNA content and rate of DNA synthesis were determined in: 1) offspring of Sprague-Dawley rats treated in utero and 2) 30 day old female BD IV rats. At various times after a single dose of ENU (90 mg/kg i.p.) each animal was given 1.7 uCi/g (^{3}H-CH_3)-thymidine (S.A. = 40 mCi/mM and sacrificed 24 hours later. Brains, kidneys, livers and lungs were collected and the DNA content and specific activity determined. Offspring of Sprague-Dawley rats treated with ENU transplacentally (at 20 day of gestation) consistently had reduced body weights compared to control animals over the period of 2 to 30 days of age. Similarly, DNA content of neonatal brains and kidneys were less than controls over the same period. The DNA content of neonatal liver and lung was less in ENU treated rats for the first 12 days in liver and 17 days in lung. The inhibition of DNA synthesis in the treated rats was observed in all of the organs studied. The suppression of the thymidine incorporation lasted for approximately 2 weeks after birth in liver and lung, for approximately 3 weeks after birth in brain and kidney. When ENU was given to 30 day old BD IV rats. DNA content and thymidine incorporation into DNA were reduced in all 4 organs examined. By 7 days post ENU treatment, the suppression of DNA synthesis was reversed with thymidine incorporation exceeding controls in brain, liver and lung but not in kidney. The observed decrease of DNA content may be indicative of cell death while the increase of thymidine incorporation may suggest restorative hyperplasia.
Supported in part by USEPA grant R805008010 to R.W.Hart and the National Center for Toxicological Research.

293.1 INCORPORATION OF EXOGENOUS ^{125}I-TYRAMINE-GANGLIOSIDE-GM$_1$ (ITG) INTO CRUDE MEMBRANES FROM RAT BRAIN. M.A. Walz*, N.E. Klemm* and I. Jeng*. (SPON: J.C. Webster). Biochemistry Dept. and Missouri Inst. Psychiatry, Univ. Missouri-Columbia, Sch. of Med., St. Louis, MO 63139

Exogenous ganglioside GM$_1$ is inserted into plasma membranes under appropriate conditions. To study such insertion, GM$_1$ labelled with ^{125}I-tyramine covalently attached has been prepared with high specific activity according to our newly-developed procedure (manuscript in preparation). The ITG was incubated with membrane sedimented from homogenized rat brain at 11,000 x g, and significant amounts of ITG were incorporated into the membrane fraction. An irreversible nature of the incorporation was indicated by failure of the label to be removed by repeated washings or incubation of the membrane-bound ITG with nonradioactive GM$_1$. In comparison, ^{125}I as the Na salt and ^{125}I-tyramine did not bind significantly, and ^{125}I linked directly to GM$_1$ bound to a lesser degree. Incorporation of ITG into the membrane fraction was time- and temperature-dependent for up to 2 hrs. and from 0 to 37°C. Over the range of ratios tested, binding of ITG was linearly related to the amount added. The modified GM$_1$ was indistinguishable from the unlabelled compound in this study. However, regardless of the amount of GM$_1$ present, only approximately 20% was recovered in the membrane-bound form. Binding of ITG was slightly increased by the addition of unlabelled GM$_1$ to the reaction mixture, and, thus, cooperativity of GM$_1$ incorporation is suggested. The characteristics of ITG binding reported here compare well with those of tritiated-GM$_1$ binding reported elsewhere (Toffano, G. et al., J. Neurochem., 35:861, 1980) and support the conclusion that ITG incorporation into plasma membranes is indistinguishable from incorporation of unlabelled GM$_1$. (Supported by the Missouri Institute of Psychiatry Intramural Funds.)

293.2 INCORPORATION OF 2-^{14}C-MEVALONATE INTO RAT BRAIN LIPIDS: ARE THERE GLYCOSYLSTEROLS IN MAMMALIAN BRAIN? B.L. Hungund*. (SPONS: S. Mahadik). Long Island Research Institute, State University of New York at Stony Brook, Stony Brook, NY 11794.

Glycosylsterols are known to be widely distributed in the plant kingdom. However, there are no studies reported indicating their presence in mammalian systems. Since mammalian brains are known to be highly enriched in glycoconjugates (gangliosides) and in view of the increasing evidence for their involvement in CNS function, this study was undertaken to see if glycosylsterols exist in brain and how much they contribute to the glycolipid content.

Twenty day old rats were injected intracerebrally with 2-^{14}C-mevalonic acid. After 4 hours brains were removed by decapitation and lipids were extracted following the procedure of Fujino and Ohnishi (Biochim Biophys Acta 574, 94-102, 1979) and partitioned according to the Folch procedure. Thin layer chromatographic and radio-autographic results indicate that there are selected radioactive bands in both neutral glycolipid and ganglioside fractions. Chemical characterization of these bands will be presented.

293.3 EFFECTS OF MATERNAL ALCOHOLISM ON MYELIN GANGLIOSIDES (GA) IN OFFSPRING. A.B. Noronha*, J.M. Gnaedinger* and M.J. Druse-Manteuffel. Department of Biochemistry, Loyola University School of Medicine, Maywood, IL 60153

Female Sprague-Dawley rats were pair-fed, using control(C) or 6.6%(v/v) ethanol(E) liquid diets. The diets are a modification of those described by DeCarli & Lieber(J.Nutr. 91:336,1967). Protein, fat & carbohydrate (including ethanol-derived calories) accounted for 21%, 29% &50% of the total calories, respectively. On postnatal days 19,23,26 or 33 E & C offspring were given an intracerebral injection of either ^{3}H- or ^{14}C-N-acetylmannosamine. Rats were sacrificed 18h later and CNS myelin was isolated. Lipids were extracted by the procedure of Folch-Pi et al.(JBC 226:497,1957). GA were extracted by combining the methods of Irwin et al. (Anal.Biochem.94:335,1979) and Vance & Sweeley(J.Lipid Res.8:621,1967), thus enabling the extraction of more monosialogangliosides than would be extracted by conventional procedures. GA were separated by thin layer chromatography (Zanetta et al., Lipids 15:1055,1980). Separated GA were either visualized with resorcinol spray, scanned and quantitated or used for the determination of radioactivity.

At all ages examined in both C & E pups, the monosialogangliosides accounted for >60% of myelin GA sialic acid. The proportion of GM$_1$ in the myelin GA fraction was 2½-3 times higher at 34d than at 20d. In contrast, the proportion of myelin GD$_{1a}$ decreased by ∿70% during this age period. Using the indicated extraction method, the proportion of myelin GM$_4$ was found to be comparable to that of GM$_1$ at 34d. Despite the fact that the monosialogangliosides predominated at all ages, the highest relative specific activity(RSA) obtained after injecting either the ^{3}H or ^{14}C precursor was associated with GT$_1$. The monosialogangliosides rarely were observed to have an RSA >1. The E and C pups had comparable proportions of individual GA and comparable distributions of radioactivity among the GA at all ages examined. The normal content and synthesis of myelin GA in E pups contrasts with their abnormal synthesis of the major myelin-associated glycoprotein(Gnaedinger & Druse, Trans.Am.Soc.Neurochem.11:153,1980).

This research was supported by grants from Loyola BRSG, the USPHS (AA03490) and from the Schweppe Foundation. Mary Druse-Manteuffel is a recipient of a Schweppe Foundation Career Development Award.

293.4 THE USE OF A MONOCLONAL ANTIBODY TO STUDY THE DEVELOPMENT OF MYELINATING CELLS. B.Ranscht, P.A.Clapshaw, J.Price*, M.Noble* and W.Seifert. Friedrich-Miescher-Laboratorium der Max-Planck-Gesellschaft, Spemannstr.37-39, D-7400 Tübingen 1, W-Germany MRC Neuroimmunology Project, University College London, Gower Street, London WC IE, United Kingdom

A hybridoma cell line has been established secreting IgG3 monoclonal antibody that specifically binds to the surfaces of oligodendrocytes and Schwann cells, the cells involved in myelin formation in the central and peripheral nervous systems, respectively. Even though a mixture of antigens was used for immunization (a synaptic plasma membrane fraction from bovine hippocampi) the antigen specificity of the monoclonal antibody could be determined: the antibody reacts strongly against the major myelin sphingolipid, galactocerebroside (GalC). This was demonstrated using both ELISA and micelle absorption with lipids purified by thinlayer chromatography. These techniques also allowed the characterization of various rabbit glycolipid antisera, revealing one to have a strong affinity to GalC and one to sulphatide. These antibodies were used together with the monoclonal antibody to examine the appearance of GalC and sulphatide on developing oligodendrocytes from rat cortex and Schwann cells from sciatic nerve both in vivo and in vitro. Using indirect immunofluorescence techniques, evidence was obtained that GalC is expressed on the surfaces of these cells 2-3 days before sulphatide. This finding was confirmed on an electron microscopic level using ferritin conjugates to visualize GalC and horseradish peroxidase to detect sulphatide on oligodendrocytes in vitro. The monoclonal GalC antibody is currently being used to study the involvement of this galactosphingolipid in myelin formation.

293.5 INCORPORATION OF P_o PROTEIN INTO LIPOSOMES: DEMONSTRATION OF A TWO DOMAIN STRUCTURE BY IMMUNOCHEMICAL AND PAGE ANALYSIS. C.L. Koski* and M.L. Shin* (SPON: M. Rennels). Dept. of Neurology and Pathology, University of Maryland Medical School, Baltimore, Maryland 21201

P_o is the major glycoprotein of periperal nerve myelin and has an approximate molecular weight of 30,000 daltons. The amphiphilic nature of this protein has been suggested previously (Roomi M.W., Biochim. Biophys. Acta., 536: 122, 1978). In the present study, we wanted to characterize this protein further. P_o was purified by Sephadex Chromatography (Kitamura K., et al., Biochim. Biophys. Acta., 455: 806, 1976) and incorporated into an artificial lipid bilayer consisting of synthetic phosphatidylcholine and cholesterol. The liposomes were fractionated on a sucrose gradient. The continued expression of P_o antigenicity by the liposomes was shown by a specific complement consumption assay employing either a multivalent antiserum against P_o or an IgM monoclonal antibody derived from a hybridoma. Both antibodies were shown to recognize P_o expressed on the surface of peripheral nerve myelin. Trypsin treatment of the P_o liposomes removed a surface antigen, as shown by subsequent failure of the monoclonal anti-P_o to activate complement. PAGE analysis of the trypsin treated P_o liposomes revealed a 23,500 dalton protein and suggested that this segment of the molecule was protected from trypsin digestion. The purified P_o protein treated with trypsin in the fluid phase was cleaved into many smaller fragments. Similar results were obtained with chymotrypsin, although a slightly smaller residual liposome-associated fragment was found.

These experimental results suggest that the P_o glycoprotein consists of two domains, a hydrophilic domain that is accesible to either trypsin or chymotrypsin digestion and a hydrophobic domain, that is potentially trypsin sensitive, but is shielded by the lipid bilayer and, therefore, preserved. Since the anti P_o-monoclonal antibody binds to P_o reincorporated into an artificial bilayer, it is evident that the orientation of the protein in the liposome is similar to that in peripheral nerve myelin.

293.6 REGIONAL FATTY ACID UPTAKE INTO RAT BRAIN. A.S. Kimes and S.I. Rapoport. Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore City Hospitals, Baltimore, Maryland 21224.

Small amounts of fatty acids are normally taken up from the blood and are incorporated into brain lipids, primarily cell membranes. It was of interest to study the uptake and regional distribution of a saturated fatty acid, palmititic acid, in brains of conscious rats. Osborne-Mendel rats (250-350 g) were anesthesized with pentobarbital. Femoral and arterial catheters were implanted. Then the rats were allowed to regain consciousness. ^{14}C palmititic acid, in tracer amounts, was administered i.v. (75 μCi/kg) and the radioactivities in the plasma and brain were followed. At various time points from 1 min to 24 hr, the rats were killed and the brains were removed and dissected into 22 regions. Levels of radioactivity in the regions and in the plasma were measured in a liquid scintillation counter. From the early time points, the (capillary permeability x surface area (PA)) was calculated in the various regions. Radioactivity increased in the brain up to 20 minutes, then remained stable for 40 minutes. There was a 50% loss of radioactivity between 1 hr and 2 hrs., followed by 22 hrs of constancy.

Plasma radioactivity was 100% palmitate for the first 30 min, as tested by thin layer chromatography. After the first 30 min, progressively increasing percentages of the plasma radioactivity were phospholipids and triglycerides.

White matter accumulated and retained consistantly lower amounts of radioactivity than gray matter over the entire time course studied. The inferior colliculus, olfactory tubercule, cerebellar gray and cortical areas accumulated consistantly higher radioactivities than did other gray matter regions. These findings suggest that steady state levels of palmitate, (after 4 hrs), can be used to study the regional functional status of the brain.

293.7 FATTY ACID-INDUCED ALTERATIONS IN ACTION POTENTIALS FROM DISSOCIATED SPINAL CORD NEURONS. D.E. Brenneman* (SPON: B.K. Schrier). Lab. Devel. Neurobiol., N.I.C.H.D., N.I.H., Bethesda, MD 20205.

The relationship between action potential (AP) characteristics and nutrient fatty acid (FA) structure was investigated in mouse spinal cord neurons. Primary dissociated cell cultures were prepared from 12-14 day old fetal mice. After 3 weeks in culture, the medium was supplemented with 100 μM fatty acid bound to bovine serum albumin (molar ratio 4:1). The duration of FA enrichment was either 18-24 hrs or 4 days. Intracellular recordings of large multipolar neurons (30-45 μ somal dia.) were made with 4 M KAc microelectrodes. Action potentials were evoked by intracellular stimulation.

Fatty acid supplementation had no effect on resting membrane potential during either testing period. After 18-24 hrs exposure, myristic acid (14:0) produced a 60% increase in AP rate of rise as compared to control cells. In addition, cells given 14:0 had a 43% increase in AP rate of fall and a significant increase ($p<0.025$) in spike height (11mV). Addition of linolenic acid (18:3) increased the AP rate of rise by 23% but had no effect on the rate of fall or spike height. Supplementation with oleic acid (18:1), linoleic acid (18:2) or arachidonic acid (20:4) had no effect on AP characteristics after 18-24 hrs exposure.

Neurons which had been incubated 4 days with 14:0, 20:4, 18:2 or 18:3 exhibited a 23-50% increase ($p<0.025$) in AP rate of rise as compared to control cells. In contrast, cells given 18:1 had a 22% decrease ($p<0.025$) from control values. Similar relationships were observed between the rate of fall and FA structure. AP height was significantly increased with 20:4, 18:2 or 14:0 but not with 18:3 or 18:1. These data indicate that FA can significantly effect AP characteristics in large spinal cord neurons and that these alterations in electrical activity are influenced by FA structure and duration of FA exposure.

293.8 FURTHER EVIDENCE FOR MYELINATION OF JP, QK, AND JP^{MSD} AXONS BY NORMAL OPTIC NERVE OLIGODENDROGLIA IN COMBINED CULTURES. Susan Billings-Gagliardi, Lori H. Adcock*, Edward D. Lamperti*, Gail B. Schwing*, Merrill K. Wolf. Department of Anatomy, University of Massachusetts Medical Center, Worcester, MA 01605.

The defects of the hypomyelinated mutant mice jp, qk, and jp^{msd} could result from primary abnormalities of axon, oligodendrocyte, or other factors. We previously reported that myelination in jp^{msd} organotypic cerebellar cultures is significantly increased by co-culture with normal optic nerve (Brain Res. 206: 193, 1981). We now have similar results with qk and jp, and have autoradiographic evidence that cells from the normal optic nerve colonize regions of mutant cerebellum in the zone where optic nerve and cerebellum fuse.

About 50% (22/41) of quaking cultures "treated" with normal optic nerve produce myelin visible in the living state. (Myelin in untreated qk cultures is invisible by this technique.) Increases in myelination up to 33-fold have been confirmed by quantitative light microscopic methods; they have been produced by optic nerve from donors at postnatal ages 0, 1, 2, 5, 7, and 9 days. No cultures treated with qk optic nerve or with normal optic nerve displaced 0.5mm from the cerebellar explants have shown any increased myelination. Successful treatments have been obtained by adding optic nerve at 0, 4, and 11 days in vitro (DIV). Myelin in successfully treated qk cultures is concentrated in the fusion zone, and regularly shows 10 or more compacted lamellae (rarely seen in qk myelin).

Previous culture studies of jp have suffered from genetic flaws in various jp stocks. We have now prepared a B6C3H jp stock which is congenic with jp^{msd}, produces jp myelin clusters in about 50% (15/31) of untreated cultures, and produces normal appearing myelin in cultures treated with normal optic nerve.

To label optic nerve cells in treated cultures, optic nerve from normal animals injected with ^{3}H thymidine was co-cultured with jp^{msd} cerebellum and studied by autoradiography. After 21 DIV heavily labeled cells were identified in the optic nerve itself and in the zone of fusion with cerebellum. Less heavily labeled cells were found directly apposed or immediately adjacent to myelin segments in this fusion zone. Labeled cells became less frequent with increasing distance from the optic nerve, even along myelin, partly because of mitotic dilution of the label. These observations provide additional evidence that the introduced optic nerve glia directly myelinate the mutant axons rather than contributing a diffusible factor.

293.9 ESTABLISHMENT OF HIGH-PERFORMANCE LIQUID CHROMATOGRAPHIC METHODS FOR THE QUANTITATIVE DETERMINATION OF TOCOPHEROLS AND UBIQUINONES IN BRAIN, AND ALTERATION AFTER DECAPITATION. K. Abe*[1,2], S. Yoshida*[1], K. Kogure[1], O. Alonso[1], B. Watson*, M. Santiso*[1], and M. Ginsberg*[1]. [1]Cerebral Vascular Disease Research Center, University of Miami, School of Medicine, Miami, FL 33101, [2]Eisai Research Lab., Tokyo, Japan 112.

Tocopherols (Toc) and ubihydroquinones (UQH_2) are known as fat-soluble antioxidants in biological systems and it has been shown that active oxygen species and free radicals decrease levels of these substances. Ubiquinones (UQ) and UQH_2 also participate as members of the respiratory chain and play a role in energy production in mitochondria. Recently, attention has been given to abnormal free radicals and tissue redox states in various types of experimental brain injury. However, the lack of simple and specific analytical methods for the determination of these substances has hindered progress in this reserach field.

We have established high-performance liquid chromatographic (HPLC) methods for the determination of Toc and the simultaneous determination of UQ and UQH_2 in brain. The procedure used was as follows: Toc, UQ, and UQH_2 were extracted from 1 ml of brain homogenate with 8 ml of a mixture of n-hexane and ethanol (5:3) containing internal standards. Four ml of the n-hexane extracts were evaporated under nitrogen gas. The residue was dissolved in ca. 100 µl of n-hexane or isopropanol. 20-40 µl of the solution were injected onto an HPLC column (NUCLEOSIL-NH_2 or C_{18}). The eluted Toc and UQ were detected with an ultraviolet detector, and UQH_2 was monitored with an electrochemical detector.

These techniques were applied to the estimation of Toc, UQ, and UQH_2 levels in rat brain after decapitation. The control values of α-Toc, UQ-9, and UQ-$9H_2$ obtained from brains frozen *in situ* were 14.75 ± 0.88, 19.90 ± 2.76 and 6.79 ± 1.00 µg/wet g tissue respectively. The amount of UQ-$9H_2$ increased by 68% immediately after decapitation, which is consistent with accumulation of reducing equivalents in the respiratory chain. However, at 3 and 15 minutes after decapitation, transformation of UQH_2 to UQ was observed concomitant with decrease (19%) of α-Toc content. This decrease in bioantioxidants may indicate that free radical reactions occur at a low rate during ischemia. Our proposed methods are so simple, sensitive, and specific that the concentration can be determined in extracts from 20-40 mg of brain.

294.1 INFLUENCE OF OPTIC NERVE AND NUCLEUS ISTHMI ON ACETYLCHOLINESTERASE ACTIVITY IN THE TECTUM OF THE FROG RANA PIPIENS. E. R. Gruberg. Res. Lab. of Electronics, M.I.T., Cambridge, MA 02139.

The superficial tectum of the frog has significant levels of acetylcholinesterase (AChE) activity. It receives major input contralaterally from the retina and bilaterally from n. isthmi. Using a two-step staining process, the contributions of these inputs to tectal AChE activity were parsed. 40 µm-thick cryostat sections were studied in control frogs and in frogs where one or both optic nerves were cut and/or one or both n. isthmi were electrolytically ablated 2 to 4 weeks prior to killing.

1) In control frogs the outermost tectal layer (corresponding to layer A of Potter's notation, which is used throughout this study) has high AChE activity, i.e., stains dark. Layers B, C, and D are very lightly stained; layer E is most intensely stained; layer F stains dark; layer 8 is lighter stained and layer G stains dark.

2) In a tectal lobe with no optic fiber input the superficial tectum is reduced in thickness, but significant AChE activity remains. Both layers A and B stain dark; layers C and D remain light; and layer E, or its remnant, shows no staining. The other superficial layers have AChE activity like the controls.

3) In a tectal lobe with no optic fiber input and no ipsilateral n. isthmi input, only layer A shows AChE activity.

4) A tectal lobe with no optic fiber input and no contralateral n. isthmi input has a staining pattern like that of 2).

5) Without ipsilateral n. isthmi input, layer A is darkest; layers B, C, and D are light; layer E stains dark; layer F has light staining; and layers 8 and G show virtually no staining.

6) Without contralateral n. isthmi input, tectal staining looks normal except that layer B is darker.

These results indicate that n. isthmi, in addition to optic fibers, contribute significantly to tectal AChE activity.

In other animals, horseradish peroxidase was injected into one tectal lobe, and nuclear yellow was injected into the other lobe. After retrograde transport, it was found that the two labels were in mutually exclusive regions of n. isthmi. The medio-ventral region of n. isthmi, which projects to the contralateral tectum, shows less AChE activity than the latero-dorsal region which projects to the ipsilateral tectal lobe.

294.2 INTRACELLULAR ACHE IDENTIFIES CHOLINERGIC NEURONS. Bruce G. Wallace and Jean Gillon.* Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford CA 94305.

In the central nervous system of the leech Hirudo medicinalis, cholinergic neurons were found to contain significantly more acetylcholinesterase (AChE) activity than non-cholinergic neurons. AChE activity was measured in extracts of individual, identified nerve cells, which can be dissected from leech ganglia relatively free of both neural and glial contamination. All activity associated with isolated cells was acetylcholinesterase. Leech blood was found to contain butyrylcholinesterase; a variable amount of this activity was found in extracts of whole ganglia. Ganglia were pretreated with saline with or without echothiophate, a charged phosphinylthiocholine derivative that irreversibly inhibits AChE. It was assumed that activity remaining after echothiophate pretreatment was intracellular. Total and echothiophate-resistant AChE activities were used to determine the intracellular and surface concentration of AChE associated with isolated cells. Excitatory motor neurons which are though to release acetylcholine (ACh) as a neurotransmitter, had approximately 10-fold higher levels of intracellular AChE than non-cholinergic cells, while all neurons had comparable levels of activity associated with their surface. This non-uniform distribution of intracellular AChE is consistent with the observation that AChE controls the accumulation of ACh in cholinergic neurons.

Based on these findings standard cholinesterase histochemical techniques were modified to stain selectively intracellular AChE. Individual neurons were identified and labelled by intracellular recording and injection of Lucifer Yellow prior to fixation and staining. A fraction of the cells in leech ganglia, including all suspected cholinergic neurons, were stained by this method. Known non-cholinergic cells were not stained. The reaction product appeared as granular deposits within the cytoplasm of stained cells. Thus, although AChE activity is widespread, selective staining of intracellular AChE may provide a useful method for identifying neurons that release ACh as a transmitter, just as high concentrations of extracellular cholinesterase often identify cholinergic junctions.

294.3 CHOLINE ACETYLTRANSFERASE-CONTAINING STRUCTURES OF THE FELINE CNS BY IMMUNOHISTOCHEMISTRY, P. L. McGeer, H. Kimura*, J. H. Peng*, and E. G. McGeer. Kinsmen Laboratory of Neurological Research, Department of Psychiatry, University of B.C., Vancouver, B. C., Canada, V6T 1W5.

Choline acetyltransferase (CAT)-containing cell bodies, fibers and terminals were detected in the feline CNS (1) using purified Fab fragments of rabbit anti-human CAT of high titer (2). Well fixed tissue was obtained by perfusing animals with 4% paraformaldehyde and 0.35% glutaraldehyde. Staining was by standard PAP techniques. Cholinergic cell bodies were observed in more than forty areas and cholinoceptive cells in more than sixt regions of the feline brain.

Major cholinergic cell systems were found to exist in the following five regions: (i) the basal forebrain including the medial septal area, nucleus of the diagonal band of Broca, and substantia innominata complex; (ii) the basal ganglia including the caudate, putamen and nucleus accumbens; (iii) the reticular formation; (iv) motor nuclei of cranial nerves; and (v) the parabrachial complex. Other less prominent systems exist. In all areas the cells were in the large to giant category.

Many cholinoceptive areas were categorized. The staining is in accord with details on cholinergic systems available from other techniques but it is apparent that many cholinergic pathways remain to be defined.

294.4 LOCALIZATION OF COMPONENTS OF THE CYTOCHEMICAL MAP OF THE CAUDATE NUCLEUS. Marjorie A. Ariano. Anatomy & Neurobiology, Univ. of Vermont College of Medicine, Burlington, VT 05405.

The intrinsic cellular elements of the rat caudate nucleus contain cyclic AMP and cyclic GMP (Ariano, et al, Neuroscience 5: 1269, 1980). The morphological localization of these potential second messenger compounds in relation to other neurochemical substances in the striatum has been assessed. Terminal varicosities containing dopamine from the nigrostriatal input have been visualized with histofluorescence (De la Torre, Neurosci. Lett. 17: 339, 1980). Dopamine terminals are anatomically situated to influence all cellular elements containing substance P and the cyclic nucleotides, as determined through subsequent immunochemical processing and re-examination of the exact area of the caudate nucleus.

Cyclic AMP has been visualized in 1) medium spiny neurons of 12-20 µm diameter, 2) oligodendroglia, and 3) astrocytic processes. The unequivocal identification of these cellular constituents has been accomplished through ultrastructural examination of caudate tissue exposed to anti-cyclic AMP antisera and processed for PAP-immunocytochemistry. Caudate elements containing cyclic GMP immunoreactivity include 1) medium spiny neurons and 2) filamentous processes of fibrous astrocytes. Identification of these structures has been accomplished through examination of anti-GFAP antibody-treated caudate tissue sections, and electron microscopic immunocytochemistry. Cyclic GMP-stained neurons exhibit a marked cytoplasmic staining and characteristically lack nuclear reaction. Astrocytic elements are less numerous than neuronal staining. This is confirmed at ultrastructural resolutions, where predominant subcellular elements positively reacting following application of anti-cyclic GMP antisera are neuronal, e.g. postsynaptic densities of type I terminal boutons and perikarya.

Substance P-containing elements have been visualized by immuno histochemical techniques. This putative neurotransmitter of striatal efferents is restricted to cells of 12-20 µm that qualitatively resemble cyclic GMP-reactive neurons, with prominent cytoplasmic staining and less nuclear immunofluorescence.

This data cytochemically demonstrates the relationship of four substances in a qualitative neurochemical map of the intact rat caudate nucleus.

294.5 THE DISTRIBUTION OF BOVINE PANCREATIC POLYPEPTIDE-LIKE IMMUNOREACTIVITY IN THE RAT CENTRAL NERVOUS SYSTEM. J. A. Olschowka, T. L. O'Donohue* and D. M. Jacobowitz. Lab. of Clin. Sci., NIMH, Bethesda, MD 20205.

Bovine pancreatic polypeptide (BPP), a 36 amino acid peptide, is produced by a specific type of endocrine cell in the pancreas and GI tract. Recently avian pancreatic polypeptide, a structural homolog of BPP, was reported in nerve fibers and cell bodies of mamallian and avian CNS. The present investigation describes the immunohistochemical localization and detailed mapping of BPP-containing varicose processes and cell bodies in the rat brain.

Normal and colchincine-treated male Sprague-Dawley rats were used. Frozen sections of the brain were stained using the indirect immunofluorescence procedure of Coons. The BPP antiserum was generously provided by Dr. R. E. Chance (Lilly Research Laboratories, Eli Lilly and Co.). Sections incubated with antisera previously preabsorbed with pure antigen served as controls. The antiserum was tested for cross reactivity by adding either VIP, CCK, α-MSH, glucagon, secretin or bombesin (10 μg/ml diluted antiserum).

The BPP staining appeared specific since preabsorption of the antiserum with BPP resulted in a complete loss of staining. The antiserum did not react with any of the other peptides tested. BPP-like immunoreactive cell bodies were observed throughout the cortex (layers II-VI), however, the majority of labeled neurons appeared subcortically. Large numbers of BPP cells were observed in the arcuate nucleus, with scattered cells in the olfactory tubercle, neostriatum, nucleus accumbens, nucleus preopticus medialis, nucleus interstitialis stria terminalis and in the area of the medial forebrain bundle. Caudally BPP cells were found in regions which contain catecholamine cell groups -- the locus coeruleus (A6), the nucleus tractus solitarius (A2) and in the area of the nucleus reticularis lateralis (A1). Delicate, varicose, BPP nerve fibers were widely distributed, but were very numerous in several subcortical areas -- nucleus accumbens, nucleus interstitialis stria terminalis, nucleus preopticus medialis, periventricular thalamic and hypothalamic nuclei, paraventricular nucleus, nucleus dorsomedialis, and caudally in the nucleus parabrachialis dorsalis, nucleus tractus solitarius and the substantia gelatinosa trigemini. This extensive distribution of BPP in the brain suggests that it is involved in significant neuronal circuitry, possibly in a neurotransmitter or neuromodulator role. However, the exact identity of this peptide and its physiological role remain to be determined.

294.6 SUBSTANCE P, ENKEPHALINS IN HUNTINGTON'S DISEASE-IMMUNOCYTOCHEMICAL OBSERVATIONS. L. L. Vacca, J. Hobbs* and D. Washington*. Depts. of Pathology and Anatomy, Medical College of Georgia, Augusta, GA 30912.

Normally, adult Sprague-Dawley and Wister rats exhibit a dense network of immunoreactive processes which contain the peptide substance P (SP) within the substantia gelatinosa (SG) of the dorsal spinal cord and the substantia nigra (SN) of the midbrain. Like the rat, the normal human also exhibits high concentrations of immunoreactive SP within SG and SN. Therefore we have become interested in examining these tissues in certain human diseases. Currently, we have directed our efforts towards Huntington's Disease (HD), a rare inherited disorder characterized in part by the severe degeneration of basal ganglia neurons and their connections. Our immunocytochemical evaluations for SP in SN indicate that the peptide clearly becomes reduced in HD specimens compared with normal (non HD) controls. Conceivably the reduced amounts of SP as an excitatory neuropeptide can influence the firing of the nigral dopamine-containing cells in HD and other movement disorders. We are continuing our immunocytochemical evaluations for SP in human spinal cord, normal and HD, as well.

The probable degeneration of SP neurons in HD suggests a new direction for research in the disease process and a novel role for SP in motor control or disturbances. We are hopeful that the rat will provide us with an experimental "model" in which SP can be manipulated pharmacologically, particularly in the SG and SN regions. To date, our immunocytochemical evaluations for SP have shown that morphine, and probably other opiate substances, can increase intraneuronal SP within SG but not within SN. These divergent data may reflect regional differences in the location of opiate receptors pre-synaptically on SP neurons in SG and perhaps post-synaptically to SP neurons in SN. Other data have shown that opiate receptors in SN occur in close association with nigral dopamine-containing cells and their processes. After morphine, we failed to observe signs of nigral degeneration. Other opiate substances are under investigation. Additionally, we have undertaken an immunocytochemical study of enkephalins (methionine and leucine) in rat and human (normal and HD) tissues.

Many thanks go to the following people: Dr. Susan Leeman and Dr. John Stewart for anti-SP sera; Dr. Eric Naftchi, Dr. Susan Abrahams, Dr. Ken Bonnet for anti-enkephalin sera and morphine treated animals; Dr. Edward Bird and Mr. Tom Stevens (RO 1 MH/NS 31 862), Dr. F. Yaghmai, Dr. P. Farmer for assistance in obtaining appropriately fixed human specimens; the Atlanta Chapter and the National Committee to Combat Huntington's Disease for their support (CCHD 10-12-04-3600-67).

294.7 LOCALIZATION OF NEUROTENSIN IMMUNOREACTIVE NEURONS IN THE SEPTAL NUCLEI OF THE RAT. C. Jenq,* J. Jew and T.H. Williams (SPON: S. Itaya) Dept. of Anatomy, Univ. of Iowa, Coll. of Med., Iowa City, IA 52242.

In previous studies, neurotensin (NT) has been found in the synaptosomal fraction, providing evidence for a neurotransmitter function. It has been localized immunocytochemically in many regions of the CNS including spinal cord, brainstem, hypothalamus and telencephalon. A substantial amount of NT has been found by radioimmunoassy in the septal area. The present study deals with localization of NT-like peptide in septal neurons of the rat using light (LM) and electronmicroscopy (EM).

Female Sprague-Dawley rats (approximately 180-230 gm) were fixed by perfusion with 0.2% glutaraldehyde and 4% paraformaldehyde in Sorensen's phosphate buffer. Some of the animals had received 50-100 μg colchicine intraventricularly 24-48 hours prior to perfusion. Serial 40μm vibratome sections were processed using a modified Sternberger PAP technique. Sections were mounted on slides for LM or flat embedded in Epon for thin sectioning.

In LM sections, the greatest number of NT-immunoreactive neurons were visualized in animals pretreated with 100μg colchicine, fewer with 50μg, and none without colchicine pretreatment. In NT-positive neurons, reaction product was distributed within the cytoplasm of perikarya and processes. NT-immunoreactive perikarya in the septal nuclei were distributed within the rostral half. The majority of these neurons were located in the intermediate portion (Swanson and Cowan nomenclature, J. Comp. Neurol. 186:621-656, 1979) of the lateral septal nucleus. Staining was not observed in controls which were incubated with NT-immunoabsorbed antiserum.

At the EM level, NT-immunoreactive neurons were observed in both colchicine- and noncolchicine-treated animals. In labeled perikarya, reaction product was present in the cytosol but absent from major organelles and the nucleus. It was often associated with microtubules in labeled dendritic profiles and with synaptic vesicle membranes in labeled axon terminals. Asymmetric (Gray Type I) synaptic contacts were seen between unlabeled axon terminals and labeled dendrites. Synaptic contacts between labeled terminals and labeled dendrites were sometimes observed and appeared to be symmetric (Gray Type II). (Supported by NIH grants NS11650 to THW and HL21914 to JJ.)

294.8 LM AND EM EXAMINATION OF SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE CENTRAL NUCLEUS OF THE RAT AMYGDALA. T.S. Gray, M.D. Cassell* and T.H. Williams. Dept. Anat. Univ. Iowa, Coll. of Med., Iowa City, IA 52242.

Somatostatin (SS) is a peptide known to inhibit growth hormone release from the anterior pituitary, though neurons immunoreactive for SS have been identified in many parts of the CNS. Although most reports have concentrated upon localization of SS in the hypothalamus or pituitary, SS-immunoreactive neurons have been identified also in many extrahypothalamic sites, including the amygdala. A description of the morphology of SS-immunoreactive neurons in the central nucleus of the amygdala (CNA) and their distribution will be presented.

Brains of Sprague-Dawley rats were fixed by perfusion with buffered 4% paraformaldehyde and 0.2% glutaraldehyde, 24-48h after intraventricular injections of 50ug of colchicine. Vibratome sections were cut at 30-40μm and processed according to a modified Sternberger immunoperoxidase procedure and mounted on slides for LM examination or flat-embedded in Epon for thin sectioning. Control sections were treated with normal rabbit serum or immunoabsorbed antiserum.

Two types of SS-immunoreactive neurons were identified in the CNA: 1) cells with multipolar perikarya, 15-20μm in diameter, with many long, smooth dendrites; 2) others with fusiform perikarya, 10-15um in diameter, with fewer long, spiny dendrites. The majority of SS-immunoreactive neurons were located in the caudal two-thirds of the dorsal part of the CNA. Labeled axons and presumed terminals were distributed throughout the rostrocaudal extent of the CNA and appeared to contact both SS-positive and SS-negative neurons.

EM examination showed many SS-immunoreactive perikarya and dendrites, with reaction product distributed throughout the cytosol. Reaction product was most concentrated in axon terminals where it was found at or near the surfaces of round agranular vesicles. A few large dense-cored vesicles, which appeared to possess labeled vesicular membranes, were observed within SS-positive perikarya, dendrites and axons. Symmetrical (Gray Type II) synaptic contacts were observed between labeled terminals and both labeled and unlabeled perikarya and dendrites. Asymmetrical (Gray Type I) synaptic contacts, with prominent postsynaptic webs, were found between unlabeled terminals and labeled dendrites. (Supported by NIH Grant NS 11650 to T.H.W.)

294.9 COLCHICINE DEPLETES AND KAINIC ACID ENHANCES ENKEPHALIN-LIKE IMMUNOCYTOCHEMICAL REACTIVITY IN THE HIPPOCAMPUS. Jacqueline F. McGinty, Illana Gozes, and Floyd E. Bloom. A.V. Davis Ctr. The Salk Institute, La Jolla, CA 92037.

The unique excitatory action of enkephalin in the rat hippocampus (HPC) has prompted intense interest in the localization of enkephalin immunoreactivity (ir) there but immunocytochemical results have been highly variable. The most extensive distribution of HPC enkephalin ir has been found in apparent mossy fibers arising from dentate granule cells (Gall, et al. Soc. Neurosci. 354, 1980). We have also observed enkephalin ir in mossy fibers but rarely in dentate granule cell bodies (antiserum A206, R. Miller, U. Chicago).

To enhance the enkephalin ir staining in HPC we administered kainic acid (KA) (1 µg/10 µl, icv) to rats several days prior to perfusion. KA destroyed the CA3-CA4 pyramidal cells and concomitantly increased the enkephalin ir in the mossy fibers. A greater number of granule cells were enkephalin positive in KA-treated rats than in controls. However, the number seemed insufficient to account for the dense mossy fiber staining unless it is assumed that the immunoreactive material in the nerve terminals arises from a non-immunoreactive precursor present in dentate perikarya.

Colchicine administration (50 µg/50 µl, icv) failed to enhance enkephalin ir in granule cell bodies, leading us to consider the report that colchicine is preferentially toxic to dentate granule cells (Goldschmidt and Steward, PNAS 77: 3047, 1980). After infusion of colchicine (3 µg/0.6 µl) into the dorsal and ventral dentate, ipsilateral granule cells exhibited a time-dependent degeneration associated with an ipsilateral decrease in enkephalin ir in mossy fibers. The toxic effect of colchicine on granule cells was also observed in preparations stained with a monoclonal anti-tubulin (Barnstable and Gozes, J.C.B. 87: 251a, 1980). Colchicine disrupted the microtubules of dentate granule cells without altering the normal pattern of tubulin ir in CA1 cells or fibers. These results suggest that the tubulin cytoskeleton is organized differently in different classes of neurons. We are using double immunocytochemical staining (McGinty and Bloom, Soc. Neurosci. 6: 354, 1980) to determine the relative changes in enkephalin and tubulin-ir during the expression of colchicine and kainate neurotoxicity.

The staining characteristics of enkephalin-ir in the HPC are sufficiently different from those observed in other brain areas to suggest the presence of some other opioid peptide instead of, or in addition to, enkephalin. The presence of multiple opiate receptor populations in the HPC lends credence to this view.

294.10 SEX RELATED VARIATION IN OPIOID BINDING DENSITIES IN LEUCOPHAEA MADERAE (BLATTARIA), G.B. Stefano and B. Scharrer. Dept. Natural Sciences Medgar Evers College, C.U.N.Y., Brooklyn, N.Y. 11225 and Dept's Anatomy and Neuroscience Albert Einstein College of Medicine, Bronx, N.Y. 10461.

In recent times there has been a burgeoning of studies concerned with the elucidation of opioid mechanisms in activities that transcend analgesic functions. Binding of (^{3}H)DALA in cerebral ganglia suspensions of Leucophaea was monophasic and saturable and when analyzed by a Scatchard plot a class of high affinity sites was found with affinity constants (Kd's) of 8.7 and 8.5 nM for male and female adults, respectively. However, the densities of the binding sites turned out to be different for the two sexes. The females had a higher affinity site receptor density (Bmax) value of 56.0, whereas the males had a Bmax value of 38.1 (pmol/g of protein). In other words, the same amount of brain tissue from the adult females had 30% more binding sites for DALA. Specific binding of DALA to brain suspensions of last instar nymphs was also found to be monophasic, saturable and of high affinity K_D value's $\simeq$ 8.5 for both males and females and Bmax values of 38.4 and 41.2(pmol/g of protein) for males and females. There appears to be no difference in binding site density per mg protein between males and females in the immature state. Specific opioid binding could not be detected in suspensions of optic lobes removed from the cerebral ganglia, suggesting that opioid receptors are confined to specific areas in the nervous tissue. Of the biogenic amines tested epinephrine and phenylethanolamine appear to be absent in the cerebral ganglion of Leucophaea. The levels of dopamine (15.3, pM/mg tissue wet weight), norepinephrine (2.29) and Octopamine (6.68) were the same in both sexes. The study demonstrates a sex-related difference in receptor density in adult animals but not in nymphs. In this ovoviviparous insect the ovarian cycle depends on activity cycles of the endocrine corpora allata which is known to be under the control of peptidergic neurosecretory elements of the brain. We surmise that an opioid neuroregulator might participate in this neuroendocrine control system.

294.11 β-ENDORPHIN (END) AND LUTEINIZING HORMONE RELEASING HORMONE (LHRH) IMMUNOREACTIVE NEURONS IN THE MEDIAL BASAL HYPOTHALAMUS (MBH) OF THE RAT. O.K. Rónnekleiv, S. Kaul* and R.L. Eskay*, Department of Psychiatry (OKR), Department of Physiology (S.K.) School of Medicine, University of Pittsburgh, Pittsburgh, PA 15261 and NIMH, Bethesda, MD (RLE).

A wealth of neurophysiological as well as neuroendocrine studies strongly suggested that LHRH neurons are located in the MBH. However, recently there has been some controversy concerning the transmitter identity of fusiform neurons in the arcuate region of the rat brain (C.J. Clayton and G.E. Hoffman, Am. J. Anatomy 155:139, 1979). We, therefore, decided to carefully evaluate the existence of LHRH positive neurons in the rat MBH and to compare its morphology as well as distribution to END.

Young adult Sprague Dawley female rats were perfused intracardially with 4% paraformaldehyde in 0.1M phosphate buffer (pH 7.2). The brains were blocked and kept overnight in phosphate buffer (pH 7.2) containing 10% sucrose. Sagittal and coronal cryostat sections were cut, mounted on gelatinized slides and kept frozen until processed by the PAP method of Sternberger (1974) for light microscopy. The β-endorphin antiserum (B-E-1) used in these experiments recognizes β-endorphin as well as β-lipotrophin on an equimolar basis. Immunoreactive END cells were evenly distributed in the pre-mammilary and the arcuate region. Furthermore, END neurons appeared to be located in the VMN region. The cells were round to fusiform with a large unstained nucleus. Characteristically, the cytoplasm was filled with dark granular golgi-like material. Fusiform LHRH neurons, demonstrated by the WP-1 antiserum, were distributed along the dorsal half of the arcuate nucleus, while the ventral part of the nucleus was filled with LHRH fibers. Cells were also seen in the VMN region often in clusters in the vicinity of blood vessels. All immunoreactive END and LHRH cells and fiber stain were eliminated by pre-absorption of the primary antiserum with synthetic β-endorphin (S-END) and synthetic LHRH respectively. On the contrary, no LHRH stain was eliminated by pre-absorption of the LHRH antiserum with S-END, indicating that the immunoreactivity of the LHRH neurons in the MBH is not due to crossreactivity with an endorphin component of the LHRH antiserum.

In conclusion, END neurons are found evenly distributed in the arcuate region of the rat hypothalamus. LHRH neurons are found mainly in the dorsal half of the arcuate nucleus and the VMN. Endogenous opiates have been found to inhibit LH release, presumably through an action on hypothalamic LHRH. Future experiments will determine the functional interaction between hypothalamic END and LHRH neurons.

294.12 THE MORPHOLOGY OF NEUROTENSIN-IMMUNOREACTIVE NEURONS AND THEIR PROCESSES IN THE CENTRAL NUCLEUS OF THE RAT AMYGDALA. M.D. Cassell*, T.S. Gray and T.H. Williams. Dept. Anat. Univ. of Iowa, Coll. of Med., Iowa City, IA 52242

Neurotensin (NT), a physiologically active tri-decapeptide, has been demonstrated by immunocytochemical methods in neurons in the central nucleus of the amygdala (CNA). Detailed studies of the morphology and distribution of these neurons are a first step towards understanding the possible functional roles of NT in the CNA.

Serial 30-40µm vibratome sections of the rat amygdala were processed by a modified Sternberger PAP-DAB immunocytochemical method (Leranth et al. 1980). All solutions used in the processing of LM sections contained 0·1% Triton-X. Sections for EM examination were post-fixed in OsO_4 and flat-embedded in Epon for thin sectioning. Control sections were incubated with normal rabbit serum and immunoabsorbed anti-NT.

Under LM, neurotensin-immunoreactive neurons were identified by the dark reaction product seen throughout the cytoplasm of perikarya and dendrites. NT-immunoreactive neurons in the CNA appear to be of a single type: multipolar, 15-20µm in diameter, with long, apparently aspinous dendrites. These neurons are located in the dorsal parts of the CNA, principally in its caudal two-thirds. Pretreatment of animals with intraventricular injections of 50-100µg of colchicine increased the observed number of immunoreactive neurons, but did not alter their distribution in the CNA. NT-immunoreactive axons and presumed terminals were observed throughout the rostrocaudal extent of the CNA, though the terminals were most concentrated in the ventrolateral parts of the nucleus surrounding unlabeled perikarya. Many labeled terminals were observed on both labeled and unlabeled neurons in the rest of the CNA. A few labeled axons were seen to pass from the CNA into the stria terminalis.

Electron microscopy confirmed and extended the LM observations. In NT-immunoreactive perikarya and dendrites, reaction product was distributed throughout the cytosol. Occasional large, dense-cored vesicles were observed in the cytosol of labeled perikarya, dendrites and axons. In labeled axon terminals, reaction product was located on or near the surface of round, agranular vesicles. Symmetrical (Gray Type II) synaptic contacts were observed between labeled terminals and both labeled and unlabeled perikarya and dendrites. Asymmetrical (Gray Type I) synaptic contacts with prominent postsynaptic webs were observed between unlabeled terminals and labeled dendrites. Supported by NIH Grant NS 11650 to T.H.W.

294.13 SUBSTANCE P, BUT NOT ENKEPHALIN, IMMUNOREACTIVITY DISTINGUISHES VENTRAL FROM DORSAL PALLIDUM. S.N. Haber and W.J.H. Nauta. Dept. of Psychol., Mass. Inst. of Technology, Cambridge, MA 02139.

The ventral pallidum seems to extend in a rostroventral direction. This has been indicated in sagittal Nissl sections (see Heimer, In Limbic Mechanisms, 1978), as well as in material stained with Perl's method for demonstrating ferric-iron (see Switzer and Hill, Neurosci. Abstr., 1979). Using immunohistochemical techniques, we have demonstrated that the distribution of enkephalin and substance P appears to correspond to this rostral extension of the ventral pallidum. Furthermore, immunoreactivity in this region appears morphologically similar to Golgi impregnations of pallidal neurons as described by Fox et al.(J. fur Hirnforschung, 1973): positive beaded fibers can be seen running longitudinally along the long, thick dendrites. The ventral pallidum is unique in that substance P immunoreactivity is dense here while in the rest of the globus pallidus staining is very light. Enkephalin-positive fibers are very dense throughout the globus pallidus including the ventral pallidum. In coronal sections both enkephalin and substance P immunoreactivity appears beneath the anterior commissure in an S-shaped configuration, flanked by areas of lighter staining: laterally the subcommissural striatum and medially the bed nucleus of the stria terminalis. In more rostral sections, staining continues ventrally with fibers dipping deep into the olfactory tubercle. Enkephalin and substance P staining can be seen capping the islands of Calleja in a fashion similar to that found in Perl-stained material (Hill and Switzer, Neurosci. Abstr., 1979). The continuity of the immunoreactivity for both peptides can be clearly seen in parasagittal sections. Enkephalin staining is observed in the main body of the globus pallidus extending beneath the anterior commissure and continuing in a rostroventral direction into the olfactory tubercle, but, while substance P staining likewise appears in the ventral pallidum, it fades out in the main body of the pallidum.

Preliminary experiments suggest that these peptide fibers originate from cells in the striatum and project in a topographic fashion to the pallidum, so that lesions of the dorsal striatum decrease enkephalin immunoreactivity in the dorsal pallidum, while lesions of the ventral striatum decrease both enkephalin and substance P in the ventral pallidum. The fact that substance P immunoreactivity distinguishes the ventral pallidum from the main body of the globus pallidus may have important implications for the functional role of this subcommissural segment of the pallidum and its relationship to the limbic system.

294.14 CO-EXISTENCE OF GAD IMMUNOREACTIVITY AND HIGH AFFINITY ^{3}H-GABA UPTAKE IN NEURONS IN DISSOCIATED CELL CULTURES OF CEREBRAL CORTEX. E.A. Neale, W.H. Oertel† and L.M. Bowers*. Lab. Devel. Neurobiol. NICHD and Lab. Clin. Sci., NIMH, NIH, Bethesda, MD 20205

The role of γ-aminobutyric acid (GABA) as a major inhibitory neurotransmitter in the mammalian central nervous system has been documented by biochemical, pharmacologic, electrophysiologic and morphologic studies. GABA-ergic neurons had been morphologically identified by the radioautographic demonstration of high affinity ^{3}H-GABA uptake, and more recently, by the immunohistochemical localization of glutamic acid decarboxylase (GAD), the GABA-synthesizing enzyme. In this study, combined immunocytochemistry and radioautography were used to demonstrate the co-existence of ^{3}H-GABA uptake and GAD immunoreactivity within the same cortical neurons.

Murine cerebral cortical neurons were studied during development in dissociated cell cultures. At various times after plating, cultures were incubated with 0.1 μM ^{3}H-GABA for 30 min at 37°C, and fixed with 4% paraformaldehyde. Cultures were then reacted with a sheep GAD antiserum, peroxidase-antiperoxidase complexes and 3,3'-diaminobenzidine for the immunocytochemical localization of GAD. Selected areas of the cultures were photographed and neurons scored for GAD immunoreactivity. The cultures were subsequently coated with radioautographic emulsion, exposed for three days, and the same culture areas re-examined for neurons labeled with silver grains as evidence of ^{3}H-GABA uptake. Nearly 5000 neurons were evaluated for GAD immunoreactivity and/or ^{3}H-GABA uptake.

There was a strong correlation between the presence of GAD and ^{3}H-GABA uptake within the same cortical neurons. Of those neurons scored in six cultures from two dissections, GAD immunoreactivity and ^{3}H-GABA accumulation were co-existent in 88% of neurons classified as GABA-ergic by one or the other of these morphologic criteria. In optimal preparations at least three weeks in culture, this correlation approached 95%. 95% of GAD-positive neurons showed ^{3}H-GABA uptake; 98% of ^{3}H-GABA accumulating neurons showed GAD immunoreactivity. In 8 day old cultures, GAD immunostaining was not detectable, and in 14 day old cultures, the anti-GAD reaction product was not as qualitatively distinct as in 22 day old cultures. However, neurons in both 8 and 14 day cultures were well-labeled by ^{3}H-GABA accumulation, suggesting the development of ^{3}H-GABA uptake prior to immunologically detectable GAD.

These studies constitute rigorous experimental evidence that ^{3}H-GABA accumulating cortical neurons contain the GABA-synthesizing enzyme, GAD.

294.15 IMMUNOCYTOCHEMICAL LOCALIZATION OF ASPARTATE AMINOTRANSFERASE AND ENKEPHALIN IMMUNOREACTIVITIES IN THE GUINEA PIG RETINA. R.A. Altschuler, J.L. Mosinger*, R.J. Wenthold, D.W. Hoffman*, and M. Parakkal*. Lab. Neuro-otolaryngology, N.I.H., Bethesda, MD and Harvard Univ., Cambridge, MA.

Indirect immunofluorescence techniques were used on cryostat sections of parformaldehyde perfused guinea pig retinas to determine the localization of aspartate aminotransferase (AAT) and enkephalin-like immunoreactivities. Previous studies have suggested that AAT is involved in the metabolism of glutamate and aspartate when these amino acids are used as neurotransmitters. We have recently demonstrated AAT-like immunoreactivity in cell bodies, axons and terminals of the auditory nerve. In the present study a band of AAT-like immunofluorescence was seen in the outer plexiform layer (OPL) of the guinea pig retina. In colchicine pre-treated animals AAT immunofluorescence was seen in photoreceptors with cell bodies in the outer portion of the outer nuclear layer giving rise to thin processes ending in large swellings in the OPL. These are likely to be cones and cone pedicles. These results support the hypothesis that aspartate or glutamate may serve as the neurotransmitter of cones. A population of AAT immunoreactive cells was also observed in the position of amacrine cells with fibers in the five distinct sublaminae of the inner plexiform layer (IPL).

Enkephalin-like immunoreactivity in the guinea pig was examined using an antiserum (RA143) raised in rabbit against a *met-enkephalin-bovine thyroglobulin* conjugate. This antiserum has been well defined by RIA and has low cross-reactivities to leucine enkephalin and beta-endorphin. Enkephalin-like immunofluorescence was seen in fibers in the inner plexiform layer. In colchicine pre-treated animals enkephalin-like immunoreactive cell bodies were seen at the inner most margin of the inner nuclear layer giving rise to immunofluorescent processes running in the IPL sublaminae one, three and five. This is the first description of enkephalin-like immunoreactivity in the retina of the mammal and agrees with previous description in several non-mammalian species.

294.16 IMMUNOCYTOCHEMICAL LOCALIZATION OF ASPARTATE AMINOTRANSFERASE AND GLUTAMINASE IN THE AUDITORY NERVE. R.J. Wenthold, W.G. Haser*, R.A. Altschuler, G.G. Harmison*, G.R. Neises*, and J. Fex. LNO, NINCDS, NIH, Bethesda, MD and Dept. Biochem., Univ. Pittsburg, Pittsburg, PA

Several lines of evidence suggest that glutamate or aspartate is the neurotransmitter of the auditory nerve. In studying the synthesis of these amino acids in the auditory nerve, it was found that the two enzymes associated with the metabolism of glutamate and aspartate, aspartate amino transferase (AAT) and glutaminase, appear to be concentrated in terminals and fibers of the auditory nerve. Both enzymes decrease in the cochlear nucleus after auditory nerve lesion and the specific activities are two to five times higher in the auditory nerve than in other nerves tested. To further study the localization of these enzymes, antibodies were made to cytoplasmic AAT from pig heart and phosphate dependent glutaminase from rat kidney. Both preparations were found to cross-react with their respective enzymes from guinea pig brain. Indirect immunofluorescence techniques were then used on cryostat sections for light microscopic visualization and ultrastructural localization was done for AAT using the peroxidase-antiperoxidase technique on vibratome sections.

With immunofluorescence techniques both antibody preparations showed rings of immunoreactivity corresponding to auditory nerve terminals on cells in the ventral cochlear nucleus of the guinea pig. The glutaminase-like immunofluorescence was of a more punctate nature. Both antibody preparations gave intense labeling of spiral ganglion cell bodies. Again the glutaminase immunofluorescence was more punctate producing a web-like appearance over ganglion cell cytoplasm.

AAT-like immunoreactivity in the ventral cochlear nucleus was examined at the ultrastructural level. Immunoreactivity was localized in terminals exhibiting the morphological characteristics of primary afferent terminals. The other classes of terminals showed no immunoreactive labelling.

In recent studies glutaminase and AAT-like immunoreactivities were examined in the retina and hippocampus of the guinea pig. In the retina a similar distribution of immunoreactivity was found for both enzymes in photoreceptor terminals in the outer plexiform layer. In the hippocampus, only glutaminase-like immunofluorescence was observed. This immunoreactivity was found in fibers in the stratum radiatum of the regio inferior.

These studies suggest that one or both of these enzymes may serve as a marker for aspartate/glutamate synapses.

295.1 ADRENERGIC RECEPTORS COUPLED TO ADENYLATE CYCLASE IN RAT PIA-ARACHNOID. G.C. Palmer and S.J. Palmer*, Dept. Pharmacol., Univ. So. Ala. Col. Med., Mobile, Alabama 36688.

Microvasculature consisting of pia-arachnoid were removed from the cerebral cortex of saline-perfused rat brains. A series of adrenergic agonists were added to homogenates of pia-arachnoid in order to evaluate receptor specificity with regard to activation of adenylate cyclase. Norepinephrine and isoproterenol with or without Gpp(NH)p (5'guanylyl imidodiphosphate) were the most potent agents in their ability to elicit adenylate cyclase. The alpha agonists, phenylephrine and methoxamine (preliminary observations), displayed an intermediate potency on enzyme activation. The selective $beta_1$-$beta_2$ agonists (dobutamine, tazolol or salbutamol, metaproterenol) exerted only weak activation of the enzyme. Dopamine was ineffective. The stimulation of adenylate cyclase by norepinephrine was inhibited by the following adrenergic agonists in descending order of potency: propranolol (mixed beta) > butoxamine ($beta_2$) > phentolamine (alpha) > practolol ($beta_1$). In preliminary work the beta adrenergic ligand, dihydroalprenolol, was found to bind to particulate fractions of pia in a stereospecific fashion. An analog of adenosine, 2-Cl-adenosine, in the presence of adenosine deaminase failed to activate adenylate cyclase with any degree of potency. However, 2-Cl-adenosine was active in isolated cerebral capillaries. Chronic treatment of rats with reserpine (one week) produced a heightened sensitivity of pial adenylate cyclase, an action not observed in corresponding capillaries. Thus, the pia-arachnoid possesses a mixed alpha-beta receptor activation of adenylate cyclase. The location of these receptors to pre- or postsynaptic sites is unknown. (Supported by NSF PCM 7911782.)

295.2 BEHAVIORAL EFFECTS OF CYCLIC GMP IN THE CAUDATE NUCLEUS. Irwin N. Lourie*, Michael M. Krieger*, Sarah A. Kilgour* and Nagendran S. Thampi. (Spon. Luis A. Marco) Res. Dept. Norristown State Hospital, Norristown,PA 19401

Previous experiments (Lourie Neuroscience Abstracts,5:564, 1979) indicate a biphasic behavioral response to intraventricular administration of dibutyrl cyclic 3',5' guanosine monophosphate (dbc-GMP) with depression at low doses (5µg) and excitation at higher doses (50ug). As part of a series of experiments to localize this effect bilateral cannula implants were directed at the caudate nucleus of 125 day old male NSH rats (n=8). 21 days following surgery subjects were equilibrated to an open field testing apparatus and handling procedures for 6 days at which time behavior patterns are stabilized. On the subsequent 4 days a randomized latin square design was used to test 4 dbc-GMP levels (0,2,8,32 µg). On day 5 all subjects were given 64 µg. All doses were delivered in 0.5 ul of saline over a period of 31 sec, 30 min prior to assay. Behavioral assay consists of analyzing the first 5 min of a 1 hr exposure to the apparatus. Data was taken in 1 min blocks in order to measure habituation effects. Following each assay the subjects were subjected to a tail pinch measure of nociception.

There was a two-fold increase in motor activity at 32 µg using both time and distance measures with no activation at the lower doses. This effect is unlike that of amphetamine in that the subjects show evidence of habituation on both motor and motivational measures. Grooming shows a biphasic effect with 40.1, 21.2, 39.8 and 12.8 sec of activity for the 0, 2, 8, 32 µg doses respectively. The magnitude of this effect seems independent of exploratory activity measures. The animals also showed a withdrawal effect that was related to cumulative dosing. This was evidenced as an apparent deficit in initial exploratory activity during the first minute. There was no loss of nociceptive responding at any dose. At 64 µg all of the animals showed evidence of convulsive behavior. A unique behavioral feature at this dose was self mutilating behavior in 3 of the eight animals.

The activation data are consistent with the findings of Baker, Psychopharm.Bull. 16:27,1980 who demonstrated the effect of cholinergic stimulation of the caudate with subsequent activation of cortical,hippocampal, and motor systems and those of Greengard Nature, 260:101, 1976 who formulated the c-GMP second messenger concept of the muscarinic action of acetylcholine.

295.3 WITHDRAWN

295.4 CYCLIC NUCLEOTIDE-DEPENDENT PHOSPHORYLATION OF ENDOGENOUS PROTEINS OF BOVINE ROD OUTER SEGMENTS. Rehwa H. Lee*, Bruce M. Brown*, Bernice S. Lieberman* and Richard N. Lolley. Dept. of Anatomy, UCLA School of Medicine, Los Angeles, CA 90024, and V.A. Medical Center, Sepulveda, CA 91343.

A role is proposed for cGMP in the visual process of rod photoreceptors. The mechanism by which cGMP modulates the activities of rod visual cells probably involves protein phosphorylation. We have identified and partially characterized the cyclic nucleotide-dependent protein kinases (CNPK) of bovine rod outer segments (ROS) using exogenous soluble proteins. We have now analyzed the endogenous substrates for CNPK. Soluble proteins that are phosphorylated by CNPK were obtained by centrifugation of ROS homogenates prepared in hypotonic buffer. After labeling with ^{32}P, the phosphoproteins were separated by SDS-PAGE and identified with autoradiography. It was found that a 33K protein (30K, using the Weber & Osborn system, BBRC, 78:572, 1978) and, to a lesser extent, a 45K protein were phosphorylated in a cyclic nucleotide-dependent manner. The concentration of the 33K protein is greater in ROS than in the complete bovine retina, suggesting that this protein is localized in ROS. The 33K protein has an isoelectric point of 5.4, a sedimentation coefficient of 6.0 S and a proposed dimeric configuration in the native state. After partial purification by density gradient centrifugation, the 33K protein was phosphorylated by partially purified CNPK with maximal phosphate incorporation achieved in the presence of either 10^{-4} M cGMP or 10^{-5} M cAMP. Illumination of ROS membranes does not appear to affect the extractability of the 33K protein. These findings support the proposal that cGMP, in regulating the activity of ROS CNPK, controls the rate at which the 33K and, perhaps, the 45K proteins are phosphorylated. These endogenous ROS proteins may be the ultimate effectors of cGMP action in rod visual cell activities. (Supported by NSF grant BNS-79-26806, NIH grant EY00395 and the Medical Research Service of the Veterans Administration.)

295.5 PHOSPHODIESTERASES OF THE CONE-DOMINANT GROUND SQUIRREL RETINA. Debora B. Farber and Dennis W. Souza*. Jules Stein Eye Institute, UCLA School of Medicine, Los Angeles, CA 90024, and V.A. Medical Center, Sepulveda, CA 91343.

There is strong evidence implicating cGMP phosphodiesterase of rod photoreceptors in the visual process. In a light-regulated manner, this enzyme catalyzes the reduction of cGMP levels of rods. Cone- and rod-dominant retinas differ in their cyclic nucleotide concentrations with a cAMP/cGMP ratio of 2.2-8.0, in cone-dominated, vs. 0.2-0.3 for the rod-enriched. In addition, light selectively reduces cAMP levels in the cone-dominant retinas; cGMP content remains unchanged.

We have separated and partially characterized several cAMP and cGMP phosphodiesterases of the ground squirrel retina. Three kinetically distinct cAMP phosphodiesterases (Kms 3.9 x 10^{-5} M, 1.8 x 10^{-4} M and 2.4 x 10^{-3} M) and one cGMP phosphodiesterase (Km 1.6 x 10^{-4} M) were found in crude retinal homogenates. Isoelectric focusing of the post-nuclear supernatant from the homogenate separated two peaks of phosphodiesterase activity at pH 4.1-4.4 and pH 4.8-4.9 which hydrolyzed cAMP; the latter peak also hydrolyzed cGMP. Other peaks of phosphodiesterase activity which used cGMP as substrate were observed at pH 4.3-4.5 and pH 4.9-5.1. Each of the isoelectrically focused fractions was subjected to sucrose gradient centrifugation. Using hemoglobin and alcohol dehydrogenase as internal markers, we estimated the molecular weights of the partially purified enzymes. Two phosphodiesterases which hydrolyzed both cAMP and cGMP had molecular weights of approximately 175,000 and 122,000, and one phosphodiesterase which selectively utilized cAMP as substrate had a molecular weight of 50,000. The enzymes were further purified by HPLC, and SDS-PAGE was used to characterize their subunit composition.

We have used a similar purification scheme for the bovine rod outer segment phosphodiesterase. Our results indicate that this enzyme has a different isoelectric point and different subunit components than the phosphodiesterases of the cone-dominant retina of the ground squirrel.

295.6 SPECIFIC INHIBITION OF PHOSPHORYLATION OF PROTEIN I, A SYNAPSE-SPECIFIC PROTEIN, BY PURIFIED ANTI-PROTEIN I ANTIBODY. S. Naito and T. Ueda. Mental Health Research Institute, Depts. of Psychiat. & Pharmacol., Univ. of Mich., Ann Arbor, MI 48109.

Protein I is a synaptic protein which serves as an endogenous substrate for cyclic AMP- and calcium-dependent protein kinases. Antibodies raised against purified Protein I have been isolated from rabbit antiserum by affinity chromatography on Protein I-conjugated agarose column. The purified antibodies were identified as immunoglobulin G by SDS-polyacrylamide gel electrophoresis and Ouchterlony double immunodiffusion precipitation test. The purified antibodies (but not immunoglobulin G purified from preimmune serum) showed the ability not only to inhibit the phosphorylation of purified Protein I by exogenous cyclic AMP-dependent protein kinase, but also to inhibit specifically the phosphorylation of Protein I by endogenous cyclic AMP-dependent protein kinase in a homogenate of rat cerebrum or in the synaptic junctional complex and synaptic vesicle fractions of bovine cerebral cortex. The antibodies to Protein I also inhibited with a similar potency calcium-dependent phosphorylation of Protein I without affecting the phosphorylation of other proteins. Moreover, the Fab(t) fragment of anti-Protein I immunoglobulin G, which was produced by tryptic digestion, retained the ability to inhibit specifically the phosphorylation of Protein I. This substrate-directed, specific inhibitor of the phosphorylation of Protein I may provide a unique probe for investigating the function of Protein I phosphorylation.

295.7 BRAIN CYCLIC NUCLEOTIDE RESPONSE FOLLOWING CENTRAL CHOLINERGIC ACTIVATION IN RATS EXPOSED TO CHRONIC LEAD. R.H. Lenox[1], G.J. Kant[2], J.L. Meyerhoff[2], Z. Annau[3]. Univ. Vermont, Burlington VT 05405[1]; Walter Reed Army Inst. Research, Washington DC 20012[2]; Johns Hopkins University, Baltimore MD 21205[3].

Neurochemical and electrophysiological studies of animals chronically exposed to lead support a role for lead in the inhibition of central and peripheral cholinergic systems (Shih and Hanin, Life Sci., 1978). Chronic lead exposure has also been reported to decrease in vivo turnover of acetylcholine in cortex, hippocampus, midbrain and striatum of the rat. Recent investigations from our laboratory have reported significant changes in both cyclic AMP and cyclic GMP in specific brain regions of rats following central cholinergic stimulation with oxotremorine(Lenox et al. Life Sci., 1980). In order to further define the state of central cholinergic responsivity in animals exposed to chronic low levels of lead,we have examined cyclic nucleotide response to oxotremorine challenge in specific brain regions of the rat.

Long-Evans rats selected for study had been derived from matched mothers exposed to lead acetate (1000 ppm) or distilled water throughout gestation and lactation. Animals with preweaning history of lead exposure were maintained on lead acetate(1000ppm) until sacrifice at 60 days of age. The matched control group of animals were maintained on distilled water until sacrifice. Animals were maintained in light-cycled chambers and all experiments took place at the same time of day. Both chronic lead and control animals received an intraperitoneal injection of oxotremorine (2 mg/kg) or saline and were placed in an activity arena 10 min prior to sacrifice by exposure to high power microwave inactivation system. All animals were pretreated with methylatropine (0.5 mg/kg)40 min prior to sacrifice. Following sacrifice and decapitation, trunk blood was collected for radioimmunoassay of plasma hormones and 21 brain regions were dissected for radioimmunoassay of cyclic AMP and cyclic GMP.

Levels of cyclic AMP in the pituitary increased 15-fold in both control and lead animals confirming our previous findings.Of the remaining regions assayed, no large differences were observed between lead and control animals. However, there was a trend in the lead animals vs. controls toward an increased cyclic AMP response to oxotremorine challenge in the substantia nigra and brainstem. Animals exposed to oxotremorine demonstrated less overall motor activity. There was a trend, however, for higher cyclic GMP levels in the cerebellum of lead animals vs. controls. These data reflect a neurochemical response to central cholinergic stimulation in animals exposed to lead concentrations existing in some environments.

295.8 MUSCARINIC CHOLINERGIC RECEPTOR REGULATION OF CYCLIC AMP METABOLISM IN CULTURED ASTROCYTOMA CELLS. R.B. Meeker* and T.K. Harden, (Spon: A.T. Dren) Department of Pharmacology, University of North Carolina School of Medicine, Chapel Hill, N.C. 27514

Incubation of 1321N1 human astrocytoma cells with 10 μM (-)-isoproterenol (ISO) results in a rapid increase (>30 x basal) in intracellular cAMP levels. The addition of 100 μM oxotremorine (OXO) concomitantly with ISO reduces the accumulation of cAMP by 50-70% and decreases the $t_{1/2}$ to steady-state from 0.9 min in the presence of ISO alone to 0.2 min in the presence of ISO + OXO. This inhibitory effect of OXO is competitively blocked by 1 μM atropine and noncompetitively prevented by the presence of 0.5 mM isobutylmethylxanthine. The capacity of intact cells to degrade cAMP was measured by incubation for 5 min in ISO or ISO + OXO followed by blockade of the synthetic reaction by the addition of a saturating concentration of propranolol. The rate constant for cAMP degradation (k_{deg}) in the absence of OXO was 0.389 min^{-1}. In the presence of OXO cAMP degradation was biphasic with over 50% of the cAMP being degraded in a rapid phase (k_{deg} = 1.334 min^{-1}; 0-30 sec) followed by a slower rate (k_{deg} = 0.300 min^{-1}) similar to that observed in the presence of ISO alone. These data suggest that activation of muscarinic receptors reduces cAMP levels in 1321N1 cells by increasing phosphodiesterase activity.

Preincubation of 1321N1 cells in 100 μM carbachol results in a rapid loss of the inhibitory effect of OXO. After a 30 min preincubation, the inhibitory activity of OXO is reduced by 50%. The properties of control and desensitized muscarinic receptors were examined using the ligand ^{3}H-quinuclidinyl benzilate (^{3}H-QNB). ^{3}H-QNB binds to a single class of sites with an affinity of 10 pM and Bmax of 50 fmol/mg protein. Rate constants of association and dissociation were 3 x 10^8 $M^{-1}min^{-1}$ and 4 x $10^{-3}min^{-1}$, respectively. A 24 hr incubation with 100 μM carbachol results in a greater than 90% loss of receptors. Receptor loss occurs with a slower time course ($t_{1/2}$ = 4 hr) than does desensitization to the inhibitory effects of OXO. Since greater than 80% of the inhibitory effect of OXO on cAMP accumulation is lost prior to a significant reduction in receptor number, it seems unlikely that receptor loss per se could account for at least the initial stage of desensitization. Supported by NIH Grant GM29536.

295.9 CELLULAR LOCALIZATION OF CYCLIC NUCLEOTIDE CHANGES IN THE RAT SUPERIOR CERVICAL GANGLION. Clark A. Briggs*, Marjorie A. Ariano and Donald A. McAfee, (SPON: Richard E. Wimer). Div.of Neurosciences, City of Hope Research Institute, Duarte, CA 91010 and Dept. Anatomy and Neurobiology, Univ. Vermont College of Medicine, Burlington, VT. 05405.

Preganglionic stimulation produces a two-fold increase in cyclic AMP content and a five-fold increase in cyclic GMP content of the ganglion. Cyclic nucleotide levels increase as a function of the frequency and duration of tetanic preganglionic stimulation, becoming maximal at 10 Hz for 30 sec. Low Ca^{2+} or Co^{2+} (2mM) inhibits cyclic GMP increases and blocks cyclic AMP increases. Also, cyclic nucleotide levels are augmented by bath application of isoproterenol, azide, and KCl (Quenzer et al. (1980) J. Pharmac.Exp.Ther. 215:297). One of our goals was to identify the type of cells showing changes in cyclic nucleotide levels following experimental manipulation of the ganglion.

Pairs of ganglia were isolated and maintained in Locke solution at 23°C; one member of each pair served as a control. At the end of the experiment both ganglia were bisected. One half was homogenized for radioimmunoassay and the other was frozen for immunohistochemistry for cyclic nucleotides. Frozen sections 8 μm thick were treated with either diluted anti-cyclic AMP or anti-cyclic GMP antisera for 1 to 3 hrs. The unbound antisera was washed off and replaced with fluorescein-coupled antirabbit goat antiserum. The fluorescent antisera are assumed to localize the remaining cyclic nucleotide antibody bound to relatively slowly diffusing cyclic nucleotides. Morphological elements were identified through the use of glyoxylic acid-induced catecholamine fluorescence and toluidine blue counterstain.

In non-stimulated ganglia, neurons and satellite cells stained for cyclic AMP. Preganglionic electrical stimulation increased cyclic AMP staining in small neurons and satellite cells while depolarization of the ganglion by KCl increased cyclic AMP staining in all cell types. Sodium azide did not increase cyclic AMP staining. Only large neurons stained for cyclic GMP and this staining increased with preganglionic stimulation, KCl, and sodium azide. These studies demonstrate that 1) cyclic nucleotides can be localized at the cellular level in the rat ganglion by immunohistochemistry; 2) cyclic AMP and cyclic GMP show a differential localization; and 3) changes in cyclic nucleotide levels can be detected by immunohistochemistry in the rat ganglion. (Supported by Grants NS 12116 and BNS 79-12394, and a Biomedical Research Support Grant to the Univ. Vermont College of Medicine).

295.10 DENERVATION SUPERSENSITIVITY IN LUMBAR SPINAL CORD FOLLOWING MID-THORACIC TRANSECTION. D.J.Jones, M.S.Giere* and B.L.Moak*. Departments of Anesthesiology and Pharmacology, The University of Texas Health Science Center, San Antonio, TX 78284

Previous studies from this laboratory have demonstrated agonist specificity for cyclic AMP accumulation in rat spinal cord tissue slices (Jones and McKenna, Neuropharmacol., 19: 669-674, 1980). The presence of descending catecholamine containing neurons in spinal cord and their interruption by transection suggests that adrenergic denervation supersensitivity might be associated with the adenylate cyclase-cyclic AMP response to catecholamines in denervated spinal cord below the transection site.

Transection of the spinal cord was performed at the mid-thoracic level following laminectomy in 125-150 Gm rats. Following various time periods, rats were sacrificed and the cervical (intact) and lumbar (denervated) spinal cord removed and sliced on a McIlwain tissue chopper (300 μm) with subsequent incubation for one hour in oxygenated Krebs-Ringer bicarbonate. Following this period, the slices were placed into incubation flasks for 15 min at which time various agonists were added. At the end of the incubation period, tissue protein was denatured and cyclic AMP measured by radioimmunoassay.

Seven days following transection there was an enhanced accumulation of cyclic AMP in lumbar spinal cord in response to norepinephrine (NE). The enhanced response was concentration dependent with the maximal increase in lumbar cyclic AMP accumulation in the presence of 10^{-5} M NE being 3-4 times greater than the intact cervical cord response. No change in NE EC_{50} was observed in responses of the denervated lumbar vs control cervical spinal cord. Supersensitivity in the lumbar spinal cord cyclic AMP system is present as early as 3 days and lasts at least 30 days (the latest time tested), and occurs in both dorsal and ventral cord sections. Enhanced responsivity is also evident in the presence of isoproterenol, but not K^+ or adenosine. These data suggest that synaptic supersensitivity exists in lumbar spinal cord following transection and that alterations in adrenergic receptor sensitivity may play a role in mediating events following deafferentation.

Supported by grants from the Morrison Trust Foundation and NIH (NS 14546).

295.11 IDENTIFICATION OF AN ESSENTIAL SULFHYDRYL GROUP FOR THE ACTIVATION OF DOPAMINE-SENSITIVE ADENYLATE CYCLASE, E. T. Suen*, P.C.K. Kwan* and Y.C. Clement-Cormier. Department of Pharmacology, The University of Texas Medical School at Houston, Houston, Texas 77025.

A sulfhydryl alkylating agent, N-ethylmaleimide was used to study the role of sulfhydryl groups in the coupling of the dopamine receptor to adenylate cyclase in striatal membranes. N-ethylmaleimide inhibited dopamine-sensitive adenylate cyclase activity in membranes pretreated with the alkylating agent. A fifty percent inhibition of dopamine-sensitive adenylate cyclase activity was observed in the presence of 10μ M N-ethylmaleimide. Similar results were observed with p-chloromercuribenzoate, a heavy metal alkylating reagent. The reducing agents, dithiothreitol, 2-mercaptoethanol, and cysteine had no effect on dopamine-sensitive adenylate cyclase activity. N-ethylmaleimide inhibited GTP and NaF stimulated adenylate cyclase activity but was without effect on adenylate cyclase assayed in the presense of manganese. Pretreatment of membranes with GPP(NH)P or G TP (γ)S prior to exposure to N-ethylmaleimide prevented the inhibitory effect of the sulfhydryl reagent on adenylate cyclase activity. N-ethylmaleimide also produced a ten fold decrease in agonist affinity for the dopamine receptor binding site which was similar to the decrease in agonist affinity observed in the presence of GTP. The effect of GTP on agonist affinity was not additive with N-ethylmaleimide. Overall, the data reveal that a reactive sulfhydryl group is important for the coupling of the components of the cyclase complex and that alkylation of the reactive sulfhydryl group modifies the activity of the guanine nucleotide binding protein. (Supported by U.S.P.H.S. Grants MH035851 and BNS 7816003)

295.12 THE EFFECT OF CHRONIC DOPAMINE AGONIST TREATMENT ON TYROSINE HYDROXYLASE AND ADENYLATE CYCLASE ACTIVITIES. K.D. Wilner*, I.J. Butler, W.E. Seifert and Y. C. Clement-Cormier. Department of Pharmacology, The University of Texas Medical School at Houston, Houston, Texas 77025.

The effect of long-term levodopa, bromocriptine or combination levodopa and bromocriptine therapy was tested on rat striatal adenylate cyclase, dopamine receptor binding and tyrosine hydroxylase activities. An oral dose of sinemet (250 mg levodopa/25 mg carbidopa) and/or intraperitoneal bromocriptine (2 mg/kg) were administered for 21 days. Following chronic sinemet treatment, an increase in the EC_{50} for dopamine stimulation of adenylate cyclase was observed in the drug treated group compared to controls. In addition, a significant increase in the number of specific (^3H) spiroperidol binding sites was observed in the drug treated group. In the chronic bromocriptine study, there was no significant change between control and experimental groups in dopamine-stimulated adenylate cyclase or (^3H) spiroperidol binding. However, the analysis of the CSF neurotransmitter metabolites HVA, 5-HIAA and MHPG indicated a significant increase in HVA following bromocriptine treatment. In addition, there was a significant decrease in tyrosine hydroxylase activity in the bromocriptine treated group as compared to the control group. Combination sinemet and bromocriptine treatment yielded similar results as with bromocriptine alone. These data suggest that the increase in the number of dopamine binding sites following chronic levodopa treatment may correlate with the behavioral supersensitivity seen in Parkinsonian patients on this drug regimen. The results also show that bromocriptine treatment abolishes the levodopa-induced increase in the number of dopamine binding sites. Thus, the data suggest a possible biochemical mechanism for the success of combination levodopa and bromocriptine therapy in the treatment of Parkinson's disease. (Supported by U.S.P.H.S. Grants MH035851 and BNS 7816003)

295.13 CYCLIC GMP METABOLISM: HIGH PERFORMANCE LIQUID CHROMATOGRAPHIC (HPLC) ANALYSIS OF RAT BRAIN SLICES. R. D. Kelson*, M. Cohn, D.J. Wooten* and M.L. Cohn, Lab. Anesthesia Research, Drew Medical School, Los Angeles, CA 90059.

Reports have shown that, following parenteral injection of morphine to rats, cyclic GMP (cGMP) content is differentially altered in various brain areas: e.g. cGMP increases in striatum and nucleus accumbens and decreases in cerebellar cortex. Cholinergic agonists have also been shown to be potent analgetics and to alter brain cGMP content. However, a cause/effect relationship between changes of cGMP concentrations and analgesia regulation has yet to be determined. Like morphine, cGMP administered centrally to rats produces profound analgesia but appears to regulate pain through a different pathway (Cohn et al, 1978). In order to clarify this evidence, we sought additional information on cGMP metabolism in the central nervous system. Since little is known about cGMP metabolic pathways, in the present study, we analyzed the catabolic conversions of the nucleotide using HPLC. Male Sprague-Dawley rats were sacrificed; brains rapidly removed on ice-prechilled plate and sectioned into various parts; sections cut into 260u slices with McIlwain tissue chopper; slices rapidly transferred into a tonometer (Instrumentation Laboratory IL237) containing oxygenated Krebs-Ringer buffer and standard cGMP (.5uM); and incubated at 37°C. Aliquots of incubation mixtures were sequentially withdrawn (0-60min), boiled for 3 min, filtered through Millipore filters (.45u) and analyzed under isocratic conditions with an Altex reversed-phase HPLC system (Cohn, Venkatesan, Cohn, 1981). The analytic profile of rat brain cortex incubated with cGMP shows appearance of guanosine monophosphate (GMP), guanosine and guanine, in this order. The fact that there is no evidence of formation of either inosine monophosphate or xanthosine suggests the absence of both GMP reductase and guanosine aminohydrolase activity under our conditions. Analysis of midbrain slices incubated as described above showed patterns identical to those of cortex slices. With our analytical procedure, we hope to determine whether alterations in cGMP concentration and/or changes in cGMP metabolism induced by morphine are linked to the analgetic properties of the narcotic. Supported by NIH (MBS) Grant RR08140.

295.14 CYCLIC AMP METABOLISM: OPPOSITE EFFECTS OF HALOGENATED HYDROCARBON ANESTHETICS AND INSECTICIDES. Major L. Cohn, Daniel J. Wooten*, Stephan J. Cohn*, Daryl Rayford*. Lab. Anesthesia Research, Drew Medical School., Los Angeles, California 90059.

The Meyer Overton lipid solubility theory is well accepted. Recent reports of strong correlations between oil/water and oil/air partition coefficients and potency of anesthetic agents (AA) support the theory. However, no theory of narcosis is all inclusive. Our recent findings that barbiturates alter cyclic AMP (cAMP) metabolism correlate with our previous behavioral data which suggests that in-vivo cAMP is a key factor in the regulation of narcosis. In the present study we compared the effects of barbiturates on cAMP metabolism to those of halothane, (HA)--a halogenated hydrocarbon anesthetic--and DDT, chlordane, and heptachlor -- three halogenated hydrocarbon insecticides (HHI). The two classes of halogenated hydrocarbons share high lipid solubility but elicit biological activities in opposite directions. Sprague-Dawley rats were sacrificed by decapitation; brains swiftly removed to ice-prechilled plate; cerebral cortex cut into slices; and slices rapidly transferred to ice-cold oxygenated (95% O_2-5% CO_2) Krebs-Ringer buffer for 10 min. preincubation with either DDT, chlordane, or heptachlor (.14-0.6 uM). Next, slices were incubated at 37°C with fresh oxygenated Krebs-Ringer buffer containing standard cAMP (.5 uM) and HHI in concentrations similar to those used in preincubation. Control slices were preincubated and incubated without HHI. Slices treated with HA were prepared as described above, then incubated with cAMP (.5uM) in a tonometer (Instrumentation Laboratory IL 237) to which HA (1%) was delivered for the duration of experiments. Aliquots of incubation mixtures were sequentially withdrawn (0-60min.); filtered through Millipore filters (.45u); and analyzed with an Altex Liquid Chromatographic (HPLC) system. Confirming our previous findings (Cohn and Cohn, 1980), HPLC analysis of control slices showed that adenosine monophosphate, inosine, and hypoxanthine are the major catabolic products of cAMP. Like barbiturates, HA led to increased formation of adenosine monophosphate and adenosine. In contrast, HHI did not shift the metabolic pattern. The fact that HHI do not alter adenylate deaminase (AD) activity supports our argument that inhibition of AD is a specific action of AA on purine metabolism. This analytical data may explain the opposite biological actions of AA and HHI: AA depress CNS while HHI produce excitatory syndrome. Agreeing with our data are close correlations shown between rate of deamination and brain ammonia production; ammonia concentrations and neural activity; and a sharp decrease in brain ammonia levels in anesthetitized rats. Supported by NIH (MBS) Grant RR08140.

295.16 ACTIVATION OF CORTICAL ADENYLATE CYCLASE BY PROTEIN PHOSPHORYLATION. Scott R. Whittemore*, Robert H. Lenox, Edith D. Hendley, and Yigal H. Ehrlich, Depts. of Physiology & Biophysics, Psychiatry, and Biochemistry, University of Vermont College of Medicine, Burlington, VT 05405

We have reported recently that protein phosphorylation mediates effects of isoproterenol on adenylate cyclase (AC) activity in rat cortical membranes (Whittemore et al, Neurochem. Res. Vol. 8, 1981 in-press). The present studies examined whether the phosphorylation of membrane-bound proteins plays a direct role in the regulation of AC. An assay system has been developed in which pre-incubation of cortical membranes under phosphorylating conditions was followed by extensive washes under conditions which minimize dephosphorylation. Cyclic AMP formation was then measured in resuspended membranes. Preincubation with 2mM ATP + 10mM $MgCl_2$ for 5 min. at 30°C resulted in a 70% increase of AC activity upon reincubation. With longer pre-incubation times, AC activity returned to control levels, suggesting that the activation of AC is reversed by de-phosphorylation. To test this possibility we used ATP-gamma-S in the preincubation buffer. This ATP analog is used by protein kinases to phosphorylate proteins, but the phosphothioester bond formed is known to resist hydrolysis by phosphatases. Preincubation of cortical membranes with ATP-gamma-S for 5 min. resulted in over 300% activation of AC. This activation was irreversible, as compared to ATP, since longer pre incubations further activated AC (740% increase after 40 min). This irreversible activation of AC was found to be dependent on a number of factors: ATP-gamma-S concentration (40μM ATP-gamma-S produced half maximal activation of AC) preincubation time, and most importantly, Mg^{2+} concentration. At 10mM $MgCl_2$ the activation by ATP-gamma-S was five-fold greater than when exogenous Mg^{2+} was not added. Further experiments indicated that this activation cannot be accounted for by changes in ATPase or phosphodiesterase activity. The use of radiolabeled ATP as a substrate for protein kinase, followed by SDS-gel electrophoresis and autoradiography, served to reveal specific phosphoproteins that may be involved in this activation of AC. These data demonstrate a direct role for membrane-bound protein phosphorylation systems in AC regulation. Together with our reports that neurotransmitters regulate protein phosphorylation activity in brain membranes (Ehrlich et al, Life Science, 26:1975, 1980), the results indicate that this process may play a role in the mechanism of receptor-coupled information transfer in the nervous system. (Supported by PHS grants DA 02747 and MH 25811).

295.17 PRELIMINARY STUDIES ON THE EFFECTS OF VARIOUS PEPTIDES ON PHOSPHODIESTERASE ACTIVITY FROM RAT BRAIN. O.Sartor* and M.A.Spirtes
Dept. of Physiol. Tulane U. Sch. of Med.,New Orleans,La.70112.

Peptide hormones are generally thought to control cyclic nucleotide levels by altering the rate of synthesis. However in some peripheral tissues, these hormones have been shown to alter the rate of breakdown as well. At this time there are no reports of transmitter or hormone-induced changes in phosphodiesterase activity from brain. This study sought to explore that potential.

A particulate enzyme fraction was prepared from rat occipital cortex or hypothalamus. The phosphodiesterase activity was assayed by a modification of the Rangel-Aldao et al method using 10^{-6} M H^3 c-AMP as substrate. Results are expressed in terms of percentage of control. Use of boiled enzyme (3.2) or the phosphodiesterase inhibitor IBMX (1.8) confirmed the existence of enzymatic activity. The lack of 100 millimolar KCl (94±7) effect suggests that the activity was primarily due to the low Km phosphodiesterase, however the stimulation by 30 micromolar $CaCl_2$ (128±2 $p<.01$) indicates that high Km enzyme is also present. In the hypothalamus, 10^{-7} M angiotensin II (101±4), 10^{-6} M bradykinin (95±5), 10^{-6} M αMSH (99±2), 10^{-6} M MIF (106±9), 10^{-6} M neurotensin (107±6), and 10^{-5} M substance P (105±5) had no effect. 10^{-6} M substance P had a small but statistically significant effect on the hypothalamic enzyme (112±5 $p<.05$). In the occipital cortex, αMSH at 10^{-6} M (98±3), 10^{-8} M (98±3), or 10^{-10} M (99±2) had no effect on the enzyme.

In whole brain, particulate c-GMP phosphodiesterase activity was assayed with 10^{-5} M H^3 c-GMP serving as substrate. IBMX inhibited activity (11±4) but MIF at 10^{-5} M (102±1) or 10^{-7} M (105±2) had no effect.

As yet there are no peptides which have been shown to effect phosphodiesterase in the brain.

295.18 CYCLIC NUCLEOTIDE AND CALCIUM LEVELS IN CEREBROSPINAL FLUID (CSF) OF AN INHERITED FELINE TREMOR (IFT). G.A. Hegreberg and M.J. Hamilton*. Dept. Veterinary Microbiology and Pathology, Wash. State Univ., Pullman, WA 99164.

Inherited feline tremors (IFT), an autosomal recessive disorder, is clinically apparent at 2-4 weeks of age and is recognized by fine intentional tremors of the head, trunk, and tail. The disease is progressive and the tremors increase in severity in the young growing kitten. Those kittens surviving beyond 16 weeks of age demonstrate remission of the tremors. During this stage of the disease,convulsive seizures, agressive behavior with unprovoked biting and hissing, diarrhea, and visual impairment have been observed. In adult cases, the clinical manifestations include convulsions, behavioral changes which include catatonia, repetitious activity, unkempt coat and a withdrawn and flattened response to attention.

A close relationship exists between divalent cations, including calcium, and the metabolism of cyclic nucleotides in nervous tissue. Changes in the CSF concentrations of cyclic nucleotides, especially a significant depression of cGMP, have been reported in psychiatric illnesses, including depressed, manic, and schizophrenic groups. A depression in the concentration of CSF calcium has also been reported in association with certain psychiatric illnesses.

Total calcium, cAMP, and cGMP were measured in the CSF of adult affected and nonaffected cats. Cerebrospinal fluid was obtained from atlanto-occipital punctures. cAMP and cGMP were determined using modifications of the radioimmunoassay methods of Steiner, et al. Reagents were obtained from New England Nuclear Co. Calcium was determined using an atomic absorption spectrophotometric method.

Results disclosed that the affected cats have a significant decrease (p 0.005) in CSF levels of cGMP (affected [n=10] [mean ± S.D.] 1.7±0.85 pmoles/ml; nonaffected [n=11] 3.1±1.17). Although cAMP was decreased in the CSF of affected cats, no statistical difference was noted between the affected and nonaffected cats (affected [n=10] 12.9±6.5 pmoles/ml; nonaffected [n=11] 15.0±7.8 pmoles/ml.). Levels of CSF calcium were not significantly different between affected and nonaffected adult cats (affected [n=8] 3.78±0.14 meq/L; nonaffected [n=21] 3.90±0.36 meq/L).

295.19 PROPERTIES OF A GONADOTROPIN-SENSITIVE ADENYLATE CYCLASE IN A LEYDIG TUMOR CELL LINE. R. V. Rebois* and P. H. Fishman*
(SPON: L. Abood). Membrane Biochemistry Section, Developmental and Metabolic Neurology Branch, National Institute of Neurological and Communicative Disorders and Stroke, The National Institutes of Health, Bethesda, Maryland 20205.

The transplantable Leydig tumor M5480P has been adapted to culture and cloned to produce several cell lines that have retained their responiveness to lutropin (LH) and human chorionic gonadotropin (hCG). The cell line most intensively studied has been designated MLTC-1. The cells appear to have a single class of high affinity and specific binding sites for hCG. Concentrations as low as 10 pM hCG are capable of inducing the production of adenosine 3':5'monophosphate (cAMP) in intact cells. Cholera toxin (CT) also stimulated cAMP production in MLTC-1 cells. Levels of cAMP increase over an order of magnitude in the presence of either the hormone or the toxin. Adenylate cyclase activity was directly assayed in membranes prepared from the cells. Activity was stimulated by hCG and LH as well as by a variety of other effectors including NaF, 5'-guanylylimidodiphosphate (GppNHp), and activated CT (plus NAD). NaF activated adenylate cyclase to the greatest extent followed by GppNHp and CT and then the hormones LH and hCG. Thus, MLTC-1 cells possess specific gonadotropin receptors which are functionally coupled to adenylate cyclase through a regulatory component which is also responsive to NaF, guanine nucleotides and CT. Only one other hormone-responsive Leydig tumor cell line has been described (Ascoli, M., Endocrinology 108: 88, 1981); it also was derived from the M5480P transplantable tumor. These unique Leydig cell lines provide ease of experimental manipulation unattainable with material taken from testes and offer an opportunity unattainable with material taken from testes and offer an opportunity to study not only the hormone-responsive adenylate cyclase system but also more characteristic properties of Leydig cells such as steroidogenesis.

295.20 GLUCOCORTICOID INFLUENCE ON A BRAIN PROTEIN KINASE. R. F. Alderson* and P. Y. Sze. Dept. of Biobehavioral Sciences, University of Connecticut, Storrs, CT 06268.

In a previous study (Alderson and Sze, Neurosci. Abst., 6, 536, 1980), we have reported the separation of two fractions of protein kinase from rat brain cytosol. One fraction (peak II), eluted at 0.2 M NaCl on a DEAE-cellulose column, is stimulated by cAMP and appears to be similar to "type II" protein kinase identified in heart muscle. The other fraction (peak I), eluted at 0.1 M NaCl on DEAE-cellulose, contains a protein kinase with a M.W. 90,000 which is not dissociated or stimulated by cAMP.

In this study, we have found that the protein kinase activity in peak I is under the influence of glucocorticoids. Two-day-old male rats were injected with corticosterone (20 µg/g, i.p., twice daily) for a period of 5 days. Littermates were injected with saline as controls. The brain (all tissue anterior to the cerebellum) was homogenized in 50 mM Tris, pH 7.4 - 1 mM DTT - 2 mM EDTA, and the homogenate was centrifuged at 40,000 g. An amount of the supernatant equivalent to exactly 25 mg protein was fractionated on a DEAE-cellulose column (2.5 ml). The elution profiles for protein kinase between the control and steroid-treated animals were compared. Peak II was found to remain unchanged following the corticosterone treatment. In contrast, peak I was substantially increased by the steroid treatment. The increase in the peak size was 40-80% from several chromatograms. To verify the differences, fractions in peak I were pooled and lyophilized, and the specific activity of the protein kinase was further determined.

Regulation of protein kinases by steroid hormones has been described in various tissues by several investigators. For example, a cAMP-dependent protein kinase in the prostate and liver is affected by gonadal steroids (Fuller et al., PNAS, 75, 223, 1978). Glucocorticoids are known to have a variety of effects in the brain. The present data show that in the neonatal brain, corticosterone treatment could modulate the activity of a cytosol protein kinase which appears to be cyclic nucleotide-independent. Although the cellular function of this protein kinase is not clear, the fact that its activity is influenced by glucocorticoids suggests that this protein kinase may be involved in some of the steroid effects in brain.

(Supported by USPHS MH-29237.)

295.21 ADENYLATE AND GUANYLATE CYCLASES OF VERTEBRATE RETINAS: BIOCHEMICAL AND HISTOCHEMICAL PROPERTIES. Suhail A. Khoury* and Debora B. Farber (SPON: H. J. Jerison). Jules Stein Eye Institute, UCLA School of Medicine, Los Angeles, CA 90024, and V.A. Medical Center, Sepulveda, CA 91343.

Biochemical measurements and histochemical localization of both adenylate and guanylate cyclase (AC & GC) activities were carried out on retinas of various vertebrates. These included retinas dominated by either cones (13-line ground squirrel) or rods (rat) and duplex retinas, containing both kinds of photoreceptor cells (chicken and teleost). In retinas of ground squirrel, AC has an apparent Km of 5×10^{-4} M (Vmax 3.3 nmol/mg protein/min) when determined in the presence of 10 mM NaF. This enzyme was further activated by NaF, by guanosine and by low concentrations of adenosine. Alloxan, calcium and higher adenosine concentrations inhibited AC in a dose-dependent fashion. Histochemically, AC was localized in the cytoplasmic infoldings of the cone outer segment, in the cilium and along the plasma membrane of the cone inner segment and at the photoreceptor synaptic terminals. AC was found also along the plasma membrane of ganglion cells and on their axons. Similar results were observed in the retinas of chicken and teleost; in the latter, AC activity was found also along the photoreceptor cell nuclear envelopes. GC in the ground squirrel retina shows two apparent Kms: 2.1×10^{-4} M and 3.7×10^{-5} M (Vmax 1.84 and 0.83 nmol/mg protein/min). This enzyme was activated with 0.1 mM ATP and inhibited in a dose-dependent manner by higher concentrations of ATP (1 mM and greater); it was also inhibited by alloxan and calcium. NaF (10 mM) reduced GC activity by 40-50%. No apparent effect of either adenosine or guanosine was detected on GC activity. Similar results were observed with the GC of rat retina and with that of bovine rod outer segments. However, the response of rod photoreceptors to NaF seemed different from that of cones. We observed a 2-fold increase in GC activity of bovine ROS and a 40% increase in the activity of the enzyme from rat retina. Histochemically, GC is localized in the intradiscal spaces of rat outer segments, in the cilium, along the nuclear envelopes and, to a lesser extent, on the photoreceptor synaptic terminals. In ground squirrel, GC is found in the cilium and along the nuclear envelopes of photoreceptor cells. A lower density of reaction product was found on the plasma membranes of ganglion cells and on their axons. Similar localizations were detected in the teleost. Thus, these studies show biochemical and histochemical differences in the synthetic enzymes of cyclic nucleotides from rod- and cone-dominant retinas. (Supported by NIH training grant EY7026 (SK), by NIH grant EY2651 and RCDA EY0144 (DF), and by the Medical Research Service of the V.A.)

296.1 SYSTEMIC ADMINISTRATION OF PUTRESCINE INDUCES GABA-LIKE BEHAVIORS IN RATS. F. D. Feng and B. B. Turner. Depts. of Psych. & Biol., Virginia Polytechnic Institute & State Univ., Blacksburg, VA 24061

Putrescine is a simple polyamine with multiple roles in cell growth and metabolism. It is also a minor precursor of the inhibitory neurotransmitter, GABA. Administration of ^{14}C-putrescine results in slight, but significant conversion to GABA in neural and peripheral tissues. We now present evidence that oral and i.p. administration of pharmacological levels of putrescine induces behaviors that are similar to those induced by GABA.

Male Sprague-Dawley rats (350-425g) were given putrescine or saline. Oral putrescine doses were 50, 250, or 1000 mg/kg; i.p. doses were 25, 50, 100, or 250 mg/kg. Behavioral observations included the time sampling of 15 behaviors over 60 min, followed by 6 additional measures: startle response, open-field ambulation, vertical grid endurance, food and water intake, body temperature, and pain responsivity to electric shock. As an indication of the duration of any analgesic effect, pain responsivity was determined again 21 hr post-treatment.

In the oral putrescine experiment, significant effects were found on all measures except grid endurance. The i.p. putrescine experiment revealed similar findings, though no significant effects were found with respect to food or water intake, or body temperature. Those behaviors scored by time sampling which were affected by putrescine treatment included grooming, sleep, rearing, gnawing, mastication stereotopy, abnormal posture/movement, and at the highest doses, "wet-dog" shakes. A positive, dose-dependent effect was seen for attenuation of initial startle intensity, facilitation of startle habituation, decreased open-field ambulation, and increased pain thresholds in both experiments. Significant hypothermia, polydipsia, and anorexia were seen with 1000 mg/kg putrescine. Additional behaviors associated with high doses included ptosis, piloerection, incomplete grooming sequences, fore-paw flicking, sedation and flacid immobility. Decrements in pain sensitivity remained at 21 hr post-treatment only in animals receiving oral putrescine.

These data provide evidence for the elicitation of a complex of behavioral changes following oral or i.p. administration of putrescine. Many of the observed behavioral effects are similar to those reported following treatment with GABA, GABA agonists, and GABA-transaminase inhibitors. The occurence of "wet-dog" shakes and pronounced analgesia suggest the facilitation of endogenous opiate systems. From the behavioral evidence obtained, we conclude that systemic administration of putrescine may modulate CNS GABA function.

296.2 RAPHE UNIT ACTIVITY IN FREELY MOVING CATS: EFFECTS OF BENZODIAZEPINES. Donald W. Preussler, Gailyn A. Howell, Christopher J. Frederickson and Michael E. Trulson. Dept. Psychol., Univ. of Texas at Dallas, P.O. Box 688, Richardson, TX 75080.

Previous studies have shown that the activity of serotonin-containing raphe neurons in cats is grossly correlated with the level of behavioral arousal or tonic motor activity. These neurons display a progressive decrease in activity with descending levels of arousal, from a maximum of 3-5 spikes/sec during active waking to complete silence during REM sleep. This suppression of activity during REM sleep may be simply due to the fact that tonic EMG activity or motoric output is at a minimum. On the other hand, raphe unit activity may be related to the state (i.e., REM sleep) of the animal. To test these competing hypotheses, in a previous study we compared raphe unit activity in normal cats with that in cats that display REM sleep without atonia (produced by lesions of the pontine tegmentum). Although the activity of raphe neurons in lesioned cats during REM sleep without atonia was significantly below that seen in these cats during waking, the level of activity was often impressive, especially in those cats that displayed the greatest degree of motor activity during REM sleep. These data suggest that the decrease in raphe unit activity during REM sleep is largely a concomitant of the atonia which characterizes that state. In order to further test this hypothesis, in the present study we examined the effects of centrally acting muscle relaxants, the benzodiazepines, on raphe unit activity in freely moving cats. Dorsal raphe unit activity was recorded by means of movable 32 or 62 u dia insulated nichrome wires. Raphe neurons were initially identified on-line on the basis of their characteristic slow and rhythmic discharge rate. This identity was later confirmed by means of histological analysis, i.e., all cells were in the densely serotonergic dorsal raphe nucleus. After obtaining 30 to 60 min of baseline unit activity, the cats were given a single i.p. injection of either saline (0.5 ml/kg), diazepam, or chlordiazepoxide HCl (0.25 to 10.0 mg/kg). These drugs produced dose-dependent decreases in raphe unit activity, from no significant change at 0.25 mg/kg to 80-90 % decreases in activity at the 10 mg/kg dose. The benzodiazepines produced ataxia and decreased EMG activity at the higher dose levels. However, raphe unit activity remained suppressed even when the cat would show high levels of tonic and phasic EMG activity during eating, grooming, or attempting to catch a mouse placed in the recording chamber. These data suggest that the benzodiazepines decrease raphe unit activity by an action on the central motor system, and are consistent with the hypothesis that the depression of raphe unit activity normally observed during REM sleep is largely a result of the centrally induced atonia that characterizes this state.

296.3 EFFECTS OF QUIPAZINE ON RAPHE UNIT ACTIVITY AND BEHAVIOR IN FREELY MOVING CATS Terriann Crisp*, Gailyn A. Howell, Donald W. Preussler and Michael E. Trulson (SPON: A. Rupert). Dept. Psychol., Univ. of Texas at Dallas, P.O. Box 688, Richardson, TX 75080.

Several recent studies have investigated the behavioral and neurochemical effects of quipazine. This drug has been reported to have multiple effects on the central serotonergic system, including a direct stimulation of serotonin receptors, inhibition of serotonin reuptake, and inhibition of monoamine oxidase, as well as decreasing the rate of synthesis and turnover of serotonin. These latter effects are considered to be secondary to a primary action of increasing the functional activity in the central serotonergic system by direct receptor activation. Numerous behavioral studies support the hypothesis that quipazine increases the activity at central serotonergic synapses. While a large number of studies have examined the serotonergic effects of quipazine using behavioral and neurochemical measures, apparently none has investigated the effects of quipazine on the serotonergic system using electrophysiological techniques. Thus, in the present study, we examined the effects of quipazine on the activity of serotonin-containing raphe neurons in freely moving cats. Dorsal raphe unit activity was recorded by means of movable 32 or 62 u dia insulated nichrome wires (see complete methodology in Brain Res. 163: 135-150, 1979). Raphe neurons were initially identified on-line on the basis of their characteristic slow and rhythmic discharge rate. This identity was later confirmed by means of histological analysis i.e., all cells were in the densely serotonergic dorsal raphe nucleus. After obtaining 30 to 60 min of baseline unit activity, the cats were given a single i.p. injection of either saline (0.5 ml/kg) or quipazine (0.5, 1.0, 2.0 or 5.0 mg/kg). Quipazine produced a dose-dependent decrease in raphe unit activity ($P<0.01$, ANOVA). The lowest dose of the drug (0.5 mg/kg) produced no significant change in raphe unit activity from saline baseline, while the highest dose (5.0 mg/kg) produced a nearly complete suppression of unit activity. The duration of suppression of raphe unit activity by quipazine was also dose related; unit activity returned to baseline levels within 1, 3, and 6 hours following doses of 1.0, 2.0 and 5.0 mg/kg of quipazine, respectively. Behavioral observations revealed that quipazine elicited a number of unique behaviors such as limb flicking, abortive grooming, investigatory behavior, and hallucinatory-like behavior, which are also elicited by LSD and related hallucinogens. Furthermore, the behavioral and electrophysiological effects of quipazine were temporally correlated. Similar behavioral and raphe unit changes were observed following administration of certain indole nucleus hallucinogens in our previous studies. However, it should be emphasized that is is unclear whether quipazine possesses hallucinogenic properties.

296.4 AMPHETAMINE POTENTIATES KETAMINE-INDUCED LOSS OF RIGHTING REFLEX AND SLEEP TIME. Marie T. Spoerlein and Christina VanderWende, (SPON: A. Sinha). College of Pharmacy, Rutgers-The State Univ., Box 789, Piscataway, N.J. 08854.

Ketamine is a dissociative anesthetic which produces psychotomimetic effects as post-anesthetic sequelae. These mind altering effects have led to the street abuse of ketamine as well as with the parent compound, phencyclidine. It is possible that a drug abuser will unknowingly use ketamine in combination with other drugs, such as amphetamine, since ketamine is sometimes cut with this drug. Voluntary poly-drug use, however, is also a potential. It would, therefore, appear essential to understand any interactions between these drugs.

Male albino, Swiss Webster mice were used for these studies. Drugs were administered intraperitoneally. Amphetamine was administered 15 min. before the ketamine. Amphetamine (5 mg/kg) increased the number of animals losing the righting reflex induced with ketamine; at 100 mg/kg of ketamine, amphetamine increased the loss of the righting reflex to 90% as compared to 60% in the control group. Amphetamine pretreatment also caused animals to sleep 2.5 times longer than the controls. Thus, amphetamine increased both the number of animals and the length of time they would sleep with ketamine alone.

Since both amphetamine and ketamine have effects on the catecholaminergic (CA) systems, the question was raised whether this potentiation of ketamine related to CA systems. Animals were pretreated with d,l-alpha methyl-p-tyrosine (MPT) (400 mg/kg) to deplete the CA's of the brain. Four hours after MPT pretreatment, the effect of amphetamine on ketamine sleep was reexamined. Ketamine (100 mg/kg) in the MPT pretreated animals now caused 90% of the animals to lose the reflex (as compared to 60% in non- MPT animals) with an average sleep time of 13 min. Amphetamine administered 15 min. before the ketamine in the MPT-treated animals caused 50% loss of righting with the same sleep time as the controls. Thus, the potentiative effect of amphetamine on ketamine was lost with MPT pretreatment. A further attempt was made to determine whether this effect of amphetamine related to the dopaminergic (DA)system. This did not seem to be the case since neither spiroperidol, a DA blocker, nor apomorphine, a DA agonist, altered the amphetamine effect on ketamine.

296.5 SHAKING BEHAVIOR IN RATS INDUCED BY THYROTROPIN-RELEASING HORMONE IS DEPENDENT ON BRAIN DOPAMINE. E.G. Drust* and J.D. Connor (SPON: C.I. Thompson). Dept. of Pharmacology, The Pennsylvania State University College of Medicine, Hershey, PA 17033.

Thyrotropin-releasing hormone (TRH) is a potent inducer of shaking behavior in rats after intracerebroventricular (icv) administration. The mechanism by which TRH produces this response was investigated by treating rats with receptor antagonists or monoamine depletors and then comparing the mean number of shakes (±SEM) in control and treated rats after injection of TRH (100 ng, icv). Pretreatment with p-chlorophenylalanine (pCPA, 400 mg/kg, ip, daily for 3 days) decreased brain 5-hydroxytryptamine (5-HT) concentrations to 15% of control ($p<0.001$) and also reduced brain norepinephrine (NE) and dopamine (DA) to 71% and 80% of control, respectively ($p<0.01$). Pretreatment with pCPA had no significant effect on TRH shakes (saline 20.3±3.6 vs pCPA 15.6±3.6). In rats pretreated with 5,7-dihydroxytryptamine (5,7-DHT, 200 µg, icv, 72h prior), brain 5-HT was reduced to 50% of control ($p<0.001$), brain NE and DA were 104% and 100% of control, respectively. Pretreatment with 5,7-DHT also had no significant effect on TRH shakes (vehicle 19.1±1.5 vs 5,7-DHT 21.3±3.9). In addition, the 5-HT receptor antagonist methysergide (10 mg/kg, ip), injected 5 min before TRH, did not affect TRH shakes (saline 25±2 vs methysergide 24±3). Naloxone (10 mg/kg, ip) injected 5 min before TRH also did not affect TRH shakes (saline 20.4±1.5 vs naloxone 23.8±1.6). Pretreatment with α-methyl-p-tyrosine (α-MpT, 200 mg/kg, ip, 21 and 5h prior) decreased brain DA and NE to 15% and 14% of control ($p<0.001$), respectively; 5-HT was 106% of control. Pretreatment with α-MpT reduced TRH shakes to 21% of control (saline 25.2±3 vs α-MpT 5.2±1; $p<0.001$). After pretreatment with 6-hydroxydopamine (6-OHDA, 2x250 µg, icv, 6 and 7 days prior), brain DA and NE were reduced to 59% and 26% of control ($p<0.001$), respectively; 5-HT was 88% of control ($p<0.05$). 6-OHDA pretreatment reduced TRH shakes to 20% of control (vehicle 28±3.2 vs 6-OHDA 5.7±0.9; $p<0.001$). A combination of 6-OHDA and desipramine (DMI, 30 mg/kg) selectively decreased brain DA (DA 54% of control, NE 82% and 5-HT 100% of control) and also inhibited TRH shakes (DMI + vehicle 26±1.6 vs DMI + 6-OHDA 8±2.8; $p<0.001$). However, after a combination of bupropion (BP, 100 mg/kg) and 6-OHDA which selectively depleted NE (NE 31% of control, DA 93% and 5-HT 90% of control), shakes induced by TRH were not significantly different from control (BP + vehicle 22±2.7 vs BP + 6-OHDA 19±2.1). The results of these studies indicate that TRH-induced shaking behavior is dependent on brain DA mechanisms and is not due to release of endogenous NE or activation of 5-HT or opiate receptors. 296.6 TOBACCO SMOKING: INFLUENCE ON HUMAN AGGRESSIVE BEHAVIOR D.R. Cherek, J.L. Steinberg, and J.T. Brauchi. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Aggressive behavior in human subjects was elicited in a laboratory setting and the effects of not smoking and smoking low (0.42mg) and high (2.19mg) doses of nicotine on that behavior was investigated.

Subjects were given the option of pressing three response devices. Pressing button A was maintained by fixed-ratio 100 schedule of monetary reinforcement, consisting of increments of ten cents indicated on a counter and paid to the subject after the session. We defined as aggressive, pressing button B or switch C which ostensibly delivered aversive stimuli by subtracting ten cents from or delivering a one-second blast of white noise to another "person". Each subject was told that at any time he may have money subtracted from him or presented with blasts of white noise which were attributed to another "person". Research subjects were not actually paired with another "person" and were informed of this after the experiment. The subtractions of money from the research subject took place automatically at random time points throughout the session in order to elicit aggressive responding. Compared to the non-smoking condition, aggressive monetary-subtraction responses (button B) were decreased in all subjects following smoking of either nicotine dose. Smoking the high dose of nicotine resulted in a greater reduction of aggressive monetary subtraction responses than the low dose. In general, smoking resulted in suppression of aggressive noise delivery responses (switch C) and increased the number of non-aggressive monetary reinforced responses (push button A). The increase in non-aggressive responding following smoking, indicates that the suppression of aggressive responding was not due to a non-selective generalized depressant action. For both doses of nicotine cigarettes contained the same amount of tar suggesting that the dose-dependent effects were due to nicotine. The relatively selective suppression of aggressive behavior observed in humans in the present study is consistent with the effects of nicotine observed in a number of infrahuman species.

296.7 COMPARATIVE DOSE EFFECTS OF CAFFEINE, THEOPHYLLINE, AND AMPHETAMINE ON RAT ACTIVITY. F. A. Holloway, H. E. Modrow*, and D. C. Bird*. Dept. Psychiat. & Behav. Sci., Univ. Okla. Health Sci. Ctr., Okla. City, Okla. 73190.

Preparatory to tolerance and dependency studies, stimulatory effects of caffeine on rat activity were assessed under several conditions and in comparison with theophylline and d-amphetamine. Spontaneous activity of rats was monitored over successive 24-hr periods with a vibration-sensitive, phonocartridge microprocessor system. Male albino rats were housed individually on ad lib food and water under 12:12 LD conditions (lights on: 0800-2000).

In Experiment 1, i.p. injections of caffeine (7 doses: 0.1-150 mg/kg), theophylline (10, 32, 56, 100 mg/kg), and d-amphetamine (0.5, 1, 2, 4 mg/kg) were administered 1-2 hrs after lights-on (n=8). All drugs produced a U-shaped dose-effect curve for activity during the 4 hours post-injection. The peak stimulatory effect for caffeine occurred between 10 and 32 mg/kg; for theophylline, between 10 and 20 mg/kg; and for d-amphetamine, between 1 and 2 mg/kg. At peak dosage, caffeine was approximately 10-fold more potent than theophylline and about 2-fold more potent than amphetamine. At the highest dose levels, caffeine but not amphetamine or theophylline still produced a small stimulatory effect.

Experiment 2 examined single vs. dual injections of drugs used in Exp. 1. Half of each dose was injected 20 min prior to and the other half immediately prior to a 1-hr activity sampling period (n=8). Single-injection dose-effect curves were comparable to those of Exp. 1. However, the two-injection procedure appeared to result in a shift to the right in caffeine but not amphetamine or theophylline dose-effect curves.

The final experiment examined caffeine injections 2 hrs after lights-on and 2 hrs after lights out (n=8). At doses of 1, 10, and 20 mg/kg, activity increases were larger for the dark than for the light sample. No light-dark differences were evident at 32 mg/kg, while at 100 mg/kg, dark-activity scores were significantly lower than light period scores.

In summary, for doses examined, caffeine's potency exceeded that for theophylline and amphetamine. Further, there is some indication of tachyphylaxis with caffeine. Finally, the pattern of caffeine-induced increases in activity differed as a function of light-dark conditions. (Supported by NIDA Grant #DA02666-01; FAH, P.I).

296.8 AMPHETAMINE AND MORPHINE: ADDITIVE EFFECTS ON ICSS THRESHOLD. Thomas F. Seeger* and Kristin R. Carlson. (SPON: J. Cooke) Department of Pharmacology, University of Massachusetts Medical School, Worcester, MA 01605.

The complex interactions of dopaminergic (DA) and enkephalinergic systems within the CNS are reflected by the behavioral consequences of amphetamine and morphine treatment. Nigrostriatal DA behaviors induced by amphetamine, such as stereotypy and turning behavior, are inhibited by concurrent morphine treatment. However, a mesolimbic DA behavior, non-specific locomotor activity increase due to amphetamine, can be potentiated by intracerebral injection of enkephalin into the ventral tegmentum.

In order to further characterize the behavioral interactions between DA and enkephalin systems in the mesolimbic system, we have tested the effects of amphetamine and morphine on self-stimulation threshold in rats implanted with electrodes in the ventral tegmental nucleus (A10 DA cell body area). A two-lever, current-decrementing threshold titration paradigm was used in order to partially control for changes in motor activity and arousal level.

Thirteen rats were successfully implanted and trained to stable responding in the titration task. The average threshold current after saline baseline runs was 117 ± 16 µA. Following D-amphetamine treatment (0.5 mg/kg 15 min prior to 15 min test period), average threshold current was decreased by 10% ($p<.01$). After morphine treatment (5 mg/kg 1 hr prior to test), threshold was similarly decreased by 15% ($p < .01$). This decrease was naloxone-reversible. When the morphine and amphetamine pretreatments were combined, an additive decrease of 24% was measured ($p < .05$ vs. morphine or amphetamine alone). These results provide further evidence of a functional interrelationship of opiates and opiate peptide systems with the mesolimbic DA system and further suggest that such interaction is opposite in direction from that seen in nigro-striatally mediated behaviors.

(Supported by USPHS grant DA-02226).

296.9 REGULATION OF MUSCARINIC RECEPTOR SENSITIVITY AND MEMORY PERFORMANCE IN RATS. C.C. Loullis, R.L. Dean, D.I. Benson*, L.R. Meyerson, and R.T. Bartus. Dept. of CNS Research, Medical Res. Div. of American Cyanamid, Lederle Labs, Pearl River, NY 10965.

Data from many laboratories demonstrate that changes in CNS cholinergic neurotransmission, induced through pharmacological and/or precursor manipulation, can have profound effects on performance of memory tasks. In general, administration of anticholinergics impairs retention while that of cholinomimetics enhances it. Recent evidence suggests that cholinergic function may also be modified by drug induced changes in receptor sensitivity. For example, when cholinergic blockers are administered chronically, an increase in muscarinic receptor density has been observed, whereas chronic administration of acetylcholinesterase inhibitors has been reported to induce a decrease in muscarinic receptor density.

In the present study we were interested in examining the relationsip between changes in muscarinic receptor binding induced by chronic administration of cholinergic agents and possible changes in performance on a memory task. Rats were implanted subcutaniously with Alza® pumps and physostigmine or scopolamine were continuously infused for 15 days. Twenty-four hours after removal of the pumps the experimental groups and sham operated control group were trained on a single trial passive avoidance task. Twenty-four hours after training they were tested for retention. Following behavioral testing, animals were sacrificed by decapitation and selected brain regions were dissected, quickly frozen and stored (-20°C) for analysis of muscarinic antagonist binding.

Animals which had previously received chronic infusions of scopolamine performed significantly better than controls, while those which previously received chronic infusions of physostigmine performed significantly worse during the retention test. No differences in training latencies were found between groups, demonstrating that alterations in motor activity cannot easily explain the observed behavioral differences. Determinations of muscarinic receptor binding, using ^{3}[H](-)QNB, revealed regional specific increases in the scopolamine-treated animals and decreases in the physostigmine-treated animals.

Results indicate that: (1) continuous, chronic infusion of drugs known to facilitate or inhibit CNS cholinergic activity can induce reciprocal changes in muscarinic receptor binding, (2) parallel changes in behavioral function, as measured by retention on a memory task, also occur, (3) a relationship between the neurochemical and behavioral changes exists, suggesting that changes in receptor function may be responsible for the behavioral effects.

296.10 SIX-HYDROXYDOPAMINE INDUCED HYPERACTIVITY: NEITHER SEX DIFFERENCES NOR CAFFEINE STIMULATION ARE FOUND. L. Erinoff*, P.H. Kelly and S.R. Snodgrass, Childrens Hospital of Los Angeles, CA 90054, and Depts. of Neurology and Physiology and Biophysics, U. of Southern California, Los Angeles, CA 90033

We investigated possible sex differences in the development of locomotor activity in rats treated neonatally with desmethylimipramine (DMI) followed by intraventricular 6-hydroxydopamine (6HDA) (Concannon, J.T. and Schechter, M.D., Pharmac.Biochem.Behav. 14:5,1981). In addition, the locomotor response to the stimulant drug caffeine was studied in the male rats after they had reached adulthood.

At 3 days of age rats were assigned to one of four litters: control males, treated males, control females, and treated females. At 3 and 6 days of age, all rats were injected with DMI(20mg/kg) followed by intraventricular injection of 6HDA(100 ug in 10 ul) or saline-ascorbate. Beginning on day 10, locomotor activity was measured for 1 hour every other day in photocell cages. Both male and female treated rats exhibited increased activity relative to controls. These differences were maximal during the fourth week of life and were maintained through day 52. No sex differences were seen in either the development or magnitude of this hyperactivity.

Male rats were used to determine the dose effect function for caffeine(0.5, 5, 15, 30 mg/kg) on locomotor activity. Control rats exhibited increased locomotor activity at 5, 15, and 30 mg/kg whereas DMI-6HDA treated rats showed no increases with any dose of caffeine. The lack of stimulation seen with caffeine in 6HDA treated rats is not likely to be due to a ceiling effect since a dose of 2.5 mg/kg of L-DOPA following pre-treatment with the decarboxylase inhibitor RO4-4602 did increase locomotor activity in these animals. We suggest that neonatal 6-HDA treatment changes receptor mechanisms involved in caffeine induced increases in activity.

296.11 MUSCIMOL ENHANCES ACTIVITY LEVEL IN THE RAT: BLOCKADE BY LESIONS OF THE ASCENDING 5-HT SYSTEMS. S.M. Sainati and S.A. Lorens. Pharmacology Dept., Loyola University Strich School of Medicine, Maywood, IL 60153

Acute microinjections of the GABA-agonist, muscimol, into the dorsal raphe (DR) nucleus of ether-anesthetized rats induces hyperactivity (Przewłocka et al, Life Sci. 25: 937, 1979). In our initial work, we replicated these findings. Muscimol (100ng/0.5µl) or vehicle solution (0.5µl) was administered via a 5µl microsyringe into either the DR or the median raphe (MR) nucleus of ether-anesthetized rats. The animals were placed in photocell chambers 15 min. post-op and their activity levels were recorded for 90 min. Injection of muscimol into the MR produced a greater increase (740%) over control than did injection into the DR (270%).

Subsequently, we implanted chronically-indwelling 26-gauge cannulae in either the DR or the MR. Beginning 7 days post-op, the animals were habituated to the testing apparatus. We then established a dose-response curve using muscimol doses of 0, 25, 50, 100, 200 and 400ng/0.5µl. This experiment confirmed that the MR is more sensitive to muscimol than the DR (peak effect of 100ng for the MR vs. 400ng for the DR).

If these muscimol effects are due to activation of GABA receptors, they should be potentiated by chlordiazepoxide (CDP) and blocked by bicuculline. We found that CDP in the subataxic dose 3.8mg/kg i.p. did not itself affect activity level, but enhanced the locomotor responses to low doses (25 and 50ng) of muscimol injected into the MR. Conversely, a subconvulsant dose of bicuculline (1.1mg/kg i.p.) completely blocked the response to 50 and 100ng of muscimol.

Finally, forebrain 5-HT was depleted by injecting the serotonin neurotoxin, 5,7-dihydroxytryptamine bilaterally into either the cerebral ventricles (75µg/5µl) or into the midbrain tegmentum (8µg/2µl) in desipramine (20mg/kg) pretreated rats. These lesions markedly attenuated the locomotor response produced by muscimol injections into the MR.

These data suggest that midbrain GABA neurons modulate activity level in the rat through a direct action on serotonergic neurons.

296.12 REINFORCING PROPERTIES OF PSYCHOSTIMULANTS REVEALED BY A CLASSICAL CONDITIONING PARADIGM. Christina Spyraki and H.C. Fibiger. Div. Neurological Sciences, University of British Columbia, Vancouver, B.C. V6T 1W5, Canada

The intravenous self-administration paradigm has provided strong evidence for the reinforcing effects of a variety of centrally-acting drugs in animals. The so-called place preference procedure is a much more simple procedure that may also be useful in studies on drug reinforcement. In the present experiments we examined the effects of systemically administered cocaine, d-amphetamine and apomorphine on place conditioning in the rat.

Groups of male Wistar rats (n = 10/group) weighing 300±20 gm. were used. The tests were conducted in an aluminum shuttle-box divided into 2 compartments that were distinctive in flooring and wall covering. In the first phase of the study (3 days) each animal was allowed to explore the shuttle-box for 15 min. and the time spent in each compartment provided a measure of preference between the two environments. In the second phase, the animals were injected with the drug on days 1,3,5,7 and confined to the less preferred ("conditioned") side of the chamber, while on days 2,4,6 and 8 the rats received a vehicle injection and were confined to the preferred side. In the third phase (day 12) each animal was placed into the shuttle-box and the amount of time spent in each compartment was recorded over 15 min.

All 3 compounds produced statistically significant conditioned place preference. d-amphetamine produced the most pronounced effect, followed by cocaine and then apomorphine. The dose effect was significant for amphetamine and cocaine ($p<.05$) but not for apomorphine. In another series of experiments, we attempted to block cocaine-induced place preference by pretreatment with neuroleptics. Neither pimozide (0.5 mg/kg) nor haloperidol (1 mg/kg) blocked cocaine-induced place preference. Furthermore, neither neuroleptic alone produced place aversion. Bilateral 6-OHDA lesions of the nucleus accumbens did not affect place conditioning produced by cocaine. Neonatal treatment with 6-OHDA that produced extensive depletions of central norepinephrine also did not affect cocaine-induced place preference.

These results demonstrate reinforcing effects of cocaine, d-amphetamine and apomorphine in the rat using the place conditioning paradigm. However, according to the more extensive studies with cocaine, it appears that the conclusions reached with this procedure may differ substantially from those obtained with the intravenous self-administration paradigm. Specifically, although studies with the latter procedure point to a dopaminergic mechanism of cocaine reinforcement, we were unable to demonstrate this in the place conditioning paradigm.

296.13 PARADOXICAL ROTATION: LONG-TERM CONSEQUENCE OF A SINGLE APOMORPHINE TREATMENT. P.B. Silverman and B.T. Ho. Neurochem.-Neuropharm. Res. Section, Texas Res. Inst. of Mental Sciences, Houston, Texas 77030.

Rats were lesioned unilaterally in the substantia nigra by stereotaxic microinjection of 6-hydroxydopamine. Lesioned, but otherwise drug-naive, rats showed slight ipsilateral (toward the lesioned side) rotation when placed in a novel environment. Treatment with apomorphine, 0.05 to 1.0 mg/kg, resulted in acute, active contralateral rotation of dose-dependent duration. Upon subsequent exposure to the rotation environment, rats that had received a single apomorphine treatment up to 9 months earlier showed a brief, intense burst of contralateral rotation. Saline-treated controls maintained their initial slight ipsilateral bias. Our data thus suggest that "paradoxical" rotation (Ungerstedt, Acta Physiol Scand. Suppl. 367, 49, 1971) is a long-term consequence of prior drug treatment. Further examination of the phenomenon revealed that paradoxical rotation showed some characteristics of associative learning, e.g., it was environmentally specific and could be extinguished by daily exposure to the rotation environment. Other characteristics were not readily reconciled with an associative learning explanation, e.g., inverse relationship to dose and no recency effect. Preliminary experiments with LSD, which acts like a direct dopamine receptor agonist in the rotation paradigm, showed that it, too, induces paradoxical rotation. Treatment with (+)-amphetamine, an indirect-acting dopamine agonist which induced acute, active ipsilateral rotation, resulted in neither paradoxical rotation nor reverse paradoxical rotation. Paradoxical rotation was abolished by ipsilateral intranigral or intracaudate injection of kainic acid, whether or not such treatment also eliminated the acute response to apomorphine. Some of our data may suggest a long-term physiological or biochemical change resulting from a single small dose of apomorphine or LSD.

296.14 LOCALIZATION OF SULFANILIC ACID, A FOOD DYE METABOLITE, IN DEVELOPING RAT BRAIN FOLLOWING INTRAPERITONEAL INJECTION. J. R. Goldenring* and B. A. Shaywitz. Lab. of Developmental Neurobiology, Pediatric Neurology, Yale University School of Medicine, New Haven, CT 06510.

Artificial food dyes have been implicated in the etiology of behavioral disturbances in children. We have previously shown that chronic ingestion of a mix of artificial food dyes causes significant behavioral changes in developing rat pups (Goldenring, et al, Life Sci., 27:1897-1904, 1980). Furthermore, sulfanilic acid, a metabolite of the azo food dyes Tartrazine (F,D &C Yellow No. 5) and Sunset Yellow (F,D&C Yellow No. 6), induces similar deficits in rat pups during their first postnatal month. In an attempt to define the mode of sulfanilic acid action, we have studied the autoradiographic localization of sulfur label in brain following intraperitoneal administration of (^{35}S)-sulfanilic acid to six-day-old rat pups.

In 24 µm frozen sections, increased uptake was seen in the central regions of the olfactory bulb and in the developing cortical layers of the cerebellum. 8 µm paraffin sections of brain fixed with Bouins fix also showed localization in olfactory bulb and cerebellum. In the cerebellum, the densest grain localization was observed over the external germinal layer. In the olfactory bulb, dense grain concentrations were seen around periglomerular cell bodies and in the deepest regions of the granule cell layer. No significant labelling was seen over the olfactory bulb glomeruli.

These results suggest that sulfanilic acid can cross the blood-brain barrier and produce a localized pattern of uptake in neonatal brain. Whether this uptake is due to neuronal or glial cell elements has not been determined yet. However, at least in the granule cell layer of the olfactory bulb, grains were not localized over cell bodies. The integrity of olfactory function is especially important for the maintenance of normal development in rats (see Teicher, et al., Neurosci. Abs., 6:633, 1980). Therefore, the localization of label in the olfactory bulb may suggest a mechanism for the behavioral effects of sulfanilic acid in developing rat pups.

296.15 ANTICHOLINERGIC-INDUCED FORWARD LOCOMOTION IN RATS TREATED WITH 6-HYDROXYDOPAMINE IN NUCLEUS ACCUMBENS, NIGROSTRIATAL PATHWAY, SPINAL SUBARACHNOID SPACE OR CEREBRAL VENTRICLES. T. Schallert, S. Farrar*, N. Lobaugh*, R. E. Wilcox and D. Vaughn*. Depts. of Psychol. and Pharmacol., Univ. of Texas at Austin, Austin, TX 78712. Intraventricular injections of the irreversible neurotoxin 6-hydroxydopamine (6-OHDA) can produce animals that are chronically akinetic, which has been attributed to the destruction of ascending catecholaminergic pathways. After several weeks, muscarinic anticholinergic drugs produce dose-dependent excessive walking in animals with these lesions (Schallert, Whishaw, Ramirez & Teitelbaum, Science, 199:1461, 1978). The dopamine receptor antagonist, haloperidol, does not block the enhanced locomotion in these otherwise severely akinetic animals. The present study extends these findings with localized microinjections of 6-OHDA into nucleus accumbens, median forebrain bundle (MFB) and spinal cord (SC) in an attempt to localize those regions that may be involved in the enhanced forward locomotion to anticholinergics.

These lesions were performed on male rats via an acutely placed cannula; pargyline, a MAO inhibiter, was administered 30 minutes prior to infusion of either 6-OHDA or vehicle. Intraventricular injections were bilateral (20 mcl; 12 mcg/mcl in artificial CSF). SC injections were made into subarachnoid space (5 mcl; 10 mcg/mcl). Accumbens and MFB injections were bilateral slow infusions (1-2 mcl; 2-4 mcg/mcl).

A battery of neurological tests was performed on all subjects for 30 days following the surgery. Severe deficits in movement initiation and ingestive behavior were found in subjects with intraventricular as well as MFB injections.

Anticholinergic-induced forward locomotion was tested by placing the animals in an activity wheel for 6 hours after injection with atropine sulfate (50 mg/kg) or, on a different day, with saline. Animals were tested every 9-10 days for 35 post-operative days. All lesioned groups showed greatly enhanced locomotion to atropine, which was most pronounced in the intraventricular, MFB and spinal groups. The effect developed and increased dramatically over the course of the five weeks after surgery.

Biochemical analyses included regional (3H)-dopamine uptake, (3H)-spiroperidol binding, (3H)-QNB binding, and (3H)-muscimol binding.

The results suggest that the chronic depletion of striatal, accumbens, and spinal catecholamines are each sufficient but not necessary for atropine-induced excessive forward locomotion. (Supported by N.I.H. grant NSAG-17274 to T.S.)

297.1 MICRODISTRIBUTION OF CATECHOLAMINE SYNTHESIZING ENZYMES IN RAT LOWER BRAIN STEM. G. Chamba*, L. Deneroy*, B. Renaud* and D. Armstrong, (SPON: A. Judd). Laboratoire de Neuropharmacologie and ERA CNRS 894, Faculte de Pharmacie, Universite Claude Bernard, Lyon, France and Laboratory of Neurobiology, Cornell University Medical College, New York, N.Y. 10021.

Since the discovery of the adrenaline (A) containing neurons in the rat lower brain stem, no comparative study of the respective distribution of the A and neighboring noradrenergic (NA) neurons has been performed. In this study we sought: (a) to determine the comparative microdistribution of the A and NA neurons; (b) to develop a microdissection procedure to isolate A or NA neurons. We therefore analyzed the distribution of the enzymes tyrosine hydroxylase (TH), dopamine-B-hydroxylase (DBH) and phenylethanolamine-N-methyltransferase (PNMT) regionally in lower brain stem of rat. Activities of all 3 enzymes were determined simultaneously by sensitive radiometric methods in supernatants obtained by sonication of brain cubes microdissected from 500 um coronal sections of the lower brain stem (5 sections rostral and 4 sections caudal to the obex each containing 8 to 18 cubes depending on the level of the section). No significant enzymatic activity was found in most of the cubes in the dorso-lateral and ventro-medial areas of the lower brain stem. In contrast, significant TH, DBH, or PNMT activities were found in the ventro-lateral and dorso-medial areas of the lower brain stem regions containing, respectively, the A_1-C_1 and A_2-C_2 CA group. In the ventro-lateral area, the distribution exhibited a small rostro-caudal difference between the maximum of TH and DBH activities (respectively 676 $\pm$ 70 and 12285 $\pm$ 720 units/mg protein) and the maximum PNMT activity (161 $\pm$ 37 units/mg protein) located 500 um more rostrally in the section lying from 500 to 1000 um rostral to the obex. In the dorso-medial area, the maximal TH and DBH activities (respectively 330 $\pm$ 30 and 6778 $\pm$ 485 units/mg protein) were present in the section immediately caudal to the obex while the maximal PNMT activity (96 $\pm$ 9 units/mg protein) occured much more rostrally in the section located from 1000 to 1500 um rostral to the obex. The localization of the three enzymes, primarily in neuronal perikarya, was confirmed at several rostro-caudal levels by immunocytochemistry. At the caudal levels, the distribution of the catecholamine containing cell bodies was restricted to relatively small areas while at the rostral levels immunoreactive cells were found scattered between the ventro-lateral and the dorso-medial part of the medulla oblongata as well as near the dorsal midline. The rostro-caudal distribution of catecholamine biosynthetic enzymes suggests a procedure for a preferential microdissection of the A neurons of the C_2 group versus the NA neurons of the A_2 group.

297.2 AN ACTIVATING ANTIBODY TO TYROSINE HYDROXYLASE. *John W. Haycock and Jack C. Waymire*. University of Texas Medical School, Dept. Neurobiology & Anatomy, Houston, TX 77025.

Immunoglobulins from sheep, immunized with rat pheochromocytoma tyrosine hydroxylase (TH), increased the catalytic activity of TH up to 20-fold. The effect occurred within minutes and was maintained for at least 48h. The activation was maximal at the minimal antibody:TH ratio required to remove TH from solution with protein A-bearing *Staphyloccocus aureus* (SAC). Kinetic analysis of the activation revealed a decrease in K_m(app) for pterin cofactor and no change in K_m(app) for tyrosine.

Two immunoglobulin fractions were separated with DEAE Sephacel chromatography. Fall-through protein (IgG2) contained neither anti-TH activity nor activating influence. The other immunoglobulin fraction (IgG1) was eluted at approx. 125mM NaCl. This later fraction contained most of the activating influence as well as most of the anti-TH activity.

The activating influence was also bound by protein-A Sepharose. Both anti-TH activity and activating influence were eluted from protein A-Sepharose at pH 6.5. Further, the active peak from DEAE Sephacel chromatography was bound on protein A-Sepharose and the activating influence was eluted at pH 6.5.

Preadsorption of the active fractions from DEAE Sephacel chromatography with SAC that were precoated with rabbit anti-sheep IgG eliminated the activating influence.

It appears then that all anti-TH antibodies are restricted to the IgG1 subclass and that, within the limited purification steps utilized, all anti-TH antibodies increase the catalytic activity of TH. Although the mechanism of the activation has not yet been determined, preliminary studies indicate that activation of TH by phosphorylation may involve sites on the protein not unrelated to those affected by the antibody. We anticipate that the antibody will prove to be useful in analyzing *in situ* and *in vivo* modifications of tyrosine hydroxylase.

297.3 REGULATION OF TYROSINE HYDROXYLASE IN RAT RETINA: IN SITU AND IN VITRO STUDIES. T. Lloyd* (SPON: P. Walicke) Depts. of OB/GYN and Pharmacology. College of Medicine, The Pennsylvania State University, Hershey, Pennsylvania 17033.

Dopamine is synthesized by a subpopulation of amacrine cells in the mammalian retina. The dopamine content and the activity of retinal tyrosine hydroxylase, the rate limiting enzyme in the biosynthesis of catecholamines, can be rapidly increased by photic stimulation. Our laboratory has confirmed that tyrosine hydroxylase isolated from light adapted rat retinas is 3-4 times as active as that isolated from dark adapted rat retinas. With the goal of studying intracellular tyrosine hydroxylation, we have developed a rapid and gentle procedure for the dissociation of rat retinas into single cell preparations. After using several more vigorous digestion procedures, we found that brief exposure (7½ min @ 37°C) to a mixture of hyaluronidase and DNase was sufficient to cause complete dissociation of the retina. Microscopic examination indicated that cell features had been preserved and the major cell types could still be identified.

Using dissociated cells and an in situ assay, we found that light stimulation caused only a 20% increase in intracellular tyrosine hydroxylation over the intracellular activity seen in retinal cells from dark adapted animals. Thus, although in vitro assays indicated that light causes a 3-4 fold activation of extractable tyrosine hydroxylase activity, this activation can be suppressed by regulatory mechanisms functioning within the cell. Intracellular tyrosine hydroxylation can be increased by exposure of the dissociated cells to EGTA in the presence of normal levels of medium Ca^{++}. This rapid activation can be blocked by levels of tetracaine or Co^{+++} which did not influence basal in situ tyrosine hydroxylase activity. These results are consistent with our observation that tyrosine hydroxylase isolated from rat retinas can be activated in vitro by exposure to cAMP-independent phosphorylating conditions and suggest that activation of tyrosine hydroxylase occurs by a Ca^{++}-dependent, cAMP-independent protein kinase.

In contrast, exposure of the dissociated retinal cells to agents known to increase intracellular cAMP levels (cholera-toxin, 8-Bromo-cAMP, or 2 chloroadenosine) results in a profound decrease of in situ tyrosine hydroxylation. Correspondingly, we have observed that exposure of the isolated enzyme to cAMP-dependent phosphorylating conditions causes a reduction of in vitro tyrosine hydroxylase activity. These studies indicate that the retina is a useful CNS model for studying regulation of tyrosine hydroxylase activity, in situ and in vitro.

297.4 SUPRANORMAL LEVELS OF RETINAL DA IN YOUNG BW RATS AND SUBNORMAL LEVELS IN OLDER ANIMALS: AN INHERITED DOPAMINERGIC ABNORMALITY. J.P.H. Wyse, Dept. Anat., Faculty of Medicine, Univ. of Calgary, Calgary, Alberta, Canada T2N 1N4.

The Bmn-wys (BW) strain of rat is affected by a number of inherited neurological defects including developmental and degenerative abnormalities of the visual system, a centrally mediated hypogalactia and altered motor activity. Although there are several possible causes for these defects it has been hypothesized that a single inherited dopaminergic abnormality underlies most if not all of the observed neurological changes in these animals (Wyse and Lorscheider, Exp. Eye Res. 32, 1981). Preliminary studies have provided evidence consistent with altered dopamine (DA) neurotransmission in the retina, hypothalamus and nigrostriatal system. For example, catecholamine (CA) histofluorescent techniques together with a sensitive CA radioenzymatic assay (REA) have revealed significantly ($p<0.05$) less retinal DA in one year old BW rats than in age and sex matched controls. The purpose of the present study was to use these same techniques to determine either if retinal DA levels in BW rats are lower throughout life than those in age matched controls or if they change with age relative to those in controls. Whole retinae, one per animal, were obtained by dissecting eyes on iced cooled glass with care being taken to ensure complete removal of the vitreal body. Catecholamine values were determined by REA and expressed as pg CA per ug total retinal protein. Mean retinal DA levels ($\bar{X}\pm$SEM,n) were determined for both BW (b) and control (c) animals at 5 weeks and at 2, 3, 6 and 12 months of age. All DA values and standard errors are normalized with respect to the appropriate control mean. DA levels were significantly higher in BW rats than in controls at 5 weeks ($p<0.001$: b=1.88±0.15, 4; c=1±0.06, 5), 2 months ($p<0.05$: b=1.72±0.28, 4; c=1±0.07, 5) and at 3 months ($p<0.005$: b=1.49±0.10, 5; c=1±0.7, 5) of age. No significant difference was observed at 6 months (b=1.16±0.08, 5; c=1±0.03, 3). In contrast the retinal DA levels were significantly ($p<0.05$) lower in BW rats (0.44±0.08, 6) than in controls (1±0.25, 4) at one year of age. From these data it can be concluded (1) that retinal DA levels in BW rats 5 weeks to 3 months of age are significantly higher than those in age matched controls (2) that there is a continuous age-related drop in retinal DA levels in BW animals relative to those in controls and (3) at some time between six months and one year of age BW retinal DA levels cross over and become lower than those in age matched controls. Results of this study provide further support of the hypothesis that BW rats are affected by an inherited dopaminergic abnormality and demonstrate that the abnormality is expressed as early as 5 weeks of age. 297.5 HPLC METHOD FOR ANALYSIS OF DOPAMINE SULFATE ISOMERS. Mary Ann Elchisak and Joanne H. Carlson*. Purdue University, School of Veterinary Medicine, West Lafayette, IN 47907.

Conjugated dopamine (DA) occurs in the tissues and fluids of many species, and much of this is thought to occur as dopamine sulfate ($DASO_4$). Since $DASO_4$ may not simply be a biologically inert metabolic waste product, and since it can occur as either of two isomers, DA-3-SO_4 or DA-4-SO_4, we have developed a method utilizing reverse-phase paired-ion high performance liquid chromatography (HPLC) to separate and quantitate each $DASO_4$ isomer.

Separations were performed on a 25 cm X 4 mm stainless steel column prepacked with 5 µm octadecyl silica. The mobile phase was 0.025 M monochloroacetic acid, pH 2.8, containing 1 mM EDTA and 4 mM n-octylamine. The flow rate was 0.5 to 0.9 ml/min. $DASO_4$ isomers were quantitated by ultraviolet detection at 280 nm or electrochemical detection utilizing a thin-layer carbon paste working electrode with the potential maintained at +0.90 or 0.95 volts vs an Ag/AgCl reference electrode. The k' values for DA-3-SO_4 and DA-4-SO_4 were 4.8 and 5.3, respectively. The minimum detectable amounts (producing a peak height twice baseline noise) of DA-3-SO_4 and DA-4-SO_4 by ultraviolet detection were 15 and 20 picomoles, respectively, and 7 picomoles for each isomer by electrochemical detection.

This method was used to determine the occurrence of DA-3-SO_4 and DA-4-SO_4 in normal human urine and rat adrenal glands. Cation exchange chromatography was used as a preliminary purification step for the urine. Excretion of DA-3-SO_4 ranged from 0.44 to 3.4 µ mol/day in six normal human volunteers. DA-4-SO_4 was not detected. DA-3-SO_4 accounted for 34 to 96 percent of the conjugated DA excreted in the urine of these six subjects as determined by an acid hydrolysis method (Carlson and Elchisak, abstract this meeting). Our previous work utilizing thin-layer chromatographic methods also detected only DA-3-SO_4 in urine from normal volunteers (Carlson and Elchisak, unpublished). In rat adrenal glands, neither DA-3-SO_4 nor DA-4-SO_4 was detected by the HPLC method described above. This negative finding was verified by the absence of any conjugated DA released upon acid hydrolysis of the same samples, even though free DA was released during the hydrolysis procedure after addition of authentic $DASO_4$ standards to the same samples.

The method described here is rapid, simple, and direct, and it should prove useful in investigations concerning the physiological role of dopamine sulfate. (Partially supported by Pharmaceutical Manufacturer's Association grant to MAE.)

297.6 HPLC METHOD FOR ANALYSIS OF FREE AND CONJUGATED CATECHOLAMINES J.H. Carlson* and M.A.Elchisak (SPON: C. Henrikson). Purdue Univ, School of Veterinary Medicine, W.Lafayette, IN 47907.

In the course of developing methods to analyze the physiological role of dopamine sulfate ($DASO_4$), we found it necessary to have a simple assay available for the analysis of free and conjugated dopamine (DA) in various body tissues and fluids. We report this procedure here, as modified to measure free and total norepinephrine (NE), epinephrine (EPI), and DA. An aliquot of body fluid or tissue supernatant containing EDTA and sodium metabisulfite was hydrolyzed in 0.4 N perchloric acid at 100°C for 120 min to convert conjugated catecholamines (CA) to free CA. The hydrolysis step was omitted for assay of free CA. The free NE, EPI, and DA were then isolated by standard alumina procedures. Conjugated NE, EPI, or DA was the difference between total and free amounts in duplicate aliquots. Dihydroxybenzylamine (DHBA) and/or deoxyepinephrine (DOE) were used as internal standards.

HPLC with electrochemical detection was utilized; conditions were similar to those employed by Davis and Kissinger (Analyt Chem, in press). The stationary phase was octadecyl silica; the mobile phase was .075 M phosphate buffer, pH 2.8, containing EDTA (1 mM), sodium octyl sulfate (30 mg/l), and methanol (5%). Flow rate was 1.2 to 2.4 ml/min. A gradient of increasing flow was used for most analyses. A thin-layer carbon paste working electrode, with the potential maintained at +0.65 or 0.70 volts vs an Ag/AgCl reference electrode, was used for detection. The k' values varied depending on the exact flow gradient conditions for each experiment, but were as follows for an 18 min flow gradient from 1.2 to 2.2 ml/min: NE, 2.2; EPI, 3.2; DHBA, 4.1; DA, 5.9; DOE, 7.1.

This method was used to determine free and conjugated NE, E, and DA in normal human urine and in rat adrenal glands. CA in urine were isolated by alumina as described above, and adrenal gland homogenate supernatants were injected directly onto the HPLC column before and after hydrolysis. The percent of each CA found to be conjugated was as follows:

	NE (SD)	EPI (SD)	DA (SD)
RAT ADRENAL (n=8)	3.2%	2.3%	.98%
HUMAN URINE (n=6)	51% (7)	57% (13)	67% (7)

DA-3-SO_4 excretion accounted for 34 to 96 % of the conjugated DA excreted in the human urine, but no $DASO_4$ was detected in rat adrenals (Elchisak and Carlson, abstract this meeting).

This method should prove useful in future investigations concerning the physiological functions of conjugated CA. (Partially supported by a PMA Research Starter Grant to MAE.)

297.7 THE SELECTIVE PHARMACOLOGICAL EFFECTS OF SOME NEW ACETYLENIC INHIBITORS ON BRAIN MONOAMINE OXIDASE. Rosa H. Huang* (SPON: G.L. Longenecker). Department of Biochemistry, University of South Alabama College of Medicine, Mobile, AL 36688.

We have synthesized three new acetylenic inhibitors, p-hydroxypargyline (HO-P), O-[3(2-acetamido)-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl]-p-hydroxypargyline (SLPS) and O-[3-[[2-[2-(2-acetamido)ethoxyl]ethyl]carbamoyl]-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl]-p-hydroxypargyline (SLPL). Their irreversible inhibition of the rat brain MAO using 5HT or PEA as the substrate was studied. The dose response relationship indicated the ratio of PI_{50} for the MAO-A to that for the MAO-B was 0.62, 2.02, 0.397 and 22.99 for HO-P, SLPS, SLPL and pargyline, respectively. The preincubation time required to block 50% of the MAO-A was 101 min for pargyline (1.8×10^{-7} M, 37°), 48 min for OH-P (5.6×10^{-7} M, 37°), 42 min for SLPS (3.2×10^{-6} M, 37°) and 28 min for SLPL (3.2×10^{-5} M, 20°). Under the same experimental conditions the preincubation time required to achieve 50% inhibition of the MAO-B was found to be 8 min, 67 min, 20 min and 75 min for pargyline, OH-P, SLPS and SLPL, respectively. The results suggested highly selective pharmacological effect on the multiple MAO forms of these acetylenic inhibitors which varied in size, polarity and hydrophobicity. (Supported by NIH grant #NS14434.)

297.8 TURNOVER OF CATECHOLAMINES (CA) IN DISCRETE HYPOTHALAMIC AREAS AND THE EFFECTS OF CHLORPROMAZINE (CPZ). Sarah F. Leibowitz, Meena Jhanwar-Uniyal* and Barry E. Levin. Rockefeller Univ., New York 10021; Dept. Neurosci., N.J. Medical School, Newark 07103.

A sensitive radioenzymatic assay was used to measure the three CA, norepinephrine (NE), epinephrine (EPI), and dopamine (DA), in five microdissected areas of the rat hypothalamus. These areas were the paraventricular nucleus (PVN), dorsomedial nucleus (DMN), lateral hypothalamic medial forebrain bundle (MFB), and two perifornical hypothalamic areas just dorsolateral (dPFH) and ventrolateral (vPFH) to the fornix. To determine the rate of CA turnover in these areas, synthesis of the CA was inhibited by the tyrosine hydroxylase inhibitor α-methyl-p-tyrosine methyl ester (α-MpT, 300 mg/kg, i.p.), and the animals (adult, male, albino Sprague-Dawley rats) were sacrificed at variable times (15-180 min) after α-MpT injection. The results of this experiment revealed a linear decline of both NE and DA levels after synthesis inhibition. The turnover rate of these two CA varied as a function of hypothalamic area, with the highest rate of NE turnover, for example, occurring in the DMN and lowest rate in the dPFH. For EPI, however, no appreciable decline in levels was detected in any site up to 3 hr after α-MpT, indicating that there may be little or no turnover of EPI following inhibition of tyrosine hydroxylase activity.

To evaluate the impact of CPZ on CA levels in the different hypothalamic areas, a separate group of rats was injected with saline or CPZ (2 mg/kg, i.p.) and sacrificed 30 min later. Only two significant changes in CA levels were detected in the CPZ-treated animals: DA levels were decreased (by 50%) in the PVN, and EPI levels were increased (by 100%) in the MFB. No significant changes in NE levels were observed. To assess the effect of CPZ on the turnover of CA, a similar experiment was conducted in α-MpT-pretreated rats that were sacrificed 3 hr after α-MpT and 30 min after CPZ or saline. In these rats, CPZ affected the disappearance or turnover of NE and DA in only one of the five hypothalamic areas analyzed. This was the dPFH area (dorsolateral to the fornix) where the turnover of these two CA was significantly potentiated.

This finding is consistent with other evidence from this laboratory suggesting that the perifornical hypothalamus may be involved in mediating the overeating caused by antipsychotics in humans as well as in rats. Perifornical hypothalamic injection of CPZ potentiates eating behavior in the rat, and overeating induced by peripheral CPZ injection is attenuated by perifornical hypothalamic lesions.

(This research was supported by grant MH 22879 and by funds from the Whitehall Foundation.)

297.9 EFFECT OF PROTEIN DIET ON HYPOTHALAMIC BIOGENIC AMINE ACTIVITY AND HORMONE REGULATION. E.J. Hawrylewicz, James Q. Kissane*, Elizabeth A. Drab*, and Henry H. Huang*. Dept. of Research, Mercy Hospital & Medical Center, Chicago, IL. 60616.

Protein diet quality influences brain development and behavior. The biologic mechanisms involved have not been defined. The hypothalamic biogenic amines; norepinephrine (NE), epinephrine (Epi), dopamine (DA) and serotonin (5-HT) have a major regulatory role controlling the function of the anterior pituitary gland. Changes in this neuroendocrine relationship due to altered protein diets may in part explain the observed biologic effects.

Virgin Sprague-Dawley rats were fed, ad libitum, isoenergetic diets consisting of 8%, 19.5% and 31% casein during conditioning, pregnancy and lactation periods. All litters were reduced to 8 pups and after weaning, the female pups were continued on their respective diet. Animals were sacrificed 3 hrs. before proestrous surge at 3 wks. after sexual maturity and 8 mos. of age. Six hypothalamic nuclei were removed by punch technique and analyzed by radioenzyme procedure for DA, NE, Epi and 5-HT.

At the age of 3 wks. after sexual maturity, significant decrease in DA conc. (ng/mg protein ± s.d.) was evident in the median eminence (16.7±19.8 vs. 43.5±23.1 and 49.2±26.5) and in the paraventricular nucleus (3.3±0.6 vs. 5.3±2.2 and 4.4±2.5) in the low protein group (8% casein) compared to the normal protein group (19.5% casein) and high protein group (31% casein). No significant decrease in DA was evident in the periventricular, arcuate, suprachiasmatic and supraoptic nuclei. NE was also significantly reduced in the periventricular nucleus, 9.4±4.1 (8%) vs. 29.3±13.4 (19.5%). In contrast, NE was significantly increased in the suprachiasmatic nucleus in the low protein group. Epi was not altered in the low protein group.

At 8 mos. of age the decreased DA concentration persisted in the paraventricular nucleus (5.2±4.3 (8%) vs. 12.0±5.0 (31%)) and median eminence (17.1±13.3 (8%) vs. 43.0±17.1 (31%)). NE also remained depressed in the paraventricular nucleus (13.5±10.6 (8%) vs. 30.6±23.7 (31%)). Epi remained unaltered. Serotonin was reduced in the median eminence; 3.2±4.7 (8%) vs. 7.2±12.7 (31%) and the supraoptic nucleus; 1.1±1.9 (8%) vs. 4.7±3.8 (31%). Serum prolactin concentration was determined in the same animals. At the age of 3 wks. after sexual maturity, low protein animals had a decreased serum prolactin concentration. DA and 5-HT data were examined in regard to the serum prolactin change. Dietary protein does affect neurohormonal regulation. (Grant No. CA-26547, National Cancer Institute).

297.10 SEQUENTIAL CHANGES OF BIOGENIC AMINE LEVELS IN NEOCORTEX, SEPTUM AND MEDIOBASAL HYPOTHALAMUS AFTER 6-HYDROXYDOPAMINE LESIONING OF THE ASCENDING NORADRENERGIC BUNDLES. T.A. Reader, O. Bosler*, C. Mercure* and L. Descarries. Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Qué., Canada H3C 3T8.

The noradrenaline (NA), dopamine (DA) and serotonin (5-HT) contents of adult rat neocortex (frontal including gyrus cinguli, between A: 7020-8920 μ in König and Klippel's atlas), septum (from A: 6670-8920 μ) and mediobasal hypothalamus (from A: 3750-4890 μ , including median eminence) were measured radioenzymatically 2, 15 and 90-120 days after bilateral microinjection of 6-hydroxydopamine (2 x 2 μg/μl) on either side of the decussation of the superior cerebellar peduncles (A: 0.16, L: 1.75 and H: -1.60 mm). By comparison with controls, NA levels were significantly ($p < 0.01$) lowered in all 3 regions and at every survival time examined (-60 to -80% in cortex, -66 to -77% in septum and -22 to -48% in hypothalamus). DA levels were also changed but followed a differential sequence in each of the regions. In cortex, DA content was normal at 2 and 15 days but considerably increased (+95%) after 90-120 days. In septum, there was an initial reduction of DA at 2 days (-43%), an augmentation at 15 days (+134%) and a return to the normal range after 90-120 days. In hypothalamus, DA was diminished by 35-52% from 2 to 90-120 days. The 5-HT levels also showed marked changes in cortex and septum but were not significantly altered in hypothalamus. Cortical 5-HT was lowered after 2 and 15 days (-35 and -61%), and increased (+57%) after 90-120 days. In septum, unchanged levels of 5-HT were found at 2 and 15 days but a large augmentation (+139%) was again measured after 90-120 days. These results indicate that, in frontal cortex and septum, the NA depletion secondary to 6-hydroxydopamine lesioning of the noradrenergic ascending bundles may be associated with marked increases in DA (also see Tassin et al., Neurosci., 4: 1569, 1979) and 5-HT levels. Moreover, the augmentation of the DA content in septum appears to be reversible within a period of 90-120 days. The interpretation of such changes will require some assessment of local turnover of the biogenic amines as well as of the sprouting capacity of DA and 5-HT terminals arising from nerve cell bodies located at various distances from their territories of innervation (Supported by MRC Grants MA-6967 and MT-3544).

297.11 EVIDENCE FOR A RELATIONSHIP BETWEEN MEDIAN EMINENCE NORADRENALINE AND PROLACTIN IN RATS. William W. Morgan and Edward G. Rennels*. Dept. Anat., Univ. Texas Health Sci. Ctr., San Antonio, TX 78284.

The involvement of median eminence (ME) noradrenaline (NA) in the regulation of prolactin (PRL) secretion is controversial. In order to investigate this relationship in vivo, 32 adult female Sprague-Dawley rats (125-140 grams) were ovariectomized and 2 weeks later were either hypophysectomized (HYPEX) or were treated by sham surgery (CONTROL). One week later one half of the HYPEX and one half of the CONTROL rats were ether anesthetized and given 2 anterior pituitary homografts under the right kidney capsule (GRAFT). The homografts were from female donors. The remaining rats were treated with the same surgical perturbations but no tissue was implanted (SHAM). Eight days later the rats were sacrificed and the ME, the remaining hypothalamus and the telencephalon were collected from each animal and frozen. The levels of NA in each tissue were subsequently determined by a radioisotope-enzyme technique and protein levels were quantified by an automated Lowry procedure. Statistical analysis of the data was performed by the analysis of variance and subsequently by the Student-Newman-Keuls test. The concentration of NA (ng/mg protein) was significantly elevated ($p<0.01$) in the ME of the HYPEX-SHAM rats (41 ± 3) (mean ± standard error of mean) as compared to the CONTROL-SHAM rats (25 ± 1). The levels of NA in the ME of the CONTROL-GRAFT (12 ± 2) and the HYPEX-GRAFT rats (12 ± 1) were not significantly different from one another but were significantly lower ($p<0.01$) than those observed in either the HYPEX-SHAM or the CONTROL-SHAM rats. The levels of NA in the other brain regions were not significantly different among the experimental groups. The results show that hypophysectomy elevates NA in the ME and that this effect is reversed by anterior pituitary homografts. Anterior pituitary homografts alone significantly decrease NA in the ME. Collectively, these data suggest an inverse relationship between NA levels in the ME and circulating PRL levels. It is hypothesized that median eminence NA may stimulate PRL secretion indirectly perhaps by effecting the release of a PRL releasing factor. Supported by DA 00755 and NS 14855 to WWM.

297.12 EFFECTS OF CENTRAL INJECTION OF 6-HYDROXYDOPAMINE ON REGIONAL CEREBRAL BLOOD FLOW, SMALL VESSEL BLOOD CONTENT, AND CEREBRAL OXYGEN CONSUMPTION IN RABBITS. E. Buchweitz, and H. R. Weiss* Dept. Physiology and Biophysics, College of Medicine and Dentistry of New Jersey, Rutgers Medical School, Piscataway, NJ 08854

Evidence has suggested that the catecholaminergic neurotransmitter systems play a role in the regulation of cerebral O_2 metabolism. Our investigation focused on the effects which long-term interruption of these systems had on the distribution of cerebral blood flow (rCBF), cerebral O_2 consumption ($C\dot{V}O_2$) and cerebral small vessel blood content (rSVBC, an index of open capillary density). Eight rabbits received bilateral intracerebroventricular injections of 100 μg 6-hydroxydopamine (6OHDA), while a control group received an equal volume of .1% ascorbic acid in 0.9% saline. 6OHDA has been shown to produce a relatively specific destruction of brain catecholaminergic neurons. The efficacy of the lesion was monitored by DA and NE determination in various brain regions. Three weeks later the animals were anesthetized with pentobarbital, artifically respired, and femoral and superior saggital sinus catheters inserted. rCBF was monitored by the injection of 141-Ce labeled microspheres (15 ± 3 μ in diameter) into the left atrium. rSVBC was monitored by determination of 59 Fe-labeled plasma siderophilin. After sacrifice 17 brain regions were isolated and radioactivity counted. Blood pressure, heart rate, and arterial and venous blood gas values were within normal ranges in both groups and were similar in the two groups. Total CBF averaged 43.6 ± 16.4 (mean ± S.D.) ml/min/100 g in control and 42.1 ± 39.4 ml/min/100 g in the experimental group. No significant changes in rCBF were noted between the groups or among the various regions of either group. O_2 extraction averaged 4.05 ± 1.86 ml O_2/100 ml blood in the control and 3.83 ± 2.31 ml O_2/100 ml blood in the experimental group. These values were not significantly different. $C\dot{V}O_2$ was not altered by treatment. rSVBC was significantly increased by 95% in the lesioned group. There were no regional differences in rSVBC in either group. This significant increase in SVBC, reflecting an increase in the number of open capillaries in the brain, may be due to the secretion of a vasodilator substance, or a decrease in the secretion of a vasoconstrictor substance. Long term interruption of catecholaminergic neurotransmission did not affect rCBF, $C\dot{V}O_2$ or O_2 extraction probably due to an adaptive alteration in the activity of other neuronal elements which maintained cerebral metabolic activity.

297.13 A SINGLE DOSE OF d-AMPHETAMINE PRODUCES AN ENDURING RECOVERY OF LOCOMOTION AFTER MOTOR CORTEX INJURY IN THE CAT. D. A. Hovda* and D. M. Feeney (SPON: D. Trevino). Dept. of Psychology, University of New Mexico, Albuquerque, NM 87131.

We have previously reported (Feeney et al., Neurosci. Abst., 6:802, 1980) that a single dose of d-amphetamine (d-AMP) given at 24 hrs. following unilateral ablation of the motor cortex produces an enduring recovery of locomotor ability in the rat. We now report an extension of these findings to the cat. Like the rat, cats with unilateral ablation of motor cortex are able to walk and run normally on a flat surface but show a serious contralateral deficit when placed on a narrow beam. The rat spontaneously recovers within 14 to 21 days, however, the cat displays a deficit for more than 60 days on this task. In this study cats were trained to walk the length of a 3.8 m x 5.1 cm beam and then a unilateral suction ablation of motor cortex (Primarily areas 4 and 6) was performed using standard procedures. These cats were given 4 mg/kg of d-AMP at 24 hrs. postsurgery. Two of the cats died and the neurological status of the other cat deteriorated. Clearly in the cat, 24 hrs. post injury is too early for d-AMP treatment, therefore, in 11 cats, drug administration was delayed until 10 days post injury, with 5 cats receiving saline as a control and 6 cats receiving 5 mg/kg d-AMP. The cats' locomotor performance on the beam was rated by two observers, one uninformed regarding drug or saline assignment. By 6 hrs. post drug treatment, there was a clear improvement in the locomotor performance of the d-AMP animals compared to the saline control group's performance. An even further improvement of the d-AMP group's locomotion compared to the saline control's agility on the beam was observed at 24 hrs. post drug. This significantly improved performance of the d-AMP group compared to the saline control level has endured for 35 days following d-AMP administration. These results in the cat support our hypothesis, that much of the locomotor deficit following motor cortex injury is attributable to a transient depression of catecholamine function in intact areas of the brain which is reversible by d-AMP.

297.14 HALOPERIDOL PRODUCES AN ENDURING BLOCKADE OF RECOVERY OF LOCOMOTION FOLLOWING MOTOR CORTEX INJURY IN THE RAT. D. M. Feeney, A. Gonzales* and Wendy A. Law*Department of Psychology, University of New Mexico, Albuquerque, NM 87131.

We previously reported (Feeney, D. M., et al. Neurosci. Abst., 6:802, 1980) that the contralateral hemiparesis produced by a unilateral motor cortex ablation in the rat is dramatically reversed by a single dose of d-amphetamine (d-AMP). After this lesion rats can locomote on a flat surface but are unable to walk or run on a narrow beam. This deficit gradually recovers over a 2 to 3 week period. However if a single dose of d-AMP (2-4 mg/kg) is given 24 hours postinjury, these motor cortex injured animals show a dramatic improvement of locomotor performance within 3-6 hrs and this improvement is maintained over the subsequent weeks of testing. This d-AMP facilitated recovery of function is blocked by administration of haloperidol (HAL) suggesting a dopaminergic (DA) involvement. We proposed that after motor cortex injury in the rat, much of the locomotor deficit is due to a transient DA depression which is reversible by d-AMP. To further test this hypothesis that recovery of DA function is important for the recovery of locomotion after motor cortex injury, we examined the effect of HAL, a DA antagonist, on recovery of this behavior. Rats were trained to run a narrow beam as previously described and the entire motor cortex was then unilaterally removed by suction ablation. All animals were retested at 24 hr postinjury and most could not maintain their balance or run on the beam. Locomotor performance was independently rated by two observers, one uniformed of subsequent drug treatment. Five of the animals were then given a single dose of saline and 6 were given 0.4 mg/kg of HAL (i.p.) immediately following the 24 hr postsurgery testing. The animals were retested every hour for 6 hours, once at 12 hours and once every other day for 30 days postdrug. The animals receiving a single dose of HAL showed a severely retarded recovery of locomotion compared to saline control animals. In addition, their performance did not reach the control group's level until 3 weeks postdrug. At 38 days postinjury when the saline control group's performance had completely recovered these animals were also given 0.4 mg/kg HAL and were tested hourly for the first 6 hrs postdrug and again at 24 hrs. This dose of HAL had no effect on locomotion in saline recovered animals. These data compliment our previous d-AMP results and indicate that DA plays an important role in the process of recovery of function after motor cortex injury.

298.1 PROCONVULSANT EFFECTS IN BABOONS OF β-CARBOLINE, A PUTATIVE ENDOGENEOUS LIGAND FOR BENZODIAZEPINE RECEPTORS. J. Rossier, C. Cepeda, T. Tanaka, R. Besselièvre, P. Potier and R. Naquet. Laboratoire de Physiologie Nerveuse and Institut de Chimie des Substances Naturelles, C.N.R.S., 91190 Gif-sur-Yvette, France.

β-Carboline-3-carboxylic acid ethyl ester (B-CCE) has been recently isolated from human urine and brain tissues. B-CCE has the property of displacing ^{3}H-diazepam from specific cerebral binding sites. It was proposed that B-CCE was a putative endogenous ligand for benzodiazepine receptors. We have studied the effects of B-CCE on two models of epilepsy in papio papio baboons: 1° kainic acid induced limbic status epilepticus and 2° natural photosensitive epilepsy.

Limbic status epilepticus was produced by a microinjection of kainic acid (10 µg) in the amygdala. Twenty days after cessation of the limbic status epilepticus, B-CCE was tested. Intravenous injection of 1 mg/Kg of B-CCE induced repetitive secondary generalized seizures. Diazepam (10 mg i.v.) prevented further possible seizures. At lower doses B-CCE induced a reappearance of interictal spikes restricted to limbic structures (0.04 mg/kg) or a localized limbic seizure (0.5 mg/kg).

The action of B-CCE on light-indiced epilepsy was also studied. Two types of baboons have been utilized : 1° naturally non-photosensitive baboons and 2° naturally photosensitive baboons. Non-photosensitive animals did not display any clinical symptom to intermittent light stimulation (ILS). However, when a single dose, ranging from 40 to 100 µg/kg was injected i.v. the animals became photosensitive and exhibited myoclonic jerks in response to ILS. Generalized seizures were induced with ILS when doses of B-CCE were slightly increased (50 to 100 µg/kg). In naturally photosensitive animals 8 µg/kg of B-CCE i.v. produced a latency shortening of the photomyoclonic response. At a dose of 20 µg/kg generalized seizures were obtained in the seconds following the exposure to ILS. The effects of B-CCE were of very short duration lasting no longer than 5 min, indicating a short half-life.

The most common proconvulsant drugs are usually active at doses over 1 mg/kg. In this study B-CCE was 50 to 100 times more active than pentylenetetrazole. The high potency of B-CCE may reflect its great affinity for benzodiazepine receptors. However B-CCE and benzodiazepine have opposite effects. Indeed the proconvulsant effect of B-CCE was antagonized by an injection of benzodiazepine. B-CCE should now be considered as an antagonist of the benzodiazepines. We are now examining if the other recently described benzodiazepine antagonists (Hunkeler et al, Nature, 290, 514,1981) are also proconvulsant in the baboons.

298.2 CHOLINERGIC NATURE OF SEPTO-HIPPOCAMPAL MODULATION OF PYRAMIDAL CELL FIRING. K. Krnjević and N. Ropert, Anaesthesia Research & Physiology Depts, McGill University, Montréal, PQ, Canada

Acetylcholine (ACh) strongly facilitates discharges of population spikes in CA1 in response to fimbria-commissural stimulation, probably mainly by reducing the effectiveness of inhibitory pathways that normally tend to suppress pyramidal firing (Krnjević, K. et al., J. Physiol., 308:73P, 1980). A comparable effect can be elicited by stimulation of the medial septum (Ropert, N. et al., Canada Physiology, 11:118, 1980). We now report that the facilitatory action of septal stimulation is susceptible to blockade by the muscarine antagonists atropine and especially scopolamine.

In these experiments on rats under urethane, stereotaxic stimulation of the hippocampal commissure at a moderate intensity (2-3 times threshold) and low frequency (<1 Hz) evoked prominent positive field responses in the CA1 pyramidal layer. When a brief tetanus (100 Hz for 100 ms) was applied in the medial septum, it produced (for a period of 20-50 ms) a striking facilitation of negative population spikes in response to the same commissural stimulus. A significant feature is that single or multiple stimulation at the critical site in the medial septum by itself evoked minimal field responses in the hippocampus. The similar modulatory effects of ACh and septal stimulation both were rapidly reversible and they were both markedly diminished after intravenous injections of atropine or scopolamine, though rather high doses of these antagonists were required to produce a major change (typically 10 mg of scopolamine per kg). This is in accordance with the fact that the most potent ACh-agonist, muscarine, was antagonized only by such high doses of scopolamine. In addition, there was evidence that nicotine receptors may also be involved in the action of ACh.

These observations confirm previous suggestions that the septo-hippocampal pathway is cholinergic. Its mechanism of operation is mainly through muscarine receptors, but there may be a significant component of nicotinic transmission; therefore full blockade of septo-hippocampal cholinergic activation may require the administration of centrally-acting nicotinic as well as muscarinic antagonists.

298.3 **MODULATION OF ACETYLCHOLINE BY THYROTROPIN-RELEASING HORMONE IS RECEPTOR-MEDIATED.** **D. J. Braitman, C. R. Auker and S. L. Hargett*. Physiology Dept, Armed Forces Radiobiology Research Institute, Bethesda MD 20014.**

We reported earlier (Braitman et al., Brain Res. 194: 244, 1980) that thyrotropin-releasing hormone (TRH) could cause long-term potentiation of slow excitatory responses to acetylcholine (ACh) on pyramidal tract (PT) neurons in sensorimotor cortex of cat. Since then we have conducted additional experiments indicating that the potentiation of ACh by TRH is a receptor-mediated phenomenon.

A multi-barrelled micropipette was used to record extracellular action potentials from neurons in sensorimotor cortex of chloralose-anesthetized cats. Ionophoretic aplication of TRH and ACh was closely paired (<1 sec separation) in 59 of 227 characterized neurons. TRH potentiated the slow excitatory response to ACh in 14 of the 59 tested cells. In each case, TRH had no excitatory action when applied alone. After paired administration of TRH and ACh, the response to subsequent applications of ACh alone was typically potentiated. This effect often lasted for several minutes before the excitatory ACh response returned to pre-TRH levels. Potentiation could be repeated on the same cell by again pairing TRH and ACh.

Eleven neurons were identified as PT cells by antidromically stimulating the medullary pyramids with a bipolar electrode. Since this potentiation is found almost exclusively on PT neurons, it supports the hypothesis that the modulatory effects of TRH on ACh responses is a receptor-mediated phenomenon found on a particular subpopulation of cells.

In order to further test the specific action of TRH on ACh, the ionophoretic applications of TRH and ACh were separated temporally by 10 to 30 sec. When separated temporally, potentiation of the ACh response did not occur. However, when TRH and ACh were paired closely on these same neurons, the ACh response was potentiated. Thus modulation of ACh by TRH does not occur unless both transmitters are present at the same time.

To demonstrate that TRH was not nonspecifically potentiating the action of other transmitters, TRH was paired with glutamate. The fast excitatory action of glutamate was never potentiated by TRH even when the ACh response was potentiated. This demonstrates that the specific modulatory action of TRH on ACh responses is not a function of a general long-lasting subthreshold effect.

These data suggest that the specific long-lasting modulation of ACh responses by TRH is receptor-mediated. This may occur by (1) TRH acting directly at the ACh receptor or at a linked receptor or (2) receptor-mediated stimulation of a second messenger that specifically acts on slow excitatory responses.

298.4 PARTIAL PURIFICATION OF A DENERVATION-DEPENDENT PHOSPHOPOLYPEPTIDE FROM RAT SKELETAL MUSCLE. S.P. Squinto*, J.A. McLane and I.R. Held. Loyola Univ. Med. Ctr. and VA Hosp., Hines, IL 60141.

Denervation of skeletal muscle results in early changes in both membrane-associated and cytosolic events which may be related to some neuroregulatory influence. We have reported that denervation of both the soleus and extensor digitorum longus (EDL) muscles of the rat result in the stimulation of adenylate cyclase and cyclic AMP phosphodiesterase (J. Neurosci. Res., in press, 1981). We have also shown that within hours after denervation there is an increase in the in vitro phosphorylation of an endogenous cytosolic polypeptide(s) of approximately 40K daltons (Neurosci. Lett. 20:295, 1980; Neurochem. Res. 6:203, 1981) which is temporarily correlated with the length of the distal nerve stump remaining attached to the muscle (Trans. Am. Soc. Neurochem. 12:230, 1981). The cytosolic 40K polypeptide has been resolved by SDS polyacrylamide gel electrophoresis from both the soleus and EDL. Samples of ^{32}P-labeled cytosolic protein in 50mM Tris:HCl, 2mM $MgCl_2$ and 0.1M NaCl were passed over Sephadex G-150 and a peak of radioactivity comparable in molecular weight to the polypeptide resolved on SDS polyacrylamide gels obtained. A radiolabeled peak of similar molecular weight was also obtained when ^{32}P-labeled cytosol was fractionated by exclusion chromatography with a mobile phase of 0.05 M sodium phosphate pH 7.4 on a Waters I-125 HPLC column. Since peaks of similar apparent molecular weight were obtained under denaturing (SDS) and non-denaturing conditions, apparently the radiolabeled polypeptide is not a subunit of a larger protein complex. Also, the denervation-dependent increase in protein kinase activity is apparently due to alterations in endogenous modulators. Combined aliquots from the cytosolic fractions of denervated and contralateral, sham-operated muscles were assayed and the results evaluated with respect to those predicted from assays with each sample separately. While the specific phosphorylating activity of the denervated sample was twofold greater than that from the sham-operated muscle, this activity with the "mixed" samples was less than the predicted value. When either sample is pre-incubated at 37°C before the initiation of the phosphotransferase reaction with α-^{32}P [ATP], then the phosphorylation of the endogenous substrate is decreased. Pre-incubation of "mixed" samples, however, produces an even greater decrease in the formation of phosphorylated product. This suggests that denervation of skeletal muscle may have an effect on the suppression of an endogenous soluble inhibitor of protein kinase. Supported by NINCDS Grant NS-11755, the Medical Reserach Service of the Veterans Administration and BRSG funds from Loyola University.

298.5 SEROTONIN EFFECTS ON PROTEIN PHOSPHORYLATION WITHIN A SINGLE LIVING NERVE CELL. José Lemos*, Ilse Novak-Hofer* and Irwin B. Levitan. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

Serotonin causes a cyclic AMP-mediated increase in potassium conductance in the identified Aplysia neuron R15 (Drummond, Benson and Levitan, PNAS 77(1980)5013-5017). This response can be inhibited by intracellular injection of the 10,000 dalton protein kinase inhibitor from rabbit skeletal muscle, indicating that protein phosphorylation may play a role in regulation of this potassium channel (Levitan and Adams, Adv.Cyc. Nuc.Res. 14(1981)647-653). To identify any phosphoproteins which might be involved in such regulation, we have injected γ-(^{32}P)ATP into R15, and have measured protein phosphorylation within this single living neuron. In addition, the cell's electrical properties were monitored throughout the experiment using voltage clamp techniques. Within 30 min after intracellular injection of 10^5-10^6 cpm of γ-(^{32}P)ATP into R15, 1000-20,000 cpm of ^{32}P were incorporated into phosphoproteins which could then be separated according to their molecular weights on SDS-polyacrylamide gels. At least 12 protein bands, ranging in molecular weight from 22,000 to 230,000 daltons, were phosphorylated within neuron R15. The extent of phosphorylation of several of these bands was altered in cells in which potassium conductance was increased by treatment with serotonin. The most consistent changes were seen in bands of molecular weight 26,000 and 135,000 daltons. The possible role of these phosphoproteins in regulation of the activity of potassium channels is under investigation.

298.6 NET OUTWARD CURRENTS OF BAG CELL NEURONS ARE DIMINISHED BY A cAMP ANALOGUE. L. K. Kaczmarek and F. Strumwasser. Division of Biology, California Institute of Technology, Pasadena, CA 91125

Both chemical and electrophysiological evidence indicate that the onset of afterdischarge and the subsequent profound enhancement of spike broadening that occur in the bag cell neurons of Aplysia are related to an increase in intracellular cAMP concentration. We have now used a two electrode voltage clamp to study the properties of isolated bag cell neurons in cell culture and their response to 8 benzylthio-cAMP (8BTcAMP). This membrane permeant and phosphodiesterase resistant cAMP analogue induces spontaneous discharge and spike broadening in both the intact bag cell cluster and isolated bag cell neurons in cell culture.

Cells were chosen, within two days of seeding, that had not yet extended elaborate neuritic networks, and were penetrated with two microelectrodes (resistances 35-50 MΩ). A delayed outward current, sometimes preceded by a transient inward current, was observed with command steps (80 msec) to between -10 and +10 mV from a holding potential of -40 mV, in Eagle's MEM made up in artificial seawater. On repetition at a frequency of 1 Hz these outward currents inactivate, enhancing the early inward currents. The inward currents, in 3 of 4 cases, were abolished by the calcium antagonist Co^{2+} (20 mM). Both the magnitude and the degree of inactivation with repetition of the outward currents were also diminished by Co^{2+} (20 mM) and by Ni^{2+}(5 mM) for these command pulses although larger commands (>+10 mV) still produced substantial inactivation with repetition.

8BTcAMP produced a decrease (31-51%) in the net outward currents between -10 and +10 mV and in their degree of inactivation with repetition. The early inward currents were however unchanged or enhanced by 8BTcAMP. We have attempted to isolate the inward currents pharmacologically in media containing TEA (50-460 mM) with either Na^+ and Ca^{2+} or with Ba^{2+} alone as carriers of inward current. Under these conditions we have not seen an effect of 8BTcAMP on the inward currents, suggesting that 8BTcAMP exerts its effect on the electrical properties of bag cell neurons by depressing an outward potassium current. We have further examined both the transient potassium current, I_A (Connor and Stevens, 1971), by command steps to -40 mV from holding potentials between -80 and -100 mV, and the voltage activated late potassium current I_K, by depolarizing commands from a holding potential of -40 mV in the presence of 20 mM Co^{2+}. Neither of these currents was affected by 8BTcAMP. These results suggest, therefore, that 8BTcAMP may diminish a calcium dependent potassium current. It remains to be determined, however, whether the pharmacological manipulations used to separate the inward and outward currents affect the ability of the cells to respond to cyclic AMP analogues or themselves effect biochemical changes such as protein phosphorylation.

298.7 CALMODULIN MEASUREMENT IN BIOLOGICAL TISSUE BY HPLC-UV DETECTION. Marty Javors*, D.H. Ross and Charles L. Bowden. Depts. Pharmacol. & Psychiatry, Univ. Tex. Hlth. Sci. Ctr., San Antonio, TX 78284.

Calmodulin is a protein which mediates many of the cellular functions triggered by intracellular calcium concentration changes. In neuronal tissue, a calcium-calmodulin complex modulates the activation of cyclic nucleotide phosphodiesterase, adenyl cyclase, Ca-Mg-ATPase activity, plasma membrane calcium transport and neurotransmitter release. To date, the measurement of calmodulin in biological tissues has required utilization of a bioassay in which the activation of phosphodiesterase activity or Ca-Mg-ATPase activity by calmodulin is observed. In this paper, we describe an HPLC method of detection for calmodulin, using UV detection at 214 nm. This assay is sensitive to 0.5 micrograms and linear to at least 20 micrograms, using purified calmodulin from three different sources. Studies with a rat brain striatal P_2 preparation indicate that 30% of the calmodulin was membrane-bound and the membrane contained approximately 2 micrograms calmodulin per mg membrane protein. Determinations of calmodulin content in cytosol and membranes of RBC's and platelets have also been made. This method provides a useful tool for the quantification of calmodulin in biological tissues.

Partially funded by Meadows Foundation Grant #81-037.

298.8 DISTRIBUTION OF CALCIUM SENSITIVE PHOSPHODIESTERASE (PDE) IN DIFFERENT RAT BRAIN REGIONS. M. S. Yang* (SPON: Mary J. Kallman). Div. of Neurosurgery, Med. Coll. VA, Richmond, VA 23298.

Using cGMP as substrate, the catabolic enzyme PDE was shown to distribute unevenly in mouse brain. The highest activities in the presence of calcium were found in the substantia nigra pars reticulata and the basal ganglia (Yang et al., J. Neurochem. 36:1272, 1981). It was also shown that several PDE isoenzymes exist in brain. One is specific for cAMP. At least one other, which can hydrolyze both cAMP and cGMP, is located in the cytosol, sensitive to calcium and inhibitable by antipsychotic drugs (Wolff and Brostrom, Adv. Cyclic Nucleotide Res. 11:41, 1979).

Quantitative histochemical analysis demonstrated that PDE distribution in rat brain is similar to that in the mouse. Furthermore, the following study sought to characterize the calcium contribution to the high PDE activity in different rat brain regions.

After homogenization in different buffers, 100,000 g ultracentrifugation and enzymatic assay (Carter et al., J. Histochem. Cytochem. 17:505, 1979), part of the total PDE activity in rat brain cortex was recovered from the supernatant fraction and the other part from the particulate. Recovery was close to 100%. PDE in the supernatant fraction was sensitive to calcium, while that in the particulate was not. The calcium-sensitive fraction of the cortex was also more sensitive to trifluoperazine and thioridazine as compared to the particulate calcium-independent fraction which was more sensitive to papavarine and IBMX when those drugs were presented at low concentrations. In the presence of EGTA, trifluoperazine failed to inhibit the supernatant enzyme. Bromocryptin and Hydergine were less effective in inhibiting both fractions.

Seven rat brain regions were studied. In the presence of 1 mM EGTA, the supernatant PDE activity showed highest activity in the cortex, followed by the striatum, the hippocampus, the thalamus, the pons, the medulla and the cerebellum. In the presence of 0.2 mM calcium chloride, activity increased in all regions, but the increase was not uniform. The enzyme activity increased by 600% in the striatum, 400% in the pons, 300% in the cortex, thalamus and medulla and only 60% in the cerebellum. The large increase in calcium-dependent activity in the striatum resulted in the striatum showing the highest activity of all regions tested. These data demonstrate that the high PDE activity in the striatum is related to a calcium-sensitive component. (This study was supported by Sandoz AG, Basel, Switzerland).

298.9 SEROTONIN-INDUCED PHOSPHORYLATION OF A 28,000 DALTON PROTEIN IN A LOBSTER NERVE-MUSCLE PREPARATION. M. F. Goy*, T. L. Schwarz* and E. A. Kravitz. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

The biogenic amine serotonin is part of a complex hormonal control system that influences the dactyl opener muscle of the walking legs of the lobster Homarus americanus. In this preparation serotonin causes an increase in transmitter release from both the excitatory and inhibitory axons that innervate the muscle. In addition, the amine acts directly on the muscle to cause a long-lasting contracture and increase the magnitude of a voltage-dependent Ca^{++} current.

To look for biochemical events that might underlie these physiological processes, intact opener muscles with their attached nerves were incubated in $^{32}PO_4^{2-}$. Phosphorylated proteins were separated by SDS polyacrylamide gel electrophoresis and detected by autoradiography. Adding serotonin to the incubation medium leads to phosphorylation of a 28,000 dalton protein. The time course of this phosphorylation is slow, like the physiological actions of serotonin; it rises over several minutes and is sustained for at least an hour. The phosphorylation can be induced by physiologically reasonable concentrations of the amine (10^{-7}M).

We have begun to investigate the significance of this phosphorylation in the physiological actions of serotonin. A variety of agents that cause contractions (high K^+, caffeine, and glutamate - the presumed transmitter of the excitatory axon) do not cause significant increases in the phosphorylation of the 28,000 dalton protein. The phosphorylation is not, therefore a consequence of contraction or its associated Ca^{++} movements.

Two other neurohormones, octopamine and proctolin, cause long-lasting contractures of the opener muscle similar to those of serotonin. Octopamine causes at most a very slight phosphorylation of this protein and proctolin has no observable effect. Thus the reaction is probably not involved in a common pathway for the three hormone-induced contractures.

The phosphorylation may be mediated by changes in cyclic nucleotide metabolism. In a homogenized preparation, cGMP and (to a lesser degree) cAMP stimulate the phosphorylation of a 28,000 dalton protein which may be identical to the protein phosphorylated in vivo. Experiments to clarify the relationship of the phosphorylation to cyclic nucleotides and the physiology of serotonin action are in progress.

298.10 MODULATION OF THE HIPPOCAMPAL α-ADRENERGIC RECEPTOR POPULATION BY LESION OF THE SEROTONERGIC RAPHE-HIPPOCAMPAL PATHWAY IN RATS. H. Ladinsky*, S. Consolo*, G. L. Forloni* and P. Grombi* (SPON: L. VALZELLI). Lab. of Cholinergic Neuropharmacology, Istituto di Ricerche Farmacologiche "Mario Negri", Milan, Italy 20157.

Electrolytic lesion of the ascending serotonergic fibers in the median raphe nucleus caused more than 90% depletion of 5-HT in the hippocampus and cortex (18 days) without affecting NE and ACh contents. α-Adrenoceptor binding of (^{3}H)WB-4101 was increased in the hippocampus but not in the frontal cortex. Scatchard analysis revealed that the increase in (^{3}H)WB-4101 binding in the lesioned hippocampus was the result of an elevated density of α-adrenergic receptors of about 30%. This phenomenon began 8 days postlesion and persisted for at least 80 days postlesion. Similar qualitative results were obtained following lesion of the median raphe nucleus with 5,7-DHT. Selectivity of the phenomenon was demonstrated as β-adrenoceptor binding with (^{3}H)dihydroalprenolol and cholinergic muscarinic receptor binding with (^{3}H)dexetimide were not significantly affected in the hippocampus. By contrast, when NE in the hippocampus was depleted by more than 90% by bilateral lesion of the ascending noradrenergic fibers with 6-OHDA (18 days), α-adrenoceptor number was not significantly changed while β-adrenoceptor number was enhanced. It is currently being investigated whether the increase in α-adrenoceptor number in the presence of unchanged NE content and in the absence of 5-HT signifies heterologous modulation of the NE receptor population by 5-HT.

298.11 EFFECT OF 6-HYDROXYDOPAMINE ON RELEASE OF ATP FROM MYENTERIC SYNAPTOSOMES PREPARED FROM GUINEA-PIG ILEUM. M. Alhumayyd* and T.D. White. Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

It has been suggested that ATP may be an inhibitory neurotransmitter in the myenteric plexus of vertebrate intestinal smooth muscle. There is also evidence that ATP may be stored and co-released with biogenic amines and acetylcholine to modulate synaptic function. Recently, we have studied the depolarization-induced release of ATP from synaptosomes prepared from the myenteric plexus of guinea-pig ileum by detecting the light produced when the released ATP reacted with firefly luciferin-luciferase present in the incubation medium. Depolarization with elevated extracellular K^+ or veratridine released ATP by a mechanism which required extracellular Ca^{2+}. In the present study we chemically lesioned the noradrenergic nerves of the myenteric plexus by administering two-doses of 6-hydroxydopamine (250 mg/kg i.p.) to guinea-pigs, the second dose being administered 3 days after the first dose. The guinea-pigs were killed 7 days after the first dose and myenteric synaptosomes prepared from the longitudinal muscle of the ileum. Control synaptosomes contained 61.7 ± 5.0 ng noradrenaline/mg protein as measured by HPLC. This was reduced to 29.2 ± 5.5 ng/mg protein by 6-hydroxydopamine pretreatment (6 experiments). 6-Hydroxydopamine pretreatment reduced K^+-induced release of ATP from synaptosomes by 25% and veratridine-induced release by 36% (6 experiments). Preliminary studies indicate that in vitro pretreatment of myenteric synaptosomes with 6-hydroxydopamine abolishes both K^+- and veratridine-induced release of ATP. These findings suggest that at least a portion of the ATP was released from noradrenergic nerve terminals and support a possible cotransmitter function for ATP and noradrenaline in this tissue. 298.12 VASOPRESSIN POTENTIATES NOREPINEPHRINE-STIMULATED CYCLIC AMP ACCUMULATION. A. C. Church. Dept. of Anatomy, Univ. of Pennsylvania, School of Medicine, Phila., Pa. 19104

Vasopressin (also known as antidiuretic hormone) is a nonapeptide which has been shown to strengthen memory by a centrally mediated action. In addition to its effets on memory (deWied, D., Nature 232:137, 1973), vasopressin has also been shown to prolong functional tolerance to both ethanol (Hoffman, P.L., et al., Nature 276:614, 1798) and morphine (van Ree, J.M., et al., Biochem. Pharmacol. 27:1973, 1978). Since lesions of brain norepinephrine (NE) systems resulted in a loss of vasopressin efficacy (Hoffman, P.L. and Tabakoff, B., Drug Alc. Depend. 4:249, 1979), a study was undertaken to determine whether vasopressin might not interact with NE stimulated cyclic AMP accumulation in brain slices.

Slices of mouse hippocampus were prepared according to Quik et al. (Biochem. Pharmacol. 27:2209, 1978) and were incubated at 37°C in Krebs-Ringer bicarbonate containing 1 mM theophylline for 60 mins. Aliquots of tissue were then removed and added to buffer containing either NE (10 uM), lysine vasopression (1 uM), both or neither. After incubating 10 mins at 37°C, the reaction was stopped by boiling. Cyclic AMP concentrations were measured by the method of Brown et al. (Biochem. J. 121:561, 1971).

In the presence of NE, cyclic AMP values were increased by about 4-5-fold over basal values, while lysine vasopressin had no significant effect. However, the mixture of lysine vasopressin and NE produced cyclic AMP concentrations which were 9-10-fold higher than basal values. Thus, vasopressin substantially potentiated the stimulative effect of NE, while producing little effect by itself. These results suggest that vasopressin is capable of neurochemically modulating the responsiveness of the hippocampal NE-cyclic AMP system. Further characterization of the vasporessin-NE interaction is currently being investigated.

298.13 CHARACTERIZATION OF ADENOSINE RECEPTORS IN RAT BRAIN. J. Patel* and P. J. Marangos. Clinical Psychobiology Branch, NIMH, Bethesda, MD 20205.

Adenosine has multiple effects in the nervous system, the most notable of which are modulation of neurotransmitter release and adenylate cyclase activity, depression of the spontaneous firing rate of cortical neurons and potent behavioral effects which include sedation. The neuromodulatory effects of adenosine are thought to be mediated by specific adenosine receptors but these receptor sites have been difficult to characterize using ^{3}H adenosine since adenosine is apparently generated in synaptosomal membrane preparations.

Using ^{3}H N^6 cyclohexyladenosine (CHA) and the enzyme adenosine deaminase it is possible to specifically label high affinity binding sites for adenosine that satisfy the criteria for specific receptors. Two populations of adenosine receptors exist in rat brain with respective K_D values of 0.7 nM and 2.4 nM. The respective B_{max} values are 230 and 120 fmoles/mg protein in rat forebrain. Adenosine deaminase treatment of the membranes is essential for maximal binding since less than 30% binding is observed in the absence of this enzyme. Regional distribution studies indicate high densities of adenosine receptors in hippocampus with lower levels observed in cerebral cortex, cerebellum and striatum and still lower levels in the spinal cord. Subcellular distribution studies are consistent with the adenosine receptor being localized in synaptosomes.

Extensive analysis of various anions and cations for their effect on ^{3}H CHA binding reveals that both copper and zinc are potent non-competitive inhibitors of binding with respective IC_{50} values of 30 μM and 150 μM. Calcium and magnesium had weak stimulatory effects on binding with EC_{50} values greater than 100 μM. Sulfhydryl reducing and alkylating agents inhibit ^{3}H CHA binding indicating that the adenosine receptor is a sulfhydryl dependent protein.

The results obtained indicate that ^{3}H CHA is an advantageous ligand to use for adenosine receptor binding studies.

298.14 ADENOSINE ANALOGS INCREASE ELECTRICAL POTENTIAL IN BRAIN SYNAPTIC MEMBRANE VESICLES. M.L. Michaelis and E.K. Michaelis. Neurobiology Section, Dept. of Human Development, Univ. of Kansas, Lawrence, KS. 66045

The purine nucleoside adenosine has been shown to modulate the release of neurotransmitters in both the peripheral and central nervous systems and to influence postsynaptic responses to released transmitter substances. The mechanism(s) by which adenosine acts to modulate neurotransmission is as yet unknown. It has been suggested that presynaptic modulators may decrease transmitter release by either decreasing the influx of Ca^{2+} upon depolarization or by hyperpolarizing the presynaptic membranes by an alteration in the membrane conductance for either Cl^- or K^+. We have used isolated, resealed synaptic plasma membrane vesicles (Life Sciences, 28:37) to study the influence of the adenosine analog 2-chloroadenosine (2-ClAdo) on synaptic membrane potentials in an effort to identify which ionic conductance is affected by this purine. The lipophilic cation [^{3}H] methyl triphenylphosphonium ($TPMP^+$) has been used to measure the membrane potential $\Delta\Psi$ which developed when resealed synaptic membrane vesicles were loaded internally with K_2-succinate and incubated in a Na_2-succinate or NaCl medium with [^{3}H] $TPMP^+$. The membranes have been found to develop a $\Delta\Psi$ of approximately -7 mV in Na_2-succinate, -28 mV in NaCl, and -2 mV in KCl, the latter condition representing the absence of a K^+ diffusion potential.

Preincubation of the K_2-succinate-loaded vesicles with 2-ClAdo led to a substantial increase in membrane $\Delta\Psi$ in the presence of a K^+ diffusion potential. The EC_{50} for the effect of 2-ClAdo was determined by log probit analysis to be 55 nM. 2-Chloroadenosine did not influence $TPMP^+$ uptake when vesicles were loaded internally with Na_2-succinate instead of K_2-succinate. Blockade of anion channels with SITS did not block the 2-ClAdo-induced increase in $\Delta\Psi$, suggesting that Cl^- fluxes are not responsible for the effects of 2-ClAdo on membrane polarity. However, adenosine receptor antagonists such as the methylxanthines did inhibit the effects of 2-ClAdo. In addition, adenosine itself (50 nM concentration) as well as several adenosine derivatives such as phenylisopropyl adenosine, ADP, and α,β-CH_2-ADP also produced rapid increases in membrane $\Delta\Psi$. These preliminary observations suggest that the adenosine-induced hyperpolarization observed in electrophysiological studies may be due to enhancement of K^+ efflux from neurons. Exactly how this event leads to a decrease in the release of neurotransmitters from presynaptic nerve terminals remains to be determined. (Supported by NIH grant NS 16364 and by 79-KS-529 from the AHA, Kansas Affiliate.)

298.15 MODULATION OF MONOAMINE OXIDASE (MAO) BY SMALL MOLECULAR PROTEINS IN PLASMA, C.T. Giambalvo and R. Becker. Rhode Island Psychiatric Research and Training Center and Dept. of Pharmacology, Univ. of Rhode Island, Kingston, RI 02881.

Human plasma contained modulators that affected platelet and striatal MAO activity when added *in vitro*. It was found that addition of plasma inhibited tryptamine deamination by platelet MAO. The inhibition was uncompetitive in nature, reversible by prior precipitation of plasma proteins by perchloric acid, but was not reversed by prior ultrafiltration of plasma through PM30 Amicon membranes that remove substances > 30,000 MW. These results suggested that the inhibitor is a small molecular weight protein. Addition of plasma also inhibited tryptamine deamination by bovine striatal MAO. The inhibition was noncompetitive, reversible by perchloric acid pretreatment as well as by prior ultrafiltration of plasma. Plasma also inhibited the deamination of serotonin by striatal MAO-A. The inhibition was non-competitive in nature, reversible by perchloric acid pretreatment but not by PM30 ultrafiltration. These results suggested that this inhibitor is a small molecular weight protein. The inhibition of platelet or striatal MAO by plasma is unlikely to be mediated by serum albumin because ultrafiltration would have removed serum albumin. Moreover, addition of bovine serum albumin *in vitro* affected the kinetic properties of MAO differently than the ultrafiltered plasma.

298.16 DIFFERENCES IN THE BRAIN RECOGNITION SITES FOR TYPICAL AND ATYPICAL ANTIDEPRESSANTS. N. Brunello*, D.M. Chuang* and E. Costa. (SPON: S. H. Koslow). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032

Repeated administrations of typical or atypical antidepressants down regulate the norepinephrine (NE) activation of adenylate cyclase in brain slices. This action requires the presence of brain adrenergic axon terminals but not that of brain serotonergic axon terminals. The synaptic membranes prepared from various areas of a mamalian brain contain high affinity binding sites for typical antidepressants (Nature 281:148, 1979). These sites are saturable, stereospecific, unevenly distributed in brain and appear to be located presynaptically on serotonergic axons (Science 210:1133, 1980). Also [^{3}H]mianserin binds to crude synaptic membranes (Eur. J. Pharmacol. 68:395, 1980); these sites appear to be associated with serotonergic synapses (J. Pharmacol. Exp. Ther. 216:142, 1981). We have investigated whether the recognition sites for both classes of drugs are exclusively located in association with serotonergic synapses and whether both drugs bind to the same type of synapses. With these studies we hoped to define more precisely the site of action of antidepressants and, indirectly, to obtain information on biochemical markers specific for affective disorders. Since serotonergic synapses have been singled out as a possible site where the recognition site of both classes of compounds is located, we began our studies by perturbing serotonergic neuronal function with intracerebral injections of 5,7 dihydroxytryptamine, with intraperitoneal injections of p-Cl-phynylalanine and have lesioned the fimbria fornix. The Bmax of [^{3}H]imipramine was reduced by the toxin injections but the extent of the reduction differed in various areas though the extent of 5HT depletion was maximal in all areas. In contrast, in the same rats the Bmax of [^{3}H]mianserin binding was increased. Chronic injections of p-Cl-phenylalanine which deplete the 5HT content of various areas maximally and uniformly caused a variable degree of increase in the Bmax of [^{3}H] mianserin binding while the binding of [^{3}H]imipramine remained unchanged. Lesions of the fimbria fornix decreased the [^{3}H] imipramine binding in the hippocampus but failed to change that of [^{3}H]mianserin. Chronic treatment with imipramine down regulated its high affinity binding; in contrast, chronic treatment with mianserin failed to down regulate its high affinity binding. From these and other results that will be presented it is concluded that the two classes of compounds bind to different sites. In both instances the sites are associated with various types of synapses suggesting as a working hypothesis that the endogenous ligand that binds physiologically to the sites where antidepressants bind, could be a cotransmitter that tunes up the sensitivity of the detection sites for a given group of postsynaptic receptors.

299.1 METABOLIC COMPARTMENTATION OF GLUTAMATE: CELLULAR LOCALIZATION OF CERTAIN RELEVANT ENZYMES AND THE INDUCTION OF GLUTAMINE SYNTHETASE IN THE BRAIN IN VIVO. A.J. Patel, A. Hunt‡ C.S.M. Tahourdin‡ R.D. Gordon‡ and S. Bunn*. MRC Developmental Neurobiology Unit, Institute of Neurology, 33 John's Mews, London WC1N 2NS, UK.

We have previously developed a model to account for kinetic observations indicating that glutamate and the associated tricarboxylic acid cycles ('cycle') are compartmented in the brain, and have assigned the functional compartments to morphological structures. It was proposed that transmitter amino acids released from nerve terminals are taken up, in part, by glial cells, where they are converted into glutamine. Glutamine in turn is taken up, after diffusion into the extracellular space, by neuronal structures and hydrolysed to glutamate, thus balancing the loss of carbon units in the 'cycle'. The availability of relatively pure separated and cultured neurones and glia in our Unit has now permitted the investigation of their biochemical properties and testing of this proposal. The results were consistent with the hypothesis in showing that the astrocyte to neurone specific activity ratio were 3.6-8.4 for glutamine synthetase (GS), 1.5-5.3 for glutamate dehydrogenase and 0.1-0.4 for glutaminase, depending upon the class of neurone and the type of preparation used for comparison. On the other hand, the specific activity of succinate dehydrogenase was more even in the different cell types, indicating that the differences in the distribution of mitochondrial enzymes are not simply related to variations in the concentration of mitochondria in the two classes of cells. The possible involvement of GS in processes associated with amino acid neurotransmission was also suggested by the observation that the activity of this enzyme was unevenly distributed throughout the CNS and in different regions of the brain the activity of GS was significantly correlated with that of glutamate decarboxylase but not with that of choline acetyltransferase. Furthermore, in agreement with previous studies on GS in chick retina in vivo and various avian and mammalian cells in vitro, we observed that the activity of this enzyme in the mammalian brain in vivo is increased by glucocorticoids. The increase was more marked in young than in adult rats and comparison of the effect on various brain areas suggested that elevation of GS was dependent on the maturational state of the region at the time of the hormone treatment. The effect of glucocorticoids on GS activity was due to induction, since the immunochemically detectable GS in cerebellar homogenates fractionated by SDS-PAGE and transferred to DBM paper showed an increase in the amount of enzyme.

299.2 RELEASE AND METABOLISM OF NEWLY SYNTHESIZED DOPAMINE IN RAT STRIATAL SLICES: EFFECT OF SELECTIVE MONOAMINE OXIDASE INHIBITION, D.D. Schoepp* and A.J. Azzaro, Departments of Neurology and Pharmacology-Toxicology, West Virginia University Medical Center, Morgantown, W.V. 26506

Studies were designed to determine the relative roles of the type A and B forms of monoamine oxidase (MAO) in the deamination of released rat striatal dopamine (DA). In vitro release and subsequent metabolism of ^{3}H-DA was examined using rat brain slices. Striatal slices were pre-incubated in the presence of ^{3}H-L-tyrosine (20 µM) followed by a short incubation period in the presence of the irreversible MAO inhibitor agents described below. Tissue pretreated in this manner was then subjected to a release incubation using varying concentrations of potassium chloride (KCl).

In the absence of MAO inhibition, KCl produced a concentration-dependent release of newly formed ^{3}H-DA as well as an increased formation of ^{3}H-deaminated metabolites; dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA). Formation of *^{3}H-DOPAC and ^{3}H-HVA were maximal at 30 mM KCl with* DOPAC representing the major deaminated metabolite. Incubation in the presence of the DA uptake inhibitor nomifensine (10^{-5}M) further enhanced the KCl-induced increase of released ^{3}H-DA as well as the formation of both ^{3}H-DOPAC and ^{3}H-HVA. Pretreatment of striatal slices with a selective concentration of the type A MAO inhibitor clorgyline (10^{-7}M) significantly decreased K^+-induced (30 mM KCl) formation of both ^{3}H-deaminated metabolites (DOPAC 11% of control, HVA 37% of control) while enhancing ^{3}H-DA present in the medium (250% of control). The type B MAO inhibitor deprenyl (10^{-7}M) did not significantly affect these parameters. However, pretreatment with both clorgyline and deprenyl (10^{-7}M) resulted in further reduction of ^{3}H-deaminated metabolites (DOPAC 2% of control, HVA 17% of control).

These results suggest that under the conditions employed, released DA is deaminated primarily by a type A form of MAO that is extraneuronal to the DA neuron. Furthermore, in the absence of the type A enzyme minor but significant metabolism also occurs via the type B form of MAO.

Supported by the West Virginia University Medical Corporation. D.D. Schoepp is a West Virginia University Foundation fellow.

299.3 CALCIUM-STIMULATED GLUTAMATE DECARBOXYLASE ACTIVITY IN SLICES AND IN BROKEN CELL PREPARATIONS OF RAT BRAIN. Barry I. Gold and Francis P. Huger. Dept. of Pharmacol., Uniformed Services Univ., Sch. of Med., Bethesda, MD. 20014.

Glutamate decarboxylase (GAD) increases activity in response to *in vitro* models of increased neuronal activity. Ca^{2+} plays an established role in excitation-secretion coupling in neurons and in many other cells. These studies were undertaken to define the role of Ca^{2+} in the regulation of GAD activity.

Slices of corpus striatum, prepared from freshly dissected brain, were incubated in an oxygenated Krebs-Ringer-bicarbonate (KRB) medium which contained varying concns of $CaCl_2$. [^{3}H]GABA synthesis was initiated by adding L-[2,3-^{3}H]glu and the reactions were terminated with 15% trichloroacetic acid (TCA). Samples were homogenized with a Polytron; centrifuged, and the supernatants were applied to a cation exchange column of AG 50W X-8(Na^+ form). [^{3}H]GABA, eluted at pH 5.5, was estimated by liquid scintillation chromatography (LSC). GABA synthesis without exogenous Ca^{2+} was 86.6 pmoles/mg wet wt/15 min at 0.5 mM [^{3}H]glu. A concn-related increase in GABA synthesis was seen in the presence of Ca^{2+}; maximum increase was 33% at 2.6 mM Ca^{2+}. GABA synthesis in the presence of 1.3 mM Ca^{2+} was completely inhibited by 1 mM La^{3+} while 1 mM La^{3+} in the absence of Ca^{2+} had no effect. The divalent cationic ionophore, A23187 at concns up to 6µM, failed to affect the response to 1.3 mM Ca^{2+}. Co^{2+} (1 mM) did not reverse the response to 1.3 mM Ca^{2+} and had no effect on synthesis in the absence of Ca^{2+}.

GAD activity was also studied in synaptic membranes derived from a crude mitochondrial pellet (P_2). Pellets were lysed in imidazole acetic acid (25 mM, pH 7.4 containing aminoethylisothiouronium bromide (AET). Membranes were washed twice by sedimentation and rehomogenization in buffer with AET and they were dialyzed for 20 h against 50 vol of buffer which contained 0.5 mM EGTA. Membranes were washed again and resuspended for assay. GAD activity was estimated in aliquots of the membrane suspensions in a reaction mixture consisting of buffer with AET, 3.0 mM [^{3}H]glu, 100 µM pyridoxal phosphate, and 100 µM Ca^{2+} or other divalent cation. The mixture was incubated for 5 min at 30° and it was terminated wth TCA. [^{3}H]GABA was estimated as above. Control GAD activity under these conditions was 705 nmoles/mg protein/5 min and activity was increased 22% in the presence of Ca^{2+}, 32% with Co^{2+}, and <10% with Mg^{2+} GAD activity was inhibited 79% by La^{3+}, 97% by Cd^{2+}, and <10% by Mg^{2+} and Sr^{2+}.

These results are suggestive that neuronal membrane Ca^{2+} recognition sites, perhaps the same as voltage-sensitive Ca^{2+} channels, are in proximity to membrane-bound GAD, and that these Ca^{2+} sites are functionally related to the regulation of GAD.

299.4 INDICATIONS OF INCREASED DOPAMINE TURNOVER IN THE NEOSTRIATUM OF RATS TREATED THREE WEEKS PREVIOUSLY WITH TOXIC DOSES OF METHYLAMPHETAMINE. G.A. Ricaurte*, C.R. Schuster* and L.S. Seiden. (SPON: R. Lim). Dept. of Pharmacol. & Physiol. Sci., University of Chicago, Chicago, IL 60637.

Following partial 6-hydroxydopamine (6-HDA) lesions of the nigrostriatal DA projection, there is an increase in neostriatal DA turnover, as evidenced by enhanced conversion of 3H-tyrosine into 3H-dihydroxyphenylalanine (DOPA) and 3H-DA (Agid et al. Nature New Biol. 245:150,1973). It has been postulated that this acceleration of DA turnover is an adaptive response to diminished DA neurotransmission resulting from partial DA neuronal loss (ibid,1973), and the increase in DA turnover at least partly underlies the recovery of function observed in 6-HDA treated animals (Zigmond and Stricker, In: Chemical Tools for Catecholamine Res. 1:319,1975). In this study, the metabolism of neostriatal DA was examined in rats previously treated with high doses of methylamphetamine (MA) since MA, like 6-HDA destroys DA terminals (Wagner et al. Brain Res. 181:151,1980; Ricaurte et al., submitted for publication). The purpose of the study was to determine whether after MA, like after 6-HDA, there is an increase in neostriatal DA turnover. DA turnover was estimated with the DOPA accumulation (Carlsson et al. Naunyn-Schmiedeberg's Arch. Pharm. 275:153,1972) and DOPAC (Roth et al., Eur. J. Pharmacol.) methods. Separate but identically treated groups of rats were assayed with each method 3 weeks after MA treatment (50.0 mg/kg x 3,8 hours apart). With the DOPA accumulation method, the DA synthesis rate constant was found to be increased in MA treated rats. However, this increase was dependent on neostriatal DA depletion size. In rats with 0-35% (n=6) DA depletions, the rate constant was not significantly different from that in controls (0.20 ± 0.01 h^{-1}), whereas in rats with 36-70% (n=9) and >71% (n=6) DA depletions, it was increased by 25 and 150%, respectively. With the DOPAC method, the DOPAC/DA ratio (an index of DA release per neuron) was also found to be increased in MA treated rats (by 66%), but only in those with >71% (n=4) DA depletions. No increase in DA turnover was detected with the DOPAC method in rats with 36-70% (n=8) DA depletions, whereas a small (25%) but significant increase was found with the DOPA accumulation method. Although the reason for this is unclear, it may be that the latter method is more sensitive than the former in detecting DA turnover changes. These results suggest that after MA, like after 6-HDA, there is an increase in neostriatal DA turnover, and that a large number of DA terminals must be destroyed before an increase in DA turnover occurs. 299.5 EVIDENCE THAT PYRUVATE CARBOXYLASE IS AN ASTROCYTE SPECIFIC ENZYME IN CNS TISSUES. R.P. Shank, G.LeM. Campbell*, S.O. Freyteg* and M.F. Utter*. Department of Physical and Life Sciences, The Franklin Institute, Philadelphia, PA 19103 and Department of Biochemistry, Case Western Reserve, Cleveland, Ohio 44106.

It has been established that pyruvate carboxylase is the most active CO_2-fixing enzyme in CNS tissues (M.S. Patel, J. Neurochem, 22, 717, 1974). Metabolic studies by Berl, Cheng and their colleagues have demonstrated that CO_2-fixation occurs predominantly (if not exclusively) in a small "synthetic" metabolic compartment that rapidly synthesizes glutamine (S. Berl et al, J. Biol. Chem. 237, 2570, 1962), and that CO_2-fixation accounts for at least 10 percent of the pyruvate carbon entering the citric acid cycle (S.C. Cheng et al, Nature 216, 928, 1967). Because glutamine synthesis is now known to occur almost exclusively in astrocytes (M.D. Norenberg, J. Histochem. and Cytochem. 27, 756, 1979) these metabolic data suggest that pyruvate carboxylase activity may occur predominantly or exclusively in astrocytes. In our experiments we have examined the cellular localization of pyruvate carboxylase using immunocytochemical techniques and assay of pyruvate carboxylation activity. The rat and mouse cerebellum was the tissue examined in most experiments. Antisera against purified rat liver pyruvate carboxylase was elicited in goats as described previously and partially purified by isolating the IgG fraction. Reaction product to pyruvate carboxylase was visualized using rhodamine conjugated rabbit anti-goat antisera and the peroxidase-antiperoxidase procedure of Sternberger. In the cerebellum specific reaction product appeared to be restricted to Bergmann glia cells and other types of astrocytes. In astrocyte-like cells obtained from the cerebral hemispheres of 3 day old rats and grown in vitro for 3 weeks there was considerable reaction product which appeared to reside in discrete organelles (presumably mitochondria). In isolated populations of cell bodies obtained from the cerebellum of 10 to 14 day old mice the activity of pyruvate carboxylase was several times greater in a population enriched in astrocytes as compared to a population enriched in granule cell bodies. Based upon these and other data we postulate that through the anaplerotic function of pyruvate carboxylase, astrocytes generate a net excess of citric acid cycle intermediates which in the form of α-ketoglutarate is released into the interstitial fluid, taken up by nerve terminals (Shank and Campbell, Life Sciences 28, 843, 1981) and used to replenish the neurotransmitter pools of glutamate and GABA. An advantage of the astrocytic localization of pyruvate carboxylase is that is allows neuronal ATP to be conserved for other energy requiring processes. (Supported in part by NIH grant NS16004).

299.6 RAT BRAIN NE METABOLISM: SUBSTANTIAL CLEARANCE THROUGH 3,4-DIHYDROXYPHENYLGLYCOL (DHPG) FORMATION. P.P. Li*, J.J. Warsh, D.D. Godse*. Section of Biochemical Psychiatry, Clarke Institute of Psychiatry, Toronto, Canada.

We have recently shown that rat brain regional DHPG concentrations are either equivalent to or greater than respective 3-methoxy-4-hydroxyphenylglycol (MHPG) levels (Warsh et al., J. Neurochem. 36: 893-901, 1981). These observations suggest that metabolic clearance of brain NE through DHPG formation may be quantitatively greater than through MHPG production in this species. As the steady state concentrations of these metabolites may not reflect their respective turnover rates, we have examined the rate of formation of these metabolites in rat brain regions using the probenecid technique.

Rat brain regional free and total DHPG and MHPG were simultaneously quantitated by selected ion monitoring mass fragmentography. Conjugated DHPG and MHPG concentrations were calculated as the difference between the free and total glycol levels. Administration of increasing doses of probenecid (100-500 mg/kg, i.p.) 90 min before sacrifice produced a dose-dependent increase of conjugated DHPG and MHPG concentrations. The maximum increment of these conjugated metabolites occurred at a dose of 300 mg/kg or higher. During the first hour following probenecid (300 mg/kg, i.p.), rat brain conjugated DHPG and MHPG levels accumulated linearly at a rate of 646 and 319 pmol/g/h, respectively. Using the probenecid technique, the estimated brain regional formation rates of conjugated DHPG and MHPG were as follows:

	Conjugated DHPG (pmol/g/h)	Conjugated MHPG (pmol/g/h)	Formation Rates Ratio(DHPG/MHPG)
Hypothalamus	2800 ± 82*	951 ± 62	3.0
Midbrain	734 ± 60*	297 ± 47	2.5
Brainstem	650 ± 67*	393 ± 58	1.6
Cerebral Cortex	372 ± 25*	281 ± 20	1.3
Hippocampus	325 ± 40*	222 ± 28	1.5
Striatum	284 ± 43	212 ± 29	1.3
Cerebellum	104 ± 19	53 ± 23	1.9

*$p<0.05$ vs conjugated MHPG formation rates

In whole rat brain and most brain regions studied, the estimated formation rate of conjugated DHPG significantly exceeded that of conjugated MHPG. These results lend additional support to the notion that formation and efflux of DHPG is the major route of metabolic clearance of rat brain NE.

299.7 TIME COURSE AND DISTRIBUTION PATTERNS IN RAT TISSUES AFTER L-DOPA ADMINISTRATION. Jackson V, Reches A*, Prasad ALN*, Fahn S. Dept. Neurol., Columbia Univ., College of P & S, New York, NY 10032.

L-DOPA is widely used therapeutically in the treatment of Parkinson's disease. While it is true that L-DOPA is converted to DA, a major part of the drug given to patients is O-methylated by COMT to 3-O-methyldopa which is therapeutically inactive. Due to the prolonged half-life of OMD, which is 12 hours, this metabolite accumulates in the blood and CSF of L-DOPA treated patients. Clinical evidence indicates that OMD interferes with the beneficial effects of DOPA, thus parkinsonian patients treated with L-DOPA deteriorate when OMD is added to their regimen. Recently, we were able to demonstrate that OMD interferes with striatal uptake utilization of L-DOPA. In the experiments reported here we have studied peripheral metabolism of DOPA in the rat over a 24 hour period to determine the distribution of DOPA and its metabolites.

Rats were injected with DOPA (250 mg/kg i.p.) and sacrificed at 1,6 and 24 h after L-DOPA treatment. Brain, liver, kidney, spleen, muscle and RBC were assayed fluorimetrically (Prasad & Fahn, 1973) for DOPA, 3-O-methyldopa(OMD), dopamine,(DA), and HVA. DOPA levels peaked at 1 h, concentrations obtained in decreasing order were: RBC, 17.61±3.82; spleen 13.47±2.33; muscle 3.89±2.42; kidney 1.91±1.80; liver 1.651±1.347 and brain 1.392±0.661 (all results are expressed as mean nmoles/g tissue ±SEM of n=5). Dopamine formation was highest at 1 h. The concentrations obtained in the kidney (104.92±11.59) were significantly higher than the levels obtained in the liver (6.77±0.982, $p<.0005$) or the brain (6.746± 0.221, $p<.0005$). The concentration of dopamine in RBC, muscle and spleen were smaller than 2 nmoles/g tissue. HVA formation as highest at 1 h, levels obtained in the kidney (119.20±11.7) were significantly higher than those of the liver (11.308±1.148, $p<.0005$ or brain (11.274±0.916, $p<.0005$) levels obtained in RBC, muscle and spleen were 3.473±0.771, 2.22±0.33, and 1.144±.33, respectively. OMD formation was highest at 6 h in muscle, 45.26±12.9; brain 24.795±4.517; RBC 20.52±2.03; and spleen 14.70±3.92. In the liver and kidney, OMD peaks at 24 h and 6 h, 5.195±.763 and 5.921±1.63, respectively. A detailed time course of OMD levels in plasma and brain in rats given DOPA 250 mg kg^{-1}, p.o. revealed a linear rise in OMD concentration with a peak at 6 hrs(brain 39.76±7.1;plasma 25.02±1.08), followed by a slow decline. It is concluded that the pattern of metabolism is different aong the tissues studied.

299.8 SEPARATION OF THREE CYSTEINE SULFINATE DECARBOXYLASE ACTIVITIES FROM HOG BRAIN. Ronald M.Spears* and David L. Martin (SPON: M. G. Pierson). Division of Laboratories and Research, New York State Department of Health, Albany, NY 12201

Cysteine sulfinate decarboxylase catalyzes one step in the biosynthesis of taurine. In an earlier study (Spears and Martin (1980) Soc. Neurosci. Abst. 151.11) hog-brain cysteine sulfinate decarboxylase (CSD) activity was resolved into two components using hydroxylapatite chromatography. Improvements in our chromatographic procedures have since enabled us to resolve three distinct components of CSD activity also using hydroxylapatite chromatography. The first two components (termed peaks I and II) did not decarboxylate and were not inhibited by glutamate whereas the third component (peak III) co-chromatographed with glutamate decarboxylase (GAD) activity. The likelihood that GAD is responsible for both CSD and GAD activities in peak III is supported by the observation of mutual competetive inhibition between cysteine sulfinate (Ki=8.5mM) and glutamate (Ki=1.6mM)for this enzyme and the finding that ATP enhanced the time-dependent, substrate-promoted inactivation of the enzyme when either glutamate or cysteine sulfinate was used as substrate. The Km values of peaks I and II CSD (0.55mM and 0.13mM for peaks I and II respectively) were much lower than the Km of peak III CSD (4.5mM). This fact, together with the strong inhibition of peak III CSD by glutamate, suggests that peaks I and II CSD are the isoenzymes involved in taurine biosynthesis.

Inhibition of peak I CSD by a variety of cysteine sulfinate substrate analogs was measured using 0.25mM cysteine sulfinate and 10 mM inhibitor. The most potent inhibitors were 3-mercaptopropionate (97% inhibition), 3-sulfonopropionate (94%) and DL-penicillamine (88%). Four closer structural analogs of cysteine sulfinate were weaker inhibitors; L-aspartate inhibited by 36%, L-cysteate by 60%, 2-amino-3-phosphonopropionate by 54%, and DL-homocysteate by 30%. In view of the large excess of inhibitor these results together with the failure of glutamate to serve as a substrate indicate that CSD has a high degree of structural specificity. The product, hypotaurine, inhibited by 38%. L-cysteine and α-ketoglutatate inhibited 53 and 69% respectively. Comparable effects were observed with peak II CSD. A high degree of purity of peaks I and II CSD has been achieved by further chromatography of each enzyme on QAE-sephadex, followed by phenyl Sepharose and finally by Sephadex G-100.

299.9 EFFECTS OF ATP, 4-DEOXYPYRIDOXINE PHOSPHATE AND INOSITOL HEXASULFATE ON BRAIN GLUTAMATE DECARBOXYLASE ACTIVITY. Mary P. Meeley*, Sandra Bloom Martin* and David L. Martin. Div. Labs. and Research, New York State Dept. Health, Albany, NY 12201 and Dept. Chemistry, Univ. of Maryland, College Park, MD 20742

A partially purified preparation from hog brain was used to study the effects of ATP, 4-deoxypyridoxine phosphate (DPX-P) and inositol hexasulfate (IHS) on glutamate decarboxylase (GAD) activity. These compounds were selected on the basis of their structural diversity. ATP is a nucleoside triphosphate known to be a potent inhibitor of GAD; DPX-P is a close structural analog of pyridoxal-5'-phosphate (pyridoxal-P), the cofactor for the enzyme; IHS is a polysulfate anion with no obvious structural relationship to either ATP or DPX-P. The substrate, glutamate, promotes a time-dependent inactivation of holoGAD, probably by means of decarboxylative transamination, thereby generating apoGAD. ATP (50 μM) has been shown previously to accelerate the glutamate-promoted inactivation in the presence or absence of added pyridoxal-P (Meeley and Martin (1980) Soc. Neurosci. Abst. 23.3). DPX-P and IHS also accelerated inactivation in the absence of added pyridoxal-P. These results indicate that inhibition by these three compounds cannot be attributed solely to competition with pyridoxal-P, although some contribution by this mechanism in the presence of pyridoxal-P cannot be ruled out by current data. IHS (IC50<1μM) was a more potent inhibitor than either ATP (IC50<50μM) or DPX-P (IC50<50μM). Reactivation of glutamate-inactivated GAD by pyridoxal-P was also examined. Previous studies have shown that inorganic phosphate (Pi) stimulates activation of apoGAD by pyridoxal-P. Following partial inactivation of holoGAD with 10 mM glutamate, a slow and incomplete recovery of activity (requiring > 30 min to reach 50% of initial activity) was observed when 20 μM pyridoxal-P and 10 mM Pi were added to the reaction mixture. However, complete and rapid (< 5 min) reactivation with pyridoxal-P and Pi occurred when GAD was inactivated with both glutamate and low concentrations of ATP (10 - 50 μM). Increasing the ATP concentration above 100 μM resulted in only partial reactivation. Also, reactivation was incomplete if 10 μM ATP was added at the same time as pyridoxal-P and Pi to GAD which had been inactivated with glutamate alone. Similar results were observed with DPX-P. The results available to date show that the effects of these compounds are remarkably similar despite their apparent structural differences.

299.10 LOCALIZATION OF RENIN ACTIVITY IN RAT BRAIN SYNAPTOSOMES. A. Husain*, R.R. Smeby*, R.C. Speth, Research Division, Cleveland Clinic Foundation, Cleveland, OH 44106.

In addition to its well known peripheral actions, angiotensin II has a variety of actions in the central nervous system, for example, induction of drinking behavior and elevation of blood pressure. However, the role of an endogenous renin-angiotensin system in brain remains controversial. The recent demonstration in this and in other laboratories of a neutral protease in brain, capable of forming angiotensin I (brain renin) did not determine its origin. To determine whether brain renin activity was localized in neuronal cells, an investigation of brain renin in subcellular fractions was carried out. Using the techniques established by DeRobertis et al, (J. Neurochem. 9: 23-35, 1962), rat brains were fractionated by differential and discontinuous sucrose density gradient centrifugation. Simultaneous measurements of the activities of brain renin and a synaptosomal marker, choline acetyltransferase (CAT), were made on each fraction obtained by differential centrifugation and on further subfractions of the crude mitochondrial pellet (P_2, 11,500 g x 20 min) obtained by discontinuous sucrose density gradient centrifugation. Five subfractions of the crude mitochondrial pellet were obtained by the following sucrose concentrations: Fraction A (<0.8M, Myelin); Fraction B (0.8-1.0M, Synaptic debris); Fraction C (1.0-1.2M, Synaptosomes); Fraction D (1.2-1.4M, Synaptosomes); Fraction E (>1.4M pellet, Mitochondria). Upon differential centrifugation, 65% of brain renin activity was recovered from the crude mitochondrial (P_2) fraction, while less than 10% of the brain renin activity was recovered from the nuclear (P_1) fraction. Brain renin activity does not appear to be enriched in the cytosol as less than 10% of the brain renin activity was recovered in the 100,000 x g x 60 min supernatant (S_3). Recovery of brain renin activity was between 90 and 117%. Within the subfractions of the crude mitochondrial pellet, the highest amount of CAT activity was observed in Fraction C, the lighter of the two major synaptosomal fractions, confirming earlier observations of DeRobertis et al. By comparison, the largest amounts of brain renin activity were observed in both of the major synaptosomal bands, Fractions C and D. The high amount of brain renin activity in the synaptosomal fractions relative to the other fractions suggests that brain renin is localized in a neuronal compartment and further supports a possible functional role of an endogenous brain renin-angiotensin system.

299.11 AMINO ACID METABOLISM IN HUMAN PLATELETS: OBSERVATIONS IN HUNTINGTON'S DISEASE. Richard M. Mangano and Robert Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228.

Blood platelets have been frequently employed as a peripheral model for many aspects of central nervous system function. Following an earlier report on the biosynthesis of glutamate and aspartate from glucose and acetate in human platelets (Puszkin et al., J. Lab. Clin. Med. 75, 234, 1970) we have now re-examined human platelet metabolism of both amino acids in view of their hypothetical involvement in the etiology of the heritable neurodegenerative disorder, Huntington's disease (HD; Coyle et al., Prog. Neuropsychopharmacol. 1, 13, 1977).

Routine assays were conducted by incubating fresh platelet suspensions (containing 1.5-2 mg platelet protein) for 10 minutes at 37°C with 50 μCi ^{3}H-acetate and 20 μCi ^{14}C-glucose. Subsequently, glutamate, aspartate and their amides glutamine and asparagine were separated according to the method of Berl et al. (J. Neurochem. 15, 131, 1968) and incorporated radioactivity and levels of all amino acids were determined. The specific activities of the compounds derived from both precursors constitute markers of the efficiency of the enzymatic cascades originating from acetate and glucose, respectively. Metabolism was determined simultaneously in control (N=9)- and HD (N=7)-platelets.

After the incubation, platelet levels of glutamate, aspartate, glutamine and asparagine in control donors were 34.8 ±14.6, 8.5 ± 2.3, 6.6 ± 1.3 and 9.7 ± 3.3 nmol/mg protein, respectively. In HD-patients, the equivalent values were 26.3 ± 3.4, 10.2 ± 2.3, 6.9 ± 1.4 and 13.0 ± 4.3, thus showing no significant differences as compared to controls. Radioactivity from ^{3}H-acetate was incorporated in all four amino acids with the specific activities of glutamine and asparagine being 25 and 100 fold lower than those of their immediate precursors glutamate and aspartate. ^{14}C-label derived from glucose could be demonstrated in glutamate and aspartate only. Platelets incubated at 4°C in all cases resulted in less than 10% of the incorporation observed at 37°C, indicating that the precursors were converted by active temperature-dependent processes. No differences between normal and HD-tissue were found in any one of the specific activities investigated.

The present findings suggest that there is no significant dysfunction in glutamate or aspartate metabolism in HD. While noting two important caveats- the possible existence of isozymes or different regulatory mechanisms for identical proteins in brain and peripheral tissue- we conclude that a genetic defect in glycolytic and tricarboxylic acid cycle enzymes is not likely to underlie HD-neuropathology.

299.12 SOLUBILIZATION OF HUMAN PLATELET MAO B WITH β-OCTYL GLUCOSIDE. M.Baron, A.S.Perumal and G.Cannova*. New York State Psychiatric Institute and College of Physicians and Surgeons, Columbia University, 722 West 168th Street, New York, N.Y. 10032

Biogenic amines are known to exert numerous physiologic effects and are involved in behavior modification. Monoamine oxidase (MAO)(E.C. 1.4.3.4.) is primarily responsible for the degradation of biogenic amines and thus determines the level of neurotransmitters in various tissues. Platelet MAO is implicated in the etiology of several psychiatric disorders, including schizophrenia. Since MAO is a membrane-bound enzyme, our immediate goal was to solubilize the enzyme. Current methods use Triton X-100 to solubilize liver MAO. Since Triton X-100 has low critical micellar concentration (0.2-0.3mM) it is difficult to remove this detergent completely even after extensive dialysis. Preliminary experiments, using a variety of detergents to extract the ^{3}H-pargyline bound MAO, showed that β-octyl glucoside was more potent in solubilizing human platelet MAO whereas Triton X-100 was most active against hamster liver MAO.

In order to solubilize and study human platelet MAO experiments were conducted to determine the influence of β-octyl glucoside on enzyme activity. Platelet MAO was assayed at the optimal concentration of 10 nmoles of phenylethylamine as substrate and inhibition was observed beyond this concentration. β-Octyl glucoside exhibited a concentration dependent inhibition of platelet MAO above 0.1%. However, this detergent is easily dialysable due to its high critical micellar concentration (25mM). More than 90% activity was recovered by dialysing overnight. In order to check whether the solubilized enzyme behaves similar to the membrane bound enzyme the inhibitory effect of increasing concentrations of deprenyl (MAO B inhibitor) and clorgyline (MAO A inhibitor) was tested with membrane bound enzyme as well as with dialysed preparations of Triton X-100 and β-octyl glucoside solubilized enzymes. The solubilized enzyme retained the characteristics of MAO B. Response to deprenyl was similar with the two preparations. However, the I_{50} values of β-octyl glucoside solubilized enzyme behaved closer to membrane bound enzyme with clorgyline whereas Triton solubilized enzyme showed less sensitivity. These results indicate that β-octyl glucoside can be used to better advantage in the solubilization and hence in the purification of human platelet MAO B.

299.13 BIOGENIC AMINE CONTENT AND TURNOVER RATES DETERMINED BY LCEC WITH THE TL-9A CELL. C. Co*, J.E. Smith and J.D. Lane (SPON: P.C. Jobe). Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

The content and utilization of the biogenic amines and their metabolites were determined simultaneously by injecting a crude tissue extract into a high pressure liquid chromatography system. The HPLC system utilized a reverse-phase μBondapak C18 column coupled with a TL-9A detector cell. This cell contained the working glassy carbon, auxiliary, and reference electrodes in the same compartment, which reduced the cell dead space to approximately 5 μl. The mobile phase was made up of 0.1M citrate-phosphate buffer, pH 3.5, containing 0.01% sodium octyl sulfate, which was filtered, degassed under vacuum, and methanol added to a final concentration of approximately 9%. Known amounts of standards [norepinephrine (NE), dopamine (DA), serotonin (5-HT), 4-hydroxy-3-methoxyphenylethyleneglycol (MHPG), 5-hydroxyindoleacetic acid (5-HIAA), homovanillic acid (HVA), dihydroxyphenylacetic acid (DOPAC), normetanephrine (NMe), tyrosine (Tyr), tryptophan (Trp), and 3,4-dihydroxybenzylamine (DHBA)] were injected into the system and the peak heights measured. The biogenic amines and their metabolites were identified by the retention time of the standards, and the peak heights determined the content. The utilization of the biogenic amines was determined by injecting radioactive precursors, 1.0 mCi [^{3}H]-tyrosine and 0.5 mCi [^{3}H]-tryptophan, through a jugular catheter which had been previously implanted. Sixty or 90 minutes prior to sacrifice, the animals were injected with the precursors, and the animals were immersed in liquid N_2. The brains were removed at -20°C, sectioned, and dissected into discrete areas. The tissue was pulverized in liquid N_2, extracted in 1N formic acid/1N acetone (v/v:15/85), delipidated with heptane/$CHCl_3$ (v/v:8/1) and concentrated by drying under dry N_2. The dried tissue extract was reconstituted with the HPLC mobile phase, 20 μl injected into the HPLC system, and the individual peaks were collected directly into individual counting vials for specific radioactivity determination. This method yielded 90% recoveries and utilizes a tissue sample as small as 8 mg wet weight. The content and turnover values are comparable to those previously reported. (Supported in part by NIH Grant MH-31835 and USPHS Research Grant DA-01999-04).

299.14 EFFECTS OF PATERNAL EXPOSURE TO CYCLOPHOSPHAMIDE ON THE F_1 PROGENY BRAIN CHEMISTRY. L. L. Hsu, P. M. Adams, J. Fabricant*, and M. S. Legator* Departments of Psychiatry and Behavioral Sciences and Pharmacology and Toxicology, The University of Texas Medical Branch, Galveston, Texas 77550.

The effect of exposing male rats (Fischer 344) to either acute (10 mg/kg) treatment with the alkylating agent cyclophosphamide (CP) or chronic (10 mg/kg 1 day X 5 days X 5 weeks) treatment prior to breeding with normal female animals was studied in the F_1 generation progeny. The present results focus on the changes produced in the brain enzymes of the F_1 progeny. Previous reports (Adams, et al., 1981) described behavioral effects produced in the F_1 progeny following comparable paternal CP exposure.

The F_1 progeny at 90 days of age were decapitated and brains were rapidly removed. Selected brain regions including cerebellum, corpus striatum, hippocampus, hypothalamus were dissected on ice and stored at -20°C until analyses. Glutamic acid decarboxylase (GAD), Choline acetyltransferase (CAT) and acetylcholinesterase (AChE) were assayed in the tissue homogenate of each brain region. Results showed that chronic paternal treatment of CP produced the following biochemical changes in the F_1 brain: (1) a marked decrease (30%, $P<0.03$) in cerebellar GAD activity but a significant increase (13%, $P<0.05$) in the striatal GAD activity of the F_1 females; (2) a marked decrease (34%, $P<0.03$) in cerebellar AChE but a significant increase (22%, $P<0.03$) in the hippocampal AChE activity of F_1 females and a 50% increase in hypothalamus AChE in the F_1 male rats.

Acute paternal treatment of CP affected brain enzyme activities of the F_1 offspring as follows: (1) It caused a 30% ($P<0.02$) decrease in hippocampal GAD activity in the F_1 males only. (2) It decreased cerebellar CAT activity significantly in both F_1 male and F_1 female offspring (26%, $P<0.009$; 26%, $P<0.03$ respectively); it caused a decrease in striatal and hypothalamus CAT activity only in the F_1 females (20%, $P<0.01$; 18% $P<0.03$) but an increase in hippocampal CAT activity in the F_1 females (14%, $P<0.05$); (3) The acute paternal treatment resulted in a 47% decrease in the cerebellar AChE activity in the male F_1 rats only whereas a 26% decrease in the hippocampal AChE activity in only the F_1 rats was observed.

These results indicate the ability of paternal exposure to a mutagenic chemical to induce brain enzymatic changes in their F_1 progeny. The extent of the induced changes in brain enzymes appears to be sensitive to the gender of the F_1 progeny.

299.15 PLASMA AMINO ACID LEVELS, BRAIN TRYPTOPHAN UPTAKE AND BRAIN SEROTONIN SYNTHESIS IN DIABETIC RATS. R.G. MacKenzie, R. Luboshitzky*, J.K. Goldman*, L.L. Bernardis, M.E. Trulson and J.H. Jacoby. V.A. Med. Center, SUNY, Buffalo, New York, 14215 and Department of Psychology, Princeton University, Princeton, New Jersey, 08540.

To determine the effects of diabetes on brain tryptophan (TRP) uptake and serotonin (5-HT) synthesis, male Sprague-Dawley rats received i.p. injections of either streptozotocin (SZ) 75mg/kg in citrate buffer pH 4.2 or buffer alone. The SZ-injected rats became diabetic as evidenced by polyphagia, polydipsia, polyuria and glucosuria. At 1 mo. post-treatment, diabetics (Ds) and controls (Cs) were injected i.v. with 100 μCi [^{3}H] TRP in 0.9% NaCl and groups of rats were killed 1, 2 and 3 hs post-injection. Plasma analysis showed that the Ds were hyperglycemic (D=466±12; C=105±3 mg%) and had vastly elevated branched-chain amino acid levels (VAL: D=706±74, C=132±11; ILEU: D=292±34, C=65±5; LEU: D=527±61, C=120±8 nmol/ml). Total TRP (bound + free) levels were low in Ds (D=41±2; C=81±3 nmol/ml) but free TRP levels did not differ (D=17±1; C=15±2 nmol/ml). In the brain, TRP was reduced by 38% in Ds (D=20±2; C=32±1 nmol/g) but 5-HT levels did not differ (D=2.71±0.04; C=2.81±0.06 nmol/g). As a relative measure of brain TRP uptake, the relative specific activity (RSA) (see Johnson and Dewey, JPET, 207, 140, 1978) of brain TRP SA/plasma TRP SA was determined for 1, 2 and 3 hs following injection of the [^{3}H] TRP tracer. Relative estimates of brain 5-HT synthesis were found by determining the RSA of brain 5-HT SA/brain TRP SA. These data are presented below:

	RELATIVE BRAIN UPTAKE BRAIN TRP SA/ PLAS TRP SA			RELATIVE 5-HT SYNTHESIS BRAIN 5-HT SA/BRAIN TRP SA		
t	1	2	3	1	2	3
D	.21±.02	.20±.02	.20±.03	6.4±0.3	7.7±0.6	7.5±0.3
C	.39±.03	.35±.02	.35±.03	3.4±0.2	5.9±0.3	5.4±0.3

We conclude that brain TRP levels are low in diabetic rats due to the high plasma levels of other neutral amino acids which can compete with TRP for transport across the blood brain barrier and that 5-HT synthesis is increased in diabetic brains to normalize 5-HT levels in the face of reduced substrate.

Supported by NIH Grants #5-F32 NS06014-02 and 1 R01 NS 12876-03

299.16 GLUTAMIC ACID DECARBOXYLASE (GAD) ACTIVITY IN CEREBRAL BLOOD VESSELS: CHARACTERISTICS AND KINETICS. Edith Hamel*, Diana N. Krause and Eugene Roberts, Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

γ-Aminobutyric acid (GABA), an inhibitory neurotransmitter in the mammalian CNS, appears to be involved in cerebrovascular function, and its synthesis has been demonstrated in cerebral blood vessels. This study was undertaken to characterize vascular GAD activity. Cerebral blood vessels from fresh bovine brains were cleanly dissected from the pia-arachnoid membranes. Microartery and capillary fractions were prepared from brain parenchyma according to Reinhard et al. (Science 206: 85-87, 1979). GAD activity in the above preparations was measured in the 27,750g supernatant of crude homogenates by a radiometric assay using ^{14}C-glutamic acid as the substrate. The ^{14}C-GABA formed was separated from unreacted ^{14}C-glutamic acid by chelation of the latter substance with copper and passage through an anion exchange column. GAD activity of the pial vessel fraction was found to be B_6-dependent and showed pH optima at 6.5, 7.2 and 8.0 with apparent Km values for glutamate of 7.59, 4.04 and 4.61 mM, respectively. The Km value for brain GAD was found to be 4.60 mM at pH 7.2. GAD activity in both pial vessels and brain parenchyma was inhibited totally by 10 mM aminooxyacetic acid, while 10 mM 3-mercaptopropionic acid (3-MCPA) inhibited 100% of the brain activity but only 58% of the vascular activity. In contrast, cysteine sulfinic acid (CSA) at 10 mM inhibited the vascular activity (49%) significantly more than the cerebral one (22%). GAD activity from rat brain and rat pial vessels was precipitated by specific anti-GAD (mouse brain) antiserum. For comparison, bovine mesenteric arteries also were assayed, and the GAD activity and pharmacology in these peripheral vessels were similar to that of the pial vessels. GAD activity was enriched in cerebral microvessels, the highest value being found in the capillary fraction, which suggests an endothelial localization. These data show that both cerebral and peripheral blood vessels can synthesize GABA. The vascular enzyme appears kinetically and immunologically similar to brain GAD, although it is affected differently by 3-MCPA and CSA. Studies are in progress to elucidate the significance of the findings. Supported in part by USPHS grant NS 12116 from the NINCDS. E. Hamel was supported by a fellowship from the Medical Research Council of Canada.

299.17 MONOCLONAL ANTIBODIES TO DROSOPHILA MELANOGASTER CHOLINE ACETYLTRANSFERASE REACT AT THE ENZYME CATALYTIC SITE. G.D. Crawford*, P.M. Salvaterra, and J.R. Slemmon*. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

We have recently reported the production of two monoclonal antibodies selective for Drosophila melanogaster choline acetyltransferase (ChAT; E.C. 2.3.1.6, Abstr. 81, Ann. Mtg. Am. Neurochem. Soc., 1981). These two antibodies were shown to directly inhibit the enzyme activity. The two cell lines were grown as ascites tumors in BALB/c mice and the IgG purified from fluids by adsorption and pH elution from a protein A Sepharose column. Scatchard analysis of enzyme inhibition curves using the purified antibodies revealed a single class of binding sites with respect to ChAT for each antibody. Affinities of 22.7 x 10^7 M^{-1} and 2.7 x 10^7 M^{-1} were determined for antibodies 1C8 and 1G4 respectively. We have used substrates and inhibitors of the ChAT enzyme to further elucidate the antigenic determinants involved in the immunological reaction. Choline does not protect the enzyme from inhibition by either antibody. Acetyl CoA, coenzyme A and adenosine diphosphate do, however, protect the enzyme from antibody inhibition. Under standard conditions protection from antibody inhibition is less for 1C8 antibody than for 1G4 consistent with the different antibody affinities for ChAT. Both antibodies thus appear to interact at or near the acetyl CoA binding site (ADP subsite) of the enzyme and not at the choline site. The observed interference of ADP for ChAT-antibody interaction has allowed the 1G4 (lower affinity) antibody to be used as an affinity resin for ChAT purification followed by elution with high concentrations of ADP. Quantitative aspects of the domain mapping and the use of 1G4 affinity resin for production of ChAT will be presented. (Supported by NS-12116).

299.18 MOLECULAR CHARACTERIZATION OF CHOLINE ACETYLTRANSFERASE FROM DROSOPHILA MELANOGASTER. J.R. Slemmon*, P.M. Salvaterra, and E. Roberts. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010. (SPON: J. Vaughn)

Choline acetyltransferase (EC 2.3.1.6), the enzyme that catalyzes the formation of the important neurotransmitter acetylcholine, was previously purified from Drosophila melanogaster in this laboratory. Subsequent studies have centered on the enzyme's molecular composition and evidence has been obtained that a major portion of it is made up of two polypeptide chains.

The polypeptide composition of the denatured enzyme, determined by polyacrylamide gel electrophoresis in SDS (PAGE-SDS, 10% acrylamide and 0.07% bis-acrylamide), showed a major protein band at 54K and a lighter band at 67K daltons. The identification of both of these bands as ChAT was accomplished in two ways. First, two-dimensional analysis of the iodinated tryptic peptides from each band indicated that they had very similar primary structures and therefore were related proteins. Secondly, immunoprecipitation of purified ChAT, with two different inactivating monoclonal antibodies to Drosophila ChAT, yielded both the 67K and 54K dalton PAGE-SDS protein bands. Both protein bands were associated with the enzyme and the molecular weight of the major component, under denaturing conditions, was 54K daltons.

The non-denatured enzyme showed only one peak of activity at 67K daltons on Sephacryl S-200 chromatography (at either pH 5.9 or 7.2). Velocity sedimentation of the native enzyme in a 5 to 20% sucrose gradient also showed a single activity peak at 5.2s consistent with a molecular weight of 69K daltons. PAGE-SDS analysis of the 67K dalton Sephacryl peak showed both a 67K dalton minor polypeptide and a 54K major polypeptide.

This discrepancy in the molecular weight of the native enzyme compared to the major polypeptides of the denatured enzyme was further investigated using PAGE-SDS at a higher acrylamide concentration (15% acrylamide, 0.1% bis-acrylamide). Under these conditions, two previously overlooked protein bands could be resolved at 13K and 14K daltons. Two-dimensional analysis of the iodinated tryptic peptides from these bands showed that the 13K dalton band had three peptides that were found in the 67K but not in the 54K dalton band. This result indicates that the 13K dalton band may have originated from the 67K dalton band. The loss of the smaller (13K dalton) polypeptide from the 67K dalton protein under denaturing conditions would be expected to generate the 54K dalton protein. Supported by NS12116.

299.19 SYNAPTOSOMAL TRYPTOPHAN UPTAKE MECHANISMS AND DEVELOPMENTAL-GENETIC VARIATION. James A. Diez. School of Biology, Georgia Institute of Technology, Atlanta, GA 30332.

Intraneuronal tryptophan (trp) concentrations appear to be significant in regulating serotonin synthesis, but is transport of trp across the neuronal membrane a regulated step? This work aims to clarify one issue about the mechanism of trp transport, and to demonstrate two different conditions where transport kinetics vary physiologically.

Synaptosomes (P_2) were prepared from whole mouse brain. The initial rate of trp accumulation was assayed by incubating P_2 with varying concentrations of ^{3}H-trp in 400 uL of HBSS for 60sec at 37°. Uptake was stopped by centrifugation after cold dilution.

When a wide range of trp concentrations (e.g., 10 uM to 5 mM) is used, a biphasic Lineweaver-Burk plot is obtained; this is often interpreted as demonstrating two uptake systems with high and low affinity (typical Km's of about 25 uM and 1 mM). Although the Km of the "low affinity system" is far above physiological levels, attempts to eliminate it by iteratively increasing the passive diffusion term do not really straighten the plot to a single high affinity uptake system. Experimental evidence for exchange diffusion was obtained by incubating pre-labelled P_2 with non-radioactive trp, but kinetic models combining exchange with one saturable uptake system did not explain the experimental data. However, an accumulation of trp greater than predicted by diffusion and a single high affinity uptake system could occur if trp is bound intracellularly. Evidence to support this hypothesis was obtained in washout experiments with trp-loaded P_2, and more directly by Sephadex G25 chromatography of pre-labelled/disrupted P_2: a significant peak of radioactive trp eluted with the void volume, clearly separated from the peak of free trp.

Physiological variation in high affinity trp uptake was found during postnatal development and in adults from several strains of mice. First, a method for storing frozen P_2 for several weeks before assaying trp uptake was developed and validated. Freezing did not affect Km; although it lowered Vmax by about 50%, differences between preparations were neither created nor obscured. For example, fresh P_2 from adult C57BL/6 and Swiss albino mice had Km's of 23 uM and Vmax= 1.87 and 1.43 nmol/hr/mg prot.; after storage, the Km's were 21 uM, and Vmax= 1.02 and 0.68. Other mouse strains showing significant differences in uptake kinetics were: C57BL/10, BALB, and C3H. In adult mice, the major strain differences were found in Vmax. The only large differences in the Km for trp uptake were found during the first 3 weeks of postnatal development; the affinity of the uptake system for trp was higher during the period of rapid brain maturation. Genetic differences in maximum uptake rates developed more slowly. (BNS 7905601)

299.20 THE MINIMUM MOLECULAR SIZE OF THE ACETYLCHOLINESTERASE FROM MANDUCA SEXTA. L.H. Silver and D.J. Prescott*. Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

Previous work has demonstrated that the central nervous system of the hawk moth Manduca sexta provides a rich source of "true" acetylcholinesterase (AchE)(EC 3.1.1.7). Optimal extraction of the enzyme was obtained with a non-ionic detergent (1% Triton X-100, 0.5MNaCl) when compared with other extraction procedures. Density gradient centrifugation of detergent extracted enzyme on 5-20% linear sucrose density gradients demonstrated that the enzyme sedimented as a single peak whose sedimentation coefficient was dependent upon the amount of enzyme layered on top of the gradient. When greater than 0.02 I.U. were applied to the gradient, a sedimentation coefficient of 8.6S (205,000 D) was obtained and extrapolation to zero units produced a minimum value of 5.7S (110,000 D). Enzyme extracted in either sodium phosphate buffer (10mM, pH 7.4) or buffer plus NaCl (1.0M) followed by velocity sedimentation in the absence of detergent demonstrated a significant amount of pelleted activity and a species with a mean value of 17.5S (600,000 D).

Detergent extracted enzyme also demonstrated a concentration dependent size in gel filtration experiments on Bio-Gel A-5m. When less than 0.3 I.U. in 0.5 ml was applied to a column of Bio-Gel A-5m (0.9 x 83 cm) a single peak of enzymatic activity eluted with a calculated molecular radius of 41.8 ± 2.7Å (113,000 D). When the sample contained 0.3 to 1.3 I.U., two peaks of enzymatic activity were observed with molecular radii of 41.8 ± 2.7Å and 79.3 ± 3.5Å (322,000 D). These values were unaffected by gel filtration in the presence of 1% alpha-methyl-mannoside suggesting that the enzyme did not interact with the gel matrix. Finally, a single enzymatic peak, which eluted in the void volume, was observed when extracts prepared in 1.0MNaCl were subjected to gel filtration.

These results suggest that the sedimentation and gel filtration pattern of the AchE isolated from Manduca sexta exhibit a marked dependence on the concentration of the enzyme. In the presence of Triton X-100, 0.5MNaCl, the enzyme may exist as a soluble aggregate, which may dissociate to an active form with a minimum molecular weight of approximately 110,000 D. This minimum molecular weight has been verified using both sucrose density gradient centrifugation and gel filtration.

299.21 THE INTERACTION OF DESIPRAMINE WITH NORADRENERGIC SYSTEMS IN RAT CEREBRAL CORTEX. M.W. Dudley*, B.W. Siegel*, R.C. Ursillo* and N.L. Wiech, Department of Pharmacology, Merrell Dow Pharmaceuticals Inc., Cincinnati, Ohio 45215.

Studies have demonstrated that chronic administration of low doses of desipramine (DMI) leads to adaptive processes which result in increased norepinephrine turnover and a down-regulation of beta receptors in the brain. Other studies have shown that DMI (10 mg/kg, b.i.d.) for 4 days also produces a marked reduction in beta receptors, whereas, norepinephrine turnover, as measured by whole brain levels of MHPG-SO_4, is decreased. Since it has been suggested that down-regulation of beta receptors is a compensatory response to increased synaptic levels of norepinephrine, it is difficult to reconcile these latter findings. Therefore, we sought to determine whether levels of DMI in the cortex bore any relationship to beta receptor down-regulation and whether norepinephrine turnover in the cortex might correlate with receptor down-regulation more than turnover as measured in the whole brain.

DMI was administered at concentrations previously shown to reduce beta receptors. The levels of DMI in the cortex were determined 24 hr after the last dose. There was no detectable DMI in cortex isolated from rats treated for 28 days with 5 mg/kg, DMI or 4 days with DMI 5 mg/kg plus yohimbine 2 mg/kg b.i.d. After treatment for four days with DMI 10 mg/kg b.i.d., the tissue level was 4.14 $\pm$ 0.1 μg/g, 24 hr after the last dose. Following a single 10 mg/kg dose, the maximum tissue level of DMI (7.28 $\pm$ 1.14 μg/g) was reached 1 hr later, but at this time there was no reduction in the number of beta receptors. Thus, there was no relationship between down-regulation and DMI levels in the cortex.

In contrast to the reported effect on whole brain MHPG-SO_4, we observed that a single 10 mg/kg dose of DMI produced a transient decrease of MHPG-SO_4 (at 1 hr) followed by an increase at 4 and 7 hours. On the fifth day of treatment with DMI 5 mg/kg, there was a similar initial decrease of MHPG-SO_4 levels with an increase at later hours.

Thus our studies show that acute DMI treatment does increase NE turnover in the cortex and that these changes might be responsible for the subsequent down-regulation of the beta receptors in this brain region.

299.22 THE ROLE OF CITRATE AND ATP-CITRATE LYASE IN SYNTHESIS OF CYTOSOLIC ACETYL-CoA IN SYNAPTOSOMES OF MATURING BRAIN. A. Szutowicz*, J. Kabata* and H. Bielarczyk*. (SPON: I. Crawford). Dept. of Biochem., Univ. of Texas Health Sci. Ctr., and VA Medical Center, 4500 S. Lancaster Rd., Dallas, TX 75235 and Dept. of Clin. Biochem., Med. Acad., 80-211 Gdansk, Poland.

Citrate is known to be an important source of acetyl-CoA for lipid and acetylcholine synthesis in rat brain. However, the mechanisms regulating the supply of acetyl units through this pathway remain obscure. Therefore, the aim of these studies was to investigate the changes in endogenous citrate metabolism during brain development when marked changes in both lipid and acetylcholine synthesis take place.

The activities of pyruvate dehydrogenase and citrate synthase in rat brain synaptosomes increased about three times until the fourth month of life. However, pyruvate utilization increased only by 60% from 4.8 to 7.8 nmol/min/mg of protein. Activity of ATP-citrate lyase decreased from 9.2 to 6.9 nmol/min/mg of protein. Also the rate of citrate accumulation in synaptosomes of adult rat brain was less than half of that found in 1 or 10 day old pups (1.15 and 2.90 nmol/min/mg of protein, respectively). 5 mM ATP-Mg decreased (50%) and 1 mM (-)hydroxycitrate increased (two times) citrate accumulation in synaptosomes at any age. However, absolute values of metabolic flux of citrate to acetyl-CoA through ATP-citrate lyase step decreased from 1.40 to 0.49 nmol/min/mg of protein during brain maturation. The addition of 0.25 mM 3-bromopyruvate decreased pyruvate consumption and citrate accumulation by 70% but completely blocked citrate utilization by ATP-citrate lyase in every age group. These data indicate that production of acetyl-CoA in synaptosol may be regulated either by adaptative age dependent changes in the permeability of mitochondrial membrane to citrate or by the inhibition of intramitochondrial synthesis of acetyl-CoA.

Metabolic parameters of cerebellar synaptosomes were the same as cerebral ones. Therefore, the rates of metabolic fluxes of pyruvate to cytosolic citrate and acetyl-CoA are presumably the same in both cholinergic and noncholinergic nerve endings. On the other hand, ATP-citrate lyase activity in whole synaptosomal fractions was about 10 times and that in cholinergic ones over 100 times higher than the flux of citrate to acetyl-CoA in the synaptosomal cytosol. Assuming that the substrates for ATP-citrate layse (CoA, ATP, citrate) are not limiting then it is possible that citrate transport may be a regulatory step in acetyl-CoA formation in synaptosol. (This work supported by the Polish Academy of Sciences Project No. 10.4.2).

300.1 CO_2 SENSITIVE NEURONS IN THE CAT PONTINE RETICULAR FORMATION. M. E. Levine,* S. M. Carlton,* D. P. Becker, J. D. Miller* and R. L. Hayes* (SPON: L. Malis). Div. of Neurosurgery, Med. Coll. of Virginia, Richmond, VA 23298.

Previous studies utilizing stimulation and ablation techniques suggest a role for the region of the locus coeruleus (LC) in the modulation of cerebrovascular responses to alterations in arterial CO_2 tensions. The present study examined whether or not neurons in the region of the LC could encode changes in $PaCO_2$.

Subjects were 17 mechanically ventilated cats, maintained under N_2O anesthesia. $PaCO_2$ was manipulated through a range of normocapnea, hypocapnea, and hypercapnea by varying the CO_2 content of the inspired gas mixture. Spontaneous single unit firing rates were monitored prior to, during, and after $PaCO_2$ alterations. An additional 5 cats underwent bilateral extracranial high cervical vagotomies prior to recording brain stem activity.

Three types of neuronal responses were seen: 1) increase in firing rate to hypercapnea and/or decrease in firing rate to hypocapnea, n=16; 2) decrease in firing rate to hypercapnea and/or increase in firing rate to hypocapnea, n=14; 3) no change in firing rate, n=15. For neurons (n=15) recorded from vagotomized animals, the distribution of response types was similar. Neuronal responses were unrelated to systemic cardiovascular changes. Cells which responded to manipulations of $PaCO_2$ clustered anatomically at the level of the principal nucleus of LC. Type 1 responses were seen in the more medial portion of the LC region. Type 2 responses occurred more laterally in the parabrachial region.

These data are consistent with the hypothesis that neurons in the region of the LC may be involved in cerebrovascular responses to changes in $PaCO_2$. Also, it appears that information from peripheral chemoreceptor afferents is not necessary for the encoding of arterial CO_2 tensions by neurons in the vicinity of LC in the cat. Supported by NIH Grant # NS 12587.

300.2 DYNAMIC RESPONSES OF CAT PULMONARY STRETCH RECEPTORS TO PRESSURE CHANGES DURING SPONTANEOUS BREATHING. C.K. Knox and M. Passatore*, Lab. of Neurophysiol., Univ. of Minn., Minneapolis, MN 55455.

The discharges of single slowly adapting pulmonary stretch receptors were recorded from small filaments of the cervical vagus nerves of 24 anesthetized, tracheotomized cats while the animals breathed spontaneously on a servo-controlled respirator. Data collected included conduction velocity and volume threshold of each unit, and the changes in firing rate to step increases in tracheal pressure superimposed on normal breathing movements. Pleural pressure and lung volume were also recorded to measure total dynamic compliance of the lungs and chest wall during the inflations.

Conduction velocities ranged from 14 to 70 m/s (average for 180 units = 35 m/s) and were uncorrelated with either volume threshold or dynamic characteristics of the unit. Thus, fiber size is not a determinant of discharge pattern. Dynamic response data were obtained from 29 receptors which had a spontaneous discharge at resting lung volume and which could be recorded long enough to complete the analysis. A series of step inflation pressures of increasing size were applied during either inspiration or expiration, and the response of the unit was computed as the change in discharge rate from that of a spontaneous control breath. Both the unit response and input pressure change were Fourier transformed to obtain the frequency response characteristic of the receptor (Bode plot). The dynamic characteristics of the stretch receptor were found to differ substantially during the two phases of the respiratory cycle: During expiration, static sensitivity is proportional to transmural pressure, while velocity sensitivity increases nonlinearly with pressure step size. During inspiration, static sensitivity decreases with time into inspiration, some units accomodating completely to the added inflation. Velocity sensitivity is, again, nonlinearly related to step size.

The results demonstrate that both the static sensitivity and adaptation properties of pulmonary stretch receptors are highly dependent on the size and time of application of lung inflation during the respiratory cycle. The difference in dynamic characteristics between the inspiratory and expiratory phases suggests that the dynamic compliance of the airways containing the receptors becomes progressively less with time during inspiration.

300.3 INTERACTIONS AMONG MEDULLARY INSPIRATORY(I) NEURONS. Jack L. Feldman and Dexter F. Speck*, Departments of Physiology and Anesthesia, Northwestern University, Chicago, Il 60611

Interactions among medullary I neurons were studied by correlating the activity of simultaneously recorded pairs of neurons in chloralose-urethane, gallamine paralyzed, thoracotomized cats artificially ventilated by a cycle-triggered pump. Two microelectrodes, mounted on a custom fabricated arc that allowed independent placement of each electrode along with precise determination of interelectrode distance (±50 um), were inserted into the regions of I modulated unit activity in the ventrolateral nucleus of tractus solitarius(NTS) and/or nucleus retroambigualis(NRA). Contralateral phrenic and ipsilateral recurrent laryngeal nerve activities were also recorded. The results of our preliminary analyses are indicated in the TABLE below [Peaks(troughs) represent the presence of bins with significantly increased(decreased) counts within 5 msec of Ø lag]. It is important to note that: 1) Over 25% (63/239) of the unit pairs showed some evidence of short-latency interaction; since extracellular spike-spike crosscorrelations tend to indicate the presence of those interactions with the largest and fastest rising PSPs, but not those with small or slowly rising PSPs, these results suggest extensive interactions among medullary I neurons. 2) All troughs occurred on one side of Ø lag only, which suggests an inhibitory projection from one neuron to the other in a given pair; this is the first evidence of inhibition between identified pairs of I neurons. (Supported by NIH Grants HL-00554, HL-23820 and NIMH Grant T32-MH16097.)

300.4 RESPONSES OF PHRENIC (Phr) AND RECURRENT LARYNGEAL (RL) NERVES TO MICROSTIMULATION AND MULTIPLE MICROLESIONS IN THE VENTRAL RESPIRATORY GROUP (VRG). Dexter F. Speck* and Jack L. Feldman (Spon. R.C. Rogers). Departments of Physiology and Anesthesia, Northwestern University, Chicago, Il 60611.

The role of VRG neurons in the region of nucleus retroambigualis in the medulla in the generation of respiratory pattern was investigated by examining the effects of microstimulation and multiple microlesions on ipsilateral RL and ipsi- and contra-lateral Phr nerve activities. These experiments were conducted in chloralose-urethane anesthetized, thoractomized, gallamine paralyzed and artificially ventilated cats. In almost all areas of the VRG where concentrated respiratory neuronal activity was recorded from tungsten microelectrodes, single shocks (10-25 uA, 80 uS) produced short-latency (4-8 mS) ipsi- and contra-lateral Phr inhibition lasting 5-25 mS followed by a brief post-inhibitory excitation. A similar pattern of response with a shorter onset latency was also seen in the discharge of inspiratory neurons in the region of the ventrolateral nucleus of tractus solitarius (vlNTS). Single shocks also elicited a short latency (3-8 mS) RL excitation lasting 4-12 mS which was followed by a period of inhibition. At some VRG sites located primarily within 0-2 mm rostral to the obex, low frequency (10-30 Hz) respiratory cycle triggered stimulation produced premature inspiratory termination and/or expiratory prolongation. Subsequent to recording spontaneous activity and the response to microstimulation at each VRG site, a 300-700 um microlesion was made by passing 10-20 uA for 30-60 seconds. After making a lesion, the electrode was removed from the brainstem and reinserted at another site within 500 um. We rarely noticed any transient or long-term changes in rhythm of Phr discharge subsequent to lesion, even after numerous previous lesions at adjacent sites; this is in contrast to the marked transient and sometimes long-term changes in Phr activity that follow small lesions in the nucleus parabrachialis medialis. Multiple microlesions in the rostal most part of the VRG near the retrofacial nucleus ("Botzinger Complex") did not alter Phr discharge [2 cats]; neither did extensive lesioning of the ipsilateral VRG [5 cats] nor extensive bilateral lesioning [2 cats]. In one cat, extensive bilateral lesions in both the VRG and vlNTS failed to significantly alter Phr respiratory patterns. These results suggest that most of the respiratory neurons within the VRG do not play a significant role, if at all, in the generation of respiratory rhythm; rather that their major function is to influence to development of activity in the inspiratory or expiratory phase of a given respiratory cycle. (Supported by NIH Grants HL-00554, HL-23820 and NIMH Grant TG-MH16097.)

300.5 EFFECT OF 5,7-DIHYDROXYTRYPTAMINE (5,7-7HT) ON BRAIN THYROTROPIN RELEASING HORMONE (TRH) AND THE RESPIRATORY RESPONSE TO TRH.
G. R. Breese, C. D. Kilts, K. Beaumont and R. A. Mueller.
Neuropharmacology Laboratory, BSRC, University of North Carolina, Chapel Hill, NC 27514

Previously we have shown that treatment of 3 day old rats with 5,7-DHT plus desmethylimipramine or pargyline severely reduces CNS serotonin without altering dopamine or norepinephrine content. The present experiments were designed to explore the effect of similar treatment on brain TRH and the control of respiration.

In 3 day old rats administration of 50 µg 5,7-DHT intracisternally produced a significant decrease in extrahypothalamic immunoreactive TRH, while not changing hypothalamic peptide content. Respiratory frequency was significantly decreased in treated animals when measured at 3-5 days intervals after treatment.

When lightly anesthetized with halothane in oxygen and placed in a plethysmograph as adults 5,7-DHT treated rats still maintained a reduced minute ventilation as a result of a reduction in respiratory frequency. Moreover, the mechanical response to CO_2 exposure indicated a decreased sensitivity to CO_2. Vagotomy in control rats did not alter basal $PaCO_2$, whereas in 5,7-DHT treated CO_2 sensitivity appeared reduced further. Animals given TRH 1-30 µg i.c.v. evidenced an increase in minute ventilation. The relative increase in mechanical response to TRH in 5,7-DHT treated rats was greater than that of control animals.

The decreased ventilation of 5,7-DHT treated rats, and the enhanced responsiveness of these rats to TRH-induced respiratory stimulation suggest that TRH related peptides may play a role in the central integration of respiration.

Supported by USPHS grant AA 02334; and HD 03110.

300.6 CENTRAL PROJECTION OF SINGLE SLOWLY ADAPTING PULMONARY STRETCH RECEPTORS (PSRs) TO THE REGION OF THE TRACTUS SOLITARIUS (TS) AS DETERMINED BY SPIKE TRIGGERED AVERAGING (STA).
A.J. Berger and D.B. Averill*. Dept. Physiology and Biophysics, University of Washington, Seattle, WA 98195.

The central projection of single PSRs to the region of the TS is not known. When HRP was injected into the right main bronchus, HRP reaction product was distributed primarily lateral and to a lesser extent dorsomedial to the TS (Kalia and Mesulam, J. Comp. Neurol. 193:467, 1980). We wished to determine which regions received terminations of single PSRs.

The central terminations of ten PSRs were mapped utilizing STA of extracellular fields (Munson and Sypert, J. Physiol. 296:315, 1979). The extracellular activity of single PSRs was recorded from the nodose ganglion in 10 anesthetized, paralyzed, artificially ventilated cats. The receptor endings were located in either the right lung or its main airways. PSRs were classified based upon axonal conduction velocities and adaptation indices. Medullary extracellular potentials were recorded with a low impedance tungsten electrode. The occurrence of a spike generated in the nodose ganglion triggered an averaging computer. The resultant average of the medullary field potentials was attributable to the terminations of the single PSR. Multiple tracts in a mediolateral plane were made at 0, +1, and +2 mm rostral to obex. Small lesions were placed in the medulla to locate recording sites; subsequently, medullary tissue was excised for histology and electrode track reconstruction.

A brief diphasic wave was presumed indicative of the presynaptic terminal potential. In the case of 4 PSRs this wave form preceded a longer lasting negative potential which has been ascribed to the postsynaptic focal synaptic potential. These focal potentials were seen at +1 mm rostral to obex. In this plane focal potentials were seen dorsomedial (2 PSRs) and ventrolateral (2 PSRs) to the TS. The maximum amplitudes of terminal potentials at +1 mm rostral to obex were recorded dorsomedial (4 PSRs), dorsolateral (4 PSRs), and ventrolateral (2 PSRs) to TS.

This is the first electrophysiologic evidence that single PSRs project to several subnuclei of the TS and not merely to the dorsal respiratory group associated with the ventrolateral nucleus. In addition, the magnitude of the central projection of PSRs is greater at +1 mm rostral to the obex than at 0 or +2 mm rostral of obex. (Supported by USPHS grant NS 14847 and RCDA NS 00378).

300.7 PROJECTIONS TO AND FROM THE EXPIRATORY NEURONAL POPULATION OF THE CAUDAL MEDULLA IN THE CAT.
M. Kalia, D. Sommer* and M.I. Cohen. Dept. Physiol., Hahnemann Med. Col., Phila., PA 19102 and Depts. of Physiol. and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Projections to and from the expiratory (E) neurons of the ventral respiratory group (VRG) in the caudal medulla were studied following the iontophoretic application of horseradish peroxidase (HRP) through a microelectrode (4 µ tip diameter) placed in a region where abundant E neuron activity had been recorded by the same electrode. Following a survival time of 48-52 hours, the brain stem, nodose ganglia and spinal cord were processed for HRP reaction product using the tetramethyl benzidine method in order to visualize both anterogradely and retrogradely transported HRP. Injection sites, 250µ to 500µ in diameter, were located in the caudal medulla in the region of the nucleus retroambigualis - nRA, (2.3 - 2.9 mm caudal to the obex, 2.5 -3.2 mm lateral to midline, 2.3 -3.2 mm below the dorsal surface). Retrogradely labeled neurons were found in: (a) the ipsi- and contralateral ventrolateral nucleus of the tractus solitarius extending 1.0-2.5 mm rostral to the obex, corresponding to the dorsal respiratory group (DRG); (b) the ipsi- and contralateral regions of the rostral medulla (3.0-4.5 mm rostral to the obex) located in the vicinity of the nucleus ambiguus, corresponding to the rostral portion of the VRG where abundant respiratory activity has been found. A few labeled neurons were found scattered in the reticular formation between the DRG and the rostral VRG. No labeled neurons were found in the contralateral nRA at the level of the injection site. HRP labeled fibers could be followed from the injection site to the contralateral ventral funiculus. These findings confirm the localization,by earlier antidromic mapping studies, of the projections to and from E neurons in the nRA. In addition our study demonstrates the bilateral efferent projection from the rostral VRG to the nRA. No labeling was found in the nodose ganglion indicating that vagal afferents do not project directly to the nRA.

300.8 RESPIRATORY INHIBITION ASSOCIATED WITH TRANSIENT HYPERTENSION DURING SLEEP AND WAKING IN UNRESTRAINED CATS.
R.B. Trelease*, G.C. Sieck, and R.M. Harper (SPON: R.D. Lindsay). Anatomy Dept. and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Numerous studies, primarily in anesthetized, non-intact animal preparations, have demonstrated that transient hypertension produces respiratory inhibition and apnea via a sino-aortic baroreceptor reflex. In order to examine the influence of induced blood pressure elevation in an unanesthetized preparation, 5 adult cats were instrumented for chronic recording of sensorimotor and hippocampal EEG, EOG, EKG, crural diaphragm EMG, and lateral geniculate nucleus activity. Catheters were advanced into the aorta and vena cava from the femoral vessels. Electrode leads and catheters were terminated at the top of the head, allowing convenient connection to the recording apparatus. All cats were allowed at least one week of post-surgical recovery before recording sessions were initiated. At the time of recording, each cat was fitted with a piezo-electric strain gauge for measuring chest wall movements. Electrical and catheter connections were made via a cable which allowed free movement within a shielded recording chamber. Aortic pressure was recorded from the arterial catheter. Small injections of phenylephrine (typical dose: 30 ug phenylephrine in 0.3 ml isotonic saline over 3 sec) were administered via the caval catheter with a sage syringe pump. Transient hypertension was thus produced during quiet wakefulness (AW), quiet sleep (QS), and rapid eye-movement (REM) sleep. Physiological signals and a time code were recorded on polygraph paper and on magnetic tape. Behavioral observations were entered on the paper record. Intervals between the onset of inspirations were derived by measuring the time between the onset of chest wall expansions and by measuring the time between onsets of diaphragmatic EMG activity. Transient hypertension produced measurable slowing of respiratory rate during all states in all cats. The most pronounced slowing, including 5-10 second apneas, occurred following pressor injections which evoked arousals from QS. Diaphragmatic EMG amplitude and burst duration also transiently decreased during some periods of respiratory slowing. Such a decline in diaphragmatic activity together with a reduction in inspiratory duration suggests that tidal volume may be decreased. Furthermore, a decrease in respiratory rate and in inspiratory duration may indicate a delay in the onset of inspiration. This pattern of respiratory inhibition with transient blood pressure elevation may be an important factor in the pathophysiology of sleep apnea syndromes.

300.9 EFFECTS OF A ROCKING BED ON BREATHING DURING SLEEP IN KITTENS. D.J. McGinty, M.S. London*, M. Stevenson*. Veterans Administration Medical Center, Sepulveda, CA, UCLA School of Medicine, Los Angeles, CA.

Disorders in breathing associated with sleep may result, in part, from deficiency in a brain stem arousal system. The medial reticular formation (RF) has been associated both with arousal mechanisms and with facilitation of breathing and is a possible substrate of the arousal effect on breathing. The vestibular system is known to have a widespread projection to medial RF neurons and was found, in acute studies, to modulate breathing. The present study investigated the effect of vestibular stimulation produced by a rocking bed on breathing and RF unit discharge during sleep in kittens.

Six 20 to 30 day old kittens were surgically prepared for chronic recording of standard sleep parameters and diaphragmatic EMG activity. Integrated diaphragmatic EMG activity was measured in both NREM and REM sleep during baseline and rocking at several frequencies. Three additional kittens were prepared with traecheal fistulas allowing insertion of a tracheal tube for pneumotachographic measurement of tidal volume. The "rocking bed" consisted of a suspended cage with a pendulum length of 40 to 60 cm and a lateral motion of 10 to 20 cm driven by a crank on a variable-speed motor.

Rocking produced a facilitation of diaphragmatic EMG activity in both NREM and REM in 5 of 6 kittens. Maximum facilitation was achieved at rocking frequencies of 0.5 and 0.55 times the baseline respiratory rate, with reduced or no facilitation at higher and lower frequencies. In kittens with fistulas minute volume was increased by 10-18% in NREM and REM during rocking compared to baseline.

Additional kittens were prepared for chronic microwire unit recording in the pontine RF. Cells with tonic activity showed modulation by rocking in NREM and tonic REM, but not phasic REM.

We conclude that vestibular stimulation produced by a rocking bed is a effective stimulus to breathing during sleep in kittens. We speculate that mechanism involves activation of medial RF neurons which have connections to brain stem respiratory neurons. Optimal facilitation occurred when the frequency of maximum tilt and acceleration (2 per rocking cycle) was equal to or slightly above the normal NREM breathing rate.

300.10 HISTOCHEMICAL PROPERTIES OF THE CAT DIAPHRAGM: DIFFERENCES BETWEEN ABDOMINAL AND THORACIC SURFACES. G. C. Sieck, R. R. Roy, R. M. Harper and V. R. Edgerton. Dept. of Anatomy, Neuromotor Control Lab. and Brain Research Institute, UCLA, Los Angeles, CA 90024.

The mammalian diaphragm is composed of anatomically distinct areas (sternal, costal and crural), reportedly varying in proportions of histochemical fiber types. Such regional variations in fiber type composition suggest possible differences in motor activation and function between diaphragmatic areas. The present study compared the fiber type proportions between the abdominal and thoracic surfaces in each part of the diaphragm. Diaphragms of 3 cats (2.5-4.0 kg) were excised and laid flat on moistened paper. 5 x 10 mm segments of muscle were cut from the sternal, right and left costal and right and left crural areas. After quick freezing in liquid nitrogen and isopentane, fiber types were categorized as fast twitch oxidative glycolytic (FOG), fast twitch glycolytic (FG) or slow twitch oxidative (SO) using myofibrillar ATPase, reduced nicotinamide adenine dinucleotide diophorase and α-glycerophosphate dehydrogenase staining procedures. Populations of 100 muscle fibers were sampled from the thoracic and abdominal surfaces of each region of the diaphragm.

Within each area of the diaphragm, the most apparent differences in fiber type composition occur between the abdominal vs. thoracic surface (abdominal-40.6%+7.3 fast (FG+FOG) vs. 59.4%+7.3 slow (SO); thoracic-70.5%+4.97 fast vs. 29.5%+3.8 slow). Thus, there was a gradation in the proportions of fiber types from predominantly fast fibers on the thoracic surface to predominantly slow fibers on the abdominal surface. In the center of the muscle, fiber type proportions were mixed. Unlike previous reports, there was little variation in fiber type composition between different diaphragmatic areas (proportions of fast fibers ranging from 34.7% to 53.0% on the abdominal surface and 63.0% to 75.3% on the thoracic surface). Variations in fiber type proportions between abdominal and thoracic sides suggest possible differences in the order of activation of motor units on each side. Previous studies have indicated that SO motor units in the diaphragm are recruited first during inspiration. The increased number of SO units on the abdominal side of the diaphragm suggests that initial activation of this side is important in inspiratory efforts. Motor units in the crura have been found to discharge continuously. Low threshold motor units (eg. SO units) firing continuously may be necessary to oppose the action of negative intrapleural pressure on the diaphragm. Delayed activation of fast-twitch motor units on the thoracic side of the diaphragm may facilitate this muscle's downward excursion during inspiration because of the higher force developed by these motor units. Supported by NIH grant HL 22418-04 and AHA Research Fellowship Award AHA-GLAA 659 to G.C.S.

300.11 ARE AMINO-ACID TRANSMITTERS IMPLICATED IN THE CENTRAL GENERATION OF THE RESPIRATORY RHYTHM ? AN IONTOPHORETIC STUDY OF MEDULLARY NEURONS. M. Denavit-Saubié, J. Champagnat and M.P. Surun (SPON : J.V. Passonneau). Laboratoire de Physiologie Nerveuse, CNRS, 91190 Gif-sur-Yvette, France.

Respiratory neurons located in the cat medulla present a rhythmic pattern of discharge in relation to the diaphragmatic activity. In these neurones bursts of spikes are spontaneously repeated and thus can be studied without artifical stimulation. The rhythmicity of these neurones arises from the periodic activity of reciprocal inhibitions and mutual excitatory connexions.

The pharmacology of these synapses was studied at the unitary level using microiontophoresis and pressure applications utilizing a mutibarrelled micropipette. Neurones recorded extracellularly in the anaesthetized bivagotomized cat were located histologically in the ventrolateral nucleus of the tractus solitarius and in the vicinity of the ambiguus nucleus. Inspiratory neurones were characterized by their discharge frequency which progressively increased during inspiration and disappered during expiration. All the neurons were sensitive to excitatory (L-Glu) and inhibitory (Gly, GABA) amino-acids.

Neuronal inhibitions which occur during expiration were specified using antagonists of inhibitory amino-acids. GABA and muscimol-induced inhibitions were blocked by bicuculline or picrotoxine, while, Gly, β-Ala or Taurine-induced inhibitions were selectively susceptible to strychnine. Two pharmacologically different inhibitions were found to be involved during expiration. 1) Strychnine reduced inhibitions that stop inspiratory discharge at the beginning of expiration. 2) Bicuculline or picrotoxine were active on inhibitions that maintain a low neuronal excitability throughout expiration. It can be concluded from these experiments that both glycine-like and GABA-like transmitters act complementarily to trigger and control the expiratory phase.

Neuronal excitations which occur during inspiration were reduced by local application of opiates and opioid peptides. These reductions of inspiratory activities were found to be antagonized by naloxone. Similarly L-glutamate induced neuronal excitations were stereospecifically reduced by opioids application. It can be presumed that transmitters involved in respiration related excitations, like L-Glu effects, are susceptible to modulation by endogenous peptides (Supported by CNRS grant n° 3586).

400 INTRACELLULAR PROTEIN KINASE INJECTION SIMULATES BIOPHYSICAL EFFECTS OF ASSOCIATIVE LEARNING ON HERMISSENDA PHOTORECEPTORS. J. Acosta-Urquidi, D. L. Alkon, J. Olds*, J. T. Neary, E. Zebley*, and G. Kuzma*. Lab. of Biophysics, NINCDS-NIH, Marine Biological Lab., Woods Hole, MA 02543.

Primary membrane changes (increased input resistance and enhanced depolarization following a light step) intrinsic to the Type B photoreceptors of the eye of the nudibranch mollusc Hermissenda crassicornis were observed to persist and to parallel behavioral changes on days following conditioning intact animals with paired light and rotation but not randomized stimuli (Crow and Alkon, Science 209: 412, 1980; West, Barnes and Alkon, Biophys. J., 33:93a, 1981). Changes in specific phosphoprotein bands (20,000 and 23,000 daltons) have also been detected in the eyes following acquisition of this long-term behavioral change (Neary, Crow and Alkon, Neurosci. 6:591, 1980). As a first test of the hypothesis that the observed changes in Type B cell membrane properties are due to changes of protein phosphorylation, protein kinase was injected into single axotomized Type B cells which were without impulses or synapses. Iontophoretic injection (-0.3 -0.9 nA, 30-60 sec) of the catalytic subunit of fresh protein kinase (CPK, bovine heart, Sigma, 1.38 units/µl in a carrier solution containing 0.95 M KAc and .05 M Tris buffer, pH 9.8) into Type B cell somata caused an increased input resistance (decreased slope conductance) compared to pre-injection values of 53% ± 2.9 SEM ($p<.005$, N=7), measured with negative pulses (0.1, 0.2, 0.3 nA, 400 msec) and of 29.2% ± 3.5 ($p<.01$, N=6) for positive pulses. Transient hyperpolarization (2-8 mV) followed CPK injection in 16/20 cells. CPK injection also enhanced the magnitude (240% ± 33, $p<.005$, N=6) of the long-lasting depolarization (LLD) (measured 30 sec after light off) which follows a 30 sec light step (10^4 ergs/cm^2-sec). Identical control iontophoretic injections of the carrier solution alone, inactive (>2-3 days old) CPK solutions, heat-inactivated CPK solutions or KAc did not affect input resistance and LLD (N=15). Bath application of 8-PCPT cAMP and 8 BT cAMP (5×10^{-4}M) also enhanced the LLD (105%, 9/9 cells, $p<.005$). The 8-PCPT cAMP (4/4 cells) also caused a clear increase of frequency and amplitude of the quantal voltage fluctuations known as "bumps". These results suggest that the observed phosphorylation changes provide a biochemical step for the production of the biophysical changes observed in the Type B cells during associative learning of Hermissenda. A possible causal sequence for this process might consist of (1) repeated stimulus pairing, (2) cumulative membrane depolarization of the Type B cell, (3) increased cyclic-AMP, (4) increased protein kinase activity, (5) increased protein phosphorylation, (6) decreased dark membrane G_K, (7) enhanced LLD response and (8) reduced positive phototaxis.

401 ^{3}H -ISOGUVACINE AS A MARKER FOR GABA NEURONS IN THE RETINA. E. Agardh* and B. Ehinger. Department of ophthalmology, University of Lund, Lund, Sweden.

Retinas from rabbit, goldfish and guinea-pig were exposed to ^{3}H -GABA, ^{3}H -muscimol, ^{3}H -nipecotic acid and ^{3}H -isoguvacine either by intravitreal injection in vivo or by incubations in a balanced salt solution and the distribution of radioactivity was then studied with autoradiography. All substances labelled a similar set of presumed amacrine cells. Incubating at 0°C, in 10^{-3}M ouabain, or in 10^{-3}M GABA inhibited the labelling by ^{3}H -muscimol whereas bicuculline 10^{-4}M, and glycine 10^{-3}M were less efficient as blockers. The result is interpreted as a neuronal uptake of ^{3}H -muscimol rather than as a GABA receptor binding. All the substances except ^{3}H -isoguvacine also labelled glia to such a degree that neuronal labelling was often disguised in rabbits and goldfish. Glial labelling by muscimol was less pronounced in guinea-pig. ^{3}H -isoguvacine gave a strong labelling of cells with the distribution of GABA neurons and only little glial labelling. ^{3}H -isoguvacine is actively accumulated by the retina and is releasable with 10 uM K^+.

402 DIVALENT IONS REGULATE ^{3}H-SPIROPERIDOL BINDING IN HUMAN PREFRONTAL CORTEX: DESENSITIZATION OF K_D 0.2 nM SITES DEPENDENT ON PRESENCE OF DIVALENT ION AND TEMPERATURE. A.C. Andorn*, J.J. Ondrejka*, L.H. Matt*, J.D. Reimnitz*, (SPON: J. Brodkey). Dept. of Psychiatry and Div. Hum. Genetics, Case Western Reserve Univ. Schl. of Med., Cleve. OH 44106.

^{3}H-Spiroperidol binds specifically to human postmortem prefrontal cortex. The association of the ^{3}H-ligand to the binding site at 37°C is not classical, in that an initial steady state is reached by 4 min. followed by a loss in specific binding (>30%) until a final steady state is reached at 50 +/- 10 min. The loss in binding appears related to a 3-fold decrease in the B_{max} of a single set of sites K_D 0.2 nM, between 4 and 60 min. The loss of binding over time is most rapid in the presence of divalent ion $Ca^{++} > Mg^{++} > Ni^{++}$. The loss of binding over time is also seen in the presence of monovalent ion, but both the rate and the % loss are reduced, as compared to divalent ions. The absoluted amount of specific binding at the initial steady state is greater in the presence of monovalent rather than divalent ion. Saturation analyses confirm these findings, showing that the increase in binding observed is related to an increase (2-fold) in the B_{max} of the sites K_D 0.2 nM at the initial steady state in the presence of monovalent as compared to divalent ion. Taken together, these data suggest that in the presence of divalent ion 50 % or more of the sites are already desensitized by the initial steady state (4 min), while in the presence of monovalent ion substantially less of these are desensitized. At 25°C, association studies are mroe classical, with a single steady state apparently reached by 20 min. and only a 10% loss in binding occurring between 20 and 60 min. The dependence of the rate of desensitization upon divalent ion and temperature, suggests that this event may be, or may be coupled to, an enzymatic event.

403 PATTERNS OF CONNECTIVITY AND SYNAPTIC STRENGTH IN CELLS OF THE SIXTH ABDOMINAL GANGLION POST-SYNAPTIC TO THE ABDOMINAL STRETCH RECEPTOR NEURONS OF THE CRAYFISH. Michael Bastiani and Brian Mulloney. Dept. of Zoology, Univ. of Calif. at Davis, Davis, CA 95616.

The SR neurons from all abdominal segments send axons into the ventral nerve cord and then posteriorly to the last (sixth) ganglion. The ipsilateral and contralateral SR neurons associated with abdominal ganglia one through four were isolated and selectively stimulated to determine the pattern of connectivity and synaptic strength between the SR neurons and cells in the sixth ganglion. A posterior to anterior gradient of connectivity and synaptic strength was discovered. For example, approximately 70% of the cells (N=100) post-synaptic to the SR neurons received EPSPs (mean=.35 mv) from the ipsilateral SR neurons of the fourth abdominal ganglion, while only 30% of the cells received EPSPs (mean=.11 mv) from the ipsilateral SR neurons of the first abdominal ganglion. In addition, connectivity and synaptic strength was greater on the ipsilateral side for any abdominal ganglion, e.g., the contralateral SR neurons of the fourth ganglion made connections with 43% of the post-synaptic cells (mean=.18 mv). Finally, a small minority of cells (4%) post-synaptic to the SR neurons exhibited the opposite pattern of connectivity and synaptic strength.

Cells exhibiting the normal pattern of connectivity and synaptic strength were identified as motor neurons and projection interneurons. A single cell with a reverse gradient in connectivity and synaptic strength was identified as a local interneuron.

It is proposed that the sequence of the SR neurons ingrowth into the sixth abdominal ganglion during development (the nearer SR neurons are assumed to arrive in the sixth ganglion earlier) and the time of maturation of the post-synaptic cells (motor neurons are assumed to mature earlier than local interneurons) can account for the patterns of connectivity and synaptic strength observed in the cells post-synaptic to the SR neurons.

404 PROPERTIES OF MOTOR UNITS IN DYSTROPHIC MOUSE EDL. D.S. Bateson* and D.J. Parry* (Spon. T. Picton) Dept. of Physiology, University of Ottawa, Ottawa, Canada.

The extensor digitorum longus muscle (EDL) of the mouse consists almost entirely of type II fibres (fast-twitch). The motor unit composition of this muscle in both normal (C57BL) and dystrophic (dy^{2J}/dy^{2J}) mice has been examined. 46 motor units have been investigated in 11 normal mice of average age 13 wks and weight 31 gms. 22 motor units have been studied in 6 dystrophic mice of average age 12 wks and weight 22 gms. Anaesthesia was by Na pentobarbitone 75 mg/kg. I.P. initially, supplemented via an indwelling peritoneal cannula as required. Complete denervation of all muscles except EDL, was followed by laminectomy from L_1 to L_5. Motor units were isolated functionally by ventral root splitting of the L_3 & L_4 roots. Units were determined to be single by all or none contraction, EMG and antidromic ventral root action potential. Motor unit tetanic tension, expressed as a percentage of whole muscle tension for both normal and dystrophic mice showed little variation, 1.81% to 11.4% (mean value ± SD = 4.6 ± 2.2%) and 2.1% to 17.5% (mean ± SD = 6.9 ± 4.0%) respectively. This suggests that the C57 EDL contains about 22 motor units while dystrophic EDL is composed of about 15. Normal mice demonstrated a distribution of motor unit times to peak twitch tension that was unimodal. The mean value was 8.8 ± 1.2 msec (standard deviation). In EDL of dystrophic mice the mean time to peak tension was 9.7 ± 1.0 msec. These times to peak showed a tendency to fall into a bimodal distribution with mean values of 7.0 and 10.2 msec. The mean conduction velocity for normal mice was 70 m/sec (±12.8 SD) and 48 m/sec (±5.6 SD) for dystrophic mice. No simple relationship between tension and conduction velocity was observed.

405 AN ENDOGENOUS SUBSTANCE IN BRAIN THAT INHIBITS SAXITOXIN BINDING TO VOLTAGE-SENSITIVE Na^+ CHANNELS. Daniel M. Becker* and Stanley M. Goldin, Department of Pharmacology, Harvard Medical School, Boston, MA 02115.

Cooperative inhibition by Na^+ of ^{3}H-saxitoxin (STX) binding to mammalian axolemma sodium channels was demonstrated; the cooperativity centered about a physiologically relevant range of Na^+ concentrations (Rhoden and Goldin, J.Biol.Chem. 254:11199,1979). This led to the hypothesis that the STX-specific site might act physiologically as receptor for an endogenous modulator of voltage-sensitive sodium flux. We report here the characteristics of an endogenous substance, partially purified from rat brain, which inhibits the binding of ^{3}H-STX to Na gate-associated binding sites in a bovine synaptic plasma membrane fraction (SPM), and which may prove to be such a modulator.

Aqueous extracts were prepared by evaporation of acetone from successive acetone-acid, acetone-water extracts of whole rat brain in a modification of the procedure of Carraway and Leeman (J.Biol.Chem. 248:6854,1973). Extracts were fractionated by gel filtration on Biogel-P2, and the fractions searched for their ability to inhibit high affinity saturable binding of [^{3}H]STX to SPM. Fractions demonstrating inhibitory activity were pooled and subjected to anion-exchange chromatography. The inhibitory substance was retained on DEAE-Sephadex and eluted in a sharp peak with choline sulfate.

The inhibitor was dialyzable, with an apparent molecular weight of less than 1000 as determined by elution position on Biogel P2. It is stable to boiling for at least 5 minutes but unlike inorganic ions, is completely destroyed at 600° after 24 h. The inhibitor is not destroyed by 45 minute incubation at 37° with 1 mg/ml pronase.

Binding of the factor to SPM reaches equilibrium within 5 min at 4°C. Dissociation, as measured by regeneration of STX-specific sites, was not seen after 12 hour dialysis at 4°C. The DEAE-purified anionic inhibitor does not contain significant amounts of ascorbic acid, known to irreversibly and nonspecifically denature other membrane proteins (e.g. Dunlap et.al., Mol.Pharmacol. 6: 105, 1979). Specificity of the factor's action was further defined by demonstration, under conditions similar to those used in the assay of STX binding, that the substance did not inhibit either the binding of ^{3}H-ouabain to the Na,K-ATPase of SPM or the specific binding of phorbol dibutyrate (Nagle et.al., Cancer Res. 41:89, 1981) to brain tissue. More detailed binding studies suggest competition to the Na^+ gate between the factor and ^{3}H-STX for binding.

406 BEHAVIORAL FREQUENCY DISCRIMINATION OF ELECTRICAL STIMULATION OF THE SUPERIOR OLIVARY COMPLEX. D. R. Berard* and K. R. Henry. Dept. of Psychology University of California, Davis, CA 95616.

We have found that electrical stimulation of the rat mid-superior olivary complex (SOC) results in behavioral frequency discriminations which are as accurate as those obtained with 80 dB acoustic stimulation over the frequency range of 200 to 3800 Hz. We chose the SOC as the target organ because it is one of the brain stem structures involved in the neural frequency following response (FFR). The FFR is a bioelectrical response which mimics the fundamental waveform of an auditory stimulus at frequencies from 0.2 to 3.9 kHz (rat) and 0.1 to 5.0 kHz (human). It has been proposed that phase locked neurons of the SOC may perform a cross-correlational analysis of volley input.

To behaviorally access the perceptual significance of the FFR, we have simulated the integrated FFR waveform by electrically stimulating the SOC with sine waves. The rats' ability to discriminate SOC stimulation was nearly identical (X^2=.42, df=15; P<.05 similarity) with their ability to distinguish the same frequencies of acoustic stimuli in order to receive reinforcing electrical stimulation of the medial forebrain bundle (MFB). Within the peak current limits of 15 to 25 μA, discrimination of SOC stimulation was improved by increased current intensity.

Discrimination of SOC electrical stimulation occured within the same frequency band as the FFR. We have estimated that over 15 contiguous critical bands for discrimination of SOC stimulation exist within the FFR frequency range.

Our data are consistant with the hypothesis that SOC stimulation provides a linear transformation of pitch information within the frequency window of 200 to 3800 hz, and that limited acoustic amplitude information can be encoded within a narrow range of stimulation current. It is possible that SOC stimulation may ultimately be used to restore partial auditory perception to the individual whose inner ear and auditory nerves have been damaged by age or other factors.

407 LONG-TERM PERSISTENCE OF UNILATERAL ANOMIA FOLLOWING COMPLETE CEREBRAL COMMISSUROTOMY. J.E. Bogen, A. Campbell* and A. Thompson*. New Hope Pain Center, Alhambra, CA 91801.

A prominent feature of the syndrome following complete cerebral commissurotomy in humans (Sperry, Gazzaniga and Bogen, 1969) is, in right-handers, an inability to name or to describe verbally objects palpated in the left hand, although the objects are handled appropriately and retrieved correctly (with the same hand) from an unseen collection. This unilateral anomia, which can be quite persistent (Bogen and Vogel, 1975), requires that the informed right hemisphere be unable to speak as well as being cognitively isolated from the speaking left hemisphere. Recent studies of callosotomized individuals (Sidtis et al, 1981) have shown in some a gradual emergence of right hemisphere capability for speech, raising the possibility that in individuals with complete commissurotomy, there might eventually emerge some right hemisphere speech. We have therefore retested, 13 to 18 years after operation, nine subjects who had complete cerebral commissurotomy as well as five subjects with partial commissurotomy (mainly the callosal trunk). The latter five subjects named objects in the left hand exactly as well as they did in the right. The former nine were correct with the left hand only 20% as often as with the right hand; in these nine patients, neither right hemisphere speech nor interhemispheric communication seems to have developed sufficiently to eliminate their left hand anomia.

408 RAT MODEL FOR FETAL SURGERY. Robert A. Brodner. Department of Neurosurgery, Hahnemann Medical College and Hospital, Philadelphia, PA 19102.

A microsurgical model in the fetal rat has been developed in which various procedures including intracranial surgery and forelimb amputation are performed. Maternal blood pressure, pulse, and temperature are monitored throughout the experiment and sterile surgical technique is used. The uterus of pregnant rats in the third trimester is exteriorized and placed upon an operative stage immersed in a temperature controlled isotonic saline bath. Employing 25 to 40 diameters magnification and microinstrumentation, uterine incision is made and the amniotic membrane is opened separately. In one group of animals a craniectomy and cerebral incision are performed followed by separate closure of the fetal scalp and amniotic membrane with 10-0 nylon microsutures. In another group, a forelimb is amputated and, again, the amniotic membrane is closed separately. The uterine wall and abdomen are then sutured in layered fashion and pregnancy is allowed to continue to completion by natural delivery. The surgical pup is identified at birth and observed for five days. It is then terminated and formalinized for histological study.

Forty-two pregnant rats have undergone surgery upon one of their fetuses. In 30 maternal rats the fetal intracranial procedure was performed. Two of these mothers succumbed after surgery yielding a maternal survival rate of 93%. Postmortem examinations were performed. The group in which fetal forelimb amputation was done had a maternal survival of 100%.

The fetal survival rate in those undergoing direct intracranial surgery was 90%, and 92% in those fetuses subjected to forelimb amputation. Every surgical fetus was observed for five days after birth and all were noted to thrive.

The inaccessibility of the fetus in its natural state has often proved to be a significant obstacle in the study of the growth, development and physiology of the fetus. In these experiments, we have demonstrated the feasibility of performing sophisticated surgical procedures in the rat fetus while maintaining a relatively normal fetal-maternal relationship. A high percentage of animals operated in utero have been recovered in a viable condition at the end of the normal gestational period thus allowing postnatal evaluation and study. This model of fetal surgery has potential application in the expanding fields of prenatal research and treatment.

409 THE ALUMINUM FORMALDEHYDE (ALFA) HISTOFLUORESCENCE METHOD FOR DEMONSTRATING THE PERIPHERAL INNERVATION OF THE GILL OF A MARINE MOLLUSC. Edward J. Catapane. Dept. Natural Sciences, Medgar Evers College and the East Coast Neuroscience Foundation, Brooklyn, N.Y. 11225.

Neurophsiology studies show that the lateral ciliated cells of the gill epithelium of Mytilus edulis are innervated from the central nervous system via the branchial nerve. Serotonin and dopamine are postulated as the central and peripheral neurotransmitters mediating cilio-excitation and cilioinhibition, respectively. The Formaldehyde Induced Fluorescence (FIF) method for visualizing the cellular localization of biogenic amines demonstrated their presence in the central nervous system and large nerve trunks of M. edulis, but was unable to demonstrate the presence of nerve fibers within the gill filaments. To do this the recent modification of the FIF method, the Aluminum Formaldehyde (ALFA) Histofluorescence method was tried. The ALFA method produced more intensely fluorescing structures than the FIF method and revealed for the first time fine branches of the branchial nerve running beneath the gill epithelium, which contain biogenic amines. Microspectrofluorometric analysis showed two distinct emision spectra for these fluorescing structures which correspond to the spectra of serotonin and the catecholamines. This study is in agreement with the earlier neurophysiological studies illustrating the monoaminergic innervation of the gill. It also demonstrates the usefullness of the ALFA histofluorescence method for visualizing monoamine containing structures in tissues of marine invertebrates.

410 BRAIN HISTAMINE H_1-AND H_2-RECEPTORS AND HISTAMINE-SENSITIVE ADENYLATE CYCLASE: EFFECTS OF ANTIPSYCHOTICS AND ANTIDEPRESSANTS. Joseph Coupet and Vera A. Szucs-Myers. Department of CNS Research, Medical Research Division of American Cyanamid, Lederle Laboratories, Pearl River, NY 10965

Several classes of psychoactive compounds have been investigated for their effects on histamine-sensitive adenylate cyclase in cell free preparations from the guinea-pig cerebral cortex. Their inhibitory actions on this enzyme system have been compared with their abilities to displace [^{3}H]-pyrilamine and [^{3}H]-cimetidine from histamine H_1-and H_2 receptor sites, respectively. The results of these studies show that compounds which inhibited the histamine-sensitive cyclase were also displacers of either [^{3}H]-pyrilamine or [^{3}H]-cimetidine or both [^{3}H]-ligands from their binding sites. In spite of the lack of a correlation between binding and cyclase antagonism, it was observed that compounds that displace both ligands showed greater inhibition of the cyclase than those that have affinities for sites labeled by one or the other ligand. It was concluded that the antihistamines, the antipsychotics and the antidepressants share a common property through their antagonism of H_1-receptors and that may be responsible for their sedative side effect.

411 EFFECT OF NERVE EXTRACT ON ATROPHY OF DENERVATED OR IMMOBILIZED MUSCLES. H.L. Davis. Department of Anatomy, University of Western Ontario, London, Ontario, Canada, N6A 5C1.

Changes in denervated muscles are due to disuse caused by paralysis of the muscle and the loss of neurotrophic substances. The relative roles of these two factors in the production of atrophy in denervated rats' extensor digitorum longus (EDL) muscles were studied. Muscles were denervated and/or immobilized (by fixation of the ankle) for 7 days. Some rats also received daily intramuscular injections of a saline extract of rats' sciatic nerves (2 mg protein/ml). Atrophy was assessed by measurement of wet weight, total protein and cross-sectional areas of types IIA and IIB fibers (in sections stained for ATPase). Both denervation and immobilization produced significant decreases in weight, protein, and areas of fiber. The group of rats with denervated EDL muscles had significantly greater atrophy than the group with immobilized muscles. In another group, denervated EDL muscles had significantly greater atrophy than contralateral muscles which were immobilized. However, when denervated muscles were injected with nerve extract, they did not differ significantly from contralateral, noninjected, immobilized muscles. Comparisons of the group of rats in which one EDL was denervated with groups in which one muscle was immobilized or was denervated and injected with nerve extract, indicated that loss of trophic influence was responsible for about 40% of the decreases in wet weight, total protein, and cross-sectional area of type IIB fibers, and the remaining 60% was due to disuse. Loss of trophic influence was responsible for only about 5% of the atrophy of denervated type IIA fibers. Therefore, inactivity and loss of neurotrophic influence were responsible for the atrophy which occurred in denervated skeletal muscles, and these two factors influenced the two types of fiber differently. The component of denervation atrophy due to loss of trophic influence could be completely prevented by injection of substances extracted from peripheral nerves.

Supported by Medical Research Council of Canada, Ontario Thoracic Society, and Multiple Sclerosis Society of Canada.

412 GLUCOCORTICOID BINDING IS DECREASED IN HIPPOCAMPUS BUT NOT CORTEX OF AGED RATS. C. H. DeFiore and B. B. Turner. Depts. of Biology & Psychology, Virginia Polytechnic Institute & State University Blacksburg, VA 24061.

The hippocampus (HC) has been implicated in spatial orientation, memory, discriminative learning, and extinction tasks. A significant percentage of the aged human population show moderate to severe impairments in these areas of performance. The HC has the highest number of glucocorticoid receptors in the brain, and glucocorticoids have been hypothesized to play a modulatory role in several HC dependent behaviors. A decrease in HC glucocorticoid receptors could mediate some of the reported behavioral deficits in the aged. A previous report of cytoplasmic binding in in aged mice found no change in glucocorticoid receptors in the hippocampus or other brain regions. This study may have been compromised by procedural considerations as evidenced by the low levels of binding obtained. We wished to determine in the rat whether the number of glucocorticoid receptors or their affinity change with age in the HC or the cerebral cortex (CX)

Sprague-Dawley male rats, 6 and 24 months of age, were adrenalectomized 12 hr before sacrifice. Rats were anesthetized with Metofane and cardiac perfusion performed with 60 ml of cold dextran-saline. Tissues from 2 young rats and 2 aged rats were used in each experiment. Brain regions were dissected on a chilled glass plate and homogenized in Tris-EDTA buffer pH 7.4 containing 10% glycerol and centrifuged at 105,000xg for 60 min. Aliquots of supernatant were then incubated in 7 concentrations of ^{3}H-corticosterone (2-30 x 10^{-9}M) and additional aliquots of 1 and 2 x 10^{-8}M unlabeled steroid to determine non-specific binding. Free steroid was removed by passage through LH-20 columns.

Reciprocal plot analysis indicated that not only does the maximal binding (B_{max}) change with age, but the apparent dissociation constant (K_d) also changes. The aged animals showed a decrease in the number of receptors compared to the young: 146±4 fmoles/mg protein (old) to 211±2 fmoles/mg protein (young), $p<.01$. The apprent K_d increased with age from 2.12±.2 to 4.62±.7 x10^{-9}M ($p<.03$). There were no differences in B_{max} or K_d between the two age groups with regard to binding in the CX. The relative deficit in HC binding thus appears to be a regional, specific effect.

These data 1)provide evidence that cytoplasmic glucocorticoid binding is substantially reduced in the aged HC, both with respect to receptor number and affinity and 2) provide a possible physiological mechanism for the functional deficits occurring in the HC with age. (Supported by a grant from the Gerontology Center, VPI & SU).

413 DISTRIBUTION OF NEUROTOXIN BINDING ACTIVITY IN RAT CNS MYELINATED AXONS. G.H. DeVries and M. Lazdunski*, Department of Biochemistry, Medical College of Virginia, Richmond, Virginia, USA and Centre de Biochimie, Universite De Nice, Nice, France.

Myelinated axons were isolated from young adult rat brainstem by the flotation procedure (DeVries, Neurochem. Res. 5:3, 1981), subjected to hypotonic shock and fractionated on a 20%-40% continuous sucrose gradient in a zonal rotor. Ten separate fractions were harvested from the gradient based on the isopycnic density of each membrane constituent of the myelinated axons. The maximal binding of a ^{3}H ethylene diamine tetrodotoxin derivative (^{3}H TTX-EN) (Eur. J. Biochem. 104:617, 1980) was determined for each fraction. In addition the specific binding of a ^{125}I labeled sea anemona toxin of Anemonia sulcata (^{125}I ATX_{II}) at a concentration of 10^{-7} M as well as the specific binding of ^{125}I labeled scorpion toxin of Androctonus australis (^{125}I AaH) at a concentration of 10^{-9} M were determined for each fraction. Under these conditions the specific binding of ^{125}I ATX_{II} was highest in all membrane fractions ranging from 1 to 10 pmoles/mg protein. The maximal binding of ^{3}H TTX-EN was about 1 pmole/mg and was found in membrane fractions whose densities ranged from 30% to 35% sucrose. The binding of ^{125}I AaH ranged from 10 fmoles/mg to 30 fmoles/mg and had a bimodal distribution in the density gradient with a peak of binding activity at 37% sucrose and another at 30% sucrose. The bulk of the ^{125}I ATX_{II} binding activity was found in fractions with a density which ranged from 28% to 32% sucrose. Clearly the binding activity of the three neurotoxins was differentially distributed in the gradient so that membrane fractions which were more enriched in the binding of one particular toxin could be identified. However, the maximal binding of all toxins was found in the 28% to 32% range of sucrose densities; we have previously reported that this fraction is enriched in axolemma (DeVries et al., Transact. Amer. Soc. Neurochem. 11:130, 1980). These results suggest that each of the neurotoxin binding sites can be dissociated from each other by density gradient centrifugation although the mechanism by which this occurs is not certain. (Supported by NIH grant 10821 and a Fogarty Foundation Fellowship)

414 MULTIPLE ^{3}H-SPIROPERIDOL BINDING SITES IN HUMAN TEMPORAL CORTEX: COMPARISON WITH OTHER BRAIN REGIONS. L.L. Dickey*, A.C. Andorn*, L.H. Matt*, J.J. Ondrejka*,(SPON: V. Rowland).Dept. of Psychiat. Case Western Reserve Univ. Schl. of Med., Cleve. OH 44106.

^{3}H-spiroperidol binds specifically to homogenates of normal postmortem human temporal cortex, Brodmann areas 41-42, a region associated with the production of auditory hallucinations (Penfield and Jasper, Epilepsy and the Functional Anatomy of the Human Brain, Little, Brown,Co., 1954). This binding is saturable, stereoselective with regard to (+) and (-) butaclamol, reversible, and is linear over defined protein concentrations. Under standard assay conditions (Andorn and Maguire, J. Neurochem.,35, 1105-1113,1980), binding reaches steady state by 2.5 +/- 0.5 min. but a 20% loss in specific binding occurs over time until another steady state is reached by 40 +/- 2 min. This is similar to our observations in the prefrontal cortex, and suggests that desensitization of binding sites might be occurring. Both steady states are reached earlier in temporal cortex. These findings suggest site densities, rates of desensitization, or site K_D could differ between the two cortical areas. Saturation analyses at both steady states indicate a multiplicity of high affinity sites, K_{Dapp} range from 40 +/- 20 pM to 0.7 +/- 0.2 nM, with respective B_{max} of 50 +/- 20 and 400 +/- 100 fmol/mg protein. These K_D are similar to those observed in the same conditions in the prefrontal cortex. The overall B_{max} is slightly greater in this region of the temporal cortex than in the prefrontal cortex. Preliminary evidence indicates that this may be due to a larger B_{max} for sites K_D 0.7 nM. Their relatively increased density in this area of the temporal cortex may indicate that they have significance for the etiology of psychotic symptoms. Both the equilibrium and non-equilibrium binding studies performed in this region indicate that temporal cortical sites are more similar to prefrontal cortical sites than to caudate sites. These findings demonstrate ^{3}H-spiroperidol binding sites in a brain region associated with a discrete psychotic symptom. Further, they suggest a similarity in binding site properties between regions involved in the modulation of perceptual experience.

415 EFFECTS OF ORAL PHOSPHATIDYLCHOLINE ON MOUSE BRAIN CHOLINE AND ACETYLCHOLINE. E.F. Domino, B.N. Mathews, A. Ortiz, S.K. Tait, and F. Fucek. Dept. of Pharmacology, Univ. of Michigan, Ann Arbor, MI 48109 and Lafayette Clinic, Detroit, MI 48207.

The report of Hirsh and Wurtman (Science 202: 223-225, 1978) that phosphatidylcholine (PC) elevates rat brain acetylcholine (ACh) stimulated a great deal of research on the possible value of PC in various human brain disorders. The purpose of the present study was to reevaluate the effects of oral PC on brain choline (Ch) and ACh in another species. Male Swiss Webster mice, 30-50 g body weight, were habituated for at least 1 wk to a 0700-1900 light, 1900-0700 dark cycle. Food and water were provided ad lib until 16 hr before the experiment, when food was removed. Mice were housed 15 to a cage. They were killed between 0800 and 1200 by focused microwave irradiation to the head. Oral PC in a dose of 250 mg/kg of Ch was given 1, 2, 4, 8, 12 and 24 hr in a 1:2 suspension with 0.9% NaCl to groups of 12-14 mice. Control groups received equal volumes of 0.9% NaCl. In some experiments, the effects of PC administration to alter the known brain ACh depleting effects of scopolamine hydrobromide (1 mg/kg, i.p., base) were also determined. In this case, the PC was given orally 4 hr before and scopolamine, i.p., 1 hr before microwave irradiation. Brain temperatures after microwaving were measured to assure adequate protein denaturation. Brain Ch and ACh were isolated by ion pair extraction in dipicrylamine in dichloromethane, demethylated by sodium benzenethiolate and measured by GC-NP detection as described by Kosh et al. (J. Chromatogr. 163: 206-211, 1979). Brain Ch levels significantly increased 4 ($P<.001$) and 8 ($P<.01$) hr after PC. However, there was no change in brain ACh. In a second series killed 1, 3, 6, and 12 hr after pretreatment with the same large dose of PC only the 6 hr pretreated mice showed a significant increase in brain Ch ($P<.01$), a finding consistent with the first series of experiments. The known depleting effects of scopolamine pretreatment on brain ACh were confirmed ($P<.001$) in a third series of experiments in which 1 mg/kg were given i.p. 1 hr previously. Scopolamine also caused a decrease in brain Ch ($P<.001$). Pretreatment with PC reversed the depletion of brain Ch induced by scopolamine, but had no effect on brain ACh. The results obtained indicate that although mouse brain Ch can be increased by oral PC there is no effect on brain ACh. If the purported beneficial effects of oral PC in various human disorders are true, they may not be due to a simple elevation in brain ACh, unless human brain is more like that of the rat than the mouse. Obviously, further studies related to possible animal species differences need to be undertaken.

416 TISSUE DISTRIBUTION OF THE 4-HYDROXYCYCLOHEXYL METABOLITE OF PHENCYCLIDINE. Mark S. Franczak, R. Stanley Burns* and Michael H. Ebert*. Lab. of Clin. Science, NIMH, Bethesda, MD 20205.

The tissue distribution of 4-phenyl-4-piperidinocyclohexanol (PPC), the major metabolite of phencyclidine (PCP) in man, was examined in the rat. In the Rhesus monkey and chronic spinal dog, PPC has properties similar to central nervous system stimulants, and a different spectrum of activity from the parent compound, PCP.

A 5 mg/kg dose of PPC was administered I.V. by tail vein injection, and animals were sacrificed by decapitation after 5, 15, 30, 60, 90, 120, 150, 180, 210, and 240 minutes. Plasma was obtained by the collection of thoracic stump blood into heparinized tubes. Following the addition of the internal standard, 0.3 to 1.5 grams of brain, heart, lung, liver, kidney, adipose, and muscle tissue were homogenized in 10 ml of 0.2 N sulfuric acid. PPC values were determined by gas chromatography-mass spectrometry using a deuterated (d_5) PPC internal standard.

The kinetic analysis of mean concentration versus time yields a plasma elimination half-life of 88 minutes, steady state volume of distribution of 11.6 liters/kg and a plasma clearance of 78.4 ml/kg/min. Disappearance half-lives of PPC in brain and adipose tissue were similar to the plasma elimination half-life with calculated values of 80 and 76 minutes, respectively. During the post-distributive phase (90 to 240 minutes), the brain to plasma concentration ratio was 1.5 to 3.0. The concentration ratio of adipose tissue to plasma was 1.5 to 2.0. The highest levels of PPC were found in the lung, kidney and liver, respectively.

PPC rapidly distributes into brain tissue, achieving peak levels within 5 minutes. The compound selectively partitions into brain resulting in levels up to 3 times greater than those in plasma during the post-distributive phase. Other studies in our laboratory indicate that in the Rhesus monkey, PPC produces an excited state with motor restlessness, increased startle response, and purposeless movements resembling athetosis. The presence of PPC in high concentrations in brain together with central nervous system stimulant properties may explain the mixed stimulant and depressant effects of the parent drug, phencyclidine. In man, PPC may be responsible for the behavioral toxicity of phencyclidine in the form of an excited state.

417 EFFECTS OF AMBIENT CATIONS ON HYPERSEROTONERGIC ANXIETY IN A HUMAN POPULATION. A. James Giannini, R. H. Loiselle* Psychiatry Dept., Northeastern Ohio Universities College of Medicine, Rootstown, OH 44222.

Previous investigations in this laboratory (Giannini, 1979; Giannini and Dvoredsky, 1981) have demonstrated a correlation between high-concentration cation atmospheres and hyperserotonergic anxiety in sensitive human populations. This study attempted to study the relationship between serotonergic metabolism and anxiety produced in an ionized environment in a general population. Twenty young male volunteers signed standard consent forms to participate.

The group was screened for serum serotonin (5HT) and 24 hour urine 5-hydroxyindoleacetic acid, (5-HIAA). Levels for all subjects were found to be within established norms. They were then collectively exposed to a cationized atmosphere for a fifteen-hour period. Serum 5HT and 24-hour urine 5-HIAA levels were then measured. Ten of the patients complained of anxiety and of these ten, two reported vertigo. Physical examination revealed a resting tremor in all ten patients reporting anxiety and none in the nonanxious group. No other signs associated with a hyperserotonergic state were noted. No significant changes in 5HT and 5-HIAA were noted in this group after exposure. Also there were no significant differences between the anxious and nonanxious subgroup.

This finding contrasts with earlier studies which correlated highly cationized atmospheres, anxiety, and increased levels of serotonin. They also differ with the findings of Dirnfield (1954) who reported increased 5-HIAA and Giannini and Dvoredsky (1981) who reported decreased levels. A possible explanation for these divergent findings rests on the fact that previous studies relied on self-selected subjects who were included in study groups solely on the basis of presenting hyperserotonergic symptomatology. This randomly selected group had no such predetermined sensitivity. Only one-half the group experienced anxiety and even in this subgroup there was no noted change in serotonin metabolism. Since cerebrospinal fluid levels for 5HT and 5-HIAA were not drawn, it cannot be determined if changes in central 5HT metabolism were greater than those noted in the periphery. It is hypothesized that sensitivity of serotonin systems to the effects of elevated atmospheric cation levels is quite variable in different individuals and that central sensitivity is greater than peripheral sensitivity.

418 APERIODIC IMPULSE PATTERNS IN A CUTANEOUS AFFERENT UNIT MODEL M.D. Goldfinger. Dept. of Biology & School of Medicine, University of Missouri, Kansas City, Missouri, 64110

The branching of many skin afferent axons is a substrate for the superposition of electrical activity elicited from each mechanosensitive branch terminal. The present work uses a mathematical afferent unit model(1)to consider the generation of aperiodic discharges of the parent axon elicited by repetitive mechanical stimulation of 2 or more (up to 20) terminals.

During multiterminal stimulation, the interspike interval distribution(IID)differs from the merged interstimulus interval distribution, due to absolute refractoriness(ARP=2 ms), recovery cycles, and mechanoreceptor fatigue (see II below). For simplicity, the amplitude of all stimuli used supports 1:1 firing for any period exceeding ARP. The general result of superposing several separate spike trains is a Poisson process (2). Two ways of approaching this ideal are described.

I. Strictly periodic inputs: During multiterminal stimulation using unequal respective periods, the mean interspike interval ($\overline{T}$) decreases with larger numbers(N) of terminals and/or by smaller differences between individual periods. All interspike interval values are between ARP and the shortest input period. With increasing N, an exponential IID falling limb is approached. The Expectation Density (ED) includes deadtime, plateau level, greater-than-plateau peaks at multiples of individual input periods, and minima due to ARP. With greater N, the ED peaks blend into the plateau noise.

II. Random variation of input periods: The waiting time for the next successive stimulation of each terminal is varied equiprobably between periods P and P' ($0<P'<P$). All interspike interval values are between ARP and P. With larger N and/or smaller P'/P, $\overline{T}$ decreases and the spike train becomes increasingly Poisson-like. Mechanoreceptor fatigue can cause a finite IID rising limb and a slowed risetime to ED plateau. Larger P'/P (eg,31 ms/33 ms;N=20) yields spike trains with ED periodicities.

These results can be speculatively applied to the Type I SA response elicited by maintained dome pressure. Assuming each final-order axon branch is, in effect, activated sequentially and can fire independently, a Poisson-like discharge pattern(eg,(3)) could occur if: (i)several branches fire with different periods; or (ii) a smaller number of branches fire randomly within a range of periods determined by the maintained stimulus intensity.

419 ALTERATION OF SPINAL CORD METABOLISM AND BLOOD FLOW IN SPINAL CORD INJURY. N. Hayashi, B. A. Green, J. Mora*, M. Gonzalez-Carvajal*, K. Abe* and K. Kogure Research Lab, Depts. of Neurosurgery and Neurology, Univ. of Miami Sch. of Med., Miami, FL 33101.

Spinal cord tissue metabolism and blood flow were studied in the gray and white matter of the rat following irreversible spinal cord injury. Local spinal cord blood flow (lSCBF), local tissue oxygen tension (lTO_2) and relative local tissue oxygen consumption ($r\text{-}lTO_2C$) were simultaneously measured in 140 rats at different time intervals using a microelectrode technique.

Pathophysiological parameters used to determine factors associated with secondary spinal cord damage included alteration of spinal cord tissue ATP, tissue pH and tissue NADH. Analyses were performed within the lesion site as well as proximally and distally using topographic techniques. Quantitative alterations of coenzyme Q and alpha-tocopherol (as an indicator of free radical reaction) were measured at different time intervals following injury.

Normal mean values of lSCBF in gray and white matter were 63 and 20 ml/100g/min., respectively. Values for $r\text{-}lTO_2C$ in gray and white matter were 3.6 and 1.1 ml/100g/min., respectively. The normal mean values for coenzyme Q_{10} and alpha-tocopherol in the rat were 12 μg/g and 12.5 μg/g, respectively.

A 100 gram-centimeter force irreversible injury at T_7 in the rat was utilized. Gray matter was damaged more than white matter within the lesion. $R\text{-}lTO_2C$ was altered more than lSCBF as evidenced by decreased tissue ATP and decreased coenzyme Q levels after 30 minutes. At two hours post injury, an NADH hyperoxidation (as a black hole) and a decrease in alpha-tocopherol also were observed. Proximal and distal to the lesion, less homogeneous patterns of lSCBF and tissue metabolism were noted. The significance of free radical reaction as a component of the sequelae has also been documented. Our data suggests that the reversibility of the lesion is determined more by the severity (reversibility) of metabolic disturbances (i.e. the maintenance of oxygen metabolism) than blood flow alterations.

420 CONTROL OF THE BLADDER AND EXTERNAL URETHRAL SPHINCTER BY THE SPINAL CORD. F. Jolesz*, P. Ruenzel* and E. Henneman. Dept. of Physiology, Harvard Medical School, Boston, MA 02115.

Severe injury to the spinal cord results in paralysis of skeletal muscles whose motoneurons lie below the level of the lesion. The specialized muscles of the external urethral sphincter and nearby perineal regions, however, become spastic after spinal transection and prevent emptying of the bladder by the detrusor muscle. The reflex discharges elicited by electrical stimulation of the pudendal nerve branches supplying the external sphincter have been recorded from the distally severed ventral roots of the first, second and third sacral segments. Electromyographic recordings from the external sphincter have also been made. Considerable electrical activity remains in these muscles after unilateral section of the sacral ventral roots. This activity is maintained after spinal transection as previously reported. In the second sacral ventral root and to a lesser extent in the third prolonged polysynaptic electrical responses are elicited by single shock stimulation of the pudendal nerve. Mechanical stimulation of the surface of the urethra, anus and adjacent perineum or an increase in bladder volume usually facilitates these reflexes. To date no monosynaptic reflexes have been elicited by pudendal stimulation. Potentiation of latent monosynaptic reflexes has been attempted by tetanizing the pudendal nerve at 500/s prior to testing with single shocks. No concealed monosynaptic reflexes were revealed by this procedure. It is tentatively concluded that there are no monosynaptic connections from the muscles of the external urethral sphincter to its motoneurons. This distinguishes the sphincter from most other skeletal muscles. Control recordings of the segmental reflexes of the sacral roots elicited by stimulation of the dorsal roots indicate the existence of well defined monosynaptic reflexes. Other skeletal muscles with motor neurons at this level of the spinal cord, therefore, have quite normal patterns of reflex activity. The absence of muscle spindles and monosynaptic reflexes and the presence of large polysynaptic reflexes indicate that reflex control of sphincter muscles may be quite different from that of skeletal muscles in general. The "spontaneous" activity of the sphincter muscles and the increase in their tone after spinal transection may be due to the polysynaptic reflexes we have noted. We are investigating procedures designed to reduce this polysynaptic activity and relax the external sphincter so that the detrusor muscle can expel urine in a normal manner.

421 SEROTONERGIC AND CHOLINERGIC INTERACTION IN THE REGULATION OF CORTICOTROPIN RELEASING HORMONE IN VIVO. J. P. Kile and B. B. Turner. Depts. of Biology & Psychology, Virginia Polytechnic Insitute & State University, Blacksburg, VA 24061.

Both serotonin and acetylcholine are known to stimulate the secretion of corticotropin releasing hormone (CRH). However, in vitro studies suggest that serotonergic stimulation of CRH secretion may be mediated instead via acetylcholine neurons that synapse directly onto CRH neurosecretory cells in the hypothalamus. This study investigated the possibility of a cholinergic system in the hypothalamus controlling the stimulation of CRH release by serotonin in the intact animal.

Male Sprague-Dawley rats were housed in single cages in a room with controlled access (lights on 0600-2000 hrs) 1 week prior to experimentation. Eleven groups of rats (n=10) were injected at 0630 hr with one or more of the following agents: saline (SAL), physostigmine (PHY), mecamylamine (MEC), scopolamine (SCO), 5-hydroxy-tryptophan (HTP), or methysergide (MET). One hr post-injection, rats were decapitated, and trunk blood collected for plasma corticosterone determination by radioimmunoassay.

In unstressed rats, PHY ($p<.001$), SCO ($p<.01$), HTP ($p<.001$), and MET ($p<.05$) groups had significantly higher corticosterone levels than the control group (SAL). When drugs were injected in combination, PHY-HTP and MEC-HTP produced increased levels of plasma corticosterone which were lower ($p<.05$) than those of the PHY group, but not different from the HTP group. MEC only slightly inhibited the HTP effect. When SCO was given with MEC and HTP this inhibition was negated. The PHY-MET group has significantly lower corticosterone levels ($p<.01$) than the PHY rats, while MEC-MET group levels were reduced to control levels.

In stressed rats (horizontal shaker 40 min, plus Metofane anesthesia 20 min), the SAL group had corticosterone levels six fold higher than in unstressed SAL rats. Similar effects to those in unstressed rats were observed for PHY, HTP, and MET groups. However, HTP group corticosterone levels were 25% higher than the PHY group levels. Corticosterone concentration in SCO and MEC groups was not significantly different from the SAL rats. MEC was able to abolish the HTP-induced rise in corticosterone. SCO when given with HTP had no significant effect.

These data suggest that: 1) in contrast to in vitro studies, serotonin actually mediates acetylcholine stimulation of CRH; 2) there is also direct control of CRH release by both neurotransmitters; 3) nicotinic receptors stimulate, whereas muscarinic receptors inhibit CRH secretion; 4) serotonin is more important in regulating CRH release during stress than in basal conditions. (Supported by an NIH BRSG grant from VPI & SU).

422 MEASUREMENT OF BLOOD FLOW BY WASHOUT OF MICROWAVE INDUCED HEATING. P. M. Lawner, L. D. Braun* and W. H. Oldendorf. Departments of Neurosurgery and Neurology, UCLA School of Medicine and Research Service, Brentwood VA Medical Center, Los Angeles, CA 90073.

A technique was developed to measure cerebral blood flow (CBF) using the washout of heat delivered by a microwave source.

Ten adult Wistar rats (275-325 g) were anesthetized with pentobarbital 50 mg/kg i.p.. A 0.25 mm diameter thermistor (Thermometrics, Edison, NJ) was placed into the right cerebral hemisphere using preset external coordinates, and a second thermistor placed through the femoral vein into the venae cava. Using a wheatstone bridge and a potentiometric recorder, the temperature difference between the two thermistors was plotted. The animal's head was exposed to a microwave source (Gerling Moore-Metabostat, Palo Alto, CA) attenuated to achieve a brain temperature elevation of $0.5^{o}C$ in 2 s, and the temperature washout curve was utilized to calculate CBF using the T 1/2 method. Three to five determinations were performed in each animal.

In a second group of 12 rats, under identical anesthetic conditions, CBF's were measured in a 125 mm^3 volume around the thermistor tip using a ^{14}C-butanol uptake technique (Van Uitert, R.L. and Levy, D.E., Stroke 9:67, 1978).

Mean CBF using thermal washout was 55.59 $\pm$ 7.47 S.D. (ml/100 g/min) while ^{14}C-butanol flow in the same area was 52.12 $\pm$ 5.87 (difference $p > 0.2$).

This technique appears to be a simple, inexpensive and reliable method to measure CBF with an ideal "indicator" delivered directly to brain parenchyma.

423 BRAIN UPTAKE OF ERYTHROSIN B, A FOOD DYE, IN ADULT RATS. H. Levitan, Z. Zilyan*, Q. R. Smith, and S. I. Rapoport (SPON: E.J. Elliott) Lab. of Neurosciences, National Institute on Aging, Baltimore, MD. 21224.

Food colors have been held partly responsible for behavioral disorders such as hyperactivity and minimal brain dysfunction in children, and at least one widely used food color, erythrosin B (FD&C Red No. 3) can change neuronal membrane physiology, neurotransmitter release and uptake, and the activity of brain Na-K-ATPase when applied directly to cells or subcellular organelles. There is no information however on whether significant levels of this dye appear in the brain after consumption or administration. In order to determine whether erythrosin B crosses the blood-brain barrier and enters the brain in detectable amounts, we have injected 14C-erythrosin B directly into the circulation of unanesthetized, male, mature (3 month old) Osborn-Mendel rats. A tracer amount of 14C-erythrosin B was injected into the femoral vein, either alone or 10 minutes following injection of a saturating concentration of non-radioactive dye. Blood radioactivity was monitored and the brain removed after 10 min, 30 min, or 2 hours. Brain radioactivity, which was measured after correcting for intravascular tracer, was negligible. In other experiments 14C-erythrosin B and 3H-sucrose were infused directly into the carotid artery of rats about 1 min after the ipsilateral cerebral hemisphere had been perfused with a saline solution to remove blood. These animals were decapitated 1 minute later and their brain was removed. In none of the 14 brain regions examined did the concentration or erythrosin B significantly exceed that of sucrose, a substance used as an indicator of brain blood volume because it penetrates the blood-brain barrier poorly. We conclude that erythrosin B does not penetrate the blood-brain barrier or enter the brain of mature rats in measurable amounts.

424 A CENTRAL INTEGRATIVE DISORDER OF SYNTHETIC FUNCTIONS: UNDERLYING PSYCHOPATHOLOGY. R. S. Lourie, C. Schwarzbeck, III*. Mental Health Studies Center, NIMH, Adelphi, Maryland 20873.

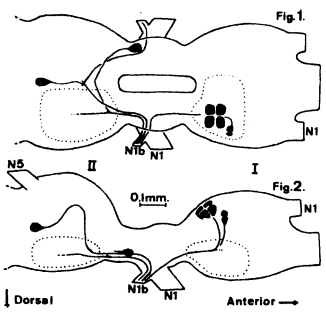
This is a report of a clinical and neuro-psychological five-year study of youngsters with a usually correctibel defect in a brain's synthetic functioning. It describes a fundamental central integrative disorder (CID), in which cognitive functions are interfered with in the presence of stress and anxiety. It results in thinking and acting becoming disorganized or even paralyzed, which then becomes the basis for a wide range of psycho-pathological patterns. In a Clinical population, 25% of patients up to 18 years of age were found to have this constitutionally based difficulty, but never as one of the wide range of presenting symptoms. It occurs in degrees from mild to severe with individual differences in the degree of stress and anxiety necessary to trigger the disorganization. It has been found in adult patients as well, but has not been studied as systematically.

Once this process starts, it usually results in a feeling of helplessness in which the mind goes blank and thinking stops or cannot be collected. It is then experienced (in a paraphrase of Kurt Goldstein's concept) as a "more or less catastrophic reaction." It inevitably is responded to with individually determined patterns of defense. The types of defenses used, in interaction with other inner and outer forces and life experiences lead to a wide variety of psychopathological symptoms and syndromes. The ones encountered in this study range from neuroses, psychosomatic reactions, character disorders, and psychoses to behavior difficulties and learning disabilities. Extreme acting out even leading to adolescents committing murders has been found in individuals whose disorganization has led to dissociated and/or hypnogogic states. Even when the disorganization is moderate in degree but appropriate environmental supports are not available, the child has difficulty in dealing with developmental stages in which anxiety is expectable. Therefore, unresolved sources of anxiety persist. Thus, attachment and impulse disorders, separation concerns, fears of body damage and anxiety stemming from oedipal conflicts can color the resulting symptom picture. There often is resulting poor self-image and other narcissistic problems. These patterns then in turn can provide additional sources of anxiety.

Individuals who have CID not infrequently are resistant in traditional psychotherapy to giving up defenses which would leave them feeling helpless. Corrective approaches to the disorganization can then expedite the use of other therapeutic modalities. Some remedial techniques have been developed.

425 NEURONS INNERVATING SOME FLIGHT MUSCLES IN A NOCTUID MOTH Bent M. Madsen* and Lee A. Miller. Biologisk Inst., Odense Universitet, DK-5230 Odense M, Denmark.

Tympanate moths can hear and avoid bats (Roeder, Science, 154:1515-1520, 1966). We are now investigating the neuroethology of evasive behavior shown by moths when exposed to ultrasound. Here we describe the structure of 8 neurons innervating the dorsal longitudinal muscles of the mesothorax in the moth Mamestra brassicae. We used standard cobalt staining techniques with intensification. Cobalt entered through the cut axons of the appropriate nerve (IIN1b). We made camera lucida drawings of 25 preparations. The results are presented schematically in Fig. 1 (ventral view) and Fig. 2 (lateral view, left side). We found 6 motor neurons (MN) in the posterior part of the prothoracic ganglion (I). Their cell bodies lie near the ventro-lateral surface of the ganglion. Each soma has a neurite that runs almost vertically to the dorsal area of the ganglion where it branches profusely (area within the dotted lines in I). A seventh MN was stained in the mesothoracic ganglion (II). The soma is located in the posterior end of the contralateral connective between I and II. The soma occupies the same position in stained, but unfixed preparations. The neurite branches profusely in the ipsilateral, dorsal neuropile (area within the dotted lines in II). An eighth neuron was stained near the midline of ganglion II. Its soma lies in the central posterior region of II. The neurite runs anteriorly and bifurcates into two axons; one exiting in each IIN1b root. Our results resemble those from the moth Manduca sexta. However, the soma of the contralateral MN lies within II in M. sexta (Casaday and Camhi, J. comp. Physiol. 112: 143-158, 1976). The medial cell in II is probably a dorsal unpaired medial (DUM) neuron (Davis and Alanis, Comp. Biochem. Physiol. 62: 777-788, 1979).



426 BLOOD CHOLINE LEVELS AND DELAYED RESPONSE PERFORMANCE IN YOUNG AND OLD RHESUS MONKEYS. J.G. Marriott, E.F. Domino, S.K. Tait*, B.N. Mathews*, F. Fucek* and J.S. Abelson. Warner-Lambert/Parke-Davis & Univ. of Michigan, Ann Arbor, MI, and Lafayette Clinic, Detroit, MI.

Numerous studies in both animals and humans have implicated cholinergic neurotransmission in the functioning of such higher cognitive process as learning and memory. In addition, evidence indicates that declines in cholinergic function may be involved in the impaired cognitive performance of normal geriatric subjects and of patients with senile dementia of the Alzheimer's type.

The present studies investigated the relationship between blood choline levels and cognitive performance in a colony of young and aged rhesus monkeys. The young adult monkeys had a mean age of 8 years, the geriatric animals 19 years. This colony of non-human primates has been used for several years to study age-related cognitive impairments. Delayed response performance of these animals was measured using automated test procedures. This behavioral task has repeatedly shown significant and reliable memory impairments in aged monkeys relative to the performance of young animals having a similar amount of experience. Chemical demethylation, gas chromatography-nitrogen detection was used to measure red blood cell (RBC) and plasma choline concentrations in these same subjects, as a peripheral marker of low affinity choline uptake.

Mean plasma choline concentrations appeared slightly higher in the geriatric animals compared to young controls ($P<.03$). RBC choline was slightly lower in old versus young animals; however, statistical analyses of this measure and RBC/plasma choline ratios showed no significant age differences. Further analyses were made comparing blood choline concentrations to delayed response performance in young and old monkeys. Although there was a trend for poor performing animals in both age groups to have higher blood choline concentrations, no significant correlations between these measures were foung using traditional statistical analyses. Administration of up to 10 g/kg of lecithin, the primary dietary source of choline, had only slight effects in raising blood choline levels of young monkeys. No improvement in performance on the memory task was found following lecithin administration in aged monkeys. In summary, blood choline levels in adult rhesus monkeys do not change appreciably with age, and cognitive declines commonly seen in aged subjects are not closely related to blood choline levels.

427 ZINC LEVELS IN TISSUES FROM ALLOXAN DIABETIC RATS. M. E. McNeill[1], E. C. Simpson[3]*, J. T. Bray[2]*, C. Smith[1]*, L. A. Webb[2]* and C. R. Morgan[1]*.

Departments of Anatomy[1] and Surgery[2], School of Medicine, and Biology[3], East Carolina University, Greenville, NC 27834.

Secondary complications associated with diabetes mellitus such as retinopathy, atherosclerosis and infertility are similar to complications that arise in zinc (Zn) deficient animals. Many patients with diabetic skin lesions show improved wound healing when treated with Zn supplement. Therefore the present study was done to probe the relationship between Zn and diabetes by determining the concentration of this trace element in selected tissues. The tissues sampled were determined by three criteria: (1) pathology associated with diabetes mellitus--the pancreas retina, testes, serum, aorta (2) centers possibly involved in modulating insulin secretion--brain, hypothalamus, hypophysis and (3) tissue known to have a high Zn concentration--pineal.

Eight male Sprague-Dawley rats made insulin deficient with an i.v. injection of alloxan (45 mg/kg) were paired with age-matched controls, housed with lights on 0700 - 1900 hrs. and fed rat chow and water ad libitum. Terminal body weight and blood glucose levels were determined at sacrifice 10 months later. Tissue samples were obtained and all samples except serum were freeze-dried at -38°C for 3 days. The dry samples were weighed and the Zn concentration was determined by flame atomic absorption spectrophotometry.

Comparisons were made using the Mann-Whitney U Test. The following table lists those tissues which showed significant differences.

		Body Weight g	Blood Sugar mg/dl	ZINC ug/g (dry weight) AH	HYPO	BRAIN	AORTA
Alloxan Diabetic	n=8	261.1	471.0	89.3	53.5	20.6	90.0
	SEM	±21.2	±17.9	±6.55	±0.53	±0.20	±4.44
Control	n=8	495.5	131.4	77.4	48.5	23.4	76.9
	SEM	± 6.01	±19.4	±1.08	±1.74	±0.36	±4.02
				p=.02	p=.01	p=.0002	p=.038

AH = adenohypophysis; HYPO = hypothalamus

Zn levels were decreased in the pancreas, testes and pineal and were increased in serum and retina (these changes were not highly significant). An inhibitory effect of Zn on in vitro insulin secretion has been reported and attributed to interference of the intracellular function of calcium in the beta cell (Ghafghazi, T., M. L. McDonald and P.E. Lacy, Diabetes, 30:341, 1981). Significant changes in Zn levels in selective tissues in insulin deficient rats suggests that Zn may play a role in endocrine function.

428 A PHARMACOLOGICAL,ADRENERGIC, AND PEPTIDERGIC EVALUATION OF DRINKING RELATING TO THE SUBFORNICAL ORGAN.

José V. Menani*; Wilson A. Saad and Luiz A.A. Camargo*

(Department of Physiology and Pathology, School of Dentistry - UNESP - Araraquara, 14.800, S.P. Brasil).

It has been shown that the subfornical organ (SFO) is sensitive to angiotensin II (A II) in inducing thirst (Simpson and Routtemberg, Brain Research, 79, 1974). Adrenergic stimulation also plays a part although at a lesser intensity (Menani, Saad and Camargo, Abstracts - Brazilian Society of Physiology,58-59, 1979). The main point in question is to verify the existance of an interaction between the adrenergic receptors and the angiotensin of the SFO in the ingestion of water. In the experiment performed, in the present investigation A II was injected into the SFO of rats with the object of inducing thirst. Next separate experiments were done using regitine and propranolol. A dose of A II had previously been injected into the SFO. The dose of 4 ng of A II provoked water ingestion which was reduced by the application of 20 nmol of propranolol and totally blocked by doses of 40 and 80 nmol. The ingestion of water in relation to the three doses of propranolol showed significantly different results in relation of one to the other: $F(2.21)=0.94$; $P<0.01$. The same results were obtained when we compared the data of the A II and the isotonic solution with the data of the doses of propranolol $F(3.30)= 33.60$; $P<0.01$. The application of 4 ng of A II into the SFO provoked a water ingestion of 3.9 ± 0.5 ml. When a dose of 80 nmol of regitine was applied previous to A II, there was an ingestion of 2.8 ± 1.4 ml, show no significant difference ($P>0.05$). Both the results of this research and also the results of research done by others show that the response initiated in the cholinergic and peptidergic receptors to induce water ingestion (SFO) could be divided at some point by catecolaminergic vias of the beta type.

429 POSTNATAL DEVELOPMENT OF THE GIGANTOCELLULAR TEGMENTAL FIELD (FTG) OF THE RAT. A.J. Miller and G. Fry*. Ctr. Craniofacial Anomalies, Univ. of Calif., San Francisco, CA 94143.

Presynaptic boutons of the FTG nucleus of the brain stem reticular formation were analyzed for changes in numerical and volumetric density during early postnatal development. A bouton was defined as that cellular structure occupied by three or more synaptic vesicles in which its membrane and that of an adjacent neuron were separated by a cleft and their cytoplasm demonstrated an increased density. Sprague-Dawley rats at postnatal ages of 1,5,10,15 and 30 days and young adult animals were perfused with a mixed aldehyde solution of 2% formaldehyde-2% gluteraldehyde in a 0.1M phosphate buffer. The tissue was prepared for electron microscopy by standard techniques. Both the myelin and boutons were analyzed using a stereological approach. The FTG was sampled at one rostro-caudal level: the transition between the medulla and pons (caudal level of VII nucleus).

Myelinated tissue did not appear until day 5, and then rapidly increased in volumetric fraction (V_{V_i}) to reach the adult level (40-45%) by day 30. The number of boutons per area (N_{A_i}) and volume (N_{V_i}) increased 3 fold within the first 15 postnatal days and reached the adult level by the 15th day ($N_{A_i} \doteq 1$ bouton/10 μm^2; $N_{V_i} = 9.3 \times 10^8$ boutons/mm^3). The percentage of FTG volume occupied by the boutons (V_{V_i}) did not increase until after day 15 but never exceeded 10% of the total volume.

The significant correlation of the Sudden Infant Death Syndrome with sleep and a critical postnatal age suggests that development of pathways within the central nervous system related to sleep,respiration and upper respiratory tract control is a key factor. Comparison of relative immature brain weights to adult size have suggested that the brain of a 13-day-old rat is comparable to that of a 15.5-month-old human infant. Our study indicates that the most rapid change in synaptic density of the FTG region is prior to this age. This suggests that during the most critical ages of this Syndrome, central neurons, particularly in the brain stem, are undergoing a rapid change in synaptic growth and contact.

430 ANALYSIS OF SUPRAPONTINE MODULATION OF HYPOGLOSSAL AND PHRENIC MOTONEURON POOLS IN HEMIDECEREBRATE CAT

J. Mitra. Pulmonary Research Lab., Case Western Reserve Univ Cleveland, Ohio 44106

It is well known that the suprapontine(SP) brain structures have a modulating influence on medullo-spinal afferent and efferent nerves. In the present one we examined the effect of SP influence on respiration. We studied SP influence on respiratory efferent output in lightly chloralose anesthetized hemidecerebrate(HD) cats and examined the hypoglossal and phrenic nerve activity at different levels of CO_2 breathing. Both these nerves show respiratory related activity which increases in amplitude with hypercapnia. We monitored integrated electrical activity of whole hypoglossal and phrenic nerves of both sides during 100% O_2 breathing and also at different CO_2 levels(5-15% CO_2 in O_2). Prior to HD, the hypoglossal and phrenic activity on both sides were similar. The animal was then hemidecerebrated at midcollicular level and retested 2 to 4 hours later. Measurement of hypoglossal and phrenic nerve activity on both the HD and intact side were thus repeated using 100% O_2 and different levels of CO_2 in order to increase neural drive. HD decreased ipsilateral hypoglossal nerve activity($p<0.02$) and increased ipsilateral phrenic nerve activity($p<0.05$) during 100% O_2 breathing and with low level of CO_2. When the animal breathed CO_2, the hypoglossal nerve activity increased alinearly on both sides, less at lower level of CO_2 than at higher levels. Between 5-10% CO_2 level the hypoglossal activity on the intact side was steeper($p<0.001$) than the HD side. However, at higher CO_2 levels($\sim$10%) the difference between the two hypoglossal nerves diminished and at 15% CO_2 not significantly different($p<0.1$). On the other hand, significant difference between the two phrenic nerves were not evident above 11% CO_2. Differences in activity between the intact and the HD side could also be eliminated by increasing the depth of anesthesia.

It is concluded that the hypoglossal motoneuron pool receives a facilitory and the phrenic motoneuron pool an inhibitory influence from SP structures. The influence of SP structures on these motoneuron pools, however, depends on the prevailing level of CO_2. At CO_2 levels of 5-10% the difference between the two sides increases, indicating that the SP influence increases. Above 10% CO_2 the difference between the two sides diminishes, suggesting that either the peripheral motoneuron pools overcome the SP influence or else the SP influence wanes. Abolition of the SP influence by increasing depth of anesthesia suggests that these modulatory influences are transmitted via polysynaptic pathways.

431 DIFFUSION IN THE BRAIN CELL MICROENVIRONMENT. C. Nicholson and J.M. Phillips*. Dept. of Physiol. and Biophys., New York Univ. Med. Ctr., 550 First Avenue, New York, N.Y. 10016

The widespread use of ion-selective microelectrodes (ISMs) in the brain cell microenvironment necessitates a re-evaluation of the concept of diffusion in the extracellular space of the brain. We have done this both at the theoretical and experimental level.

We used the concept of volume averaged variables, as applied to porous media (Lehner, 1979, Chem. Eng. Sci. 34:821) to derive an extended form of Fick's Law for the complex environment of the brain. This approach yields two new parameters that reflect the geometry of the extracellular space. The first is volume fraction which indicates the amount of intercellular space available to the diffusing ion. The second parameter is tortuosity which relates to the increase in average path length of a diffusing particle as it circumnavigates cellular obstructions.

Using point iontophoresis (Lux & Neher, 1973, Exp. Brain Res. 17: 190) and ISMs selective for ions not normally present in the brain, we experimentally confirmed the theoretical concepts in the rat cerebellum. We used the cations tetramethylammonium and tetraethylammonium and the anions hexafluroarsenate and alpha-naphthalene sulfonate. The volume fraction was 0.21 ± 0.02 (mean$\pm$SEM), the tortuosity was 1.55 ± 0.05 and we found no significant difference using cations and anions.

Our results show that the brain cell microenvironment allows diffusion of small ions, and probably of other neuroactive molecules, in conformity with an extended form of Fick's Law. Under many conditions, the volume fraction and tortuosity combine so as to substantially increase the effective strength of an ionic source. These studies are also consistent with the view that the migration of K^+ in the brain involves processes in addition to simple diffusion (Nicholson, Phillips & Gardner-Medwin, 1979, Brain Res. 169:580). 432 SYNAPTOGENESIS IN HUMAN NORMAL AND DOWN'S SYNDROME NEOCORTEX. T.L. Petit, J.C. LeBoutillier*, D.P. Alfano and L.E. Becker*. Department of Psychology, University of Toronto and Department of Pathology, Hospital for Sick Children, Toronto, Ontario, Canada.

Delineation of the normal patterns of central nervous system development is a necessary prerequisite to elucidating the possible neural mechanisms underlying various neuropathological conditions. Previous observations on normal and aberrant features of brain development have indicated alterations in dendritic growth and branching, reduced numbers of dendritic spines and altered dendritic spine morphology in some cases of human mental deficiency. This investigation was undertaken to examine synaptic development in human normal and Down's syndrome neocortex.

Post-mortem tissue was obtained from six normal and four Down's syndrome brains ranging in age from twelve weeks post-conception to four weeks postnatal. Tissue was processed using routine osmium and EPTA staining procedures and photomicrographs were systematically taken throughout the molecular layer of the sensorimotor neocortex. Synaptic density was determined by counting the number of synapses per 15,000X field. Pre- and post-synaptic length, width and area, and synaptic cleft width were measured using 300,000X photomicrographs from EPTA stained tissue.

An increase in synaptic density over the range of ages examined was observed for both normal and Down's syndrome tissue. No obvious differences were apparent in the development of synaptic density in Down's syndrome tissue. Synaptic length, width and area were observed to increase, while synaptic cleft width remained fairly constant throughout the range of ages examined in both normal and Down's syndrome tissue. All parameters appeared to be reduced in Down's syndrome tissue during the later stages of development examined. However, due to the small number of brains, extending over a wide range of developmental ages, it is as yet difficult to reach any firm conclusions regarding altered synaptic development in Down's syndrome neocortex.

This research was supported by grants from the Ontario Mental Health Foundation, the Physicians' Services Incorporated Foundation and the Natural Sciences and Engineering Research Council of Canada.

433 MIMICRY OF ADRENERGIC STIMULATION BY C5a ANAPHYLATOXIN IN THE RAT BRAIN. Nicole Schupf and Curtis Williams, Dept. Psychology, Manhattanville College and Dept. Biology, SUNY Purchase, Purchase, NY 10577.

A soluble exogenous antigen reaction (EAR) system has been shown to alter eating patterns when administered directly to the perifornical hypothalamus. Treatment with rabbit specific antibody and antigen, ovalbumin (OA), induced eating in saline treated rats and increased the eating response to norepinephrine (NE). These effects mimic those of focally applied NE. The aggregation of PMN cells at the site following EAR treatment suggests the activity of leukotaxins and the possibility that the complement cascade had been activated by the immune complexes with the production of the anaphylatoxins C5a and C3a. Both peptides are cytoactive in the periphery, causing smooth muscle contractions, vasoconstriction and degranulation of mast cells.

Should the psychopharmacological effects of the EAR be mediated by the anaphylatoxins, fresh rat serum activated by immune complexes would induce a similar response at the site. We treated fresh rat serum with aOA·OA complexes to produce classical anaphylatoxin (rat CAT). As with the EAR system, there was a significant increase in food intake following injection of rat CAT (1µl, 1/8 dilution activated serum) into the perifornical hypothalamus. Food intake following injection of heat-inactivated (56°, 30 min) rat serum treated with immune complexes, in which CAT cannot be formed, was comparable to that following a saline injection.

Serum carboxypeptidase rapidly cleaves the carboxy-terminal arginine from the anaphylatoxins. C3a(des arg) is inactive while, C5a(des arg) in the rat retains residual leukotactic and anaphylatoxic properties. The anaphylatoxic activity of the rat CAT, therefore, is considered to be primarily C5a(des arg). We injected purified human C5a (kindly supplied by Dr. T.E. Hugli) into the perifornical hypothalamus 20 minutes prior to a saline injection. C5a (0.6 - 5.0 pmol in 1 µl) caused a significant and dose dependent induction of eating behavior while a slight non-significant suppression of water intake was seen. These results, again, mimic the activity of NE at this site. Preliminary results with receptor blockers support the alpha-adrenergic association of the C5a effect: C5a induced eating is blocked by phentolamine but not by propranolol nor by haloperidol.

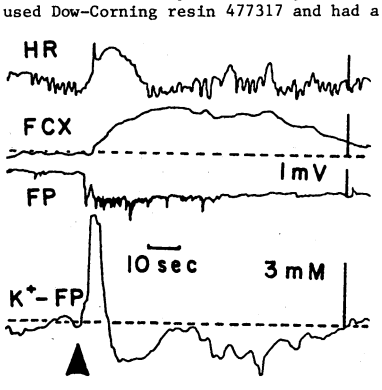
The results of these experiments suggest that immune complexes formed or deposited in the brain might entrain a variety of behavioral disturbances depending on the specific sites affected. The results further suggest that the effect may depend upon focal complement activation and that associated production of anaphylatoxin interferes with catecholaminergic function.

434 THE EFFECT OF AMYGDALOID LESIONS ON CHOOSING BETWEEN SIGNALLED AND UNSIGNALLED INESCAPABLE SHOCK BY RATS. R.N. Shull and M.G. Gaston*. Dept. of Psych., Calif. State Univ., L.A., CA 90034.

It has been clearly demonstrated that many types of animals prefer signalled over unsignalled electric shock, whether that shock is avoidable, escapable, or inescapable, and, for rats, a preference for signalled shock has been found, using a variety of different apparatus and procedures (Badia et al., Psych. Bull. 86:1107, 1979). The present experiment was designed to determine whether amygdaloid lesioned rats would acquire a preference for that side of a two-compartment box in which unavoidable and inescapable electric shock was signalled by a tone over the opposite side of the same box in which shock was unsignalled. Subjects tested were 19 male Long-Evans hooded rats (approx. 350-450 g.). Nine of these had been randomly chosen to receive bilateral electrolytic (2 mA for 30 s) amygdaloid lesions (two week recovery period), while five underwent sham operations and five were left intact. Histology later showed that all lesioned animals sustained substantial bilateral amygdaloid damage with the greatest destruction occurring in the basolateral nucleus. An experimental session (six sessions per subject) consisted of 30 scrambled shocks (0.8 mA, 3 s. duration) delivered to a grid floor according to a variable interval 75 s. schedule. When a subject was on the side of the box with vertical stripes, shocks were unsignalled; when on the side with horizontal stripes, shocks were immediately preceded by a 5 s., 80 db, 1350 Hz tone. Sham-operated and intact controls did not differ significantly on any measure and their data were pooled for analyses. Two-tailed t-tests demonstrated that while controls showed a significant preference for the signalled side ($t[9]=11.13$, $p<.001$), the lesioned animals failed to show a significant preference for either side ($t[8]=-1.02$). Visual observation of the subjects during the testing sessions showed that the external behaviors of the lesioned rats did not differ from those of the controls except that the lesioned rats made significantly fewer crossovers per session ($F[1,18]=12.39$, $p<.005$), although all subjects ran from one end of the box to the other in a repetitive fashion during shock delivery and displayed some degree of conditioned vocalization to the tone after several tone-shock pairings. It seems, then, that the lesioned animals in the present experiment were capable of displaying "normal" emotional behavior but "abnormal" instrumental behavior as compared to controls. The lesioned animals' failure to show a preference could have been due to a deficit in their ability to utilize environmental cues, suggesting that the amygdala is involved in the coupling of internal motivational-emotional states to appropriate overt motor behaviors.

435 MEANINGFUL STIMULI EVOKE EXTRACELLULAR POTASSIUM SHIFTS IN CONSCIOUS CAT FRONTAL CORTEX. James E. Skinner and Mark Molnar*. Neurophysiol. Sect., Neurol. Dept. and Neurosci. Prog., Baylor College of Med., Houston, TX 77030 and Inst. Psychol., Hungarian Acad. Sci., Budapest.

Previous observations in our laboratory have shown: 1) meaningful stimuli (e.g., novel, conditioned or reinforcing stimuli) will evoke an extracellular negative slow potential in the frontal cortex that lasts for 20-30 secs; 2) event-related membrane potential and input resistance shifts in frontocortical neurons accompany the slow extracellular potentials; and 3) event-related cyclic AMP concentrations rapidly rise in the underlying cortex and then slowly decline as a negative linear correlate of the slow potential amplitude. Our present results show that extracellular potassium shifts are also temporally correlated with the extracellular event-related slow potential. In a few locations, rapid decreases occur that are followed by slow recovery. When the ion-sensitive electrode is in a different location, the same stimulus can evoke a different pattern of potassium shifts as shown below. In this figure, there is an initial brief increase (K^+ - FP) followed by a decrease that persists for the duration of the negative polarity of the extracellular field potential recorded at the same location (FP). This latter pattern seems to be the most common type encountered in the anterior sigmoid cortex at a depth of 0.5 to 1.0 mm. FCX is the record from a nearby surface to depth transcortical pair of electrodes. HR shows the heart rate response. The potassium ion-selective electrode used Dow-Corning resin 477317 and had a tip diameter of 5 microns. The stimulus (arrow) was the presentation of sardines. Identical responses were obtained in three separate trials. The best temporal correlate of the long duration negative FP is the decrease in extracellular K^+. This result is compatible with a membrane mechanism of inactivation of a potassium current, as is the case for the slow-EPSP. Fig. 1. Event-related extracellular potassium shifts. K^+ - FP = actual potassium concentration change. (HL17907 & NS11535)



436 THE EFFECT OF PERINATALLY ADMINISTERED ETHANOL ON THE POSTNATAL DEVELOPMENT OF THE PURKINJE CELL IN THE MOUSE CEREBELLUM. D. E. Smith and D. L. Davies. Department of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

While the gross teratologic effects of alcohol on development have been known for decades, it has been only recently that investigators have begun to study the subtle microscopic changes which occur when the developing nervous system is subjected to an alcoholic insult. In the cerebellum, there is a reduction in the Purkinje and granule cell populations following the administration of alcohol during the perinatal period (Bauer-Moffett and Altman, Exp. Neurol. 48:378, 1975; IBID, Brain Res. 119:249, 1977; Barnes et al., Soc. Neurosci. Abst. 5:152, 1979). In order to examine possible changes in cerebellar morphology, a series of experiments were initiated using a strain of mice known to have a high preference for and behavioral tolerance to ethanol (C57BL/6J). Time-pregnant mice were divided into three groups: controls fed mouse chow and water ad libitum; experimentals fed a chocolate-flavored liquid (Nutrament) formulated to contain 25% of its caloric value as ethanol (5.4% v/v); and nutritional controls pair-fed isocaloric amounts of the same diet with sucrose replacing the ethanol. Administration of ethanol and sucrose diets began on gestation day 12 and continued until postnatal day 7; at which time, the ethanol and sucrose diets were discontinued and the groups returned to a chow and water diet. Litters were sacrificed on postnatal days 7, 14 and 21 for evaluation of cerebellar development. Some pups were processed for Golgi analysis, while others were perfused with a buffered paraformaldehyde-glutaraldehyde solution for ultrastructural examination. The material was routinely sectioned in the parasagittal plane. The most striking observation in the Golgi material was the altered morphology of the Purkinje cell. Normally, the Purkinje cell exhibits perisomatic spines at 7 days, but a rudimentary apical dendrite is also present (Meller and Glees, Neurobiology of Cerebellar Evolution and Development, p. 783, 1969). Perisomatic spines are present in the ethanol-treated group, but there is no evidence of an apical dendrite. By 14 days, the control Purkinje cells have well-developed arbors, but the ethanol-treated group displays an arbor that is more truncated and disoriented. In addition, some of the Purkinje cell bodies display grotesque silhouettes. At 21 days, there is less discernible difference between the three groups suggesting that the plasticity of this system allows for recovery from this form of alcoholic insult.

This investigation was supported by a grant from the Distilled Spirits Council of the United States, Inc.

437 STRUCTURE, INPUT, COUPLING AND PHYSIOLOGY OF THE GIANT DESCENDING NEURONS (GDNs) OF THE FLY (Musca). N.J. Strausfeld, J. Bacon, U. Bassemir* and D. Nässel*. EMBL, 69 Heidelberg and MPIV, 8131 Seewiesen, W. Germany.

Amongst descending neurons connecting cerebral to thoracic neuropil there is a prominent pair of cells whose axons lie most dorsal in the connective and have the largest diameters (20-35 µm). We are studying the structure and function of these cells (GDNs) using Co^{2+}, HRP and Golgi staining, and by intracellular recording with Lucifer-filled electrodes. Dendrites and terminals have been mapped in relation to several classes of optic lobe neurons, antennal receptors and motoneuron axons to dorsal longitudinal flight muscle. Cobalt transneuronally stains GDNs from some antennal receptor axons whereas Co^{2+}, HRP and Lucifer transneuronally stain one class of small-field visual cells of the lobula (Col A's) from the GDNs. After identifying GDN-Col A assemblies by light microscopy, E.M. studies on the same preparation reveal that although many profiles are presynaptic to GDN dendrites, only certain profiles had Co^{2+}-Ag deposits in mitochondria and in presynaptic sites. Postsynaptic sites in GDN, opposite Co^{2+}-Ag-containing Col A terminals, show extensive accumulations of Co^{2+}-Ag. Thus Co^{2+} is resolved at certain synapses only. There is no evidence of extracellular leakage. Lucifer also passes between the same cell types. Although Col A cells contain synaptic ribbons and vesicles the above observations indicate a dual nature of GDN-Col A and antennal-axon GDN-junctions, and their possible electrotonic and chemical nature is being investigated.

We have made intracellular recordings from GDNs in the ventral cord. Large (<15 mV) psp's were observed in response to mechanical stimulation of the antennae and to visual stimulation of the compound eye. Spike activity in GDNs could not be evoked by these stimuli even though other identified DNs did spike. However, the GDN would spike on release from hyperpolarization when recording near its terminal. Possibly the GDN is integrating and non-spiking in the ventral cord, and spike initiation is in the mesothoracic ganglion. Alternatively, the state of arousal in the C.N.S. of constrained preparations may be insufficient to reveal true spiking nature of the GDN. These aspects of physiology, and the post-embryonic development of GDNs, are currently being investigated.

Comparative anatomy of descending pathways in Musca, Calliphora and Drosophila reveal certain species specific features of GDN morphology of terminal processes in the pro- and mesothorax. However, in Musca and Drosophila, there is apparent coupling of GDN pairs via a point of contact in the mesothoracic ganglion as revealed by Lucifer and Cobalt, respectively. Certain other descending neurons are dye-coupled ipsilaterally to the GDN dendrites of Musca.

438 THE EFFECT OF HIPPOCAMPAL ABLATIONS IN RATS ON REWARD MAGNITUDE SHIFTS. P. N. Strong, E. Swain*, P. Taylor*, and M. Raboy*. Psychology Department, University of South Florida, Tampa, FL 33620.

Contrary to Franchina & Brown we found that hippocampectomized rats do respond to magnitude of reward shifts but, as we predicted, they do not show a negative contrast effect. Furthermore, unlike naive rats, hippocampectomized rats appear to show a positive contrast effect which may be due to their insensitivity to the stimulus generalization decrement due to reward magnitude changes. Significant differences between our motivating and feeding procedures compared to Franchina & Brown appear to explain the differences between the two studies.

439 ROLE OF MONOAMINES IN POSITIVE FEEDBACK OF ESTROGEN ON LH SECRETION. R.F. Walker* (SPON: B. Peretz) Sanders-Brown Research Center on Aging and Dept. of Anatomy, U. Kentucky Med. Ctr., Lexington, KY 40536

These experiments were designed to investigate how monoamines control daily phasic LH secretion in estrogen-treated, ovariectomized rats. Drugs which block catecholamine (α-methyl-p-tyrosine, AMT, 200mg/kg) or serotonin (p-chlorophenylalanine, pCPA, 250mg/kg) synthesis were given 3 days after ovariectomized rats received sc implants of estradiol pellets. Either drug, given alone, blocked the LH surge on the subsequent day, however AMT, caused a greater depression of basal LH levels (120ng/ml vs 170ng/ml at 1300h). Phasic LH secretion was restored by administration of monoamine precursors 5-hydroxytryptophan (5-HTP) for serotonin or l-dihydroxyphenylalanine (l-DOPA) for catecholamines. In another study, the restorative effect of 5-HTP or l-DOPA on phasic secretion of LH was tested in estrogen implanted rats in which the LH surge was blocked by AMT and pCPA treatment. LH surges were blocked and basal serum LH levels were depressed when total monoamine synthesis was blocked by both drugs. Neither 5-HTP nor l-DOPA alone, restored phasic LH secretion, though basal serum LH levels were elevated by l-DOPA treatment (301ng/ml vs 150ng/ml at 1300h). In the final study, 5-HTP or l-DOPA was injected into ovx rats at 1200h, 12 days after receiving sc implants of estradiol; a time when the daily LH surge is greatly diminished in amplitude (2800ng/ml on day 3 vs 350ng/ml on day 12). 5-HTP was more effective than l-DOPA in restoring phasic LH secretion (29% vs 20%). However, LH surges were reinstated in 89% of the 5HTP treated rats if they were pretreated with pCPA. Pretreatment with αMT of rats receiving l-DOPA, was not effective in restoring LH surges. Estimation of hypothalamic serotonin content at several time points over 24 hours in rats implanted with estrogen for 12 days showed that the serotonin circadian rhythm, which is required for phasic LH secretion, is damped by prolonged and continuous estrogen exposure. These data suggest that estrogen induced phasic LH secretion occurs in response to a daily serotoninergic signal superimposed upon a background of catecholamine-mediated, basal LH secretion. Furthermore, extinction of the daily LH surge in ovx rats bearing estrogen implants, may follow attenuation of the serotonin circadian rhythm resulting from chronic steroid exposure.

440 AUTORADIOGRAPHIC ANALYSIS OF I^{125}-PROLACTIN BINDING AND UPTAKE BY EPENDYMA OF THE RAT CHOROID PLEXUS. R.J. Walsh and B.I. Posner*. Dept. of Anatomy, George Washington Univ., Washington, D.C. 20037, Dept. of Medicine, Royal Victoria Hospital, Montreal, Canada.

Light and electron microscopic autoradiography were used to localize I^{125}-prolactin that was specifically bound to ependyma of the rat choroid plexus. Experimental adult male rats received a jugular vein injection of ovine I^{125}-prolactin (3.22 x 10^8dpm) while control animals received an identical dose of I^{125}-prolactin plus a 500-fold excess of unlabelled prolactin. Two experimental and two control animals were sacrificed by intracardiac perfusion of Ringer's lactate followed by glutaraldehyde fixative 3, 20, 40, and 60 minutes after hormone injection. Choroid plexus was removed and processed to Epon. One micron, iron hematoxylin prestained sections were coated with NTB-2 nuclear emulsion, exposed for 21 days, and analyzed in the light microscope by counting silver grains per 6960 μm^2 unit area. Thin sections were coated with a monolayer of Ilford L4 emulsion, exposed for 3 months, developed for fine silver grains with gold latensification (Kopriwa, Histochemie, 37:1 (73)), and analyzed by the direct scoring method.

Quantitation of silver grains at the light microscopic level indicated that excess unlabelled prolactin caused an 85% inhibition in the intense autoradiographic reaction observed over ependyma of all experimental animals, reaffirming the presence of specific prolactin binding sites on choroid ependyma (Walsh et al., Science 201:1041 (78)). Electron microscopic autoradiographs from experimental animals revealed the majority of silver grains (67%) were localized to the basal and lateral plasmalemma of the ependyma at 3 minutes post-injection. With increasing time, there was a dramatic decrease in the incidence of silver grains over the plasmalemma such that only 16% were localized to this portion of the cell 60 minutes after hormone injection. Concommittant with a decrease in silver grains over plasmalemma, there was an increase in grains localized to cytoplasmic vesicles and tubules (21% at 60 min.) and lysosomal bodies (37% at 60 min.). All other cytoplasmic organelles and the apical plasmalemma exhibited insignificant radiolabel at all times. The results are consistent with other studies regarding the localization and fate of polypeptide hormones at target cells, i.e., maximum hormone binding occurs at the plasmalemma shortly after initial exposure to the hormone with subsequent internalization and translocation to intracellular vesicles, vacuoles, and lysosomes.

441 GROWTH HORMONE RESPONSE TO APOMORPHINE ADMINISTRATION AND IN VITRO LITHIUM RATIOS PREDICT SUCCESS OF LITHIUM THERAPY IN THE SCHIZOPHRENIAS. Frank P. Zemlan, Jack Hirschowitz*, Robert Hitzemann and David L. Garver. Department of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Blood samples from 31 patients with RDC schizophrenic symptoms were assayed for peak plasma growth hormone (GH) response to apomorphine administration (0.75mg s.c.) and the in vitro lithium ratio. Patients then entered a 2 wk lithium carbonate (Li) trial with symptomatology assessed with the serial New Haven Schizophrenic Index (NHSI). Designated Li responders were patients showing a >35% improvement in NHSI scores. Of the 31 patients, 6 responded to Li therapy (n=5 DSM-III Schizophreniform Disorder, n=1 Schizophrenic Disorder) and 25 did not respond (n=1 Schizophreniform Disorder, n=24 Schizophrenic Disorder).

The mean GH peak for Li responders was 38.7 + 5.7ng/ml, while the peak level for non-responders was 18.4 + 2.5ng/ml ($p<0.002$). If 20ng/ml is taken as the cut-off peak GH response, then all Li responders fell above this point. For patients with a peak GH response $\geq$ 20ng/ml a significant decrease in serial NHSI scores was observed ($p<0.01$) with no effect of the Li trial seen in patients with a peak GH $\leq$ 20ng/ml.

Mean in vitro lithium ratios for the Li responders was 0.452 + 0.057 while the ratio for nonresponders was 0.356 + 0.026. If 0.390 is taken as the cut-off lithium ratio, then 80% of the Li responders fell above this point. The percent improvement in NHSI scores among patients meeting only the GH criterion was 32%, while among patients meeting both the Li ratio and GH criteria, a 67% improvement was observed during the Li trial. The doubling in the percent improvement among patients meeting both criteria was due to the fact that all Li non-responsive patients with peak GH response $\geq$ 20ng/ml were excluded employing the additional Li ratio criterion. That is, using peak GH response alone to predict success of the Li trial, 50% of the predicted Li responders did not turn out to be actual Li responders. Using both biological markers to predict response on the Li trial, a purer population of Li responsive patients was isolated.

The present data suggest that these two biological markers can isolate a subgroup of schizophrenic patients responsive to Li treatment, as well as, the existence of biological abnormalities characteristic of Li responsive schizophrenic patients.
